
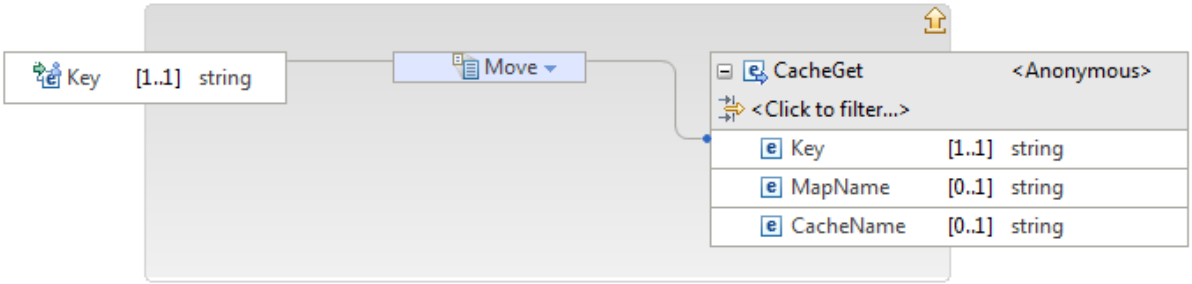
5. Double-click the **Cache Get** transform to edit the nested map.

   Note: To edit the nested map, you can also perform any of the following operations:
   - Click the **Cache Get** link in the **Cache Get** transform.
   - Click the arrow in the upper right corner of the **Cache Get** transform.
   - Place the mouse over the **Cache Get** transform, and click **Click here** in the pop-up window.

   The output elements of the nested map are the predefined parameters that are required to perform the **Cache Get** transform. If you mapped elements to the **Cache Get** transform, the elements are displayed as input elements in the nested map.
6. Required: Provide a value for the **Key** parameter of the **Cache Get** transform by using one of the following options:

   Note: The **Cache Get** transform is marked with an error until a value is provided for the **Key** parameter.
   - Map an element from the input tree.
   - Set a fixed value for the key by right-clicking the **Key** parameter in the **Cache Get** transform, clicking **Add Assign**, and adding the required value in the Properties pane. For more information about the **Assign** transform, see "Assign" on page 1289.
   - Set a value for the key by using a user-defined property; see "Accessing user-defined properties from a Mapping node" on page 1479.

   For example, in the following image, the content for the **Key** parameter is provided by mapping an element that is named **Key** from the input tree.



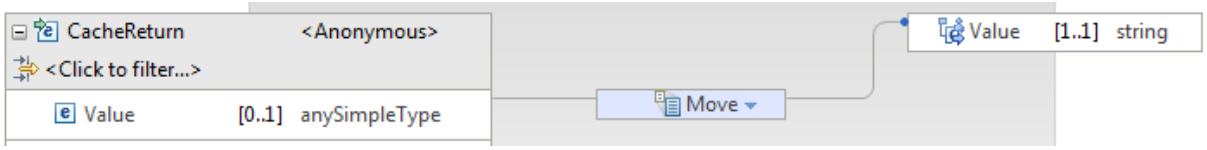
7. Optional: Map or assign values to the **MapName**, or **CacheName** and **MapName** parameters; for information about valid values for these parameters, see "Cache Get" on page 1291.
8. Navigate out of the **Cache Get** transform by clicking the arrow icon ( ).
9. Double-click the **Cache Return** transform to edit the nested map and process the returned value.

   If you mapped the **Cache Return** transform to an element from the output tree, the element is displayed in the nested map.
10. Optional: Map the **Value** element in the **Cache Return** to an element in the output tree.

    The predefined **Value** input element in the **Cache Return** nested mapping has a default schema type of `xs:anySimpleType`. If you know the type of the Java object in the cache, you can map directly to a target element that has the schema type that matches the Java Object type; see "Schema types that are returned for each supported Java Object type" on page 1298.

    If the entry in the cache might have one of several Java Object types, you can apply mapping casts to the predefined **Value** input element. For more information, see "Cache Return" on page 1297.

    For example, in the following image, the **Value** element in the **Cache Return** transform is mapped to the element that is named **Value** in the output tree.



11. Optional: Right-click the **Cache Get** transform and select **Cache** > **Failure** to implement a nested mapping that is called if the **Cache Get** transform fails. For more information, see "Handling global cache exceptions in a graphical data map" on page 1522.

    Note: You can also add a **Cache Failure** transform by placing the mouse over the **Cache Get** transform and selecting the **Cache Failure** icon ( ).
12. Save the graphical data map.

Results

You retrieved a value from the global cache.

What to do next

Complete the following tasks:

- Make sure that your global cache is available; see Configuring the embedded global cache or Connecting to a WebSphere eXtreme Scale grid.
- Add the map to a message flow, and deploy the message flow.

For more information about the **Cache Get** transform, see "Cache Get" on page 1291.

Removing a key-value pair from the global cache by using a Mapping node

You can use a Mapping node to remove a key-value pair from a map in an embedded cache or a WebSphere eXtreme Scale grid.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see "Creating a message map" on page 1382.

About this task

You can use a **Cache Remove** transform in a Mapping node to remove data from the global cache.

Interactions with the global cache happen outside the message flow transaction, and are committed immediately. If an error occurs downstream of the node that interacts with the global cache, the cache interactions are not rolled back.

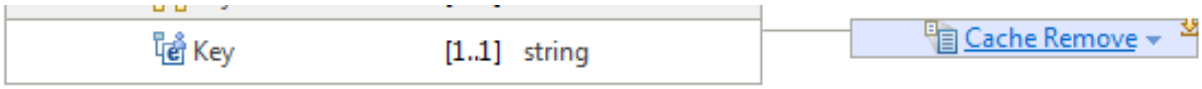
To configure a graphical data map to remove data from the global cache, complete the following steps:

Procedure

1. Open the graphical data map in the Graphical Data Mapping editor.
2. In the toolbar, click the **Cache Remove** icon ( ) to add a **Cache Remove** transform to the canvas.
3. Provide values for the parameters in the **Cache Remove** transform by completing one of the following steps:
   - Map the input elements to the **Cache Remove** transform.

     Note: You can also select the elements before you click the **Cache Remove** icon. The elements that you select are then automatically mapped to the **Cache Remove** transform.
   - Identify fixed values or user-defined properties to assign to the parameters.

   For example, in the following image, the Key element is mapped to the **Cache Remove** transform.

4. Double-click the **Cache Remove** transform to edit the nested map.

   Note: To edit the nested map, you can also perform any of the following operations:

   - Click the **Cache Remove** link in the **Cache Remove** transform.
   - Click the arrow in the upper right corner of the **Cache Remove** transform.
   - Place the mouse over the **Cache Remove** transform, and click **Click here** in the pop-up window.

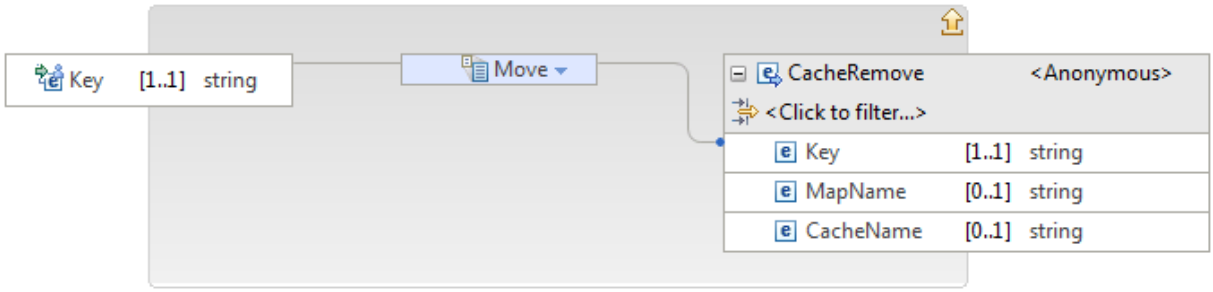
   The output elements of the nested map are the predefined parameters that are required to perform the **Cache Remove** transform. If you mapped elements to the **Cache Remove** transform, the elements are displayed as input elements in the nested map.

5. Required: Provide a value for the **Key** parameter of the **Cache Remove** transform by using one of the following options:

   Note: The **Cache Remove** transform is marked with an error until a value is provided for the **Key** parameter.

   - Map an element from the input tree.
   - Set a fixed value for the key by right-clicking the **Key** parameter in the **Cache Remove** transform, clicking **Add Assign**, and adding the required value in the Properties pane. For more information about the **Assign** transform, see "Assign" on page 1289.
   - Set a value for the key by using a user-defined property; see "Accessing user-defined properties from a Mapping node" on page 1479.

   For example, in the following image, the content for the **Key** parameter is provided by mapping an element that is named **Key** from the input tree.



6. Optional: Map or assign values to the **MapName**, or **CacheName** and **MapName** parameters; for information about valid values for these parameters, see "Cache Remove" on page 1296.
7. Optional: Right-click the **Cache Remove** transform and select **Cache** > **Return** to implement a nested mapping that is called if the **Cache Remove** transform completes successfully.

   Note: You can also add a **Cache Return** transform by placing the mouse over the **Cache Remove** transform and selecting the **Cache Return** icon ( ).

   The nested mapping in the **Cache Remove** transform provides an input element (Value) for the **Cache Return** transform. The input element provides the value of the global cache entry that was removed.

   The predefined **Value** input element in the **Cache Return** nested mapping has a default schema type of `xs:anySimpleType`. If you know the type of the Java object in the cache, you can map directly to a target element that has the schema type that matches the Java Object type; see "Schema types that are returned for each supported Java Object type" on page 1298.

   If the entry in the cache might have one of several Java Object types, you can apply mapping casts to the predefined **Value** input element. For more information, see "Cache Return" on page 1297.

   At run time, if no entry exists in the global cache with the provided key, the **Cache Remove** transform still completes successfully and invokes the **Cache Return** transform but the Value element does not exist.
8. Optional: Right-click the **Cache Remove** transform and select **Cache** > **Failure** to implement a nested mapping that is called if the **Cache Remove** transform fails. For more information, see "Handling global cache exceptions in a graphical data map" on page 1522.

   Note: You can also add a **Cache Failure** transform by placing the mouse over the **Cache Remove** transform and selecting the **Cache Failure** icon ( ).
9. Save the graphical data map.

Results

You removed a key-value pair from the global cache.

What to do next

Complete the following tasks:

- Make sure that your global cache is available; see Configuring the embedded global cache or Connecting to a WebSphere eXtreme Scale grid.
- Add the map to a message flow, and deploy the message flow.

For more information about the **Cache Remove** transform, see "Cache Remove" on page 1296.

Handling global cache exceptions in a graphical data map
Add a **Cache Failure** transform to your **Cache** transform group to handle exceptions that might be raised as a result of a **Cache** transform.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see "Creating a message map" on page 1382.
- Add a **Cache** transform to the graphical data map; see "Accessing a global cache by using a Mapping node" on page 1514.

About this task

If you want a graphical data map to handle exceptions that are returned as a result of a **Cache** transform, instead of stopping the map, you can add a **Cache Failure** transform to the **Cache** transform group. The **Cache Failure** transform is an optional transform in each of the **Cache** transform groups, and can be added or removed as required. If an exception is raised by the **Cache** transform, and you did not add a corresponding **Cache Failure** transform, the map operation is stopped and the exception is passed by the Mapping node to the message flow, where it can be caught by a **TryCatch** node or passed to the input node.

To add a **Cache Failure** transform to a **Cache** transform group by using the Graphical Data Mapping editor, complete the following steps:

Procedure

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, right-click a **Cache Put**, **Cache Get**, or **Cache Remove** transform, and then select **Cache** > **Failure**.

   Note: You can also add a **Cache Failure** transform by placing the mouse over the **Cache** transform and selecting the **Cache Failure** icon ().

   A **Cache Failure** transform is added to your **Cache** transform group.
2. Connect the **Cache Failure** transform to specify how any exceptions from the **Cache** transform are processed when the map is run. If the **Cache Failure** transform is present and is connected to one or more output objects, then the exception is caught and processed by the **Cache Failure** transform.

   Important: If the **Cache Failure** transform is present but is not connected, the following actions are taken:

   - The exception is caught by the **Cache Failure** transform and is ignored.
   - The map is marked with a warning.
3. Double-click the **Cache Failure** transform to open the nested map and further define the transform. For more information, see "Cache Failure" on page 1290.

Results

You added a **Cache Failure** transform to a **Cache** transform group in your graphical data map and configured the **Cache Failure** transform to handle exceptions that are returned by the **Cache** transform. If you want the execution of the map to stop when the **Cache** transform receives an exception, remove the **Cache Failure** transform from the **Cache** transform group.

Mapping database content

Use a message map to map or modify database content.

About this task

In the Graphical Data Mapping editor, you can access a database and manipulate your business data.

- You can use database content as input data for a graphical data map transform.
- You can use database transforms to modify database content.
- You can use a database transform to invoke a database stored procedure.

During the development phase, you must configure the database before you can access the data from a message flow in the IBM App Connect Enterprise Toolkit. IBM App Connect Enterprise supports the databases that are listed in IBM App Connect Enterprise Requirements.

For each database transform in your message map, the Graphical Data Mapping editor uses a database definition file (`.dbm` file) to determine the name and structure of the database that you want to access.

When your message map has been deployed, the IBM App Connect Enterprise runtime component connects to the database that is used by transforms in a map, by using a JDBC Providers Policy. The name of the JDBC Providers Policy must match the data source that was used in the Toolkit when the map was created (the discovered database name). You must also ensure that the JDBC Providers Policy is placed in the configured default policy project.

IBM App Connect Enterprise can access databases that are set up on the local computer or on a remote server, subject to restrictions. For more information, see IBM App Connect Enterprise Requirements.

The following topics guide you through the steps that are involved in mapping database content:

- “Creating a database definition (.dbm file) by using the New Database Definition File wizard” on page 1475
- “Selecting data from a table” on page 1523
- “Modifying data in a database by using mapping ” on page 1525
- “Calling a stored procedure from a map” on page 1532

Optionally, you can use JDBC connection pooling with your JDBC Providers policy to manage your database resources. For more information, see JDBC Providers policy.

Selecting data from a table

To map an output element from a database table, use the Graphical Data Mapping editor to retrieve the relevant rows from the database and then populate the output elements with values from the database.

Before you begin

You must complete the following tasks:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see “Creating a message map” on page 1382.

Procedure

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, click the **Select rows from a database** icon.

    .If you include a Select transform within a ForEach nested transform, the IBM App Connect Enterprise runtime component issues one SQL select to the database for each iteration of the ForEach transform.
2. In the **"New database select"** wizard, select the database, table, and column from which you want to select data. To add a database definition file, or to discover a new database by connecting to a database server, click **Add database...**. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475.
3. In the **SQL where clause** field, use supported SQL to specify the criteria for selecting the rows from the selected column of your database table.

   Build a supported SQL statement by dragging items from the **Table columns** and **Operators** panes to the **SQL where clause** field.

   To include values in your SQL statement, drag items from the **Available inputs for column values** pane to the **SQL where clause** to add them as parameters, or type literal values such as `'abc'` or 123 directly in the **SQL where clause**.

   Parameters from the **SQL where clause** are listed in the XPath expression table. You can edit the XPath expressions to refine the input, for example to add a specific array index for a dragged repeating field. A default **SQL where clause** is created for you, which selects all rows in your selected database table.

   Note: If you edit the text of the **SQL where clause** directly:

   - Ensure that the case of your table and column names match that of your database.
   - Avoid the use of double-quotes around table and column names.
   - Use only the supported SQL keywords that are presented in the Operators pane.
   - Ensure that each parameter placeholder is inserted as a question mark followed by an optional unique number and a space character, and also ensure that each parameter placeholder is defined with an XPath expression in the parameter table below the SQL where clause.
4. Optional: Select **Treat warning as error**.

   If this option is selected, the first SQL operation that results in a warning from the selected database raises an exception.

   Important: Database warnings are vendor-specific. For more information about database warnings, see the documentation for your database product.
5. Click **OK**.

   A **Select** transform, is created, and the data that you selected is displayed in the graphical data map.
6. Connect the **Select** transform to the required output object in the map.

   The **ResultSet** input to the **Select** transform is a repeating structure that contains one instance for each row that is selected by your configured **SQL where clause**.
7. Click the **Select** transform to further define the transform.

   A nested map is created, in which you can select the specific transforms that are required for the input and output elements.

What to do next

- If you want exceptions that are returned from the database server when the SQL operation is run to be handled by the map, instead of having such exceptions stop the map and being reported, you can add a Failure transform into the transform group; see "Handling database exceptions in a graphical data map" on page 1535.

Modifying data in a database by using mapping
Use the Graphical Data Mapping editor to insert, update, or delete rows of data in a database table.

About this task

You can use database transforms in your graphical data maps to insert new rows of data, or to update or delete existing rows of data, in your database tables. For each database transform in your graphical data map, the Graphical Data Mapping editor uses a database definition file (`.dbm` file) to determine the name and structure of the database that you want to access. You can start the wizard to create a database definition file when you create a database transform in a graphical data map.

If you connect elements from an input object to database columns within a database transform in your graphical data map, every input message that is processed by your map at run time must include those elements. If a message is either missing an element that is connected to a database column, or does not provide a valid value for that database column, an exception is raised when the message is processed by the map. Input elements that you connect to nullable database columns must provide either a valid value, or the NULL value. For more information about null values, see XMLNSC empty elements and null values.

When you add a database Insert, Update or Delete transform to a graphical data map, the transform is displayed as an additional output target to which you can connect input objects. When your map is run, a database transform calls a single operation on the configured database server. If you connect a repeating input element to the database transform, the Graphical Data Mapping editor moves the database transform inside a nested "For Each" transform from the repeating input.

A database Insert, Update, or Delete transform are created as a transform group, comprising the database operation and a Return transform. The database operation transform for Insert and Update are nested transforms in which the individual mapping to the database table columns are made. The Return transform is an optional transform that allows a nested mapping to be entered if the database operation is successful. If you do not want to use the Return transform, you can delete it from the transform group. If you must provide some mapping for when a failure is returned from the database operation, you can add a Failure transform into the transform group. The Failure transform provides a nested transform that is entered if the database system returns a failure.

If the insert, update, or delete is conditional on a test result, you can change the Insert, Update, or Delete transform to an If transform. Before you change the transform, ensure that the Insert, Update, or Delete transform is not part of a transform group. Remove any Return or Failure transform then select an If transform in place of the Insert Update or Delete. The Insert, Update, or Delete transform is moved into the nested mapping of the If transform. You can then add any required Return and Failure transforms.

The following topics describe how to modify data in a database table:

- “Inserting data into a table” on page 1525
- “Updating data in a table” on page 1527
- “Deleting data from a table” on page 1528

Inserting data into a table
Use the Graphical Data Mapping editor to insert data into a database table.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see “Creating a message map” on page 1382.

About this task

To insert a row, or multiple rows, into a database table by using the Graphical Data Mapping editor, complete the following steps:

Procedure

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, right-click the canvas, and select **Database** > **Insert into table**. Alternatively, select a schema element as an input object, and then click the **Insert a row into a database table** icon.

   The **Insert** wizard is displayed.
2. In the **Database** field, select the database that you want to modify. To add a database definition file, or to discover a new database by connecting to a database server, click **Add database...**. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475.

   To use a different database name at run time, you can override this value by setting the **Name of the database** property of the JDBC Providers policy that connects to your database; see JDBC Providers policy (JDBCProviders).
3. In the **Schema** field, select the database schema that you want to use to build the transform.

   To use a different database schema at run time, you can override this value by setting the **Name of the database schema** property of the JDBC Providers policy that connects to your database; see JDBC Providers policy (JDBCProviders).
4. In the **Table** field, select the table that you want to modify.
5. Optional: Select **Treat warning as error**.

   If this option is selected, the first SQL operation that results in a warning from the selected database raises an exception.

   Important: Database warnings are vendor-specific. For more information about database warnings, see the documentation for your database product.
6. Click **OK**.

   An **Insert** transform and a **Return** transform are created as a transform group, and are displayed in your graphical data map. The **Return** transform is an optional transform type. If you do not need to use the **Return** transform, you can delete it from your graphical data map.
7. Optional: To replace a **Return** transform that you deleted from your graphical data map, right-click your **Insert** transform and select **Database** > **Utilize return**.
8. In the Graphical Data Mapping editor, connect input objects to the **Insert** transform to define the content of your inserted row.

   - Connect a non-repeating element to the **Insert** transform to insert a single row into the selected database table.
   - Connect one or more repeating elements to the **Insert** transform to insert multiple rows into the selected database table. To connect multiple repeating elements, select your repeating elements, then right-click the **Insert** transform and select **Add Connection**.

   If you connect a single repeating element, the **Insert** transform is nested inside a **For Each** transform. If you connect multiple repeating elements, the **Insert** transform is nested inside a **Join** transform. In either case, the nested transform opens so you can continue to edit your **Insert** transform.
9. Click the **Insert** transform to create connections to the columns in your inserted row, and to further define the transform.
10. Optional: If you need to provide handling for the connected source element being Missing, Empty or Nil, you can set a Database Policy. See "Behavior when modifying database column values from optional source elements" on page 1535.
11. Optional: Connect the **Return** transform to implement a nested mapping that is called if the **Insert** operation was completed successfully.
12. Optional: Click the **Return** transform to further define the transform.

    A nested map is created, in which you can select the specific transforms that are required for the input and output elements.

What to do next

- If you want exceptions that are returned from the database server when the SQL operation is run to be handled by the map, instead of having such exceptions stop the map and being reported, you can add a Failure transform into the transform group; see "Handling database exceptions in a graphical data map" on page 1535.
- Set up a JDBC connection to the database that you want to access.

Updating data in a table
Use the Graphical Data Mapping editor to update data in a database table.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see "Graphical Data Mapping editor" on page 1266.

About this task

To update a row of data, or multiple rows of data, in a database table by using the Graphical Data Mapping editor, complete the following steps:

Procedure

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, right-click the canvas, and select **Database** > **Update Table**. Alternatively, click the **Update a row in a database table** icon.

   The **New Database Table Update** wizard is displayed.
2. In the **Database** field, select the database that you want to modify. To add a database definition file, or to discover a new database by connecting to a database server, click **Add database...**. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475.
3. In the **Schema** field, select the database schema that you want to use to build the transform.
4. In the **Table** field, select the database table that you want to modify.
5. Optional: Select **Treat warning as error**.

   If this option is selected, the first SQL operation that results in a warning from the selected database raises an exception.

   Important: Database warnings are vendor-specific. For more information about database warnings, see the documentation for your database product.
6. In the **SQL where clause** field, use supported SQL to specify the criteria for selecting rows from your database table.

   Build a supported SQL statement by dragging items from the **Table columns** and **Operators** panes to the **SQL where clause** field.

   To include values in your SQL statement, drag items from the **Available inputs for column values** pane to the **SQL where clause** to add them as parameters, or type literal values such as `'abc'` or 123 directly in the **SQL where clause**.

   Parameters from the **SQL where clause** are listed in the XPath expression table. You can edit the XPath expressions to refine the input, for example to add a specific array index for a dragged

repeating field. A default **SQL where clause** is created for you, which selects all rows in your selected database table.

Note: If you edit the text of the **SQL where clause** directly, take care to:

- ensure the case of your table and column names match that of your database.
- avoid the use of double-quotes around table and column names.
- only use the supported SQL keywords that are presented in the Operators pane.

7. Optional: Select **Insert when a row does not exist** if you want to insert a new row in your database table when no existing row meets the criteria of your **SQL where clause**.

   If this option is selected, the map checks the "number of rows updated" return from the database server for the Update SQL operation. If the "number of rows updated" is zero, the map issues an insert SQL operation. For the insert operation to succeed, your **Update** transform must explicitly provide valid values for all mandatory database columns. If you want a row that is inserted in this way to use different values to those that are provided by your **Update** transform, consider adding a conditional **Insert** transform inside the **Return** transform.

8. Click **OK**.

   An **Update** transform and a **Return** transform are created as a transform group, and are displayed in your graphical data map. The **Return** transform is an optional transform type that provides a nested mapping that is entered only if the associated **Update** was successful. If you do not need to use the **Return** you can delete it from your graphical data map.

9. Optional: To replace a **Return** transform that you deleted from your graphical data map, right-click your **Update** transform and select **Database** > **Utilize return**.

10. In the Graphical Data Mapping editor, connect input objects to the **Update** transform to define the content of your updated row.

    If you connect a repeating element, the **Update** transform is nested inside a **For Each** transform, and this nested transform is opened so that you can continue to edit your **Update** transform.

11. Click the **Update** transform to create connections to the columns in your updated row, and to further define the transform.

12. Optional: If you need to provide handling for the connected source element being Missing, Empty or Nil, you can set a Database Policy. See “Behavior when modifying database column values from optional source elements” on page 1535.

13. Optional: Connect the **Return** transform to implement a nested mapping that is called if the **Update** operation was completed successfully.

    The nested **Return** transform provides a built-in input, "NumberOfRowsUpdated", and additional inputs can be connected.

14. Optional: Click the **Return** transform to further define the transform.

    A nested map is created, in which you can select the specific transforms that are required for the input and output elements.

What to do next

- If you want exceptions that are returned from the database server when the SQL operation is run to be handled by the map, instead of having such exceptions stop the map and being reported, you can add a Failure transform into the transform group; see “Handling database exceptions in a graphical data map” on page 1535.

Deleting data from a table
Use the Graphical Data Mapping editor to delete data from a database table.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see "Creating a message map" on page 1382.

About this task

To delete a row of data, or multiple rows of data, from a database table by using the Graphical Data Mapping editor, complete the following steps:

Procedure

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, right-click the canvas, and select **Database** > **Delete from Table**. Alternatively, click the **Delete a row from a database table** icon.

   The **New Database Table Delete From** wizard is displayed.
2. In the **Database** field, select the database that you want to modify. To add a database definition file, or to discover a new database by connecting to a database server, click **Add database...**. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475.
3. In the **Schema** field, select the database schema that you want to use to build the transform.
4. In the **Table** field, select the database table that you want to modify.
5. Optional: Select **Treat warning as error**.

   If this option is selected, the first SQL operation that results in a warning from the selected database raises an exception.

   Important: Database warnings are vendor-specific. For more information about database warnings, see the documentation for your database product.
6. In the **SQL where clause** field, use supported SQL to specify the criteria for selecting the rows that you want to delete from your database table.

   Build a supported SQL statement by dragging items from the **Table columns** and **Operators** panes to the **SQL where clause** field.

   To include values in your SQL statement, drag items from the **Available inputs for column values** pane to the **SQL where clause** to add them as parameters, or type literal values such as `'abc'` or 123 directly in the **SQL where clause**.

   Parameters from the **SQL where clause** are listed in the XPath expression table. You can edit the XPath expressions to refine the input, for example to add a specific array index for a dragged repeating field. A default **SQL where clause** is created for you, which selects all rows in your selected database table.

   Note: If you edit the text of the **SQL where clause** directly:

   - Ensure that the case of your table and column names match that of your database.
   - Avoid the use of double-quotes around table and column names.
   - Use only the supported SQL keywords that are presented in the Operators pane.
   - Ensure that each parameter placeholder is inserted as a question mark followed by an optional unique number and a space character, and also ensure that each parameter placeholder is defined with an XPath expression in the parameter table below the SQL where clause.
7. Click **OK**.

   A **Delete** transform and a **Return** transform are created as a transform group, and are displayed in your graphical data map. The **Return** transform is an optional transform that provides a nested mapping. It is entered only if the associated **Delete** was successful. If you do not need to use the **Return** transform, you can delete it from your graphical data map.

8. Optional: To replace a **Return** transform that you deleted from your graphical data map, right-click your **Insert** transform and select **Database** > **Utilize return**.
9. Optional: Connect the **Return** transform to implement a nested mapping that is called if the **Delete** operation was completed successfully.
10. Optional: Click the **Return** transform to further define the transform.

    A nested map is created, in which you can select the specific transforms that are required for the input and output elements.

What to do next

- If you want exceptions that are returned from the database server when the SQL operation is run to be handled by the map, instead of having such exceptions stop the map and being reported, you can add a Failure transform into the transform group; see "Handling database exceptions in a graphical data map" on page 1535.

Data type considerations for mapping database content
Data type handling using the Graphical Data Mapping editor to read or modify data in a database table requires consideration of the type of Database server that will be connected to from the run time. The map may require to make explicit type casts, in order to avoid mapping node exceptions or database server exceptions being thrown.

IBM App Connect Enterprise can access databases that are set up on the local computer or on a remote server, subject to restrictions.

IBM App Connect Enterprise supports the databases that are listed in IBM App Connect Enterprise Requirements (SOE).

Data types considerations for mapping database content during development

During the development phase, you must configure a database before you can access the data in a map.

To configure a database, you define a database definition file. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475.

A database definition file holds the physical data model that details all the database resources, such as the schema, the tables, and other resources, that you need access to.

Note: A database definition file in the IBM® Integration Toolkit is not automatically updated. If you modify your database, you must re-create the database definition file describing the connection to the database.

For each database transform in your message map, the Graphical Data Mapping editor uses the database definition file (`.dbm` file) to determine the name and structure of the database that you want to access.

When you map a database table in a message map, the data types of the database columns are provided by the database definition file.

You can use the **xs:type** cast transform or custom transforms, such as **Custom XPath**, to ensure that data from elements mapped to the database columns are of the correct type.

Data types considerations for mapping database content at run time

At run time, a JDBC Providers policy is used to determine the database to connect to. You must enable the JDBC connection to the database before you execute a map that requires data from a database. See JDBC Providers policy.

Note: The name of the JDBCProvider service must be identical to the name of the database.

When you use a Mapping node that includes a map with database transforms, you must consider the database server behavior:

- If your database server can provide at run time table parameter meta data, the Mapping node validates the input data to a database transform in a map and performs any allowed implicit type casting, before sending the SQL statement to the database for execution.

  Note: The Mapping node applies any required **xs:type** cast transforms before passing data in SQL statements. If there is no valid type cast between the type of the presented value and the type defined by the database meta data, a **run time exception** is thrown by the Mapping node that is executing the map.
- If your database server cannot provide at run time table parameter meta data, during development, you must define the **xs:type** cast transform to ensure that all data values that will be passed to the database, as parameters to Where clauses or to populate a column in a table, match the data type requirements of the database server.

  Note: Not all database servers supported by IBM App Connect Enterprise provide querying of table meta data in a way IBM App Connect Enterprise can currently process. IBM App Connect Enterprise cannot currently obtain table meta data when connected to the following database server types:

  – Microsoft_SQL_Server
  – Oracle
  – Sybase_JConnect6_05
  – solidDB

  When a database system cannot provide table meta data at run time, the Mapping node cannot perform validation and implicit type casting. The data element values are passed to the database server in the type they are presented, without any casting being performed. This can result in the database system rejecting the value and throwing a **database exception**.

Behavior when a database server can provide at run time table meta data information

The resulting data type of values that are set to the database systems are determined depending on how the input element is wired to the database transform:

- Column values set via **Move** transforms from an message tree element are passed as its given type when it is a base SQL type. For example: Integer, otherwise as character string formatted as per the IBM App Connect Enterprise `getValueAsString()` MbElement method.
- Column values set via **Custom XPath**, **Custom Java** or **Custom ESQL** functions are passed as the type returned by the function.
- Column values set via **Assign** transform will always be passed as character string. If you require a specific type to be assigned, you must use a **Cast** transform of the appropriate `xs` type constructor. For example, to assign the value 1 to an Integer type column, use the `xs:int()` **Cast** transform and set a value of '1' instead of an **Assign** transform.

When using values in **Where** clauses for **Select**, **Update** and **Delete**, the types are determined as follows:

- Literal values are typed according to standard SQL syntax, such as quote character strings, unquoted numbers and so on.
- Values set via XPath expressions to a message tree element are passed as its given type when it is a base SQL type. For example: Integer, otherwise as character string formatted as per the IBM App Connect Enterprise `getValueAsString()` MbElement method.

Behavior when a database server cannot provide at run time table meta data information

When a database system cannot provide table meta data at run time, the Mapping node cannot perform validation and implicit type casting. The data element values are passed to the database server in the type they are presented, without any casting being performed. This can result in the database system

rejecting the value and throwing a **database exception**. The database server raises a SQL invalid type exception.

To resolve this error, you must manually add explicit type casting in the map. Use the **xs:type** transform in the XPath expression of the **Where clause** when you set a value in a target database column or when you pass a value for a stored procedure parameter.

Working with database servers that are not listed in the product SOE for IBM Integration Bus Version 10

This section only applies if your database server is not listed under IBM App Connect Enterprise Requirements (SOE)

By default, the Mapping node queries table meta data by calling **java.sql.PreparedStatement.getParameterMetaData()**. If the database server you are connecting to does not fully implement this JDBC interface method, the mapping can fail due to an **SQL exception** from the database server. For example, the database server might respond by returning the exception java.sql.SQLFeatureNotSupportedException.

You can set the environment variable **MQSI_MAP_DB_PARAMETERMETADATA_SUPPORT** to control whether the Mapping node queries the database server for table meta data at run time.

To set the environment variable, complete the following steps:

1. Create a file in the following directory:
   - On Windows: *work_path*`\Common\profiles`
   - On Linux and UNIX: *work_path*`/common/profiles`

   where *work_path* is the machine-wide IBM App Connect Enterprise working directory.

   Note: To verify the machine-wide IBM App Connect Enterprise working directory, enter the following command in a command console:

   ```
   echo %MQSI_WORKPATH%
   ```
2. Edit the file to set the environment variable. for example, you can enter `MQSI_MAP_DB_PARAMETERMETADATA_SUPPORT = DatasourceName1:true DatasourceName2:false`.
3. Set the environment variable. For more information, see Setting up a command environment.

Calling a stored procedure from a map
Use the Graphical Data Mapping editor to call a stored procedure by using the Database Routine transform.

Before you begin

Before you start:

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see “Creating a message map” on page 1382.

About this task

You can use the Database Routine transform to call a stored procedure from a database.

Note: For information about the support for stored procedures, see “Support for stored procedures” on page 1318.

The Database Routine transform acts as a nested mapping, into which you can wire inputs to construct mappings to set the input parameter values for the stored procedure call. The routine input parameters

are displayed as outputs of the Database Routine nested mapping. You cannot wire any output from the Database Routine transform.

Use the Return transform within the Transform group of the Database Routine to map any output parameters, return values, or **ResultSets** produced by calling the Database Routine. You can wire any additional inputs that you want to map when the Database Routine call completes successfully. The output parameters, any return value, and any returned Result sets you defined for the Database Routine are provided as inputs in the nested Return mapping. You can wire the Return to a single or multiple sibling output elements to enable the returned data to be mapped to the map output.

Procedure

Using the Graphical Data Mapping editor, complete the following steps:

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, right-click the canvas, and select **Database** > **Call Database Routine**.
   - Alternatively, select a schema element (or elements) as an input parameter value. Optionally, select a schema element (or elements) as an output value.
   - You can also use drag-and-drop to create the Database Routine transform. Connect the input object to the output object, and a transform is automatically created. Select the transform, and choose **Database Routine** from the **Transforms** list.
   - You can also click the **Call a stored procedure in a database** icon. 

   The Database Routine wizard is displayed.
2. In the **Database** field, select the database that you want to call the routine from. To add a database definition file, or to discover a new database by connecting the IBM App Connect Enterprise Toolkit using JDBC to a database server, click **Add database...**. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475. You must select the **Routines** option during the discovery process.

   To use a different database name at run time than the name used in the IBM App Connect Enterprise Toolkit, you can override this value by setting the **Name of the database** property of the JDBC Providers policy that defines how to connect to your database; see JDBC Providers policy (JDBCProviders).
3. In the **Schema** field, select the database schema that defines the stored procedure that you want to call from the map.

   To call the stored procedure from a different database schema at run time, you can override this value by setting the **databaseSchemaNames** property of the JDBC Providers policy that defines how to connect to your database; see JDBC Providers policy (JDBCProviders).
4. In the **Routine** field, select the stored procedure that you want to call into the Database Routine transform in the map.
   a) If the selected routine can return a value, a **Return value** check box is displayed. If you want to make the return value available for mapping in the Return transform, check this box.

   Note: The selected **Routine** then populates the following locked fields:

   - **Type**: states whether the type of the selected **Routine** is a stored procedure .
   - **Parameters**: details of the parameter names, mode, and type for the selected **Routine**.
   - **Max ResultSets**: if the Database definition file for the **Routine** provides this information, states the maximum Result sets. Otherwise, it is blank.

   These fields can be displayed by clicking **Display Routine parameter details...**
5. Optional: Select **Treat warning as error**.

   If this option is selected, and calling the Database Routine in the configured runtime database returns an SQL warning, it is handled as if the database is raising an exception. If the Failure transform is

present, then it enters its nested mapping. Otherwise, the map execution stops, and an exception is raised from the Mapping node that is running the map.

Important: Database warnings are vendor-specific. For more information about database warnings, see the documentation for your database product.

6. Optional: If the selected **Routine** can return Result sets, and you want to map values from them, you must define their order and column contents.
   a) If your Database definition file defined the number of Result sets, then **Result sets list** is pre-populated with one **ResultSet**, and displays the maximum number that can be returned. Use the **Add** and **Delete** buttons to populate the **Result sets list**, up to any maximum number defined in the database definition file. You must order the Result sets as they are defined in the Database Routine code.
   If you only want to map data from, for example, the second result set, you must still include the first result set in the table because they are accessed by their positional order.
   b) Select each Result set, and use the check boxes in **Available table columns** to add column definitions to the Result set to match what the Database Routine returns. You only need to define the Result set columns that you want to be available for mapping.

   Note: If you want to map from a column in a specific table, and other tables have a column with the same name, you must add column definitions for all the columns that have the same name as the column that you want to be available for mapping. You must also add the columns in the same order that the columns appear in the result set.
7. Click **OK**.

   The Database Routine, and its grouped Return transform are displayed in your graphical data map. If you made any selections in the mapping input/output, all selected inputs are wired into the Database Routine, and outputs are wired to the Return transform. If you made no selections, then the new transform appears in the map unconnected.
8. Provide any required values for **IN** and **INOUT** mode parameters for the Database Routine.

   The input parameters for the selected stored procedure are displayed as outputs in the nested Database Routine transform.
   a) Connect the required input elements to the Database Routine, and within the nested map provide transforms to set a value for each parameter.

   The Database Routine is entered only once, making one call to the database system. You must set cardinality for any repeating elements that are connected into the Database Routine transform, or use a function transform to provide a single value to the parameter.

   Note: If any parameter is not given a value, the database server might return an exception if it cannot provide a default value. If the resulting output value of the transforms setting the parameters is not the correct type for the Database Routine, or the content is invalid, for example, exceeding a maximum length, a database exception might occur.
9. Provide any required mapping for the output elements from data that is returned from the Database Routine. This data can include **OUT** and **INOUT** mode parameters, optional **Routine** return values, and one or more Result sets. The **Routine** outputs are displayed as inputs in the nested Return transform.
   a) Optional: Connect any additional input elements that you might require merged with the Database Routine data to the Return transform. Connect the Return transform to one or more output elements of the map. Provide transforms within the nested Return map to set the connected outputs from the provided Database Routine output values.

What to do next

Next:

- If you want exceptions that are returned from the database server when the Database Routine is called to be handled by the map, instead of having such exceptions stop the map and being reported, you can add a Failure transform into the transform group; see "Handling database exceptions in a graphical data map" on page 1535.
- Set up a JDBC connection to the database that you want the run time to call the Database Routine into.

- If you want to modify the available columns in the Result sets for mapping, use the Properties view of the Database Routine transform, and then update the Return nested mapping.

Handling database exceptions in a graphical data map
Add a Failure transform to your graphical data map to handle exceptions that might be raised as a result of a database transform.

About this task

If you want the map to handle exceptions that are returned from the database server when the SQL operation is run, instead of such exceptions stopping the map and being reported, you can add a Failure transform to the transform group. The Failure transform is an optional transform in each of the database transform groups, and can be added or removed as required. If an exception is raised by the configured database server, and you have not configured a corresponding Failure transform, the map operation is stopped.

To add a Failure transform to a graphical data map by using the Graphical Data Mapping editor, complete the following steps:

Procedure

1. With a graphical data map (`.map`) file open in the Graphical Data Mapping editor, right-click a **Select**, **Insert**, **Update**, **Delete**, or **Database Routine** transform, and then select **Database** > **Handle Failure**.

   A **Failure** transform is created, and is displayed in your graphical data map.
2. Connect the **Failure** transform to specify how any exceptions from the database transform are processed when the map is run. If the Failure transform is present in the graphical data map, and is connected to one or more output objects, then the exception is caught and processed by the Failure transform. Database transforms additionally have a **Treat warnings as exceptions** option.
   - **Important:** If the Failure transform is present in the graphical data map, but is not connected, then the exception is caught by the Failure transform, and is ignored.
   - If the **Failure** transform has been deleted from the graphical data map, then the exception is handled by the Mapping node in your message flow, and is handled in the same way as other message flow exceptions.
3. Click the **Failure** transform to open the nested map and further define the transform.

Results

You have added and configured a **Failure** transform into your graphical data map. If you want the failure to cause the execution of the map to stop when the database transform receives an SQL exception, remove the **Failure** from the transform.

Behavior when modifying database column values from optional source elements
When updating or inserting database columns, you can define different behaviors for a missing, empty, or nil source.

Behavior with no Database Policy

When Inserting or Updating data into a database column by connecting a transform which is defined as optional in the schema model, you might want to consider the behavior for the possible source input states: Missing, Empty, or Nil. The behavior can be default or customized by enabling a Database Policy.

Table 1 defines the source states and the behavior without a Database Policy enabled.

Tables 2 and 3 define the behavior of enabling a Database Policy to check the source state and to then take a specific configured action.

Table 61. Behavior with no Database Policy on transforms linked to a column in an Insert or Update operation

Source state	Definition	Behavior
Missing Source	The input document does not contain the source element.	The column will not be passed in the SQL statement sent to the database server. The outcome is determined by the definition of the target column in the database: • If the column is defined with a default value, this value is set by the database system. • If the column is defined as nullable, and no default is defined, the column is set to null by the database system. • If the column is defined as not nullable, and no default is defined, the database will return a SQL exception.
Empty Source	The input document contains the source element, but that source is empty.	IBM App Connect Enterprise passes the value returned by "getValue" for the source element as the parameter value for the column in the SQL statement sent to the database. For example, an element of the String type will return the empty String value, so the target database column would be set with an empty string, "".
Nil Source	The input document contains the expected source, and it is nil.	The value returned by "getValue" is set to NULL.

Behavior for Insert with an enabled Database Policy

When Inserting data into a database column, you can enable a database policy on each transform mapping a single value from a source element. This allows you to choose one of the following actions for each of the input source states: Missing, Empty, or Nil.

Table 62. Behavior with a Database Policy enabled on transforms linked to a column in an Insert operation

Actions for source state	Behavior
Exclude column from database operation	Insert the database default value for the column. The column is excluded from the SQL statement sent to the database. This option is only enabled if the target database column has a default value defined in the database model from the associated `.dbm` file.
Insert the empty String value ""	This option is only enabled if the target database column is defined as any character string type in the database model from the associated `.dbm` file.
Set to NULL	This option is only enabled if the target database column is defined as nullable in the database model from the associated `.dbm` file.
Throw a map error	Produces a map error: • Missing: BIP3970 • Empty: BIP3971 • Nil: BIP3972

Behavior for Update with an enabled Database Policy

When Updating data in a database column, you can enable a database policy on each transform mapping a single value from a source element. This allows you to choose one of the following actions for each of the input source states: Missing, Empty, or Nil.

Table 63. Behavior with a Database Policy enabled on transforms linked to a column in an Update operation

Actions for source state	Behavior
Exclude column from database operation	The column is excluded from the SQL statement sent to the database. The value of the column currently in the database is not changed.
Set to the empty String value ""	This option is only enabled if the target database column is defined as a character string type in the database model from the associated `.dbm` file.
Set to NULL	This option is only enabled if the target database column is defined as nullable in the database model from the associated `.dbm` file.
Throw a map error	Produces a map error: • Missing: BIP3970 • Empty: BIP3971 • Nil: BIP3972

Referencing message maps in your solution

You can reference a message map and a submap during the development phase. You can also reference a message map dynamically at runtime.

About this task

Message maps and submaps are resources that can be used more than once in your solutions. For example, a message map can be used by one or more Mapping nodes in a message flow.

Procedure

Choose any of the following options to reference a message map or a submap in your solution:

- Reference a message map: You can reference a message map by configuring the **Mapping routine** property in a Mapping node. For more information, see "Referencing an existing message map from a Mapping node" on page 1537.
- Dynamically reference a message map at runtime: You can define a message map dynamically at runtime by setting the local environment **MappingRoutine** element in your message flow before the message reaches the Mapping node where the message map needs to be used. For more information, see "Dynamically selecting a message map" on page 1538.
- Reference a submap: You can call a submap from a graphical data map in the Graphical Data Mapping editor by using the **Submap** transform. For more information, see "Calling a submap" on page 1540.

Referencing an existing message map from a Mapping node

A message map can be used by one or more Mapping nodes in a message flow. You can reference a message map by configuring the **Mapping routine** in a Mapping node.

About this task

The Mapping node invokes a map-based transform.

The input to the Mapping node is the input message assembly that is propagated from the upstream node.

The output of the Mapping node is the new message assembly that is created by the mapping operations and propagated from the output terminal of the Mapping node.

Procedure

To reference an existing message map from a Mapping node, complete the following steps:

1. In the **Application Development** view, double-click the message flow that contains the Mapping node that you want to modify.

   The message flow opens in the Message Flow editor.
2. In the Message Flow editor, click the Mapping node that you want to modify.

   The Mapping node properties are displayed in the Properties view.
3. In the Properties view, select the **Basic** tab.
4. Next to the **Mapping routine** field, click **Browse**.

   The **Data Transformation Map Selection** window opens.
5. From the list in the **Data Transformation Map Selection** window, select the message map that you want to reference from your selected Mapping node, and click **OK**.

   Message maps are listed in the format `{`*BrokerSchemaName*`}:`*MapName*.

   `{default}` indicates that no broker schema is used by the message map.
6. Save and close your message flow.

Results

Your Mapping node references the message map that you selected.

Dynamically selecting a message map

To dynamically assign a message map to a Mapping node at runtime, you must pass the new map name in the local environment tree. You must define the new map name in the **MappingRoutine** element. The value you set in the **MappingRoutine** element overrides the map name that is set in the **Mapping routine** property of the Mapping node.

About this task

You can create, deploy, and run a message flow that invokes a different message map at a Mapping node.

You can override the mapping routine that is used to transform a message instance by specifying a new mapping routine in the local environment **MappingRoutine** element. You must specify the new mapping routine in the local environment tree that is upstream of the Mapping node that you need to modify.

The mapping routine qualified name that is provided in the **MappingRoutine** element must be defined in a map file that has to be deployed to the integration node in a BAR file where the message flow is deployed.

You can use any of the following message flow nodes to set the value of the local environment **MappingRoutine** element:

- Mapping node
- Compute node
- JavaCompute node

Procedure

To override at runtime the message map configured during development in a Mapping node, you must complete the following steps:

1. Required: Reference a message map in the Mapping node. This is the default message map executed by the Mapping node. For more information, see "Referencing an existing message map from a Mapping node" on page 1537.

   You must configure the name of the mapping routine that contains the statements to execute against the database or the message tree in the Mapping node property **Mapping Routine**. By default, the name that is assigned to the mapping routine is: `{default_broker_schema}:DefaultMsgFlowName_MappingNodeName`, where *default_broker_schema* is the broker schema where the message flow is located, and *DefaultMsgFlowName_MappingNodeName* is the name of the message flow concatenated with the name of the Mapping node.
2. In your message flow, add a new Mapping node located before the Mapping node where you want to assign dynamically a message map. Then complete the following configuration steps in the new Mapping node:
   a) Add the local environment tree to the input message assembly.
   b) Add the local environment tree to the output message assembly.
   c) Optional: Add database tables if you require information available in an external database.
   d) Configure a **Move** transform between the input local environment tree and the output local environment tree.
   e) Configure a transform to set the output local environment tree **MappingRoutine** element. You can also add a condition to the transform.

      You must define the value for **LocalEnvironment** > **Mapping** > **MappingRoutine**.

      A light bulb will appear on the left hand side of the transform.
   f) Click the yellow light bulb, and then select **Group the conflicting transforms in an override group**.

Results

You have configured your message flow to dynamically assign a message map to a Mapping node. In the first Mapping node, you have defined the logic to set the local environment **MappingRoutine** value. In the Mapping node where you want to dynamically assign a message map, you have defined a message map.

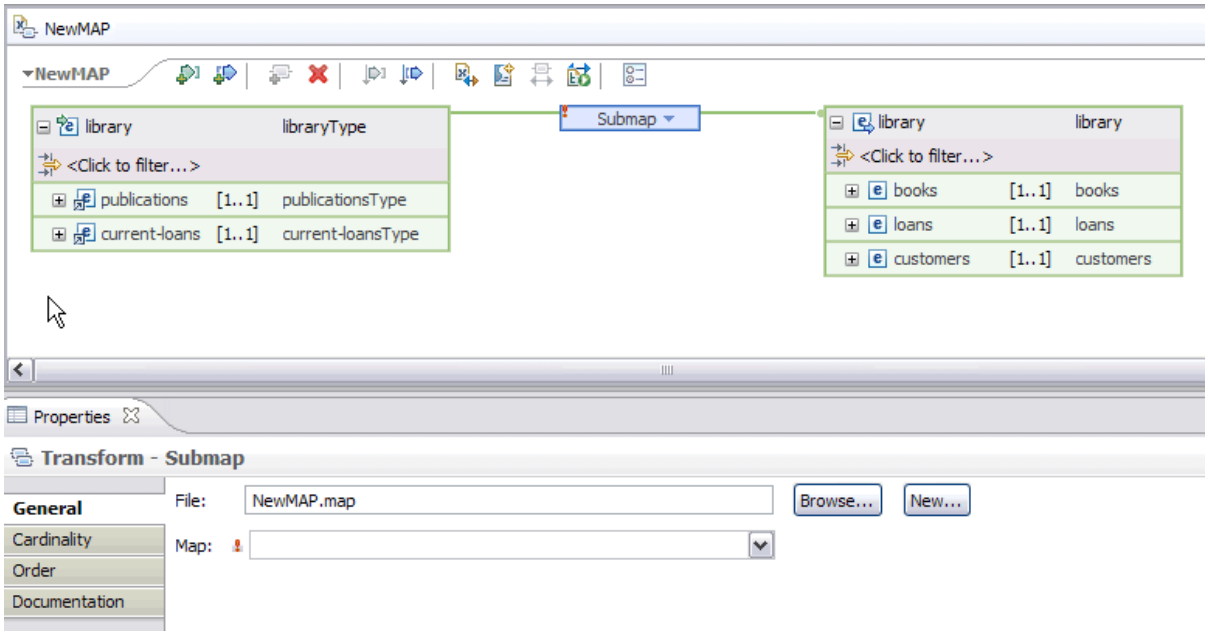
Calling a submap
You can call a submap from a graphical data map in the Graphical Data Mapping editor by using the **Submap** transform.

Procedure

Complete the following steps to call a submap from another graphical data map:

1. Create a connection between global input and output elements in a graphical data map, and then select the **Submap** transform on the connection:

   For example:



2. Click **Browse** in the Properties view of the **Submap** transform.

   The **Submap Selection** wizard is displayed where the dialogue box will display the submaps that are available.

3. Select a submap, and click **OK**.

   You can choose to display only the valid maps that can be selected, by clicking **Show only applicable maps**.

Results

The submap is displayed in the Graphical Data Mapping editor, and you can edit it in the same way that you would edit any graphical data map. For information about how to edit maps, see "Editing message maps" on page 1394.

Transforming a SOAP message in a message map

In IBM App Connect Enterprise, a SOAP message is described by a generic model that includes the SOAP *Envelope* and optionally *Attachments*. You define your SOAP message parts in a message map by using the **Cast** function.

About this task

A SOAP message consists of an *Envelope* and optionally *Attachments*. The envelope contains a SOAP header and a SOAP body. A SOAP body can include SOAP faults.

When you use SOAP nodes in IBM App Connect Enterprise, you can manipulate the following type of messages:

- A SOAP message that is described by a generic model and that contains the SOAP operation-specific data.
- An XML message that contains only the SOAP operation-specific data.

In addition to the standard SOAP parts, the SOAP message generic model includes a *Context* part that includes contextual information about the current SOAP message that is processed. This part is the only one in a message map whose structure is included automatically. You must define the other SOAP message parts manually by using the **Cast** function.

IBM App Connect Enterprise supports SOAP 1.1 and SOAP 1.2 messages.

Depending on the message domain that you configure in your input node, you might have to consider the differences between SOAP 1.1 and SOAP 1.2 when transforming SOAP messages.

- If you receive a SOAP message through a SOAPInput node, the SOAP parser handles SOAP 1.1 or SOAP 1.2 automatically. The SOAP domain uses a common logical tree format that is independent of the exact format of the web service message. For details of the SOAP tree format, see SOAP tree overview.
- If you receive a SOAP message through an HTTPInput node, the XMLNSC parser handles your SOAP 1.1 or SOAP 1.2 message differently. When you create a message map, you must be aware of the SOAP version, and configure the correct SOAP 1.1 or SOAP 1.2 schema when you create and configure your graphical data map.

Depending on the nodes that you use when you model your message flow or your service operation, and the message domain you configure, you must use a different schema model:

- If you use the SOAP nodes excluding the SOAPExtract node, you must map the **SOAP_Domain_Msg** in the SOAP domain.
- If you use the SOAP nodes including the SOAPExtract node, and the Mapping node is wired after a SOAPExtract node, you must map the schema associated with your operation in the XMLNSC domain. You use the SOAPExtract node to remove SOAP envelopes, allowing just the body of a SOAP message to be processed.
- If you use HTTP nodes or MQ nodes, you must map the SOAP 1.1 or the SOAP 1.2 schema as the root model of the map in the XMLNSC domain.

The following table summarizes the different types of nodes and domains that you can use to map a SOAP message and the schema that you must use when you use a message map to transform a SOAP message.

Table 64. Schemas to use when transforming a SOAP message

Message domain	Nodes usage	Schema to configure in a message map
XMLNSC	All SOAP nodes within an integration service operation subflow.	Schema for operation request or response.
XMLNSC	SOAPInput nodes in flows that have a SOAPExtract node before the Mapping node.	Schema for operation request.

Table 64. Schemas to use when transforming a SOAP message (continued)		
Message domain	**Nodes usage**	**Schema to configure in a message map**
XMLNSC	SOAPReply or SOAPRequest nodes that might be preceded in a flow by a SOAPEnvelope node.	Schema for operation request or response.
SOAP	SOAPInput nodes that are wired directly to the Mapping node.	IBM-provided SOAP_Env where the body `xsd:any` has a mapping cast to the schema for the operation request.
SOAP	SOAPReply or SOAPRequest nodes that are wired directly to the Mapping node.	IBM-provided SOAP_Env where the body `xsd:any` has a mapping cast to the schema for the operation request or response.
XMLNSC	Flows that do not contain SOAP nodes. For example, flows that contain HTTP nodes, MQ nodes, or FileInput nodes.	IBM-provided SOAP 1.1 or SOAP 1.2 schema where the body `xsd:any` has a mapping cast to the schema for the operation request or response.

The following table compares the SOAP message structure with the IBM App Connect Enterprise SOAP message generic model:

Table 65. Comparison between the SOAP message structure and the IBM App Connect Enterprise SOAP message representation			
Standard SOAP message parts	**Status**	**IBM App Connect Enterprise SOAP message parts**	**IBM App Connect Enterprise Status**
		Context	Required
SOAP header (part of the SOAP envelope)	Optional	Header (part of the SOAP_Domain_Msg)	Optional
SOAP body (part of the SOAP envelope)	Required	Body (part of the SOAP_Domain_Msg)	Required
SOAP faults (part of the SOAP body)	Optional	Fault (part of the Body)	Optional
SOAP Attachments	Optional	Attachment (part of the SOAP_Domain_Msg)	Optional

Procedure

Complete the following steps to configure the **SOAP_Domain_Msg** when the Mapping node is connected directly from a SOAPInput node with no SOAPExtract node:

1. Define the transformation for the **Context** object by using one of the following approaches:
   - Copy the **Context** object by using the **Move** transform.
   - Copy the **Context** object by using the **Move** transform, and then use the **Override** function if you want to modify a few elements with an **Assign** transform or a **Move** transform.
   - Define transforms for all the **Context** elements that you want to maintain in the output object.

2. Define the transformation for the **Header** object by using one of the following approaches:
   - Copy the **Header** object by using the **Move** transform.

   - Copy the **Header** object by using the **Move** transform, and then use the **Override** function if you want to modify a few elements with an **Assign** transform or a **Move** transform.
   - Define transforms for all the **Header** elements that you want to maintain in the output object.

   You define SOAP header parts by using the **Cast** function. You can cast attributes and other header parts. Then, define transforms between the input elements and the output elements in each header part.

   The SOAP Header element contains application-specific information, including attributes that define how you process the SOAP message.
3. Define the transformation for the **Body** object.

   You define SOAP body parts by using the **Cast** function. You can cast attributes and other body parts. Then, define transforms between the input elements and the output elements in each body part.

   Complete the following steps to define the SOAP body parts and their transformations:

   a) Cast attributes that are defined as *xsd:any* into a specific type. Then, define a transform between the input attribute and the output attribute.

   b) Cast wildcard elements that are defined as *xsd:any* into a specific type.

   c) Cast a base type element to a derive type element. A derive type element is also known as an extension type element.

      In a message map, you cast a base type to a derive type or extension type so that you can define transformations between subtypes of a data type.

      For example, addresses are represented differently for different countries. You might want to map addresses from different countries into a common complex structure for addresses.

   d) Define transforms between the input and output body elements.

   Note: When you use a schema model for your SOAP message or the built-in SOAP domain message, you can also define the **xsd:any** by using the **Add User-Defined** function. However, you are recommended to use the schema models that are part of the WSDL service definition, if they are available.
4. Define the transformation for the **Attachment** object by using one of the following approaches:
   - Copy the **Attachment** object by using the **Move** transform.
   - Copy the **Attachment** object by using the **Move** transform, and then use the **Override** function if you want to modify a few elements with an **Assign** transform or a **Move** transform.

   You define SOAP attachment parts by using the **Cast** function.

Example

Complete the steps in any of the following use cases to learn how to configure the **SOAP_Domain_Msg** when the Mapping node is wired directly from a SOAPInput node with no SOAPExtract node:

- Configure a SOAP message when you use a conditional transform to map an input element to an output element. For example, you create and configure the **If, Else if, and Else** transform to control the flow of the mapping between elements that are defined as a specific or a derive type in the input and output message assembly by setting conditions. For more information, see "Mapping a SOAP message by using a conditional transform" on page 1544.

- Configure a SOAP message to transform some input elements to output elements. Use the **Override** function, **Assign** transform, and **Move** transform. For more information, see "Mapping a SOAP message by using the Override function" on page 1546.

What to do next

Define more transforms between the input **SOAP_Domain_Msg** and the output **SOAP_Domain_Msg**. For more information, see "Specifying a transform (mapping operation)" on page 1430.

Mapping a SOAP message by using a conditional transform
You define SOAP message parts in a message map by using the **Cast** function and then you define transforms between its elements. To map between elements that are defined as specific or derived types, you might want to define some conditional transforms. You can configure the **If, Else if, and Else** transform to control the flow of the mapping between elements.

About this task

When you use an **If, Else if, and Else** transform between your **SOAP_Domain_Msg** input object and **SOAP_Domain_Msg** output object, you must manually configure each element in the **SOAP_Domain_Msg**. You must map each element in the **SOAP_Domain_Msg** input object to the corresponding output object so that you do not lose the information of the element.

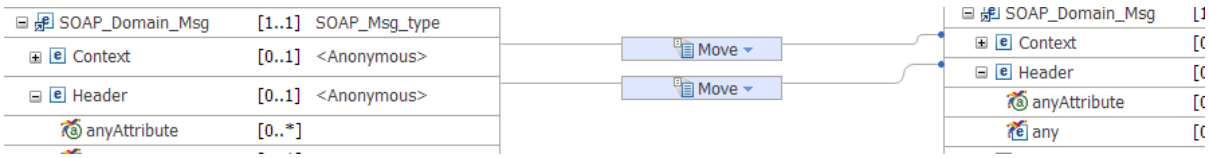
Note: Elements that are part of the input object and do not have a transform that is defined to an output object are deleted from the output structure and their value is lost.

Procedure

Complete the following steps to configure the **SOAP_Domain_Msg** when the Mapping node is wired directly from a SOAPInput node with no SOAPExtract node:

1. Define the transformation for the **Context** object.

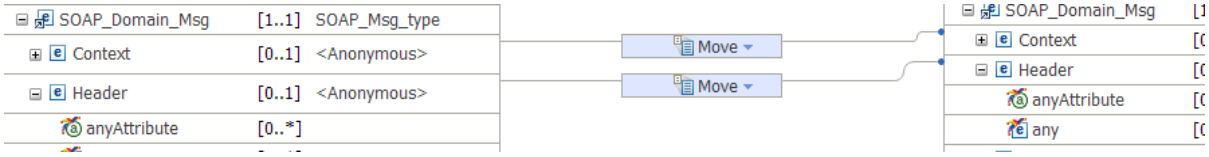
   Copy the **Context** object by using the **Move** transform. For more information, see "Specifying a transform (mapping operation)" on page 1430.



2. Define the transformation for the **Header** object.

   You can define a **Move** transform between the input **Header** object and the output **Header** object to copy the structure and all its elements.

   Copy the **Header** object by using the **Move** transform.



3. Define the transformation for the **Body** object. Define SOAP Body parts by using the **Cast** function. You can cast attributes and other body parts. Then, define transforms between the input elements and the

output elements in each body part. For more information, see "Casting elements in a message map" on page 1398.

a) Cast attributes that are defined as *xsd:any* into a specific type. Then, define a transform between the input attribute and the output attribute.

b) Cast wildcard elements that are defined as *xsd:any* into a specific type.

c) Cast a base type element to a derive type element. A derive type element is also known as an extension type element.

In a message map, you cast a base type to a derive type or extension type so that you can define transformations between subtypes of a data type.

For example, addresses are represented differently for different countries. You might want to map addresses from different countries into a common complex structure for addresses.

d) Create and configure the **If, Else if, and Else** transform to control the flow of the mapping between elements that are defined as a specific or a derive type in the input and output message assembly by setting conditions.

4. Optional: Define the transformation for the **Attachment** object. Copy the **Attachment** object by using the **Move** transform.

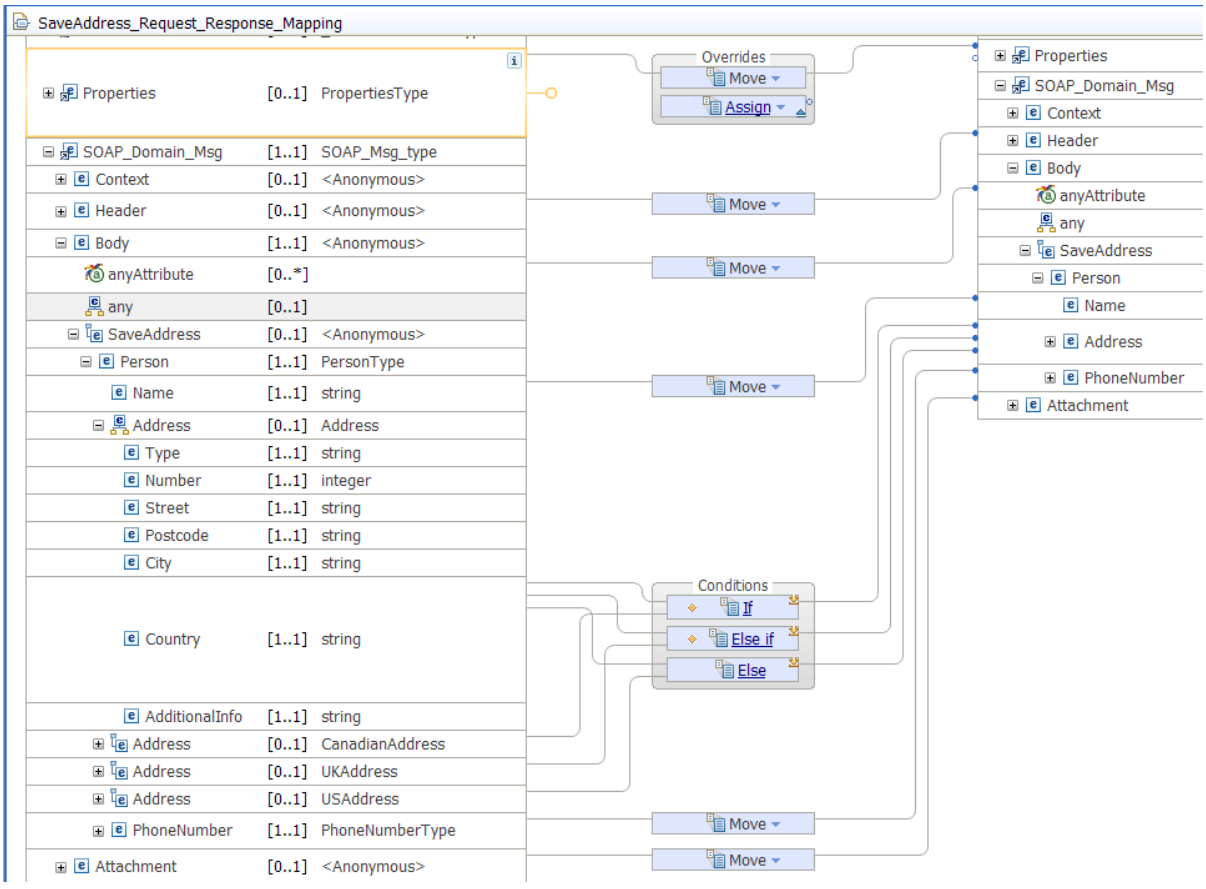
You define SOAP attachment parts by using the **Cast** function.

Results

You have a message map that transforms a SOAP message. The message map contains a nested map that uses the **If, Else if, and Else** transform.

Example

The following figure shows a message map after you complete the previous steps to transform a SOAP message:



What to do next

Define more transforms between the input **SOAP_Domain_Msg** and the output **SOAP_Domain_Msg**. For more information, see "Specifying a transform (mapping operation)" on page 1430.

*Mapping a SOAP message by using the **Override** function*
In a SOAP message, you can use the **Override** function to copy a complex type from the input message to the output message, while you update some of the child elements in the complex type with an **Assign** transform, and a **Move** transform.

Before you begin

You define your SOAP message parts in a message map by using the **Cast** function. For more information, see "Casting elements in a message map" on page 1398.

About this task

Note: You can include **Move** transforms and **Assign** transforms within an **Override**.

Procedure

Complete the following steps to configure the **SOAP_Domain_Msg** when the Mapping node is wired directly from a SOAPInput node with no SOAPExtract node:

1. Define a **Move** transform to copy all the elements in the input **SOAP_Domain_Msg** message unchanged.
2. Change the value of at least one element by using an **Assign** transform or a **Move** transform.
3. Apply a quick fix to configure the **Override** function. Select the option **Group the conflicting transforms in an override group**.

Results

You transformed the SOAP message by using the **Override** function.

What to do next

Define more transforms between the input **SOAP_Domain_Msg** and the output **SOAP_Domain_Msg**. For more information, see "Specifying a transform (mapping operation)" on page 1430.

Creating or transforming a BLOB output message by using a graphical data map

Use the Graphical Data Mapping editor to create or transform a message using the BLOB message domain.

About this task

When you create a new map, the BLOB message is available under the "IBM supplied message models" category in the map input and output selection tree. If you select a BLOB message as the map output, the output domain in the output message assembly is automatically set to BLOB. For more information about creating a new map, see "Creating a message map from a Mapping node" on page 1385.

To populate the data of a BLOB message, you must wire a transform that will provide hexBinary formatted data to the child 'value' element of the message. You can use the built-in function `iib:hexBinaryValue($<var>)` in a Custom XPath transform, to format data into the required hex binary string.

When you transform a BLOB message, you must wire the value element of the input BLOB message into a transform that accepts an `xsd:hexBinary` type. For example, you could use a Move transform to set the BLOB binary data into an XML output message element that has either an `xsd:hexBinary` or `xsd:base64Binary` type.

If you are transforming only the Message Assembly headers and folders (for example, Properties and Transport headers), you can pass the message body data through unmodified by using the BLOB domain and a Move transform from the BLOB input message to the BLOB output message.

Mapping from a BLOB message to an output message using a graphical data map

You can use the Graphical Data Mapping editor to transform a message in the BLOB message domain.

About this task

When you create a new map, the BLOB message is available under the "IBM supplied message models" category in the map input and output selection tree. Select the BLOB message as the map input, and then select your required output message and set its domain in the output message assembly (for example, `XMLNSC`).

For more information about creating a new map, see "Creating a message map from a Mapping node" on page 1385.

The BLOB message provides a single element value of type `xsd:hexBinary`. When you transform a BLOB message, you must wire the value element of the input BLOB message into a transform that accepts an `xsd:hexBinary` type. For example, you could use a Move transform to set the BLOB binary data into an XML output message element with either an `xsd:hexBinary` or `xsd:base64Binary` type.

Creating or transforming a JSON message by using a message map

You can use the Graphical Data Mapping editor to create or transform a JSON object message or a JSON array message. You can provide the model of your JSON message in a JSON schema file or a REST API swagger document or an OpenAPI 3.0 document. Alternatively, you can define your JSON data by using the **Add User Defined** function in the map.

About this task

When you create a message map, you can choose to provide the model of the JSON data from a JSON schema or REST API Swagger document or an OpenAPI 3.0 document in a supported project container. Alternatively, you can define your JSON data by using the **Add User Defined** function in the map, or an equivalent XML schema model.

When you work with a JSON model, you can use a JSON schema, a Swagger document, or an OpenAPI 3.0 document in either JSON or YAML format. You can also use the JSON elements and types to perform mapping casts. For more information, see "Casting elements in a message map" on page 1398.

Procedure

Follow the steps in either of the following topics to create or transform a JSON message:

- "Creating or transforming a JSON message by using a JSON schema" on page 1547
- "Implementing a REST API operation by using a message map" on page 1580
- "Creating or transforming a JSON output message by using the User Defined function to model the JSON data" on page 1552
- "Modeling a JSON message for use in a message map by using an equivalent XML schema model" on page 1572

Creating or transforming a JSON message by using a JSON schema

You can use the Graphical Data Mapping editor to create or transform a JSON message with a data model defined from a JSON schema or a Swagger document.

Before you begin

Ensure that you have a JSON schema or Swagger document to provide the model for your data. If you do not have a JSON schema model, you can model and transform your data using the **Add User Defined** function, as described in the following topics:

- "Graphically modeling a JSON object in a message map" on page 1557
- "Graphically modeling a JSON array in a message map" on page 1560

About this task

When you create a message map for a Mapping node, you can choose to have the input and output message body data defined through a JSON type in a supported JSON schema.

When you select this option, the map is created with the input and output data fully defined by the JSON schema data definitions in the referenced JSON schema file. When you create a message map to transform JSON data in this way, the map must be located in the same shared library or REST API as the JSON schema file.

When working with a JSON model, you can use a JSON schema or Swagger document in either JSON or YAML format. You can also use the JSON elements and types to perform mapping casts; for more information, see "Casting elements in a message map" on page 1398.

Procedure

Use a message map to transform data to or from a JSON data model in a JSON schema, by following these steps:

1. Ensure that your JSON schema model is available for use by the message map:
   a) Put your JSON schema file (with a `.json`, `.yaml`, or `.yml` extension) in one of the following containers:
      - Application
      - REST API project
      - Integration Service project
      - Shared library
      - Static library

      Note: Your message map and JSON schema file must be stored in the same project.

      Ensure that the schema model file conforms to the JSON Schema draft 4 specifications and meets the requirements specified in "JSON schema requirements for message maps" on page 1549.
   b) Ensure that the container selected to create the new message map is the one that contains the JSON schema or Swagger documents that need to be referenced. Also ensure that the model definitions meet the requirements specified in "JSON schema requirements for message maps" on page 1549.
2. Create a new message map by starting the **New Message Map** wizard, either from the context menu or by double-clicking a Mapping node. If you are creating a message map for a REST API operation request or response mapping, ensure that you start the **New Message Map** wizard by double-clicking

the Mapping node in the operation subflow. For more information, see "Implementing a REST API operation by using a message map" on page 1580.

a) On the first panel of the wizard, select a map that is called from a Mapping node; submaps are not supported with models from JSON schema.

b) Ensure that the container selected for the new message map is the same shared library or REST API project that contains your JSON schema file.

c) Click **Next** to move to the **Select inputs and outputs** panel. Expand the **JSON Types** folder under the shared library or REST API project folder, to view and select the required type. You can also enter part of the Type name in the filter boxes, to limit the search.

- JSON array types are prefixed with `JSONArray_`.
- The root level type from a JSON schema file is the basename of the containing file, suffixed with `_JsonType`.
- The type names are unique in a JSON schema file. If two JSON schema files provide a type with the same name, you must select the required type by using the filename to distinguish them.
- If your JSON data is not located in the message body (for example, if you have a REST request node that is configured to place its response in the environment), you can add a mapping cast to specify `Environment.Variables.any` when the map is created and opened in the editor.

d) If you have selected a JSON type that is not in the same Toolkit container as the one in which the map will be created, an error is displayed and you cannot continue until all the map and JSON schema files are located in a single shared library or REST API container.

When performing a mapping cast, the elements and types from JSON schema and Swagger documents located in the same container as the map will be included in the list of available options.

e) Click **Finish**, and the map is opened in the Graphical Data Mapping editor.

3. Complete the required transformation logic in the message map, by using any of the available transform types. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282 and "Editing message maps" on page 1394.

   In addition to transforming the message data, you can interact with resources as described in the following topics:

   - "Mapping database content" on page 1523
   - "Using Java in a message map" on page 1370
   - "Accessing user-defined properties from a Mapping node" on page 1479

What to do next

Deploy the solution with the message map, and exercise it to verify that the output message is as required. For more information, see "Troubleshooting a message map" on page 1587.

JSON schema requirements for message maps

You can use the Graphical Data Mapping editor to create and transform JSON messages with the data model that is defined from a JSON schema or REST API swagger document, which can be in JSON or YAML format.

The following requirements apply to both JSON schema and to the model definitions from an OpenAPI v3 or Swagger v2 document. For more information, see Swagger.

- JSON schema must be well formed, valid, and must conform to the JSON Schema draft 4 specifications.

  You can use an external tool to validate the JSON schema file before you import it and use it for message maps. For example, see http://jsonlint.com.

- JSON schema must be in either JSON format with a `.json` file extension, or YAML format with a `.yaml` or `.yml` file extension.

- JSON schema must be located in one of the following project containers:
  - Application
  - REST API project
  - Integration Service project
  - Shared library
  - Static library

  Note: Your message map and JSON schema file must be stored in the same project.
- When you are using a JSON schema for a Mapping Cast, such as mapping the output of a REST request node that is configured to place its output in environment tree, bear in mind that cast types and elements are provided for only the following types:
  - Root-level JSON type, with the same name as the schema file
  - Top-level JSON types
  - JSON types defined in the `components.schemas` section of an OpenAPI v3, or the `definitions` section of a Swagger 2 document.

  The elements for a JSON array are suffixed with `JSONArray`, and the complex types for a JSON array are prefixed with `JSONArray`.
- Heterogeneous JSON arrays, in which the type of each entry can vary, appear in the message map with the `Item` field that represents an array entry that is defined as an `any` type. You can cast this `any` type to the heterogeneous JSON array types only if the JSON schema defines them through JSON references.
- While external "$ref"s are supported in OpenAPI v3 documents, the JSON schema `"$ref"` keyword is supported only for internal references in a Swagger 2 document.
- The JSON schema "not" keyword, which can be used to exclude specific types from a JSON object, is not supported.
- To enable message mapping, all JSON data types that are to be mapped from or to must be explicitly modelled.
  - You cannot map from or to JSON data if it is present only because the JSON schema keyword `additionalProperties` is set to `true`. To be able to graphically map to or from data, it must be explicitly present in the model so that it appears as a named input or output in the map. Therefore, it is beneficial to use JSON schema models that set: `"additionalProperties": false`.
  - A JSON empty object, *"{}"* appears in the map as an element "_matchAnything", and allows a mapping cast to be applied. For more information, see Casting with JSON schema types.
- It is good practice to enable JSON domain message validation when you develop and test maps.
- For example:
  - A JSON schema data member with type `"string"` and property `"maxLength": 10`

    This type can have a transform that is applied in the map that sets the length in excess of 10 characters. This would not cause a map design validation or runtime error.
  - A JSON enum can be set incorrectly to a value not matching one of the enumerations.
- JSON schema data defined as type `"number"` is processed in the Mapping node by using a Message Assembly tree type of `"double"`. This might lead to the output JSON text providing the data in a scientific (exponential) notation. To avoid this, use the JSON schema type `"integer"`.
- In the message map, optional/required/number of occurrences is modelled as `"minOccurs"` and `"maxOccurs"`. The JSON schema keyword `"required"` sets `"minOccurs=1"`, otherwise it is set as `"minOccurs=0"`
- A JSON schema `"enum"` with mixed type entries appears as a `"string"` type in the message map.

- The JSON schema "oneOf" and "anyOf" keywords, which are used for structuring and combining more complex JSON schema, are supported as follows:
  - Specifying a JSON type or null:
    - To define a type as either a primitive or null. For example:

```
"NullableNums": {
       "oneOf": [
         {
           "type": "integer",
         },
         {
           "type": "null"
         }
       ]
}
```

    - To define a type as either an object or null, where the object can be defined inline or through $ref. For example:

```
"Address" : {
 "oneOf": [
  {"type": "null"},
   {"$ref":"#/definitions/Address"}
         ]
}
```

    In these cases, the map presents the JSON type in the map ready for wiring transforms. The properties show that the type is defined as nillable.
  - To define a JSON schema top-level type as an object or array of a $ref type. For example:

```
  "oneOf": [
    {
      "$ref": "#/definitions/Account"
    },
    {
      "type": "array",
      "items": {
        "$ref": "#/definitions/Account"
      }
    }
  ]
```

    In this case the New Message Map wizard, or the Map Editor Add Input or Output dialog provides two entries for the JSON type, one as an Object and the other as an Array (in the example, these are Account and JSONArray_Account).
  - Support for the "oneOf" and "anyOf" keywords was enhanced to handle a list with multiple types. For example:

```
"Contact" : {
"properties": {
"conType": {
"type": "string"
}
},
"oneOf": [
            {"type": "null"},
            {"$ref":"#/definitions/Address"},
            {"$ref":"#/definitions/TelContacts"}
        ]
        }
```

    In this case the map initially displays the JSON object "Contact" with only the "conType" child, or with no content when the JSON object has no properties. You can right-click "Contact" and apply a mapping cast to one or more of the types from the list that is provided in the JSON schema; in this example, the types are "Contact_Address" and "Contact_TelContacts". For more information, see “Casting with JSON schema types” on page 1405.

- The JSON data element names must also be a valid XML name.

  Note:

  Naming issues might not be detected in the Integration Toolkit, but they might lead to the deployment of the message map to fail with a `Map script generation` error with a cause of `invalid grammar`.

If these conditions are not met, you might see the following effects:

- When you create a new message map, the JSON types from the JSON file are not offered in the **New Map Wizard**.
- When creating a message map for a REST API operation subflow, the option **Message map with input and output for REST API operation** is offered, but when clicking **Finish** the wizard does not complete and an error is displayed.
- If a JSON schema file that is used by a message map is modified such that it is no longer supported, the message map is marked with an error that reports the JSON type from the JSON schema file is now unresolved. For example:

  ```
  Unable to locate object named "mlib://SafesForceAllModelsShlib/Contact#/-/simpleType{http://
  www.ibm.com/iib/msl/json}Contact". LeadToContact.map Map Reference Problem

  The null input or output object /Contact.json could not be found. LeadToContact.map Map
   Problem
  ```

  When the JSON schema file that is used by a message map is modified and the map has not been edited and saved again, you might have to invoke the `clean` action through the menu option **Project** > **Clean**.
- The cause of the failure to process a JSON schema for a message map is logged in the Integration Toolkit Eclipse Error Log.

Creating or transforming a JSON output message by using the User Defined function to model the JSON data
You can use the **Add User Defined** function in the Graphical Data Mapping editor to create or transform a JSON object message or a JSON array message.

About this task

When you create a message map, you can choose to provide the model of the JSON data from a JSON schema, or you can define your JSON data by using the **Add User Defined** function in the map. This topic explains how to use the **Add User Defined** function. For information about using a JSON schema, see “Creating or transforming a JSON message by using a JSON schema” on page 1547.

Predefined models are available under the IBM supplied message models category in the map input and output selection tree.

- You select **JSON (JSON object message model supplied by IBM)** to create a JSON object message.
- You select **JSON (JSON array message model supplied by IBM)** to create a JSON array message.

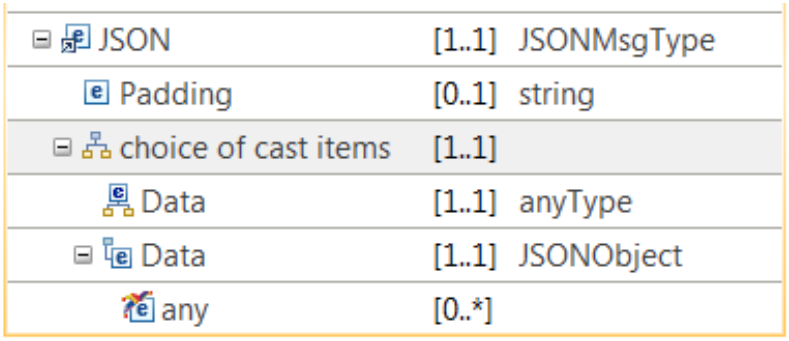
When you select any of the JSON message models as the map output, the output domain in the output message assembly is automatically set to JSON.

The predefined JSON message contains a single element value of type **JSONMsg_type**. This element contains the following child elements:

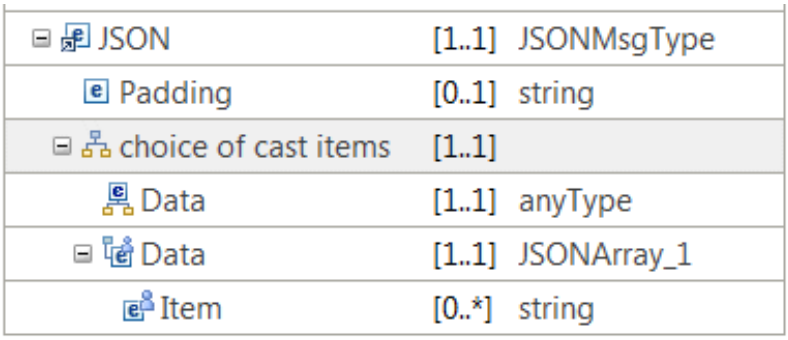
1. A **Padding** element: This element is optional. You define its value to pass a user-defined JavaScript function call used by JSONP services.
2. Two **Data** elements: You define only one of the **Data** elements to model your JSON message.
   - You define the element **Data**, of type **anyType**, by using the **Cast** function. You define this element when you have a schema model that defines your JSON message. If you create your map

programmatically, you can cast **Data** to some type in an external schema file, which can define either a JSON object or a JSON array message.

- You define the element **Data**, of type **JSONObject**, by using the **Add User-Defined** function. You define this element when you want to transform some elements of your JSON object message. You can also use the **Cast** function to define the JSON message, or a part of it, with a schema model.



- You define the element **Data**, of type **JSONArray_1**, by using the **Add User-Defined** function. You define this element when you want to transform some elements of your JSON object message. You can also use the **Cast** function to define the JSON message, or a part of it, with a schema model.



Procedure

You can complete any of the following actions on JSON messages in the Graphical Data Mapping editor:

1. You can define a JSON object without a schema model graphically. Use the **Add User-Defined** function to add an element, and select one of the supported simple types. For more information, see "Graphically modeling a JSON object in a message map" on page 1557.
2. You can define a JSON array without a schema model graphically. All the elements in the array are of the same type. Use the **Add User-Defined** function to add an element, and select **JSONArray_Default** as its type. For more information, see "Graphically modeling a JSON array in a message map" on page 1560.
3. You can define a multidimensional JSON array without a schema model graphically. Use the **Add User-Defined** function to add multiple elements, and select **JSONArray_Default** as their types. For more information, see "Graphically modeling a multidimensional JSON array in a message map" on page 1565.
4. You can create a JSONP message, or transform a message that is modeled in a different message domain into a JSONP message. For more information, see "Graphically modeling and transforming a JSONP message in a message map" on page 1579.
5. You can define a JSON message by using your own schema model. Use the **Cast** function to add a JSON message. For more information, see "Modeling a JSON message for use in a message map by using an equivalent XML schema model" on page 1572.
6. You can use the Graphical Data Mapping editor to implement a REST API operation. For more information, see "Implementing a REST API operation by using a message map" on page 1580.

Graphically modeling a JSON message in a message map
In the Graphical Data Mapping editor, you can use the **Add User-Defined** function to create a JSON message that contains JSON objects, JSON arrays, or both.

About this task

If you have a JSON schema model, you can use it in your map in a shared library or REST API; for more information, see "Creating or transforming a JSON message by using a JSON schema" on page 1547. If you do not have a JSON schema model, you can create a map selecting the predefined JSON message and define your JSON data by using the **Add User-Defined** function as described in this topic.

Note: You cannot use both JSON schema and user-defined elements a message body. However, you can create a map that has the input message body defined by JSON schema, and the output message or local environment defined by using the **Add User-Defined** function.

Procedure

Complete the following steps to create a JSON message for which you do not have a schema model:

1. Create a message map. Select one of the following JSON supplied models as the input or output of the map:
   - **JSON (JSON object message model supplied by IBM)** to create a JSON object message
   - **JSON (JSON array message model supplied by IBM)** to create a JSON array message

   For more information, see "Creating a message map" on page 1382.
2. Qualify the content under the **Data** element by using the **Add User-Defined** function.

   A JSON message consists of name-value pairs, which are known as JSON objects, and ordered collections of values, which are known as JSON arrays.

   a. To define a JSON object in the JSON output message, use the **Add User-Defined** function to add an element, and select one of the supported simple types. For more information, see "Graphically modeling a JSON object in a message map" on page 1557.

   b. To define a JSON array in the JSON output message, use the **Add User-Defined** function to add an element, and select **JSONArray_Default** as its type. For more information, see "Graphically modeling a JSON array in a message map" on page 1560.

   c. To define a multidimensional JSON array in the JSON output message, use the **Add User-Defined** function to add multiple elements, and select **JSONArray_Default** as their types. For more information, see "Graphically modeling a multidimensional JSON array in a message map" on page 1565.

   Note: When you use the Graphical Data Mapping editor to transform a JSON message, ensure that the JSON element names that you define by using the **Add User-Defined** function are valid according to the XML rules for naming elements. JSON allows a wider range of characters than XML, for example a JSON object might include the **@** character, however, the Graphical Data Mapping editor allows only element names that are valid in XML or XPath.

3. Define transforms between the input elements and the output elements.
   - Use the **Assign** transform to set a fixed value without the use of input data.
   - Use the **Create** transform to create an empty JSON object, or a NULL JSON object, without the use of input data
   - Use the **Move** transform to copy an input element value to the output element.
   - Use the **If** transform, a custom transform, or the **XPath** transform to define the condition that determines the value of an output element.
   - Use the **Append** transform, the **Group** transform, the **For Each** transform, the **Join** transform, a custom transform, or the **XPath** transform to set the value of a JSON array.
   - Use the **Select** transform or the **Database Routine** transform to set the value with data available in a database system.
   - Use the **xs:type** transform to cast the value of a simple input element to a specific data type.
   - Use the **fn:type** transform to set the value by using XPATH 2.0 functions.
   - Use the **Custom Java** transform to enter your own Java code.
   - Use the **Custom ESQL** transform to call your own ESQL code.
   - Use a **Custom XPath** transform with the function `iib:nullValue()` to set a JSON object to NULL, or a JSON array to NULL.

   For more information, see “Specifying a transform (mapping operation)” on page 1430.

Example

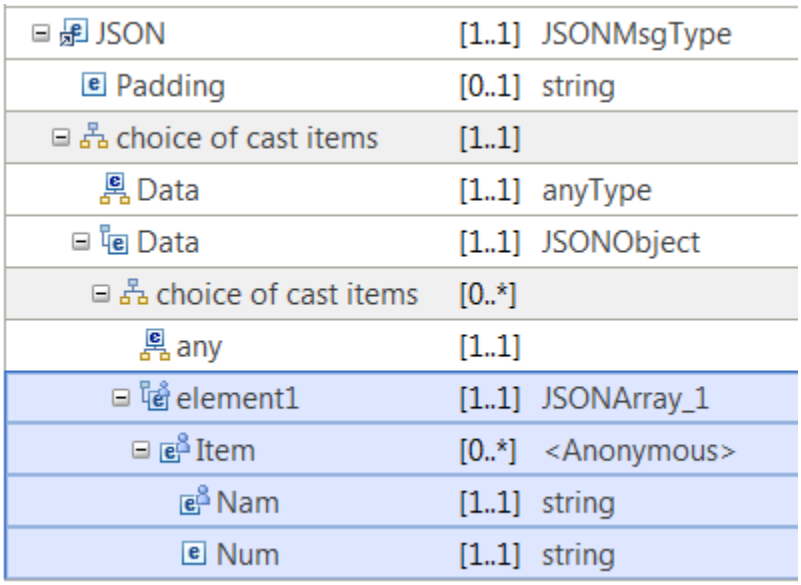
This example shows how to model in a message map the following JSON object message:

```
{"element1":[{"Nam":"val1","Num":1},{"Nam":"val2","Num":2}]}
```

To define this JSON message, you must

1. Add a user-defined element of type **JSONArray_Default**, and change its name to `Message`.
2. Set the type of **Item** to **Anonymous**.
3. Add two elements that represent the object-value elements in the array. The display name in the map is representative of the name of the object. At run time, the Graphical Data Mapping editor uses the name of the objects that are passed in the message.

The following figure shows the map after you complete the previous steps:

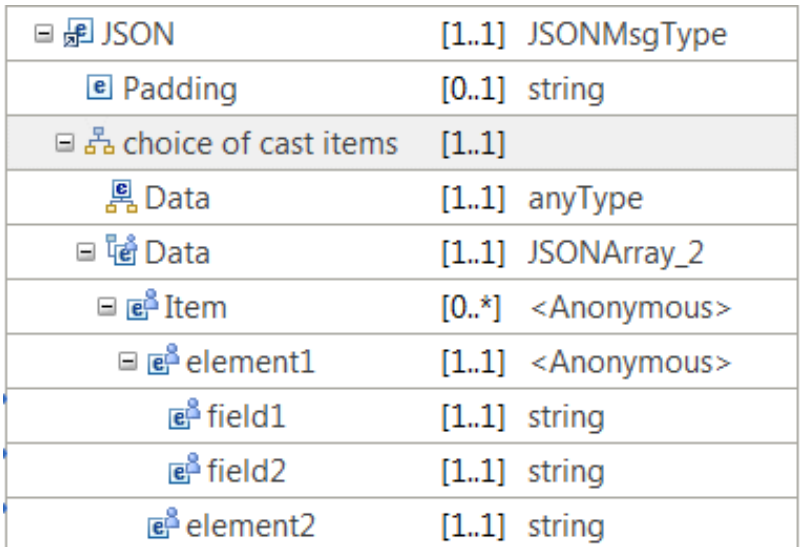


The message tree for the JSON message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x2f030fa0]
   (0x01000000:Object):Data = (
     (0x01001000:Array):element1 = (
       (0x01000000:Object):Item = (
         (0x03000000:NameValue):Nam = 'val1' (CHARACTER)
         (0x03000000:NameValue):Num = 1 (INTEGER)
       )
       (0x01000000:Object):Item = (
         (0x03000000:NameValue):Nam = 'val2' (CHARACTER)
         (0x03000000:NameValue):Num = 2 (INTEGER)
       )
     )
   )
 )
```

This other example shows how to model in a message map the following JSON array message:

```
[{"element1":{"field1":"Sweet","field2":"Flower"},"element2":"me@bbloggs.com"}]
```



The message tree for the JSON array message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x292051a0]
    (0x01001000:Array):Data = (
      (0x01000000:Object):Item = (
        (0x01000000:Object   ):element1 = (
          (0x03000000:NameValue):field1 = 'Sweet' (CHARACTER)
          (0x03000000:NameValue):field2 = 'Flower' (CHARACTER)
        )
        (0x03000000:NameValue):element2 = 'me@bbloggs.com' (CHARACTER)
      )
    )
```

What to do next

Deploy the message map and verify that the output message is valid. For more information, see “Troubleshooting a message map” on page 1587.

Graphically modeling a JSON object in a message map
In the Graphical Data Mapping editor, you can use the **Add User-Defined** function to create a JSON object.

Before you begin

Create a message map with the output domain set to JSON. For more information, see "Graphically modeling a JSON message in a message map" on page 1554

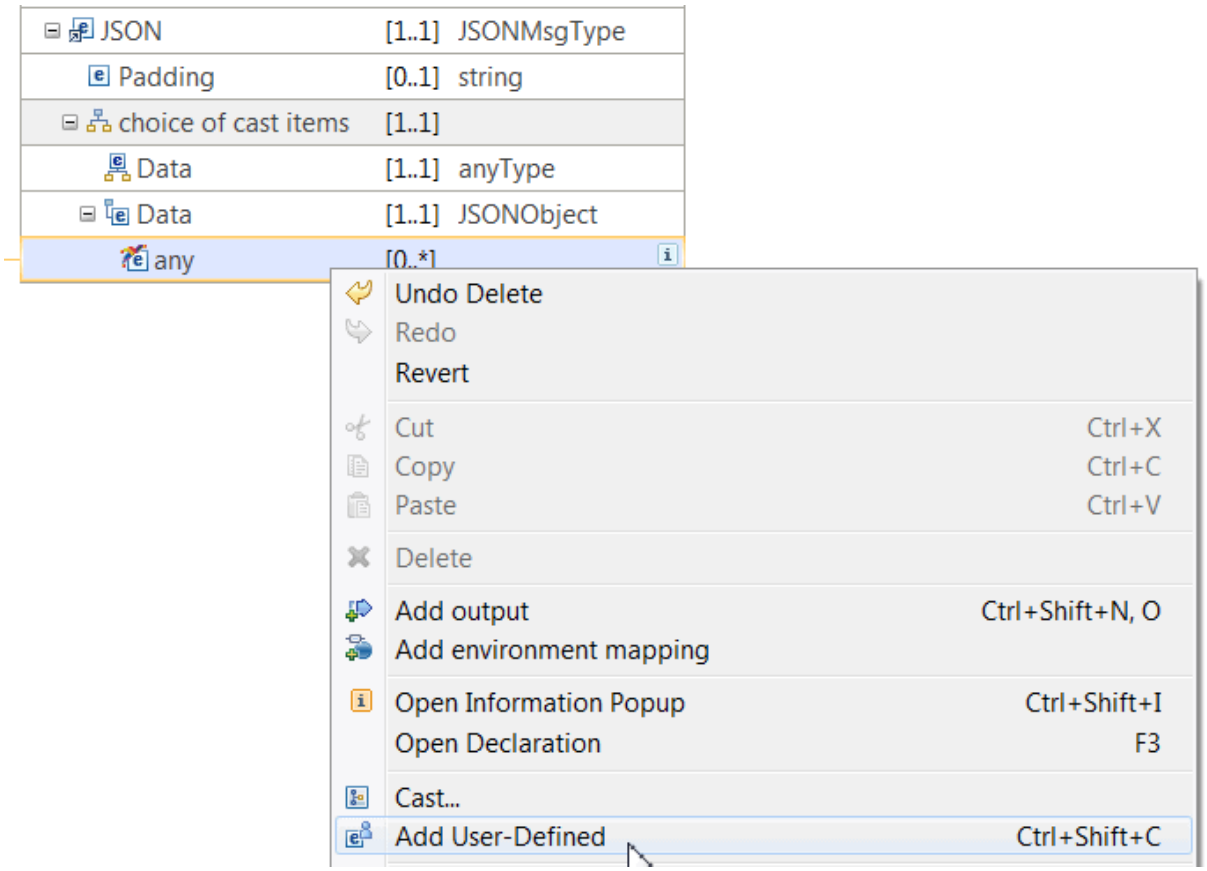
About this task

If you have a JSON schema for your message data, you can use that as described in "Creating or transforming a JSON message by using a JSON schema" on page 1547. Alternatively, you can model a JSON object in your message map by following these steps:

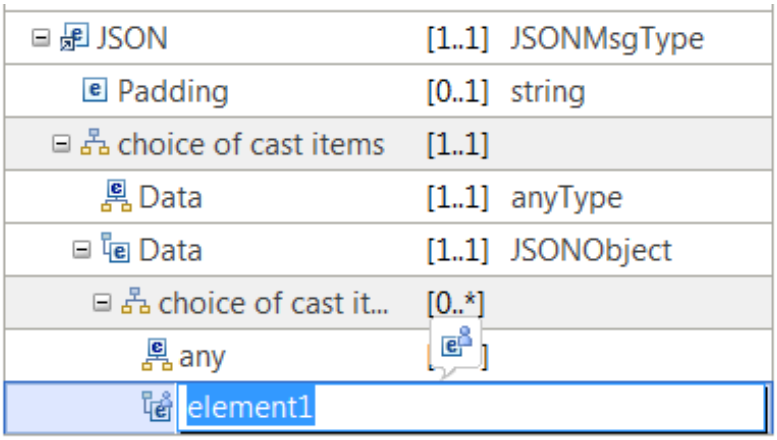
Procedure

To create a JSON object message with one name-value pair, complete the following steps:

1. Right-click **any**, and select **Add User-Defined**.



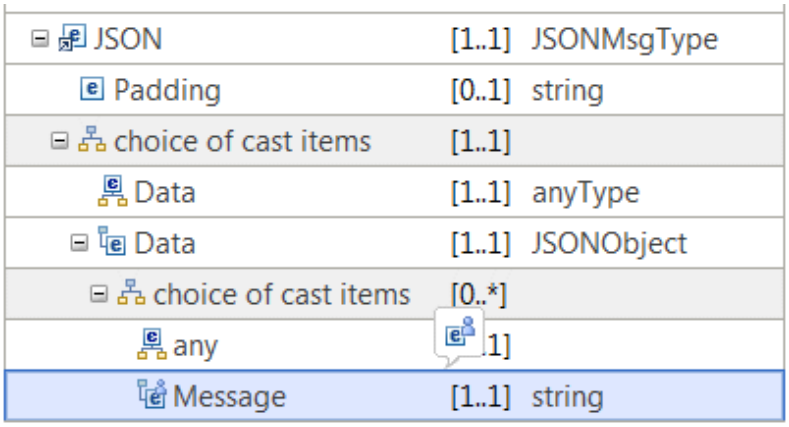
You can see **element1** created under the **any** element.



2. Click **element1** and enter the name of the JSON element.

   For example, enter **Message** for the following JSON message:

```
{"Message":"Hello World"}
```



3. Select the data type of the JSON element. You can select any of the following simple data types:

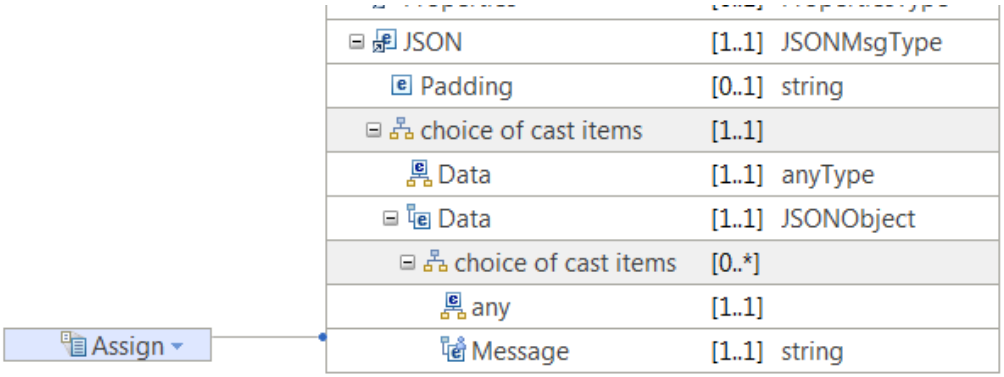
   - Anonymous: Use this type to define a JSON object.
   - Boolean
   - date
   - dateTime
   - decimal
   - double
   - duration
   - float
   - hexBinary
   - int
   - long
   - string
   - time
   - Global type, that is, a type based on an XML schema, a DFDL schema, or a message set. (You access your global types by selecting the option **Browse**.)

   To set the type, select the user-defined element. Then, complete one of the following steps:

   - In the map, click the type of the user-defined element to open the **Type Selection** window. Then, choose the type of the element.
   - In the **Properties** page, select the properties page drop-down to choose the type of the element.
   - In the **Properties** page, click **Browse** to open the **Type Selection** window. Then, choose the type of the element.

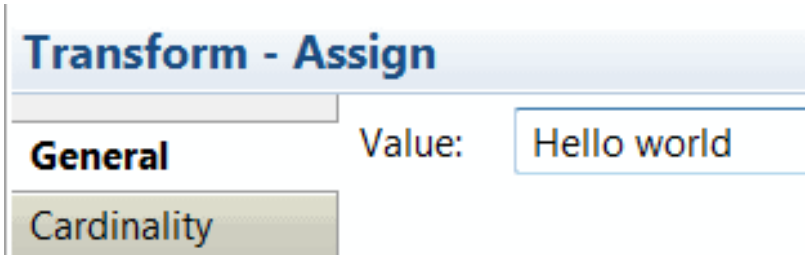
   When you change the type to **Anonymous**, the Graphical Data Mapping editor adds a child element.

4. Select a transform. For example, use an **Assign** transform to set the fixed value of a simple element.



5. Set the value of the element in the Properties view. In the **General** tab, enter a value in the **Value** property.

   For example, enter `Hello world` to set the value of the element Message.



Results

You create a simple JSON object message with one name-value pair.

The message tree for the following JSON message

```
{"Message":"Hello world"}
```

is described in the following trace:

```
Message: ( ['json' : 0xc552990]
  (0x01000000:Object   ):Data    = (
    (0x03000000:NameValue):Message = 'Hello World' (CHARACTER)
 )
```

What to do next

Deploy the message map and verify that the output message is valid. For more information, see “Troubleshooting a message map” on page 1587.

Graphically modeling a JSON array in a message map
In the Graphical Data Mapping editor, you can use the **Add User-Defined** function to create a JSON array in a JSON message. You can create JSON arrays where all occurrences of the array are of the same type.

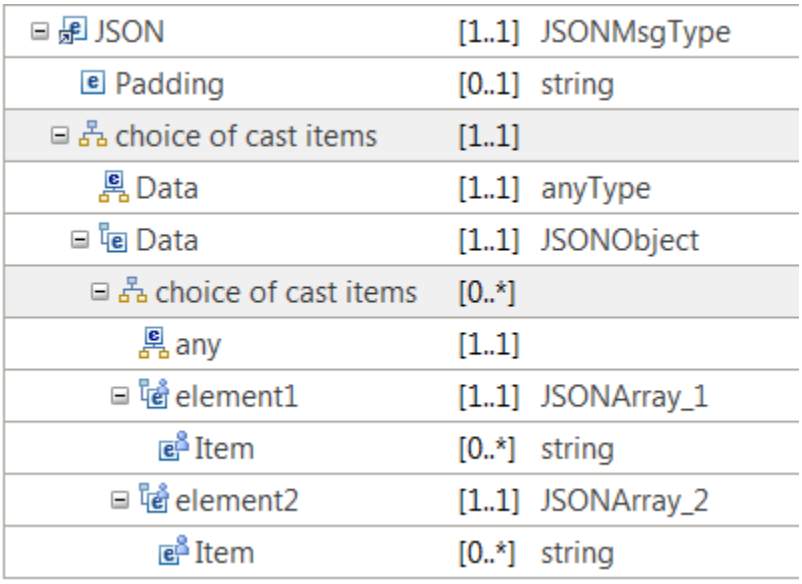
Before you begin

Create a message map with the output domain set to JSON. For more information, see “Graphically modeling a JSON message in a message map” on page 1554

About this task

To create a JSON array in a JSON message by using the **Add User-Defined** function, you must set the type of the user-defined element to **JSONArray_Default** and then set the type of the **Item** element to the required type.

When you define multiple arrays in your map, each JSON array has a type **JSONArray_N**, where **N** describes the unique id of the array in the map.



You can reuse the definition of a JSON array in your message map. For more information, see "Reusing a JSON message, a JSON object, or a JSON array in a message map" on page 1572.

Procedure

Complete the following steps to create a JSON array in a JSON message:

1. Right-click **any**, and select **Add User-Defined**.

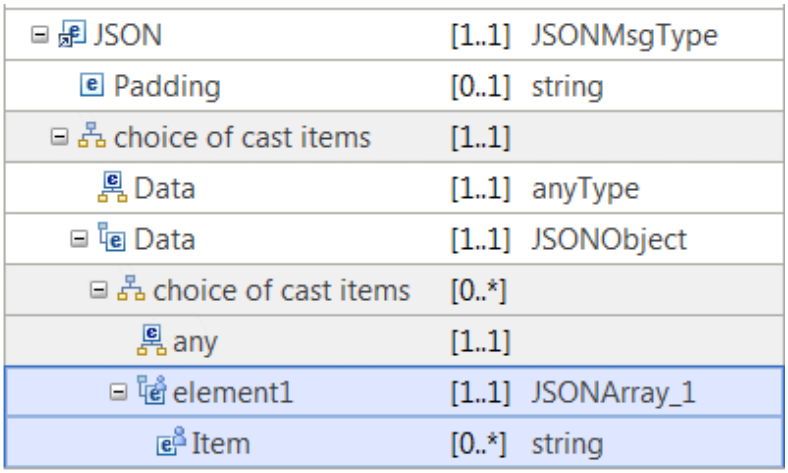
   The element **element1** is created under the **any** element.
2. Click **element1** and enter the name of the JSON array.

   By default, the user-defined element is created as a **string** element.
3. For **element1**, click **string**, and select **JSONArray_Default** as its type.

   The repeating element **Item** is created automatically. **Item** is used internally by IBM App Connect Enterprise. You cannot change this name. **Item** will not appear in your JSON data. Item is the logical

tree representation of each instance in the JSON array. For more information, see JSON parser and domain.

You cannot change the cardinality of **Item**. For more information, see "Configuring the cardinality of a user-defined element" on page 1412.



Note: **Item** is the name of the repeating element that describes the JSON array. All the values in the array have the same type. You set the type of **Item**. The first and the last element in the array is of the same type.

4. Use any of the following transforms to set the value of a JSON array:
   - Use the **For Each** transform to set the JSON array output value when you have a repeating input element. For more information, see "For Each" on page 1320.
   - Use the **Append** transform to add occurrences of the array in the order of the inputs to the transform, which can be singleton or repeating. For more information, see "Append" on page 1285.
   - Use the **Join** transform when you have multiple repeating input elements that you must combine into a single repeating output element. For more information, see "Join" on page 1332.

Example

This sample shows how to model in a message map the following JSON array. The JSON array is created as an element of a JSON object message:

```
{"Message":["valueA","valueB"]}
```

To define this JSON message, you must

1. Add a user-defined element of type **JSONArray_Default**, and change its name to `Message`.
2. Set the type of **Item** to string.

The following figure shows the map after you complete the previous steps:

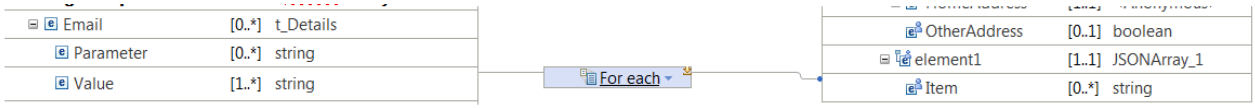
JSON	[1..1]	JSONMsgType
Padding	[0..1]	string
choice of cast items	[1..1]	
Data	[1..1]	anyType
Data	[1..1]	JSONObject
choice of cast items	[0..*]	
any	[1..1]	
Message	[1..1]	JSONArray_1
Item	[0..*]	string

The message tree for the JSON array in a JSON message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x2f0312d0]
    (0x01000000:Object):Data = (
      (0x01001000:Array):Message = (
        (0x03000000:NameValue):Item = 'valueA' (CHARACTER)
        (0x03000000:NameValue):Item = 'valueB' (CHARACTER)
       )
     )
)
```

When you use a **For Each** transform to set the value of the array elements, notice the difference of how the output message is created. The output differs based on how you connect the input and output elements. In this example, you can see how to transform an input message with two email addresses.

When you wire the transform to the element **Item** of type **string**, you get one array with multiple output elements:



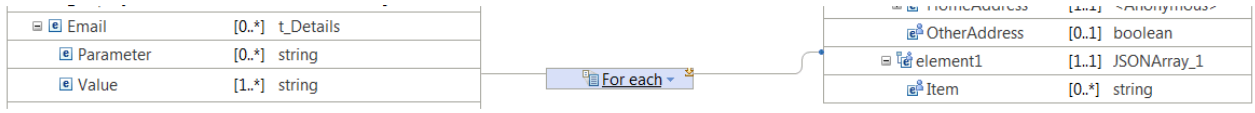
The following code is the message map representation of the JSON array as shown in the previous figure:

```
    (0x01001000:Array    ):element1      = (
       (0x03000000:NameValue):Item = 'myfirstemail@bbloggs.com' (CHARACTER)
       (0x03000000:NameValue):Item = ' mysecondemail@bbloggs.com' (CHARACTER)
     )
```

The JSON array that is created has two elements:

```
"element1":["myfirstemail@bbloggs.com"," mysecondemail@bbloggs.com"]
```

When you wire the transform to the element **element1** of type **JSONArray_1**, you get two arrays with the same name in the output:



The following code is the message map representation of the JSON array as shown in the previous figure:

```
 (0x01001000:Array    ):element1      = (
       (0x03000000:NameValue):Item = 'me@bbloggs.com' (CHARACTER)
     )
     (0x01001000:Array    ):element1      = (
```

```
        (0x03000000:NameValue):Item = ' mysecond@bbloggs.com' (CHARACTER)
      )
```

The JSON elements that are created are two arrays with the same name:

```
"element1":["myfirstemail@bbloggs.com"],"element1":[" mysecondemail@bbloggs.com"]
```

What to do next

Deploy the message map and verify that the output message is valid. For more information, see "Troubleshooting a message map" on page 1587.

Graphically modeling a multidimensional JSON array in a message map
In the Graphical Data Mapping editor, you can use the **Add User-Defined** function to create a multidimensional JSON array, also known as a nested JSON array.

Before you begin

Create a message map with the output domain set to JSON. For more information, see "Graphically modeling a JSON message in a message map" on page 1554

About this task

If you have a JSON schema for your message data, you can use that as described in "Creating or transforming a JSON message by using a JSON schema" on page 1547. Alternatively, you can model a multidimensional JSON array in your message map by following these steps:

Procedure

To create a multidimensional JSON array in a JSON object message, complete the following steps:

1. Right-click **any**, and select **Add User-Defined**.

   The element **element1** is created under the **any** element.
2. Click **element1** and enter the name of the JSON array.

   By default, the user-defined element is created as a **string** element.
3. For **element1**, click **string**, and select **JSONArray_Default** as its type.

   The repeating element **Item** is created automatically. You cannot change this name. Item is the logical tree representation of each instance in the JSON array.
4. Set the type of **Item** to **JSONArray_Default**.

   A second **Item** element is created automatically.

JSON	[1..1]	JSONMsgType
Padding	[0..1]	string
choice of cast items	[1..1]	
Data	[1..1]	anyType
Data	[1..1]	JSONObject
choice of cast items	[0..*]	
any	[1..1]	
element1	[1..1]	JSONArray_1
Item	[0..*]	JSONArray_2
Item	[0..*]	string

5. Set the type of the nested **Item** element.

   You can use any of the following types:

   - Anonymous: Use this type to define a complex structure.
   - Boolean
   - date
   - dateTime
   - decimal
   - double
   - duration
   - float
   - hexBinary
   - int
   - long
   - string
   - time
   - JSONArray_Default: Use this type to define nested JSON arrays.
   - Global type, that is, a type based on an XML schema, a DFDL schema, or a message set. (You access your global types by selecting the option **Browse**.)
6. Use any of the following transforms to set the value of a JSON array:
   - Use the **For each** transform to set the JSON array output value when you have a repeating input element.
   - Use the **Append** transform to add occurrences of the array in the order of the inputs to the transform, which can be singleton or repeating.
   - Use the **Join** transform when you have multiple repeating input elements that you must combine into a single repeating output element.

Example

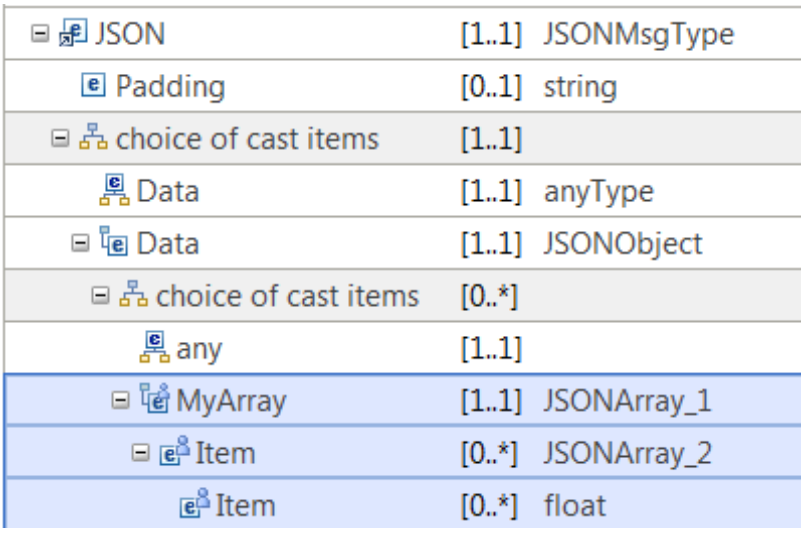
This sample shows how to model in a message map a two-dimensional JSON array in a JSON object message:

```
{"MyArray":[ [1.1], [2.1, 2.2] ]}
```

To define this JSON message, you must

1. Add a user-defined element of type **JSONArray_Default**, and change its name to `MyArray`.
2. Set the type of **Item** to **JSONArray_Default**.
3. Set the type of the nested **Item** element to `float`.

The following figure shows the map after you complete the previous steps:



The message tree for the JSON message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x2f033910]
   (0x01000000:Object):Data = (
     (0x01001000:Array):MyArray = (
       (0x01001000:Array):Item = (
         (0x03000000:NameValue):Item = 1.1E+0 (FLOAT)
       )
       (0x01001000:Array):Item = (
         (0x03000000:NameValue):Item = 2.1E+0 (FLOAT)
         (0x03000000:NameValue):Item = 2.2E+0 (FLOAT)
       )
     )
   )
 )
```

What to do next

Deploy the message map and verify that the output message is valid. For more information, see “Troubleshooting a message map” on page 1587.

Transforming heterogeneous JSON data in a message map
In the Graphical Data Mapping editor, you can use the **Add User-Defined** function to transform heterogeneous JSON data.

Before you begin

Create a message map with the output domain set to JSON. For more information, see “Graphically modeling a JSON message in a message map” on page 1554

About this task

The approach for modeling JSON heterogeneous data is to define each structure as a union of the different data that can be present in each possible form. Then, set the data, which is present in some instances of the data, as optional.

By default, when you model JSON data in the Graphical Data Mapping editor, you create objects and arrays where all instances are the same. All objects with the same name have the same set of data fields, and all entities in an array have the same set of data fields. This use case matches the most common usage of JSON data formats.

JSON allows entries in JSON arrays to have different structure and types. For JSON Objects, some JSON applications may also allow the same name for contained objects or values which may then have different structure and types. The JSON specification states: "The names within an object SHOULD be unique." For

more information, see The JavaScript Object Notation (JSON) Data Interchange Format). Only use this format if it is required by the external applications. This format of JSON data is termed heterogeneous JSON data.

If you have a JSON schema for your message data, you can use that as described in "Creating or transforming a JSON message by using a JSON schema" on page 1547. Alternatively, you can model heterogeneous JSON data by using the **Add User-Defined** function as described in this topic, or you can use an equivalent XML schema model as described in "Modeling a JSON message for use in a message map by using an equivalent XML schema model" on page 1572.

In the Graphical Data Mapping editor, the following rules apply when you model a heterogeneous JSON array:

- All entries in the array must contain either objects or values.
- You can model heterogeneous JSON data object arrays by using the **Add User-Defined** function.
- To model heterogeneous JSON value arrays, where the type of each instance can vary, you must use an external schema to provide the type of the **Item** element that represents each value entry in the array.

Procedure

Complete the following steps to model heterogeneous JSON data in the Graphical Data Mapping editor:

1. Build a union of the possible data fields, and set the elements that do not exist in every instance as optional.
   a) Use the **Add User-Defined** function to add user-defined elements to the map.
   b) In the **Properties** page of each element, configure the element's **General** tab to set the minimum occurrence to **0** so that the element is optional.

   Alternatively, you can use an external schema to provide the type of the **Item** element that represents each value entry in the array. The type can be defined as a schema union of simple types or an **xsd:anySimpleType**.
2. To model a JSON object with the same named but different typed contained objects, add the object once and then set the **maximum occurrence** of its cardinality to indicate the number of occurrences. The single object is a union of the possible content.
3. Use conditional mappings to read or construct the output data in each instance. For more information, see "Choosing a transform to define a conditional mapping" on page 1367.

   When you map to a heterogeneous JSON value modeled as a union of possible types, you must ensure the input data or value that is returned from the transform is of the type that is required for the instance being set. You can use the **xs:<type>** cast functions to set the data type that is required.

Example

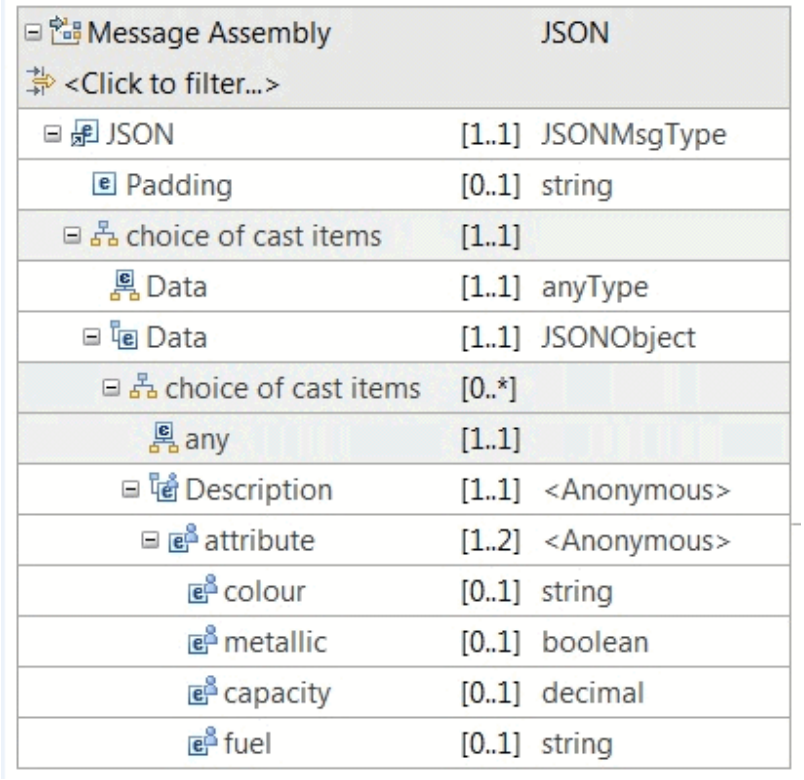
This example shows how to transform a JSON object message that describes a vehicle that uses two heterogeneous JSON data objects with different named values into a heterogeneous JSON array message where each entry is a data object with different named values.

The input application produces a heterogeneous JSON object message that describes a vehicle that uses two heterogeneous JSON data objects. Each JSON data object is called **attribute** and contains different name-value elements. The input JSON Data is as below:

```
{ "Description" : {
      "attribute"  : {
          "colour" : "blue",
          "metallic" : true
      },
      "attribute"  : {
          "capacity" : 1.4,
          "fuel" : "diesel"
      }
  }
}
```

In the map, the **Description** object is modeled with an attribute object that can occur twice (**maximum occurrence** set to be **2**).

- The heterogeneous attribute object contains the name - values **colour** and **metallic** or **capacity** and **fuel**.
- Each of the name - values is modeled as optional (**minimum occurrence** set to be **1**).



The target application requires this information as a heterogeneous JSON array:

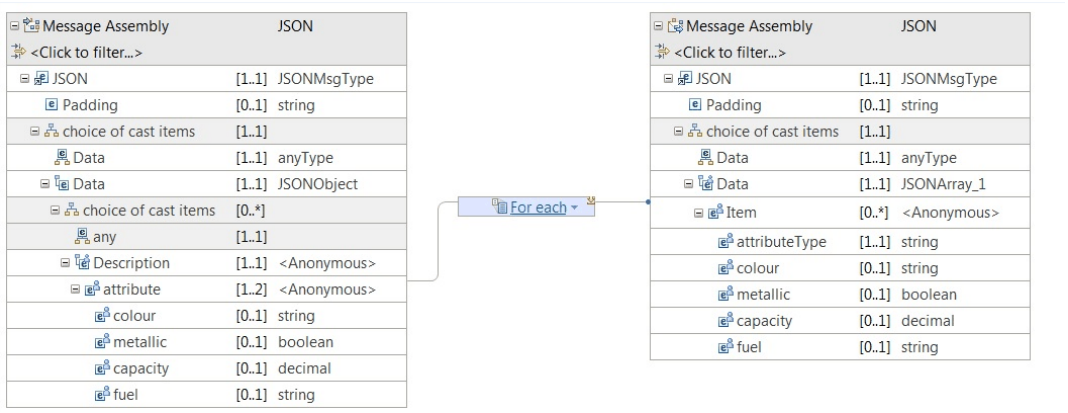
```
[{"attributeType":"Paint","colour":"blue","metallic":true},
{"attributeType":"Engine","capacity":1.4E+0,"fuel":"diesel"}]
```

In the map, the output JSON array is defined as the union of the possible data fields:

- The array is represented by a JSON object of type **Anonymous**.
- The first element is a single required element **attributeType**. All entries in the array contain this name-value.
- The other name-value elements are **colour**, **metallic**, **capacity**, and **fuel**. These elements do not occur in all entities in the array. All these elements are defined as optional. Each element has its property **minimum occurrence** set to be **0**.

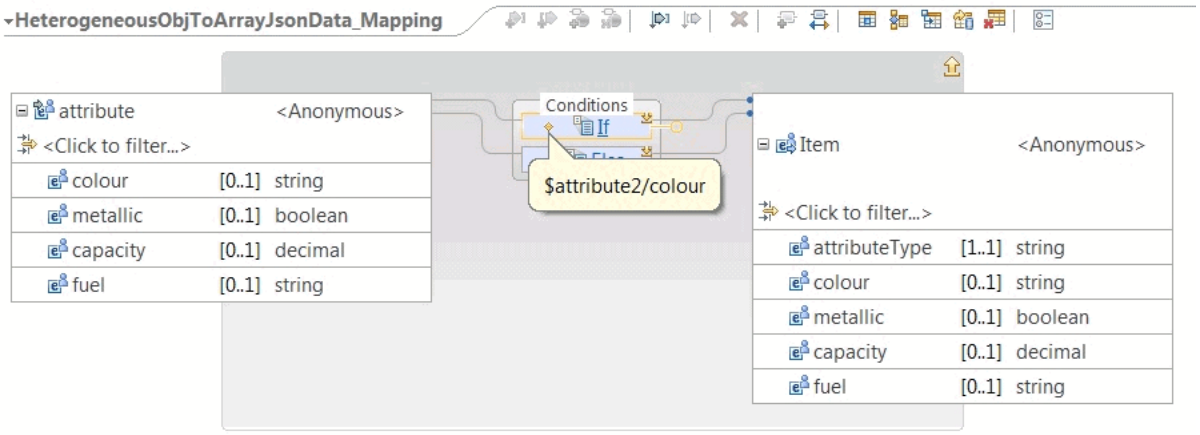
JSON	[1..1]	JSONMsgType
Padding	[0..1]	string
choice of cast items	[1..1]	
Data	[1..1]	anyType
Data	[1..1]	JSONArray_1
Item	[0..*]	<Anonymous>
attributeType	[1..1]	string
colour	[0..1]	string
metallic	[0..1]	boolean
capacity	[0..1]	decimal
fuel	[0..1]	string

To transform from the input to the required output, you use the **For Each** transform to create each of the entries in the array from the same named (repeating) attribute input objects.

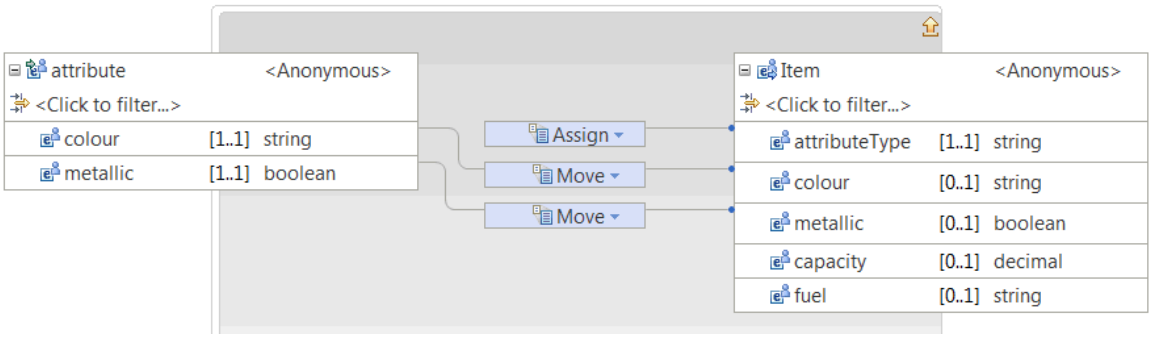


Inside the nested map associated with the **For Each** transform, you define an **If** transform that checks whether the **attribute** element contains **colour** or **capacity**.

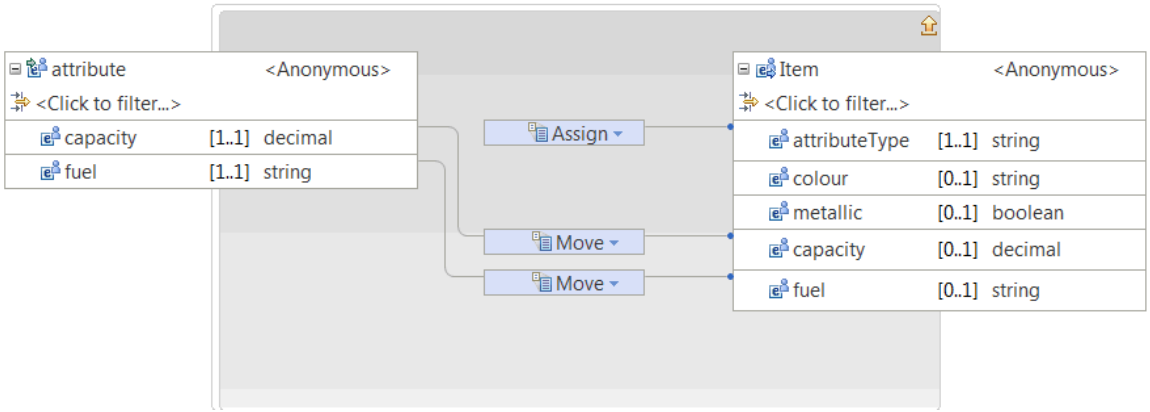
1. You define the **If** condition to check for **colour**: `$attribute2/colour` When this expression evaluates to true, the transformation in the nested map associated with the **If** is applied.
2. The **Else** path does not require a condition. When the **If** expression evaluates to false, the transformation in the nested map associated with the **Else** is applied.



The nested map that is associated to the **If** transform sets the **attributeType** element to **Paint** and copies the value of the other elements unchanged.



The other nested map that is associated to the **Else** sets the **attributeType** element to **Engine** and copies the value of the other elements unchanged.



When you run this map, you get the following JSON message:

```
[{"attributeType":"Paint","colour":"blue","metallic":true},
{"attributeType":"Engine","capacity":1.4E+0,"fuel":"diesel"}]
```

You obtain the following output tree structure:

```
(0x01000000:Object):JSON       = ( ['json' : 0x298f1e00]
    (0x01001000:Array):Data = (
      (0x01000000:Object):Item = (
        (0x03000000:NameValue):attributeType = 'Paint' (CHARACTER)
        (0x03000000:NameValue):colour        = 'blue' (CHARACTER)
        (0x03000000:NameValue):metallic      = TRUE (BOOLEAN)
      )
```

```
      (0x01000000:Object):Item = (
        (0x03000000:NameValue):attributeType = 'Engine' (CHARACTER)
        (0x03000000:NameValue):capacity      = 1.4E+0 (FLOAT)
        (0x03000000:NameValue):fuel          = 'diesel' (CHARACTER)
      )
    )
  )
```

What to do next

Deploy the message map and verify that the output message is valid. For more information, see "Troubleshooting a message map" on page 1587.

Reusing a JSON message, a JSON object, or a JSON array in a message map
In the Graphical Data Mapping editor, you can reuse JSON objects and JSON arrays that you define by using the **Add User-Defined** function. You can also define reusable JSON structures with an XML schema.

About this task

You can reuse JSON objects and JSON arrays between message maps or between message assemblies.

Procedure

You can use any of the following methods to define a JSON message, a JSON object, or a JSON array that you plan to reuse in a map:

- Define a JSON message, a JSON object, or a JSON array by using the **Add User-Defined** function. Then, choose any of the following methods to reuse an existing JSON definition:
  - Use copy and paste functions available in the map through the menu.
  - Use the **Browse** functionality that is available when you change the type of an element in your map.

  For more information, see "Graphically modeling a JSON message in a message map" on page 1554, "Graphically modeling a JSON object in a message map" on page 1557 and "Graphically modeling a JSON array in a message map" on page 1560.
- Define a JSON message, a JSON object or a JSON array with an XML schema. Then, use the **Cast** function to reuse the JSON object or JSON array definition.

  For more information, see "Modeling a JSON message for use in a message map by using an equivalent XML schema model" on page 1572.

What to do next

Deploy the message map and verify that the output message is valid. For more information, see "Troubleshooting a message map" on page 1587.

Modeling a JSON message for use in a message map by using an equivalent XML schema model
If you do not have a JSON schema for your JSON message data, you can use the following procedure to create an equivalent XML schema model that can be used in one or more message maps.

About this task

Graphical data mapping requires a supported message model of your message data.

If you have a JSON schema for your message data, you can use it as described in "Creating or transforming a JSON message by using a JSON schema" on page 1547. If you do not have a JSON schema, you can model a JSON message that contains JSON objects, JSON arrays, or both, by following the steps in this topic to create an equivalent XML schema model, which you can then use in one or more message maps with the `Cast` function in the Graphical Data Mapping editor. For more information, see "Graphically modeling a JSON message in a message map" on page 1554.

The following steps detail how to use an XML schema model in one or more message maps to define the JSON data from a corresponding XML schema type. Alternatively, you can define the JSON data in-line in the map by using the **Add User-Defined** function.

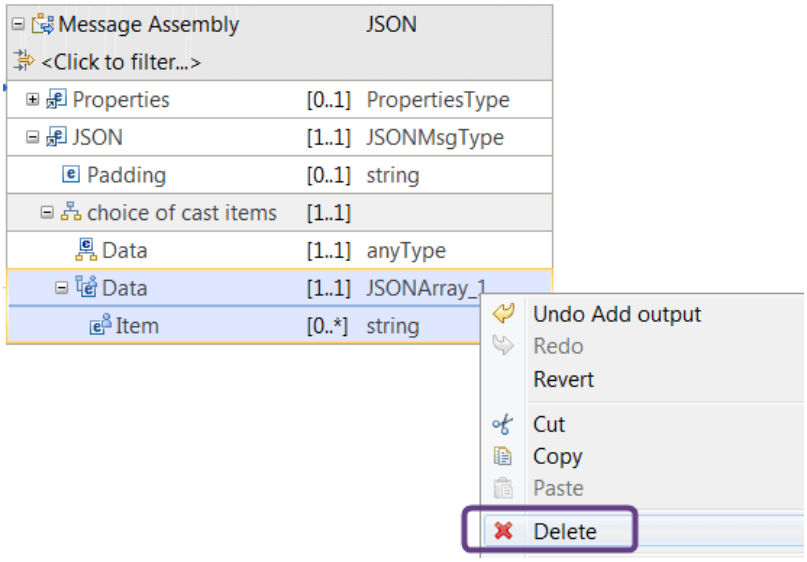
Procedure

Complete the following steps to create a JSON message based on a schema model:

1. Create a message map. Select one of the following JSON supplied models as the output of the map:
   - **JSON (JSON object message model supplied by IBM)** to create a JSON object message
   - **JSON (JSON array message model supplied by IBM)** to create a JSON array message

   For more information, see "Creating a message map" on page 1382.
2. Delete the predefined **Data** object. Choose one of the following options:
   - If you select **JSON (JSON object message model supplied by IBM)** in the previous step, delete the **Data** element of type **JSONObject**.

   - If you select **JSON (JSON array message model supplied by IBM)** in the previous step, delete the **Data** element of type **JSONArray_1**.



Note: In the Graphical Data Mapping editor, you can only have one **Data** element in a JSON message if you use a schema model to define the JSON message.

3. Provide a definition of the required JSON message by using the **Cast** function to redefine the **Data** element from anyType to your schema type.

   For more information, see "Casting elements in a message map" on page 1398.

   When you cast the *JSON.Data* element to define the JSON message structure, you can only use global schema types from your schema models. For the input side of the map, the global schema type must be defined in the default namespace.

   For example, if you build a JSON input with a cast to an element in a none empty namespace, the Mapping node runs without throwing an error. However, you might not get the expected output. You can use a user trace to see that the presence of the namespace can be deduced as the cause of the map failure:

   a. First, you see that the map successfully locates JSON.Data.

   b. Next, you see BIP message `BIP3959I: The Mapping node is traversing the input tree by using the nodetest ''element(Data)'' and the relationship ''child''. The number of matching elements is ''1''.`

   c. Finally, you see that the map fails to locate anything for the subsequent JSON objects. You see BIP message `BIP3959I: The Mapping node is traversing the input tree by using the nodetest ''element({http://schema014_T}:testMsgNsImpIn)'' and the relationship ''child''. The number of matching elements is ''0''.`

   When you cast the *JSON.Data.any* on the output side of the map to define the JSON message, you can use a global schema type from a non-default namespace. It is recommended that you use schema types in the default namespace because the Mapping node creates the elements with namespaces, but the JSON serializer then removes them.

   The Mapping node creates the elements with namespaces and the JSON serializer ignores them.

   Note: When you define a JSON message by using the **Cast** function, you must comply with the following rules:

   - You must define the schema definition for the type of a JSON object in the default namespace of the project where the map is defined.
   - You must define the schema definition for a JSON array in the target namespace: `http://www.ibm.com/iib/msl/json`.
   - You must use the following naming convention for the name of the type of a JSON array: `JSONArray_`*`unique_name`*, where *unique_name* is any combination of valid XML characters. For example, you can name a type as `JSONArray_ofBooleans` if the type is an array of Boolean elements. You can name a type `JSONArray_ofMyAddrObjects` if the type is a complex type.
   - The schema of a JSON array must contain a sequence with a single repeating element named `Item`.
   - You can only use global, not local, schema types from your schema models.
   - Optionally, you can define the JSON object or JSON array as nillable in the schema model to support the JSON null value.

4. Define transforms between the input elements and the output elements below `JSON.Data`. You must not wire any transform directly to the output `JSON.Data` element. You can map to its child elements only.
   - Use the **Assign** transform to set a fixed value without the use of input data.
   - Use the **Create** transform to create an empty element, or a nil element without the use of input data.
   - Use the **Move** transform to copy an input element value to the output element.
   - Use the **If** transform, a custom transform, or the **XPath** transform to define the condition that determines the value of an output element.
   - Use the **Append** transform, the **Group** transform, the **For Each** transform, the **Join** transform, a custom transform, or the **XPath** transform to set the value of a JSON array.
   - Use the **Select** transform or the **Database Routine** transform to set the value with data available in a database system.
   - Use the **xs:type** transform to cast the value of a simple input element to a specific data type.
   - Use the **fn:type** transform to set the value by using XPATH 2.0 functions.
   - Use the **Custom Java** transform to enter your own Java code.
   - Use the **Custom ESQL** transform to call your own ESQL code.

   For more information, see “Specifying a transform (mapping operation)” on page 1430.

Example

The following examples present XML schema types that model some example JSON data objects and arrays.

Example for a JSON object message

This example shows how to define a schema model for a JSON object message in the default namespace:

```
{ "Nam" : "A Name", "Num" : 1 }
```

The message tree for the JSON message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x2f030fa0]
    (0x01000000:Object):Data = (
          (0x03000000:NameValue):Nam = 'A Name' (CHARACTER)
          (0x03000000:NameValue):Num = 1 (INTEGER)
    )
  )
```

The following code shows the schema file that defines the JSON object message:

```
<?xml version="1.0" encoding="UTF-8"?>
   <xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema">
    <xsd:complexType name="MyJsonObjType1">
     <xsd:sequence>
      <xsd:element name="Nam" type="xsd:string" nillable="true"></xsd:element>
      <xsd:element name="Num" type="xsd:int" nillable="true"></xsd:element>
     </xsd:sequence>
    </xsd:complexType>
</xsd:schema>
```

The following figure shows the map after you cast the **Data** element of the JSON object message to the schema model **MyJsonObjType1**:

JSON	[1..1]	JSONMsgType
Padding	[0..1]	string
choice of cast items	[1..1]	
Data	[1..1]	anyType
Data	[1..1]	MyJsonObjType1
Nam	[1..1]	string
Num	[1..1]	int

Example for a JSON array message

This example shows how to model a JSON message that is an array of Boolean elements. You define a schema model for the following JSON array message in the default namespace:

```
[ true,false ]
```

The message tree for the JSON array message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x292051a0]
    (0x01001000:Array):Data = (
      (0x01000000:NameValue):Item  = TRUE (BOOLEAN)
      (0x01000000:NameValue):Item  = FALSE (BOOLEAN)
     )
)
```

The following code shows the schema file that defines the JSON array message in the target namespace **http://www.ibm.com/iib/msl/json**:

```
<?xml version="1.0" encoding="UTF-8"?>
  <xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"  targetNamespace="http://www.ibm.com/
iib/msl/json">
     <xsd:complexType block="#all" name="JSONArray_ofBoolean">
        <xsd:sequence>
            <xsd:element maxOccurs="unbounded" minOccurs="0" name="Item" nillable="true"
 type="xsd:boolean"/>
        </xsd:sequence>
   </xsd:complexType>
</xsd:schema>
```

The following figure shows the map after you cast the **Data** element of the JSON object message to the schema model **JSONArray_ofBoolean**:

JSON	[1..1]	JSONMsgType
Padding	[0..1]	string
choice of cast items	[1..1]	
Data	[1..1]	anyType
Data	[1..1]	JSONArray_ofBoolean
Item	[0..*]	boolean

Example for JSON object message with an array of objects

This example shows how to model a JSON message that is an array of objects.

```
[ { "nam":"one","val":1 },{ "nam":"two","val":2 }]
```

The message tree for the JSON object message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x292051a0]
    (0x01001000:Array):Data = (
                        (0x01000000:Object):Item = (
                                                   (0x03000000:NameValue):nam = 'one' (CHARACTER)

                                                   (0x03000000:NameValue):val = 1  (INTEGER)

                                                    )
                        (0x01000000:Object):Item = (
                                                   (0x03000000:NameValue):nam = 'two' (CHARACTER)

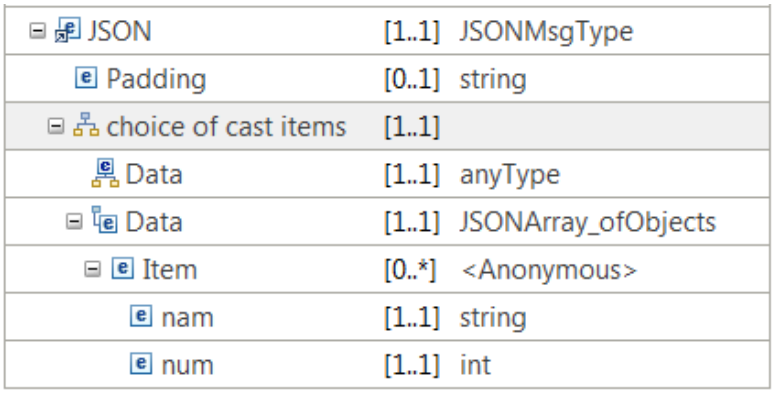
                                                   (0x03000000:NameValue):val = 2 (INTEGER)
                                                   )
                             )
)
```

You define a schema model for the JSON object message in the default namespace.

The following code shows the schema file that defines the JSON array. You define the **JSONArray_ofObjects** type in the target namespace **http://www.ibm.com/iib/msl/json**:

```
<?xml version="1.0" encoding="UTF-8"?>
    <xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema" targetNamespace="http://
www.ibm.com/iib/msl/json">
         <xsd:complexType block="#all" name="JSONArray_ofObjects">
             <xsd:sequence>
                 <xsd:element maxOccurs="unbounded" minOccurs="0" name="Item" nillable="true">
                     <xsd:complexType>
                         <xsd:sequence>
                            <xsd:element name="nam" type="xsd:string" nillable="true"/>
                            <xsd:element name="num" type="xsd:int" nillable="true"/>
                         </xsd:sequence>
                    </xsd:complexType>
              </xsd:element>
            </xsd:sequence>
        </xsd:complexType>
 </xsd:schema>
```

The following figure shows the map after you cast the **Data** element of the JSON object message to the schema model **JSONArray_ofObjects**:



Example for JSON Object message containing a JSON array

This example shows how to model a JSON object message that contains a JSON array.

```
{ "state":"ok", "array":[ { "nam":"one","val":1 },{"nam":"two","val":2 } ] }
```

The message tree for the JSON object message is described in the following trace:

```
(0x01000000:Object):JSON       = ( ['json' : 0x292051a0]
    (0x01000000:Object):Data = (
```

```
             (0x03000000:NameValue):state= 'ok' (CHARACTER)
             (0x01001000:Array):array= (
                              (0x01000000:Object):Item = (
                                                  (0x03000000:NameValue):nam = 'one' (CHARACTER)

                                                  (0x03000000:NameValue):val = 1  (INTEGER)

                                                           )
                              (0x01000000:Object):Item = (
                                                  (0x03000000:NameValue):nam = 'two' (CHARACTER)

                                                  (0x03000000:NameValue):val = 2 (INTEGER)
                                                           )
                                             )
                               )
)
```

The object message is defined in the default namespace and imports the type of the JSON array element from the second schema. The following code shows the schema file that defines the JSON object message:

```
<?xml version="1.0" encoding="UTF-8"?>
    <xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:mjatns="http://www.ibm.com/
iib/msl/json">
      <xsd:import namespace="http://www.ibm.com/iib/msl/json"
 schemaLocation="MyJsonArrayTypes.xsd"/>
         <xsd:complexType name="MyJsonObjWithArrayType1">
             <xsd:sequence>
                 <xsd:element name="state" type="xsd:string" nillable="true"></xsd:element>
                 <xsd:element name="array" type="mjatns:JSONArray_ofObjects" nillable="true"></
xsd:element>
              </xsd:sequence>
         </xsd:complexType>
    </xsd:schema>
```

The following code shows the schema file that defines the JSON array. You define the **JSONArray_ofObjects** type in the target namespace **http://www.ibm.com/iib/msl/json**:

```
<?xml version="1.0" encoding="UTF-8"?>
   <xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema" targetNamespace="http://www.ibm.com/
iib/msl/json">
       <xsd:complexType block="#all" name="JSONArray_ofObjects">
           <xsd:sequence>
                <xsd:element maxOccurs="unbounded" minOccurs="0" name="Item" nillable="true">
                                 <xsd:complexType>
                                           <xsd:sequence>
                                                 <xsd:element name="nam" type="xsd:string"
 nillable="true"/>
                                                 <xsd:element name="num" type="xsd:int"
 nillable="true"/>
                                           </xsd:sequence>
                                 </xsd:complexType>
                </xsd:element>
         </xsd:sequence>
     </xsd:complexType>
    </xsd:schema>
```

The following figure shows the map after you cast the **Data** element of the JSON object message to the schema model **MyJsonObjWithArrayType1**:

JSON	[1..1]	JSONMsgType
Padding	[0..1]	string
choice of cast items	[1..1]	
Data	[1..1]	anyType
Data	[1..1]	MyJsonObjWithArrayType1
state	[1..1]	string
array	[1..1]	JSONArray_ofObjects
Item	[0..*]	<Anonymous>
nam	[1..1]	string
num	[1..1]	int

Note: The XML schema can be extended if you need to use the message model in another IBM App Connect Enterprise component, for example a Route node or a monitoring event from a message flow node. For the map cast, you can define an XML schema type, for example `MyJsonObjType1`. If you want to use the schema type in the XPath expression builder, for setting a match expression for the Route node or the monitoring event data path, you add a schema element definition for the "Data" element of the JSON domain as follows:

```
<xsd:element name="Data" type="MyJsonObjType1"></xsd:element>
```

What to do next

Deploy the message map and verify that the output message is valid. For more information, see “Troubleshooting a message map” on page 1587.

Graphically modeling and transforming a JSONP message in a message map

You can use the Graphical Data Mapping editor to create or transform a JSONP object message or a JSONP array message. You can provide the model of your JSONP message in a JSON schema file in a shared library project. Alternatively, you can define your JSON data by using the **Add User Defined** function in the map.

About this task

A JSONP service, or Remote JSON service, is a web service that returns JSON data padded with a user-defined JavaScript function call.

When you configure a message map to transform a JSON message, the Graphical Data Mapping editor puts the JSON padding in the top-level **Padding** element, and the JSON data under the **Data** element. If JSON padding is detected by an input node, the name of the client-side script is placed in the top-level **Padding** element.

You can also use the Graphical Data Mapping editor to configure a message flow to provide a JSONP response. When a JSON message is serialized and the top-level **Padding** element has a value, the JSON message is wrapped in the provided client-side script name.

Procedure

Create or transform your JSONP data by completing one of the following tasks:

- Map your data by using a JSON schema. This option requires the JSON schema and map to be in the same shared library. For instructions on how to complete this task, see “Creating or transforming a JSON message by using a JSON schema” on page 1547.

- Map a user defined JSON object or a user defined JSON array. For instructions on how to complete this task, see "Creating or transforming a JSON output message by using the User Defined function to model the JSON data" on page 1552.

What to do next

Deploy and test the message map. For more information, see "Troubleshooting a message map" on page 1587.

Implementing a REST API operation by using a message map

You can use the Graphical Data Mapping editor to implement a REST API operation. When you create a map for a REST API operation, you can choose to have the map input and output defined automatically from the definitions in the REST API Swagger document or OpenAPI 3.0 document.

About this task

When you create the map for a Mapping node in a subflow that implements a REST API operation, you can select the option **Message map with input and output for REST API operation *operation_name***. When you select this option, the map is created with the input and output data fully defined by the JSON schema data definitions in the REST API Swagger document or OpenAPI 3.0 document.

The local environment is automatically added to the map input and any path or query parameters are added under **Local Environment** > **REST** > **Input** > **Parameters**, ready for you to connect transforms. A Task transform is pre-wired to **Local Environment** > **REST** > **Input** to help you locate this information.

The map input message body is populated according to the operation request body, and the output message body is populated according to the response body. When the body is defined as a model or JSON array, the map is created with a JSON domain message. When there is no body, or a simple type, the map is created with a BLOB domain message.

Note: If you update the REST API and change either the path or query parameters, or the request or response body, the message map is updated automatically to reflect the new definitions when it is reopened. If existing transforms were wired, they might become invalid or disconnected and the map requires modification to match the new data model. If the map was created when there was no request or response body defined for the operation, you must re-create the map to add one later.

Ensure that you are aware of the requirements for JSON schema with message maps. For more information, see "JSON schema requirements for message maps" on page 1549.

If you are implementing a REST API operation in which the processing can be achieved by using the "Transform types in the Graphical Data Mapping editor" on page 1282, you can implement the operation by using a single message map, as described in the following procedure. However, if the processing for your REST API operation requires that you transform to an intermediary data format and use additional nodes as part of your implementation, follow the procedure that is described in "Implementing a REST API operation with intermediary processing by using message maps" on page 1582.

Procedure

To implement an operation in a REST API by using a single message map, complete the following steps:

1. Create or open the subflow for the REST API operation.

   The REST API must be saved before a new message map for an operation can be created; this ensures that the required information in the Swagger document or the OpenAPI 3.0 document is current and consistent.
2. Add a Mapping node to the subflow.
3. Create the message map by double-clicking the Mapping node to open the **New Message Map** wizard. The wizard detects that the map is being created for the current REST API operation, and preselects the option **Message map with input and output for REST API operation *operation_name***. Click **Finish**.

4. The REST API operation message map is created in the REST API project and opened in the Graphical Data Mapping editor.
5. The input data from the REST API is provided in the map. This is located in the Local Environment, which is automatically added to the map input. Any REST API path or query parameters defined for the operation are automatically defined under **Local Environment** > **REST** > **Input** > **Parameters**.

   A **Task** transform is added to the map with its input connected to **Local Environment** > **REST** > **Input**, and enables you to locate the REST API input data that might be required in the mappings. You can remove the Task when you have completed your mappings. The map can be deployed and run with a **Task** transform, with no effect.

   Note: Input form and array type parameters are not supported.
6. The message body of the map input and output is also automatically defined by the REST API Swagger document or OpenAPI 3.0 documents.

   The input message body is defined as one of the following types:

   - JSON, with the data type of any request body defined for the operation in the Swagger document or OpenAPI 3.0 document.
   - BLOB, when the operation has no request body data

   The ouput message body is defined as one of the following types:

   - JSON, with the data type defined for the HTTP status 200 response. If there is no status 200 response, either the default response or the first response defined in the Swagger document or OpenAPI 3.0 document is used.
   - BLOB, when the operation has no response body data.

   The Data type of the JSON input or output is defined in the following way:

   - If the REST API operation request or response is defined as a model type (JSON reference to a type in the Swagger document or OpenAPI 3.0 document definitions) it has a type name as the model name; for example, `Pet` or `Department`. If it is an array of a type that is defined in the model, the type name is prefixed with `JSONArray_`; for example, `JSONArray_Pet`.
   - If the API operation request body is defined inline by a Swagger schema statement or an OpenAPI 3.0 schema statement, its type name is formed as:

     ```
     <Json type>_<operation name>_body
     ```
   - If the API operation response body is defined inline by a Swagger schema statement or an OpenAPI 3.0 schema statement, its type name is formed as:

     ```
     <Json type>_<operation name>_<http status code>
     ```

     For example:

     ```
     string_getSurname_200
     ```

     or

     ```
     object_getItem_200
     ```
   - If the request or response body is defined as an inline array, the type name is prefixed with `JSONArray_`; for example, `JSONArray_string_getAllSurnames_200`

7. Complete the required transformation logic in the map to implement the REST API operation, using any of the "Transform types in the Graphical Data Mapping editor" on page 1282. For more information, see "Editing message maps" on page 1394.

   In addition to transforming the message data, you can interact with resources as described in the following topics:

   - "Mapping database content" on page 1523
   - Using Java in a message map
   - "Accessing user-defined properties from a Mapping node" on page 1479

What to do next

Deploy the REST API with the message map and exercise the operation to verify that the output message is as you expected. For more information, see "Troubleshooting a message map" on page 1587.

Implementing a REST API operation with intermediary processing by using message maps

You can use the Graphical Data Mapping editor to implement a REST API operation. When you create a map for a REST API operation, you can choose to have the map input and output defined automatically from the definitions in the REST API Swagger document or OpenAPI 3.0 document.

About this task

When you create the map for a Mapping node in a subflow that implements a REST API operation, you can select the option **Message map with input and output for REST API operation *operation_name***. When you select this option, the map is created with the input and output data fully defined by the JSON schema data definitions in the REST API Swagger document or OpenAPI 3.0 document.

The local environment is automatically added to the map input and any path or query parameters are added under **Local Environment** > **REST** > **Input** > **Parameters**, ready for you to connect transforms. A Task transform is pre-wired to **Local Environment** > **REST** > **Input** to help you locate this information.

The map input message body is populated according to the operation request body, and the output message body is populated according to the response body. When the body is defined as a model or JSON array, the map is created with a JSON domain message. When there is no body, or a simple type the map is created with a BLOB domain message.

Note: If you update the REST API and change either the path or query parameters, or the request or response body, the message map is updated automatically to reflect the new definitions when it is reopened. If existing transforms were wired, they might become invalid or disconnected and the map will require modification to match the new data model. If the map was created when there was no request or response body defined for the operation, you must re-create the map to add one later.

Ensure that you are aware of the requirements for JSON schema with message maps. For more information, see "JSON schema requirements for message maps" on page 1549.

The following procedure describes the steps that you need to follow if you are implementing a REST operation that involves transforming to an intermediary data format as part of its processing. This is the case if your flow contains nodes that use a different message model from the one that is defined in the REST API. In this situation, you need to use a Mapping node at the beginning of the REST API operation subflow and another Mapping node at the end of the subflow. The first Mapping node takes the REST input from the Swagger document or OpenAPI 3.0 document and transforms it to an intermediary format to be used by your processing nodes. At the end of the subflow, the second Mapping node is required to transform from the intermediary format to the format required by the REST API operation response.

To summarize the sequence of events:

1. Transform from the message format of the REST API operation request to the format of the intermediary processing input (format *X*)
2. Process data using message format *X* and, when it is completed, return the format of the intermediary processing result (format *Y*)

3. Transform from message format *Y* to the format required by the REST API operation response.

Note: If you are implementing a REST API operation in which all the processing can be achieved by using the "Transform types in the Graphical Data Mapping editor" on page 1282, you can use a single message map, by following the procedure described in "Implementing a REST API operation by using a message map" on page 1580.

Procedure

To implement a REST API operation that involves intermediary processing to transform between data formats, complete the following steps:

1. Create or open the subflow for the REST API operation.

   The REST API must be saved before a new message map for an operation can be created; this ensures that the required information in the Swagger document or OpenAPI 3.0 document is current and consistent.
2. Add a Mapping node to the subflow.
3. Create the message map by double-clicking the Mapping node to open the **New Message Map** wizard. The wizard detects that the map is being created for the current REST API operation, and preselects the option **Message map with input and output for REST API operation *operation_name***. Click **Finish**.
4. The REST API operation message map is created in the REST API project and opened in the Graphical Data Mapping editor.
5. The input data from the REST API is provided in the map. This is located in the Local Environment, which is automatically added to the map input. Any REST API path or query parameters that are defined for the operation are automatically defined under **Local Environment** > **REST** > **Input** > **Parameters**.

   A **Task** transform is added to the map with its input connected to **Local Environment** > **REST** > **Input**, and enables you to locate the REST API input data that might be required in the mappings. You can remove the Task when you have completed your mappings. The map can be deployed and run with a **Task** transform, with no effect.

   Note: Input form and array type parameters are not supported.
6. The message body of the map input and output is also automatically defined by the REST API Swagger document or OpenAPI 3.0 document.

   The input message body is defined as one of the following types:

   - JSON, with the data type of any request body defined for the operation in the Swagger document or OpenAPI 3.0 document
   - BLOB, when the operation has no request body data

   The ouput message body is defined as one of the following types:

   - JSON, with the data type defined for the HTTP status 200 response. If there is no status 200 response, either the default response or the first response defined in the Swagger document or OpenAPI 3.0 document is used.
   - BLOB, when the operation has no response body data.

   The Data type of the JSON input or output is defined in the following way:

   - If the REST API operation request or response is defined as a model type (JSON reference to a type in the Swagger document or OpenAPI 3.0 document definitions) it has a type name as the model

name; for example, `Pet` or `Department`. If it is an array of a type defined in the model, the type name is prefixed with `JSONArray_`; for example, `JSONArray_Pet`.

- If the API operation request body is defined inline by a Swagger schema statement or OpenAPI 3.0 schema statement, its type name is formed as:

```
<Json type>_<operation name>_body
```

- If the API operation response body is defined inline by a Swagger schema statement or OpenAPI 3.0 schema statement, its type name is formed as:

```
<Json type>_<operation name>_<http status code>
```

For example:

```
string_getSurname_200
```

or

```
object_getItem_200
```

- If the request or response body is defined as an inline array, the type name is prefixed with `JSONArray_`; for example, `JSONArray_string_getAllSurnames_200`

7. Select and delete the output message assembly that was created in the map.
8. Click the **Add an output object** button in the editor to add the required map output, and select the required message format of the input to the intermediary processing (format *X* in the example used earlier in this topic).

   The message format can be any of the supported formats described in "Input and output messages to a message map" on page 1276.

   Note: If the format is defined in a JSON schema model, the JSON schema file must be placed in the REST API project container.
9. Add a second Mapping node as described in Steps #unique_1774/unique_1774_Connect_42_mapadd and #unique_1774/unique_1774_Connect_42_mapwiz.
10. Select and delete the input message assembly that was created in the map.
11. Click the **Add an input object** button in the editor to add the required map input, and select the required message format for the result of the intermediary processing (format *Y* in the example used earlier in this topic).

    The message format can be any of the supported formats described in "Input and output messages to a message map" on page 1276.

    Note: If the format is defined in a JSON schema model, the JSON schema file must be placed in the REST API project container.
12. Complete the required transformation logic in the message maps to implement the REST API operation, using any of the "Transform types in the Graphical Data Mapping editor" on page 1282. For more information, see "Editing message maps" on page 1394.

    In addition to transforming the message data, you can interact with resources as described in the following topics:

    - "Mapping database content" on page 1523
    - "Using Java in a message map" on page 1370
    - "Accessing user-defined properties from a Mapping node" on page 1479

What to do next

Deploy the REST API with the message map and exercise the operation to verify that the output message is as you expected. For more information, see "Troubleshooting a message map" on page 1587.

Deploying message maps

By default, message map files are deployed in BAR files as a part of an application, integration service, or library that provides an integration solution. You can also deploy a map as an independent resource if you are managing your message flows that way. If you change a message map, you must redeploy your integration solution or independent message flows.

About this task

When an integration solution or message flow containing a Mapping node is deployed, message maps that are referenced in the **Mapping routine** property of the Mapping node are resolved and validated. This preparation occurs at deployment time, rather than when the first message is flowed through the node.

This behavior has the following advantages:

- There is no drop in performance from initializing a message map when the first message is flowed through the node.
- The message map and its dependencies, such as any referenced message models, are resolved and validated during deployment to ensure that the message map runs successfully on first message.
- The message map syntax is validated during deployment to ensure that the message map runs successfully on first message.
- When IBM App Connect Enterprise is restarted, the message map syntax and its dependencies are validated before the message flow can be restored.

To avoid a deployment failure, you must include all the message map dependencies, referenced schemas, ESQL modules, Java classes, and other resources in your BAR file. You must resolve any message map static errors such as an invalid XPath expression. If these requirements are not met, you receive a BIP message that reports the map generation failure.

By default, any map that is in the BAR file but not referenced in the **Mapping routine** property of the Mapping node is not validated on deployment. If the map is used dynamically by a Mapping node, by selecting it in a LocalEnvironment override (`LocalEnvironment.Mapping.MappingRoutine = '{brokerSchemaName}:mapName'`), it is validated and prepared when it is first used.

You can configure an integration node or server to validate and prepare all message maps on deployment, by setting the **generateAllMapsOnDeploy** property to `true` in the `server.conf.yaml` configuration file or on the **mqsichangeproperties** command. For example, to set the property for an integration node, you can use the following command:

```
mqsichangeproperties --integration-node integrationNodeName --property generateAllMapsOnDeploy
 --value true
```

To set the property for an integration server (either an independent integration server or a server that is managed by an integration node), you can set it in the `server.conf.yaml` configuration file:

```
generateAllMapsOnDeploy: true
```

The integration server must then be restarted for this change to take effect.

If you set the **generateAllMapsOnDeploy** property to `true`, ensure that all `.map` files in your application, library, and integration project are intended for use by a Mapping node that is in the BAR file. If any other `.map` files are found in the application, library, or integration project, they might cause deployment to fail.

Procedure

When you deploy message maps, the behavior of IBM App Connect Enterprise is as follows:

- Behavior when you deploy or redeploy a BAR file:
  a) All message maps are validated to ensure that all the map dependencies can be resolved at run time. This validation step checks that the referenced message models such as XML schema files, DFDL schema files, and message set files, and the referenced submaps can be resolved.
  b) The message maps and their dependencies are generated to an executable form. This step also checks that the contents of the map and submaps are valid, and that they have no errors such as an invalid XPath expression.
  c) If the message maps and their dependencies are valid and can be successfully generated, they are persisted in both the deployed and generated forms to the configuration store. Otherwise, the deployment is stopped and you receive a BIP message that reports the map generation failure.
- Behavior after deployment:
  a) Background processing is started to compile the generated message maps to Java byte code so that they can benefit from JIT optimization. The Java byte code for each map is persisted on completion of the compilation.
- Behavior when the first message flows runs after deployment or redeployment:
  a) If the background compilation processing is complete, the Mapping node runs the java byte code and the JIT optimization starts.
  b) If the background compilation processing is not complete, the Mapping node runs the map initially in the generated form until the compilation is complete. Then, JIT optimization starts.
- Behavior for any subsequent messages that flow after deployment or redeployment:
  a) The prepared message map runs. If the background processing is completed, the JIT optimization starts.
- Behavior when you restart IBM App Connect Enterprise, that is, when you restart an integration node, an integration server, an integration solution, or a message flow:
  a) If the compiled Java byte code for the map is available, it is loaded and the Mapping node runs this code as soon as the first message is processed. Then, JIT optimization starts.
  b) If the generated form for the map is available and loaded, background processing is started to compile the generated map to Java byte code so that they can benefit from JIT optimization. The Java byte code for each map is persisted on completion of the compilation.
  c) If neither the generated or the compiled map code are available, the map is processed in the same way as when you deploy or redeploy a BAR file.

Troubleshooting a message map

Diagnose and solve problems that you encounter when you use message maps.

Procedure

- In the IBM App Connect Enterprise Toolkit, you can use the Flow exerciser to check the input message that you pass to a map. You can also check the output message of a map after the transformation logic is applied.

  The Flow exerciser is a tool that is available from the flow editor and the integration service editor. You can use the Flow exerciser to perform the following set of tasks:

  1. Deploy the resource to an integration server and set the integration server to recording mode.
  2. Create and send an input message or previously saved recorded message to the input node of the message flow.

     Note: You can also send messages to the message flow by using an external client.
  3. Highlight the message path on the message flow and any subflows that are associated with the message flow.
  4. Display the content of the logical message tree for a message that passed through a connection in the message flow.
  5. Save the content of the logical message tree as a recorded message that you can send to the message flow later.

  For more information, see Testing your message flow by using the Flow exerciser.
- In the development environment, you have different ways to access an error or warning that occurs in a map.

  a) In the **Problems** view, you can double-click a problem or warning. Then, in most cases, the Graphical Data Mapping editor opens and navigates to the transform with the error or warning.

  Note: Sometimes the error is nested deep inside other mappings so it is hard to locate. Double-clicking the error that shows in the **Problems** view takes you to the transform with the error quickly.

  b) In the Graphical Data Mapping editor, you can see an error or a warning as an icon (or marker) associated with the transform where the problem or warning occurs in your map. You can hover over the icon to show the message.

  When an error or warning is present in a nested mapping, the Graphical Data Mapping editor shows the icon on the parent transform.
- During deployment, you cannot add a message map with an **Error** marker to a BAR file until the errors are resolved.

  For more information, see “Deploying message maps” on page 1585.
- In the run time environment, you can use a user trace to troubleshoot transformation logic that you build in your message map. The Mapping node reports the running of a message map as detailed user trace events.

  The user trace events report the entry and completion of each transform in a map, and the setting of values in the map output.

  The collection and review of IBM App Connect Enterprise user trace enables you to troubleshoot transformation logic that you build in your message maps.

  The following topics describe how to diagnose problems by using user trace:

  – Controlling user trace
  – User trace

Using or converting legacy resources into message maps

If you want to deploy legacy message maps (`.msgmap` format) in IBM App Connect Enterprise, you must first convert them into message maps in `.map` format, which the IBM App Connect Enterprise Mapping node can consume.

About this task

Legacy message maps cannot be deployed in IBM App Connect Enterprise until they have been converted.

A legacy message map is a message map that was created as a `.msgmap` file in WebSphere Message Broker Version 7 or earlier.

The functions provided by the following legacy message flow nodes in WebSphere Message Broker Version 7 (and earlier versions) were replaced with the new Mapping node in later versions of WebSphere Message Broker and IBM Integration Bus:

- DataDelete node
- DataInsert node
- DataUpdate node
- Extract node
- Mapping node
- Warehouse node

Procedure

Follow these guidelines when you use legacy message maps and legacy message flow nodes in your integration solutions:

- IBM App Connect Enterprise does not support WebSphere Message Broker Version 7.0 legacy message maps (`.msgmap`). You can import message flows that contain legacy message maps into the IBM App Connect Enterprise Toolkit. However, you can view these message flows in read-only mode only, and you cannot deploy and run them. If you try to deploy a BAR file that contains a legacy message map, you see a BIP2355 error message. Before you run a message flow that contains a legacy message map or a legacy Mapping node, you must convert them by following the instructions in “Using or converting legacy resources into message maps” on page 1588.
- You must change the transformation logic in your integration solution when a legacy message map is invoked from an ESQL CALL statement. For more information, see “Converting a legacy message map that is called from an ESQL statement in a Compute node” on page 1605.

  A message map cannot be called from an ESQL CALL statement.

Changes in behavior in message maps converted from legacy message maps

In IBM App Connect Enterprise, you transform data graphically by using a message map. These maps are managed through the Graphical Data Mapping editor. You define your transformation logic by using XPath 2.0 expressions. You can also call Java methods, ESQL procedures, or complex XPath expressions by using specialized transforms such as the **Custom Java**, **Custom XPath**, or **Custom ESQL** transforms.

Behavior changes during the development phase

Nulls behavior

When you convert a legacy message map (`.msgmap`) that includes handling for nilled elements, check how a message map handles NULL values. For more information, see “Handling nulls in message maps” on page 1368.

- In ESQL, a special NULL value is defined, and is distinct from empty. When you assign NULL to a named element, or set the element from the returned NULL value of a called ESQL function, you delete the element from the tree.

  In a message map, the ESQL NULL produces an empty element, or an empty element with the `xsi:nil` attribute set when the element is defined as nillable in the model. Consequently, in some cases the output of the map might include unexpected empty elements that can cause processing problems, including XML schema validation violations. Such problems typically occur when an ESQL user-defined function that returns ESQL NULL in some conditions is called. To avoid these problems, add a condition to the Custom Transform to prevent it from being invoked if it would return NULL.

Mapping from missing inputs

In ESQL-based legacy message maps, writing a NULL to an output element did not create the element. However, in the converted message map, this action can produce an empty element.

When a legacy message map ran certain transforms, and the input data was missing, the input was set as NULL; therefore, no output element was created. In the converted message map, these cases can produce an empty output element:

- For transforms that are completely self-defined (such as **Move**), and if the input and output elements are defined as optional (`minOccurs=0`), the converted message map handles the missing input element, and no output element is created.
- If the output element is defined as mandatory, the element is created in order to conform to the schema model.
- For transforms that are internally defined to produce some output value even if the input element is missing (such as **Custom ESQL**, **Custom Java**, or **Submap**), the converted message map cannot automatically handle the missing input element. In this situation, you can add a condition such as `fn:exists($input)` to prevent these transforms producing the empty output element.

Some transforms, such as the XPath `fn:concat()` function, require exactly one data value for each parameter. When you are using these types of function, be aware that the legacy `.msgmap` might have provided an empty string for a NULL or missing input; however, the new XPath based `.map` provides an empty sequence, which results in an XPath runtime error because a single data value has not been provided. To solve this problem, you can modify the parameter so that it is wrapped in an XPath coalesce expression, in the following form:

```
(( $input, '' )[1])
```

This coalesce expression causes the parameter to be set to one of the following values:

- The first value from the "`$input`" element, if it exists
- The empty string ", if the "`$input`" element is missing.

Limitations on the conversion of `esql:coalesce` calls

Because there is no XPath equivalent for ESQL NULL, you can convert `esql:coalesce` calls (that have multiple arguments) in a legacy message map only if all of the arguments of the call (except for the final argument) have one of the following three forms:

- A simple source reference; for example, `$source/path/item`.
- An expression without any source reference. For example, the following are valid arguments: 123, `'myString'`, `esql:current-time()`, or `fn:string-length("some-text")`.
- A function (other than `esql:coalesce`), whose arguments also have one of these three forms, and where no more than one argument includes a simple source reference. For example, the following are valid arguments: `fn:current-date()`, `esql:func1(esql:func2($source/path/item))`, or`xs:int(fn:substring($source/path/item, 3, 5))`.

Note: There is no limitation on the conversion of `esql:coalesce` calls that have a single argument, or on the final argument of an `esql:coalesce` call that has multiple arguments.

If the `esql:coalesce` call is in a valid form, and is converted without error, you must review and test the converted transform to ensure that it results in equivalent function.

If you convert a legacy message map that contains an `eqsl:coalesce` call that is not in a valid form, for example, `esql:coalesce(esql:func($source/path/item1,$source/path/item2))`, a **Task** transform is created with details of the error, and you must manually convert the `eqsl:coalesce` call to provide the equivalent function. For more information, see "Managing conversion errors on converted legacy message maps" on page 1598.

Assigning literal values to output elements

Use the Assign transform to set literal values in output elements. The Assign transform uses a string representation, which is assigned to the relevant output element and so must be formatted according to its type. The property value does not need to be in quotation marks, as any quotation marks would be passed as part of the string value. To provide an explicitly typed value, use the `xs:<type>` Cast transform with no input wiring.

Literals in conditional expressions

You could build expressions in the legacy message mapping editor that implied a type cast and used the underlying string value representation.

The Graphical Data Mapping editor uses XPath expression syntax and enforces strict typing. For example, testing a Boolean-typed element for the string literal value **true** would cause a type exception.

You can use the `xs:<type>` functions in your expressions to avoid these incorrect typing issues.

Java methods in conditional expressions

Legacy message maps allowed the use of Java methods with `MbElement` parameters types. The Graphical Data Mapping editor uses standard XPath expression execution and can support only Java methods with standard Java parameter types. For more information, see "Defining a Java conditional expression for a transform" on page 1439.

Complex type text values in condition expression

A legacy message map did not require you to be explicit when accessing mixed content text values from a complex type element in a condition expression.

The Graphical Data Mapping editor is based on standard XPath syntax, and requires the explicit use of **/text()** to signify that the mixed content text value is to be used. As a result, a converted map with a conditional expression that referenced mixed content text values might fail until the path expression is extended to add the missing **/text()**.

Literals in submap calls

The legacy message map editor did not correctly validate the typing of submap inputs. You could edit the normal element path value of a submap input, and instead provide an untyped literal value.

The Graphical Data Mapping editor requires that all submap inputs are wired to an appropriately typed input element.

"For each index" counter variables

Some transformations require the use of the "For each index" counter value. The WebSphere Message Broker Version 7 message map provided the **`msgmap:occurrence`** function to obtain the current loop count. The Graphical Data Mapping editor provides a **`For loop`** counter variable which can be used to provide equivalent function. The name of this variable is fixed format `$<For each primary input element name>-index` can be obtained using content assist `ctrl-space` in the relevant "ForEach transform" **Filter properties expression** panel, or in the content assist in any nested transforms.

Explicit casting of variables in conditional expression

While using conditional expressions like the `If` transform, for complex expressions or when a return value from ESQL function was being compared with a variable, you could add explicit type casting in expressions using `xs:<type>( $<var> )`. An example of an `If` transform for checking the variable of DATE datatype: function:

```
isStartdate() =xs:date($test)
```

Behavior changes during the deployment phase

In IBM App Connect Enterprise, message maps can be deployed only as source. You must provide any of the following resources before deploying your solution:

- For text and binary messages, you must provide the DFDL schema file or the message set that defines your input and output messages.
- For XML messages, you must provide the XML schema files that define your input and output messages.

If your message is modeled in a message set, the message map requires the message set schema (`.xsdzip` file) to be deployed to run your message map. If your existing message set is used for text and binary formats only, you can deploy your message map with only a `.dictionary` file in the BAR file. In this case, you must modify the message set to additionally set the XMLNSC domain support option, so it is added to a BAR file with both a `.dictionary` file and `.xsdzip` file. If this option is not set, a warning is displayed in the **Problems** view, along with a quick fix action.

Behavior changes at run time

- In IBM App Connect Enterprise, the Graphical Data Mapping editor has a dedicated Java based run time. As a result, map execution benefits from full support for XPath 2.0 and Java JIT optimization, which offers increased reliability.
- A message map can be invoked only from a Mapping node.
- A submap can be invoked only from a top level message map, that is, a map consumed by a Mapping node.
- The message map runs in the Java virtual machine of the integration node. You must ensure that the integration node is configured correctly. For more information, see "Setting the JVM heap size" on page 2762.

Timezone handling

If you use a Mapping node that includes XPath datetime, or Assign transforms to set the value of output elements that are defined as `xs:date`, `xs:dateTime`, or `xs:time` and you want the timezone included, you must set the environment variable MQSI_USE_TIMEZONE to any value.

Planning the conversion of a legacy message map
Before you convert a legacy message map, review this section to help you plan the migration.

About this task

If you want to deploy legacy message maps (`.msgmap` format) in IBM App Connect Enterprise, you must first convert them into message maps in `.map` format, which the IBM App Connect Enterprise Mapping node can consume.

Legacy message maps, which have not been modifiable since WebSphere Message Broker Version 7, could be deployed in later versions of WebSphere Message Broker; however, they cannot be deployed in IBM App Connect Enterprise until they have been converted.

Procedure

Complete the following tasks to plan the conversion of a legacy message map to an IBM App Connect Enterprise message map:

1. Verify that all the projects that include resources used by the legacy message map are available in your workspace, and the project dependencies are defined.

   The conversion process needs access to all projects that include resources used by the legacy message map, so that it can convert your map transformations automatically.
2. Identify the legacy message map resources used in your transformations:
   a) Check the input and output structures of the legacy message map.
      - Are you doing transformations that include the local environment tree?
      - Are you doing transformations that include data structures with *xsd:any* elements?

      For more information, see "Converting a legacy message map that includes transformations of the local environment tree or xsd:any elements" on page 1600.
   b) Check your transformation for any of the following types:
      - Transformations that include calls to user-defined ESQL procedures. For more information, see "Converting a legacy message map that includes user-defined ESQL procedures" on page 1601.
      - Transformations that include calls to ESQL mapping functions. For more information, see "Converting a legacy message map that includes ESQL mapping functions" on page 1602.
      - Transformations that include calls to message map functions. For more information, see "Converting a legacy message map that includes calls to message map functions" on page 1604.
      - Transformations that include calls to relational database operations. For more information, see "Converting a legacy message map that includes relational database operations" on page 1605.
      - Transformations that include calls to a message map. For more information, see "Converting a legacy message map that is called from an ESQL statement in a Compute node" on page 1605.

What to do next

1. Define schema models for any *xsd:any* element in your input or output structures. You can also use the **Add user-defined** function to qualify the *xsd:any* element. This approach is recommended when the *xsd:any* element only involves a small number of elements. If you reuse the same structure in multiple maps, it is recommended that you create a schema model.
2. Run the conversion process. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.
3. Review the newly created message map and complete the post-conversion tasks. For more information, see "Managing conversion warnings on converted legacy message maps" on page 1594 and "Managing conversion errors on converted legacy message maps" on page 1598.
4. Update the message flow that includes the legacy message map to include the new Mapping node and reference the newly created message map. For more information, see "Replacing a legacy Mapping node" on page 1606.
5. Deploy and test your message flow. For more information, see Deployment rules and guidelines.

Converting a message map from a `.msgmap` file to a `.map` file

You must convert legacy message maps (`.msgmap` format) to graphical data maps (`.map` format) before you can deploy or modify them.

Before you begin

Before you convert a legacy message map, complete the following steps:

1. Import your resources from WebSphere Message Broker. For more information, see Importing resources from previous versions. Alternatively, you can migrate the Toolkit development resources. For more information, see Migrating development resources.
2. Verify that all the projects that include resources used by the legacy message map are available in your workspace, and the project dependencies are defined.

3. Review "Changes in behavior in message maps converted from legacy message maps" on page 1588 and "Considerations for mapping messages modeled in message sets" on page 1274.

About this task

In IBM App Connect Enterprise, if you want to deploy or modify a legacy message map (`.msgmap` format), you must first convert it to a graphical data map (`.map` format). A graphical data map is known as a message map in IBM App Connect Enterprise.

Note: The conversion process is not reversible. However, you can run the conversion of a legacy message map multiple times. You must rename the converted legacy message map by removing *_backup* from the converted map name.

To use a converted legacy message map in your message flows, you must replace legacy Mapping nodes with new Mapping nodes. For more information, see "Replacing a legacy Mapping node" on page 1606.

Procedure

To convert a legacy message map to a message map by using the IBM App Connect Enterprise Toolkit, complete the following steps:

1. Start the conversion process: In the **Application Development** view, right-click the message map that you want to convert, and click **Convert Message Map from .msgmap to .map**.

   To covert multiple legacy message maps, right-click a folder, project, application, or library that contains one or more maps, and click **Convert Message Map from .msgmap to .map**.

   - Your converted message map is created, and is displayed in the **Application Development** view.
   - Your legacy message map is renamed *MessageMapName*`.msgmap_backup`, and is displayed in the **Application Development** view.
2. Open the converted map in the Graphical Data Mapping editor: In the **Application Development** view, double-click your new message map.

   The message map opens in the Graphical Data Mapping editor.
3. Review the transformation logic that was created by the conversion process to ensure that it produces the correct output for your application:
   a) Review and replace each **Task** transform. For more information, see "Managing conversion errors on converted legacy message maps" on page 1598.

      If your legacy message map contains complex mapping structures that the conversion process was not able to recreate, your message map includes **Task** transforms to assist you in manually recreating those structures.

      Task transforms are listed in the **Problems** view.

   b) Review all the conversion annotation icons () that are associated to transforms in your map. For more information, see "Managing conversion warnings on converted legacy message maps" on page 1594.

      Conversion annotation icons are displayed on the lower left of the transform in the Graphical Data Mapping editor.

      You can accept or reject all the transforms in a converted map in a single click.

Results

Your legacy message map is converted to a message map that can be deployed, and that can be modified by using the Graphical Data Mapping editor.

What to do next

Modify each message flow that references the legacy message map so that new Mapping nodes reference your new message map. For more information, see “Replacing a legacy Mapping node” on page 1606.

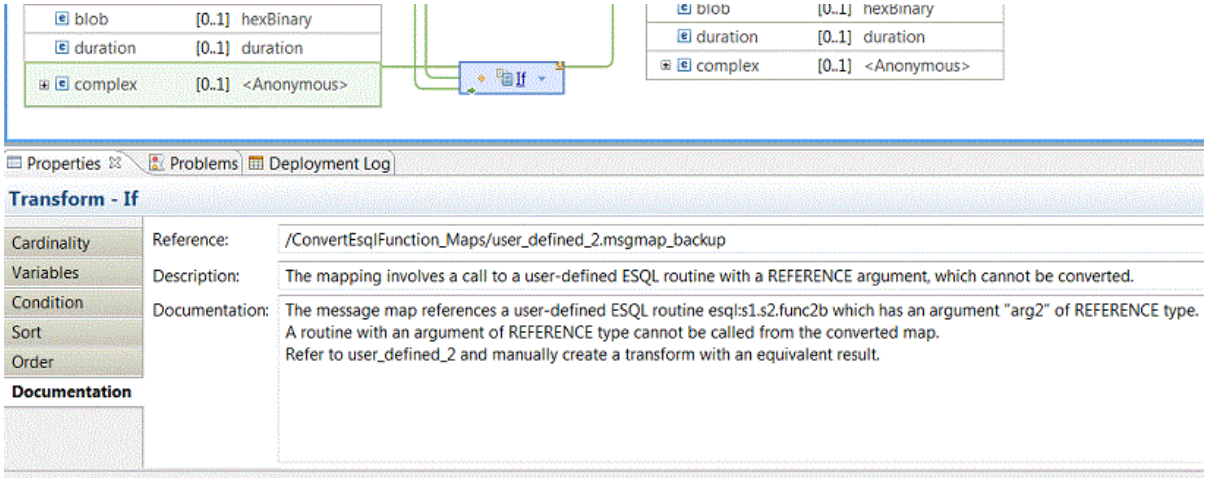
Managing conversion warnings on converted legacy message maps
You can accept or reject conversion actions suggested by the map conversion process when you transform a legacy message map into a message map.

About this task

If you convert a legacy message map (`.msgmap` file) to a message map (`.map` file), and your message map contains complex mapping structures that the conversion process is able to re-create, your new map might include warnings on one or more of the transforms that are created by the conversion process.

These warnings are displayed in the Graphical Data Mapping editor as conversion annotation icons ( ).

Note: The conversion process creates one warning per transform that needs to be reviewed. You must check all the warnings present on one or more of the transforms in your converted map because the output of the converted transform might be different to the behavior in your original message map.



If a transform contains a conversion warning, it will have a small green arrow in the bottom-left of the transform.

Procedure

In the Graphical Data Mapping editor, open your converted map, and complete the following actions to resolve the conversion warning:

1. Select a transform with a warning.
2. Review the transform properties in the **Properties** view to ensure that the transformation logic is correct.

3. Accept or reject the proposed transform. Select one of the following actions:
   a) Select **Accept Converted Transform** to remove the conversion warning and accept the transformation logic implemented by the conversion process.
   b) Select **Reject Converted Transform** to remove the warning. The conversion process replaces the converted transform with a **Task** transform. Then, manually re-create the transformation logic.
      i) Select the **Task** transform.
      ii) In the **Task** transform **Properties** view, check out the information provided in the **Documentation** tab.
      iii) Edit the **Condition** property of the transform and manually define the transformation logic.

      In the **Documentation** tab of the transform, the map conversion process includes the mapping structure from your legacy message map.
   c) Select **Accept All Converted Transforms** to remove all the conversion warnings in your map and accept all the transformation logic implemented by the conversion process.
   d) Select **Reject All Converted Transforms** to remove all the conversion warnings. The conversion process replaces each transform with a **Task** transform. Then, manually re-create the transformation logic.

What to do next

Check the following conversion warning descriptions and the actions you can take to resolve them:

Conversion warning description	Action to resolve it
The Java method call {0} cannot be converted. Before conversion, a Java method should be have been `java:[package name].[class name].[method name]([arguments])` Refer to {1} and create a Custom Java Transformation.	The mapping cannot be converted due to a syntax error in the Java method call {0}. To automatically convert the Java method, provide a "java:[package name].[class name].[method name]([arguments])". Alternatively, define a Custom Java Transform and implement your Java code.
The message map references the function {0}. The numbers of inputs provided by the message map and expected by the function definition are {1} and {2}, respectively. The extra input is:{3} Refer to {4} to resolve the discrepancy.	Review the input connections to the transform and remove the one that is not needed. For more information, see “Converting a legacy message map that includes ESQL mapping functions” on page 1602.
The message map references the function {0}. The numbers of inputs provided by the message map and expected by the function definition are {1} and {2}, respectively. Refer to {3} and provide values for all inputs.	Review your input connections and add the missing ones. The transform is missing at least one input connection For more information, see “Converting a legacy message map that includes ESQL mapping functions” on page 1602.
The following submap input in the message map was an expression not corresponding to any mapping input. Connect the input to a mapping input which will provide the value of the expression. Refer to {0} for the original mapping.	Connect the missing inputs to the submap.

Conversion warning description	Action to resolve it
The signature for Java method {0} in class {1} is not found in the workspace within the referenced projects and the Java build path. Refer to {2} for the original mapping and make sure the Java method is accessible from the map.	Define a project reference from the project containing the message map to the Java project that contains the Java class and method.
Review the definition being used as the cast for {0}, since it is defined in the following schemas. {1}	Check that the schema used to cast an `xsd:any` element or attribute is the correct one.
The connection to input {0} was converted from expression {1}. There is more than one element that can be identified as {1}. Review the input connection, and move the connection to another {0} if appropriate.	The transform was converted from a mapping with an ambiguous input.
The transformation code was converted from {0}. It is advised to review to ensure equivalent transformation outcome. Refer to {1} for the original function usage.	Review the transformation logic.
The transform was converted from a "for" statement, and produces one output for each instance of the input {0}. However, the output of the transform {1}, by definition, may expect only one occurrence. User review is advised to ensure the output is as expected. Refer to {2} for the original mapping.	Review the transformation logic.
The function {0} was converted from {1}. It is advised to review to ensure equivalent transformation outcome. Refer to {2} for the original function usage.	Review the transformation logic.
The transform was created by converting a non-trivial mapping in an older version of message map. User review is advised to ensure equivalent transformation outcome. Refer to {0} for the original mapping.	Review the transformation logic.
The transform was converted from a call to a user-defined ESQL function. All inputs of this transform are optional, if the user-defined ESQL function returns NULL when none of the inputs are present, an unexpected empty output element could be produced. To avoid an empty output element, consider setting a condition on the transform as shown below so that the transform will only be performed when at least one input exists: t{0} Refer to {1} for the original mapping.	A condition might be needed on the transform.

Conversion warning description	Action to resolve it
The message map references a user-defined ESQL routine {0} which has an argument {1} of REFERENCE type. A routine with an argument of REFERENCE type can be called from the converted map only if the following statements are true: • The reference variable is used to access only the input element or descendants of the input element. • The input element and any descendants that are accessed by using the reference variable are defined in the input message model. Refer to {2}, review and test the transform to ensure an equivalent result.	Check that the converted map gives the correct result.
The transform was converted from an XPath expression involving an XML type cast. Before conversion, XPath functions were implemented in the runtime using equivalent ESQL functions. Some of these ESQL functions have more lax value typing than defined in the XPath specification of the function. The Graphical Data Mapper provides conforming XPath functions. As a result, the transform may fail at runtime with invalid value for type casting issues. In particular, the ESQL equivalent function may have provide a default value when the parameter value was empty. To resolve these type of issues, add conditions to detect and prevent the values that are invalid for the XPath function parameters being passed to the function. For example, the following condition will make the transform executed only when all inputs exist: \t{0} Refer to {1} for the original mapping.	A condition might be needed on the transform. For more information, see “Converting a legacy message map that includes ESQL mapping functions” on page 1602.
The XPath expression was converted from an expression involving a call to the msgmap:exact-type function. It is advised to review to ensure equivalent transformation outcome. Refer to {0} for the original function usage.	Review the XPath expression. For more information, see “Converting a legacy message map that includes calls to message map functions” on page 1604.
The transform involves the following input element which involves a text content: Determine if the element or its text content is the intended mapping input or output. If necessary, modify the corresponding connection. Refer to {0} for the original mapping.	Review the XPath expression. For more information, see “Changes in behavior in message maps converted from legacy message maps” on page 1588.
The transform involves the following output element which involves a text content: Determine if the element or its text content is the intended mapping input or output. If necessary, modify the corresponding connection. Refer to {0} for the original mapping.	Review the XPath expression. For more information, see “Changes in behavior in message maps converted from legacy message maps” on page 1588.

Conversion warning description	Action to resolve it
The XPath function call was converted from {0}. Ensure the argument number, order and type matches the supported function specification. Refer to {1} for the original function usage.	Review the XPath expression against the XPath specification.

Managing conversion errors on converted legacy message maps
The conversion process creates a **Task** transform with an error when it cannot automatically convert a legacy message map transformation. You can use any of the transforms in the Graphical Data Mapping editor to reconstruct an equivalent transformation. Typically, you might use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic.

About this task

These errors are displayed in the Graphical Data Mapping editor as **Task** transforms marked with an error.

You can see the error description associated with the conversion in the **Problems** view or by hovering over the red exclamation symbol associated to a **Task** transform.

Procedure

In the Graphical Data Mapping editor, open your converted map, and complete the following actions to resolve the error:

1. Select a **Task** transform.

   The transform properties are displayed in the **Properties** view.
2. In the **Properties** view, click the **Documentation** tab to review details about the mapping structure that was not re-created by the conversion process.

   In the **Documentation** tab of the transform, the map conversion process includes the mapping structure from your legacy message map. For example, you can find the following description for conversion of unsupported legacy transforms:

   ```
   The expression {0} used for {1} cannot be automatically converted into a supported transform.
    \n\
   Refer to {2} and manually create a transform with an equivalent expression.
   ```
3. Change the **Task** transform to a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform.

   Click the arrow in the transform box, and select a transform from the list of available ones. For more information, see “Editing message maps” on page 1394.
4. Configure the transform properties to manually re-create the transformation logic.

What to do next

Check the following conversion error descriptions and the actions you can take to resolve them:

Conversion error descriptions	Action to resolve it
The statement {0} cannot be automatically converted into a supported transform. Refer to {1} and manually create mappings to perform the corresponding transformation.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic.

Conversion error descriptions	Action to resolve it
The expression {0} cannot be automatically converted into a supported transform. Refer to {1} and manually create a transform with an equivalent expression.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic. If the expression is `esql:coalesce`, see "Limitations on the conversion of esql:coalesce calls" on page 1589.
The expression {0} used for {1} cannot be automatically converted into a supported transform. Refer to {2} and manually create a transform with an equivalent expression.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic.
The XPath function call {0} for {1} is not supported. Refer to {2} and manually create a transform with an equivalent expression.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic.
The message map contains an erroneous expression. An attempt is made to convert the expression. Refer to {0} and review the converted expression.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic.
The message map references a user-defined ESQL routine {0} which has an argument {1} of REFERENCE type. A routine with an argument of REFERENCE type cannot be called from the converted map. Refer to {2} and manually create a transform with an equivalent result.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic. For more information, see "Converting a legacy message map that includes user-defined ESQL procedures" on page 1601.
The message map references a user-defined ESQL routine {0} which has an INOUT argument {1}. When a routine with an INOUT argument is called from the converted map, the argument must behave like an IN argument. Refer to {2} and the ESQL routine.	Check the **Documentation** tab of the **Task** transform to get details of the original expression. Use a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform to re-create the transformation logic. For more information, see "Converting a legacy message map that includes user-defined ESQL procedures" on page 1601.

Converting a legacy message map that includes transformations of the local environment tree or xsd:any elements

Before you convert a legacy message map that includes transformations of the local environment tree or *xsd:any* elements, you must provide the XML schema of the input and output data structure in a library. The library with the schemas must be visible by the project hosting the imported legacy message map.

About this task

In a message map, the Variables folder in the local environment tree is represented by *xsd:any*. In IBM App Connect Enterprise, you must qualify the Variables folder to provide the elements for your map. For more information, see "Mapping data in the local environment tree" on page 1464.

When you convert a legacy message map, you can encounter any of the following conversion behaviors:

- You have an *xsd:any* element and the schema model associated to the message set that you use to qualify it in your map. The conversion process casts the *xsd:any* element to the schema model automatically.
- You have an *xsd:any* element and no schema model describing its structure. The conversion process fails the first time. You must define the model and run again the conversion process.
- You have a legacy message map where you edit the path expression in your map to define the element that must be read to qualify the *xsd:any* element. The conversion process fails the first time. You must define the schema model and run again the conversion process.

If you only need to qualify a small number of elements, then, you might want to consider using the **Add user-defined** function instead of defining a schema model. For more information, see "Defining user-defined elements" on page 1408.

Procedure

In the **Application Development** view, complete the following steps to convert a legacy message map that includes transformations of the local environment tree and of *xsd:any* elements:

1. If you use the local environment tree in your legacy message map transformations, create an XML schema model in a library project. The model must define the Variables folder data structure.
2. If your input message or your output message include *xsd:any* elements that you use as part of your transformations, define the XML schema model for each one.
3. Start the conversion process: Right-click the message map that you want to convert, and click **Convert Message Map from .msgmap to .map**.
4. Open the converted map in the Graphical Data Mapping editor: Double-click your new message map.
5. Review the conversion errors and build the list of unresolved elements. For more information, see "Managing conversion errors on converted legacy message maps" on page 1598.
6. Create XML schema models for each unresolved data structure in a library that is referenced by the project hosting your converted map.

   For more information, see "Mapping data in the local environment tree" on page 1464.
7. Delete the converted legacy message map.
8. Rename the converted legacy message map by removing *_backup*.
9. Rerun the conversion process: Right-click the message map that you want to convert, and click **Convert Message Map from .msgmap to .map**.

   The conversion process casts automatically your *xsd:any* elements. Any related errors to unresolved elements disappear.

What to do next

Continue converting your legacy message map. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.

Converting a legacy message map that includes user-defined ESQL procedures
When you convert a legacy message map that includes ESQL procedures, the conversion process converts each ESQL procedure to an equivalent **Custom ESQL** transform that invokes the ESQL. A **Task** transform is added to your converted map when an ESQL procedure does not fulfill the requirements to be called from a map on a Mapping node.

Procedure

Check the conversion process behavior when you convert a legacy message map to a message map that includes ESQL procedures:

1. Check that the conversion meets the requirements for ESQL modules that are called from a graphical data map; see "Requirements for ESQL modules that are called from a graphical data map" on page 1309.
2. Each converted ESQL procedure is deployed as source. If you are not using IBM App Connect Enterprise application and library projects to store your ESQL procedures, check that the ESQL procedures have unique names because they are deployed independently to the same integration server.
3. Check whether the legacy message map includes ESQL procedure that uses the ESQL REFERENCE data type.

   By default, the conversion process converts ESQL procedures as follows:

   - An ESQL procedure that does not use the ESQL REFERENCE data type is converted to **Custom ESQL** transform. For more information, see "Custom ESQL" on page 1308.
   - An ESQL procedure that uses the ESQL REFERENCE data type is converted to **Task** transform. You must then replace the **Task** transform to complete the map conversion. You can replace the **Task** transform with a **Custom XPath** transform that provides equivalent function. You can also use a **Custom Java** transform or a **Custom ESQL** transform.

   If you have confirmed the requirements that are associated with the ESQL REFERENCE data type are met (see "Requirements for ESQL modules that are called from a graphical data map" on page 1309), and you want an ESQL procedure that uses the ESQL REFERENCE data type to be converted to a **Custom ESQL** transform instead of a **Task** transform, set a preference by completing the following steps:

   a. From the IBM App Connect Enterprise Toolkit menu, click **Windows** > **Preferences** > **Integration Development** > **Convert Message Map from .msgmap to .map**
   b. Select the check box for **Allow the conversion of user-defined ESQL procedures that include REFERENCE parameters**.
4. Check whether the ESQL procedure has an INOUT argument.

   The conversion process converts an ESQL procedure that has an INOUT argument to a **Custom ESQL** transform where the INOUT argument is converted as an IN argument. You can replace the **Custom ESQL** transform with a **Custom XPath** transform, or a **Custom Java** transform when the default conversion transform is not valid.
5. Consider whether the ESQL procedure can return a NULL value.

   In a legacy message map that is executed in generated ESQL, the output target is not created if the ESQL procedure returns a NULL value. In the converted `.map` file, the target output element is created with an empty value if the ESQL procedure returns a NULL value. It might be necessary to add an XPath condition expression to the **Custom ESQL** transform in the converted `.map` file to prevent the ESQL being called in situations where it would return an ESQL NULL value. For more information, see "Nulls behavior" on page 1588.

What to do next

Continue converting your legacy message map. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.

Converting a legacy message map that includes ESQL mapping functions
When you convert a legacy message map that includes ESQL mapping functions, the conversion process converts some ESQL functions to equivalent XPath 2.0 functions (`fn:functionName`), or to cast type functions (`xs:type`). A **Task** transform is added to your converted map when there is no automatic conversion for an ESQL function.

Before you begin

If your legacy message map includes `esql:coalesce` calls, check that the format of the calls can be converted; see "Limitations on the conversion of esql:coalesce calls" on page 1589.

Procedure

Check the conversion process behavior when you convert a legacy message map to a message map that includes ESQL mapping functions:

1. When a legacy message map includes calls to predefined ESQL mapping functions, each ESQL function call is converted to an XPath expression, cast type function, or to a **Custom XPath** transform in the converted map. For each expression, `xs:type` function, or **Custom XPath** transform in the converted map, complete the following steps:
   a) Check that the expression, `xs:type` function, or **Custom XPath** transform re-creates the required behavior.

      If your ESQL mapping function has optional input parameters, you must implement conditions to handle this situation. By default, the conversion process assumes that all input parameters are mandatory.

   b) For each expression, `xs:type` function, or transform, check that the correct number of inputs is connected.

      In earlier releases of WebSphere Message Broker Version 8, the number of inputs wired to a transform and required to implement a transformation in a legacy message map was not enforced. When the Graphical Data Mapping editor converts a transform that includes an ESQL mapping function, it creates an XPath function that conforms to the XPath 2.0 specification, and wires the input elements to the transform as defined in the legacy message map. As a result, a converted map might have more inputs than the XPath expression requires, or less inputs than the ones required to perform the calculation. Consequently, the converted map will fail to run when you deploy it.
2. If there is no XPath equivalent of an ESQL mapping function, the function is replaced with a **Task** transform in your converted map. You must replace each of these **Task** transforms with a **Custom**

XPath transform, a **Custom Java** transform, or a **Custom ESQL** transform that re-creates the required behavior.

a) Check the **Documentation** properties of the transform in the converted map for more information on how the ESQL function was implemented in your legacy message map.

The following ESQL mapping functions that you can use in a legacy message map have no XPath equivalent in message maps:

- Certain mathematical functions:
  - ACOS
  - ASIN
  - ATAN
  - ATAN2
  - BITAND
  - BITNOT
  - BITOR
  - BITXOR
  - COS
  - COSH
  - COT
  - DEGREES
  - EXP
  - LN
  - LOG
  - LOG10
  - MOD
  - POWER
  - RADIANS
  - RAND
  - SIGN
  - SIN
  - SINH
  - SQRT
  - TAN
  - TANH
- Decimal function:
  - TRUNCATE
- Certain String functions:
  - LTRIM
  - RTRIM
  - TRIM-LEADING
  - TRIM-TRAILING
  - REPLICATE
  - SPACE
  - TRIM-BOTH(Singleton FROM Source)

The simple form TRIM-BOTH (Source) is converted.

- Certain field functions:
  - ABITSTREAM
  - BITSTREAM
  - SAMEFIELD
- Certain date time functions:
  - TIMESTAMP
  - CURRENT-GMTDATE
  - CURRENT-GMTTIME
  - CURRENT-GMTTIMESTAMP
- All INTERVAL- functions
- The ESQL LIKE function
- The ESQL FOLLOWING form of the ESQL POSITION function
- All SQL functions
- The UUIDASCHAR and UUIDASBLOB functions

What to do next

Continue converting your legacy message map. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.

Converting a legacy message map that includes calls to message map functions
The conversion process converts a number of supported calls to predefined legacy message map functions (`msgmap:functionName`) to an XPath expression, or a **Custom XPath** transform.

About this task

If there is no XPath equivalent of a message map function, the conversion process creates a **Task** transform instead.

The following legacy message map functions have no XPath equivalent:

- msgmap:element-from-bitstream
- msgmap:cdata-element
- msgmap:db-path

Procedure

Complete the following steps to convert a transformation that includes a call to a message map function that is not converted automatically:

1. Select a **Task** transform.
2. In the **Task** transform **Properties** view, check out the information provided in the **Documentation** tab.
3. Replace the **Task** transforms with any of the available transforms. Consider using a **Custom XPath** transform, a **Custom Java** transform, or a **Custom ESQL** transform.
4. Manually re-create the equivalent transformation logic of the message map function.

What to do next

Continue converting your legacy message map. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.

Converting a legacy message map that includes relational database operations
You must manually convert a transformation that includes relational database operations.

About this task

A legacy Mapping node connects to a database via ODBC. A database configuration file describes the ODBC configuration to your database. You configure the database information in your legacy message map by setting the **Data Source** property in the map.

In IBM App Connect Enterprise, the Mapping node connects to databases via JDBC type 4 connections. You configure the database connection details in a JDBC Providers policy.

Database transforms in a message map use support for JDBC connections that are built into the IBM App Connect Enterprise run time.

For information about constructing database transforms and configuring your JDBC database connection, see "Mapping database content" on page 1523.

When you convert a legacy message map that includes database operations, the conversion process creates a **Task** transform for each database operation in the legacy message map. You have to manually replace that **Task** transform.

Procedure

To recreate the transformation logic of a transformation that includes a relational database operation, you can use any of the following transforms when replacing the **Task** transform in the new message map:

- "Select" on page 1338
- "Update" on page 1342
- "Delete" on page 1319
- "Database Routine" on page 1318
- "Insert" on page 1332

What to do next

Continue converting your legacy message map. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.

Converting a legacy message map that is called from an ESQL statement in a Compute node
To convert a legacy message map that is called from an ESQL CALL statement in a Compute node, you must implement your ESQL logic in a Mapping node, and call the converted legacy message map through a **Submap** transform.

Before you begin

Review "Changes in behavior in message maps converted from legacy message maps" on page 1588 and "Considerations for mapping messages modeled in message sets" on page 1274.

About this task

In IBM App Connect Enterprise, a graphical data map cannot be called from ESQL statements in a Compute node. You cannot modify or deploy a legacy message map in a BAR file.

Before you can modify or deploy a legacy message map (`.msgmap` format), you must convert it to a message map (`.map` format) and modify your message flow logic.

Procedure

To convert a legacy message map that is called by an ESQL CALL statement in a Compute node, complete the following steps:

- Replace the Compute node and the legacy message map with a new message map and Mapping node:
  a) Convert the legacy message map (`.msgmap`) to a new message map (`.map`), as described in "Converting a message map from a .msgmap file to a .map file" on page 1592.
  b) Replace each Compute node that includes a call to the legacy message map with a Mapping node.
  c) Create a new message map for each Mapping node.

     In this message map, complete the following steps:

     a. Create a message model that defines the overall input and output data structure to the Mapping node.
     b. Define the transforms that implement equivalent logic to the ESQL routine.
     c. Replace the CALL statement with a **Submap** transform. For more information, see "Submap" on page 1339.
     d. Configure the converted legacy message map as the mapping routine of the **Submap** transform.
- Replace the called message map with an ESQL function that provides equivalent logic.

What to do next

Deploy and test your message flow. For more information, see Deployment rules and guidelines.

Replacing a legacy Mapping node
A legacy Mapping node (created in WebSphere Message Broker Version 7), cannot reference a graphical data map (`.map` file). If you want to reference a graphical data map in IBM App Connect Enterprise, you must replace the legacy Mapping node with a new Mapping node, which is supported in IBM App Connect Enterprise.

Before you begin

Before you replace a Mapping node, you must complete the following task:

- Import your resources from IBM App Connect Enterprise. For more information, see Importing resources from previous versions.

You might also need to complete the following task:

- Convert a message map to a graphical data map. For more information, see "Converting a message map from a .msgmap file to a .map file" on page 1592.

About this task

If you import your integration solutions from WebSphere Message Broker Version 7, you must convert your legacy message maps and Mapping nodes before you can deploy the message flows that use them.

If you want to reference a graphical data map (`.map` file) in a Mapping node, you must use a Mapping node that was created in WebSphere Message Broker Version 8 (or later) or in IBM App Connect Enterprise.

To replace a legacy Mapping node by using the IBM App Connect Enterprise Toolkit, complete the following steps:

Procedure

1. In the **Application Development** view, double-click a message flow that contains one or more legacy Mapping nodes.

   The message flow opens in the Message Flow editor.
2. In the Message Flow editor, identify a legacy Mapping node that you want to replace.

3. In the Palette, expand the **Transformation** section, and then drag a new Mapping node from the Palette to the canvas of the Message Flow Editor.

   A new Mapping node is added to your message flow, and is assigned a default name.

   If you rename the node, the name that you choose must be unique in the message flow.

   If you do not change the default name at this time, you can change it later, as described in Renaming a message flow node.
4. Select your new Mapping node.

   The node properties are displayed in the Properties view.
5. In the Properties view, a default value is entered in the *Mapping routine* property, and must be replaced by choosing one of the following actions:
   - To reference an existing graphical data map, click **Browse...** to locate it, or specify your `.map` file in the format `{`*`BrokerSchemaName`*`}:`*`MapName`*. `{default}` indicates that no Broker schema is used by the graphical data map. For more information, see "Referencing an existing message map from a Mapping node" on page 1537.
   - To create a new graphical data map, double-click the Mapping node, or right-click the Mapping node and click **Open Map**. For more information, see "Creating a message map from a Mapping node" on page 1385.
6. Move the existing connections from your legacy Mapping node to your new Mapping node. For more information, see Connecting message flow nodes.
7. Select your legacy Mapping node and press the delete key (**del**) to remove it from your message flow. For more information, see Removing a message flow node.
8. Repeat steps "3" on page 1607 through "7" on page 1607 for each legacy Mapping node that you want to replace in your message flow.

Results

You have removed your legacy Mapping nodes and replaced them with new Mapping nodes.

What to do next

Deploy and test your message flow. For more information, see Deployment rules and guidelines.

Developing ESQL

Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

About this task

You must create, for each node, an ESQL module in which you code the ESQL statements and functions to tailor the behavior of the node. You can access message content, or database content, or both, to achieve the results that you require. ESQL modules are maintained in ESQL files, managed through the Integration Development perspective.

This section provides the following information:

- "ESQL overview" on page 1608
- "Managing ESQL files" on page 1615
- "Writing ESQL" on page 1629

You can use the ESQL debugger, which is part of the flow debugger, to debug the code that you write. The debugger steps through ESQL code statement by statement, so that you can view and check the results of every line of code that is run.

ESQL overview

Extended Structured Query Language (ESQL) is a programming language defined by IBM App Connect Enterprise to define and manipulate data within a message flow.

This section contains introductory information about ESQL.

- For descriptions of ESQL user tasks, see "Writing ESQL" on page 1629.
- For reference information about ESQL, see ESQL reference.

Read the following information before you proceed:

- An overview of message flows in "Message flows overview" on page 483.
- An overview of message trees in "The message tree" on page 500, and the topics within this container, paying special attention to "Logical tree (message assembly)" on page 501.

ESQL is based on Structured Query Language (SQL) which is in common usage with relational databases such as DB2. ESQL extends the constructs of the SQL language to provide support for you to work with message and database content to define the behavior of nodes in a message flow.

The ESQL code that you create to customize nodes within a message flow is defined in an ESQL file, typically named `<message_flow_name>.esql`, which is associated with the integration project. You can use ESQL in the following built-in nodes:

- node
- node
- node
- node

You can also use ESQL to create functions and procedures that you can use in the Mapping node.

To use ESQL correctly and efficiently in your message flows, you must also understand the following concepts:

- Data types
- Variables
- Field references
- Operators
- Statements
- Functions
- Procedures
- Modules

Use the ESQL debugger, which is part of the flow debugger, to debug the code that you write. The debugger steps through ESQL code statement by statement, so that you can view and check the results of every line of code that is run.

ESQL data types overview

A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

Within an integration node, the fields of a message contain data that has a definite data type. It is also possible to use intermediate variables to help process a message. You must declare all such variables with a data type before use. A variable's data type is fixed; If you try to assign values of a different type you get either an implicit cast or an exception. Message fields do not have a fixed data type, and you can assign values of a different type. The field adopts the new value and type.

It is not always possible to predict the data type that results from evaluating an expression. This is because expressions are compiled without reference to any kind of message schema, and so some type errors are not caught until run time.

ESQL defines the following categories of data. Each category contains one or more data types.

- Boolean
- Datetime
- Null
- Numeric
- Reference
- String

ESQL variables overview
An ESQL variable is a data field that is used to help process a message.

You must declare a variable and state its type before you can use it. The data type of a variable is fixed; if you code ESQL that assigns a value of a different type, either an implicit cast to the data type of the target is implemented or an exception is raised (if the implicit cast is not supported).

To define a variable and give it a name, use the DECLARE statement.

The names of ESQL variables are case-sensitive; therefore, make sure that you use the correct case in all places. The simplest way to guarantee that you are using the correct case is always to define variables using uppercase names.

The IBM App Connect Enterprise Toolkit marks variables that have not been defined. Remove all these warnings before deploying a message flow.

You can assign an initial value to the variable on the DECLARE statement. If an initial value is not specified, scalar variables are initialized with the special value NULL, and ROW variables are initialized to an empty state. Then, you can change the value of a variable by using the SET statement.

ESQL Variables declared at Module level 'belong' to a single node. However, variables declared at the Schema level are also given to each node that references that schema. So although variables at schema level are only declared once, each ESQL node has its own copy, which is not shared with any other node (unless the variable is marked SHARED).

Three types of built-in node can contain ESQL code and therefore support the use of ESQL variables:

- node
- node
- node
- node

Scope, lifetime, and sharing characteristics of variables

The scope, lifetime, and sharing characteristics of variables describe how widespread and for how long a particular ESQL variable is available:

Scope
Is a measure of the range over which a variable is visible. In the integration node environment, the scope of variables is typically limited to the individual node.

Lifetime
Is a measure of the time for which a variable retains its value. In the integration node environment, the lifetime of variables varies but is typically restricted to the life of a thread within a node.

Sharing characteristics
Indicate whether each thread has its own copy of a variable or whether one variable is shared between many threads. In the integration node environment, variables are typically not shared.

Types of variable

External

External variables (defined with the EXTERNAL keyword) are also known as *user-defined properties*, see "User-defined properties in ESQL" on page 1610. They exist for the entire lifetime of a message flow and are visible to all messages passing through the flow. You can define external variables only at the module and schema level. You can modify the initial values of external variables (optionally set by the DECLARE statement) at design time, by using the Message Flow editor, or at deployment time, by using the BAR editor. You can query and set the values of user-defined properties at run time by using the IBM Integration API.

Normal

Normal variables have a lifetime of just one message passing through a node. They are visible to that message only. To define normal variables, omit both the EXTERNAL and SHARED keywords.

Shared

Shared variables can be used to implement an in-memory cache in the message flow , see "Optimizing message flow response times" on page 2765. Shared variables have a long lifetime and are visible to multiple messages passing through a flow, see "Long-lived variables" on page 1611. Shared variables exist for the lifetime of the integration server process, the lifetime of the flow or node, or the lifetime of the node SQL that declares the variable (whichever is the shortest). Shared variables are initialized when the first message passes through the flow or node after each integration node startup.

See also the ATOMIC option of the BEGIN ... END statement. The BEGIN ATOMIC construct is useful when a number of changes must be made to a shared variable and it is important to prevent other instances seeing the intermediate states of the data.

User-defined properties in ESQL

Access user-defined properties (UDPs) as variables in your ESQL program by specifying the EXTERNAL keyword on a DECLARE statement. For example, the ESQL statement `DECLARE today EXTERNAL CHARACTER 'monday'` defines a user-defined property called today with an initial value monday.

Before you can use a user-defined property, you must define the property in the Message Flow editor when you construct a message flow that uses it. When you define a UDP in the Message Flow editor, you must define a value and the property type. The value can be a default value, which varies according to the type of the UDP. The value that is assigned to the UDP in the Message Flow editor takes precedence over a value that you have assigned to the UDP in your ESQL program.

You can also define a UDP for a subflow. A UDP has global scope and is not specific to a particular subflow. If you reuse a subflow in a message flow, and those subflows have identical UDPs, you cannot set the UDPs to different values.

Before you deploy the message flow that uses the UDP, you can change the value of the UDP in the BAR editor. If you try to deploy a message flow that contains a UDP that has had no value assigned to it, a deployment failure occurs. For more information, see "Configuring a message flow at deployment time with user-defined properties" on page 1749.

You can also modify the value of a UDP at run time, by using the administration REST API. For more information, see "Setting message flow user-defined properties at run time by using the administration REST API" on page 436.

You can use UDPs to set configuration data, and use them like typical properties. No external calls to user-written plug-ins or parsing of environment trees are involved, and parsing costs of reading data out of trees are removed. The value of the UDP is finalized in the variable at deployment time.

You can declare UDPs only in modules or schemas. You can query, discover, and set UDPs at run time, to dynamically change the behavior of a message flow. For more information, see "User-defined properties" on page 569.

You can access UDPs from the following built-in nodes that use ESQL:

- Compute

- Database
- DatabaseInput
- Filter

For a description of how to access a UDP from a JavaCompute node, see "Accessing message flow user-defined properties from a JavaCompute node" on page 1784.

Long-lived variables
You can use appropriate long-lived ESQL data types to cache data in memory.

Sometimes data has to be stored beyond the lifetime of a single message passing through a flow. One way to store this data is to store the data in a database. Using a database is good for long-term persistence and transactionality, but access (particularly write access) is slow.

Alternatively, you can use appropriate long-lived ESQL data types to provide an in-memory cache of the data for a certain period of time. Using long-lived ESQL data types makes access faster than from a database, although this speed is at the expense of shorter persistence and no transactionality.

You create long-lifetime variables by using the SHARED keyword on the DECLARE statement. For further information, see DECLARE statement.

Long-lived data types have an extended lifetime beyond that of a single message passing through a node. Long-lived data types are shared between threads and exist for the life of a message flow (the time between configuration changes to a message flow), as described in the following tables.

Table 66. Short lifetime variables

	Scope	**Life**	**Shared**
Schema & Module	Node	Thread within node	Not at all
Routine Local	Node	Thread within routine	Not at all
Block Local	Node	Thread within block	Not at all

Table 67. Long lifetime variables

	Scope	**Life**	**Shared**
Node Shared	Node	Life of node	All threads of flow
Flow Shared	Flow	Life of flow	All threads of flow

Features of long-lived ESQL data types include:

- The ability to handle large amounts of long-lifetime data.
- The joining of data to messages fast.
- On multiple processor machines, multiple threads can access the same data simultaneously.
- Subsequent messages can access the data left by a previous message.
- Long lifetime read-write data can be shared between threads, because there is no long-term association between threads and messages.
- In contrast to data stored in database tables in the environment, this type of data is stored privately; that is, within the integration node.
- ROW variables can be used to create a modifiable copy of the input message; see ESQL ROW data type.
- It is possible to create shared constants.

A typical use of these data types might be in a flow in which data tables are 'read-only' as far as the flow is concerned. Although the table data is not actually static, the flow does not change it, and thousands of messages pass through the flow before there is any change to the table data.

Examples include:

- A table which contains a day's credit card transactions. The table is created each day and that day's messages are run against it. Then the flow is stopped, the table updated and the next day's messages run. These flows might perform better if they cache the table data rather than read it from a database for each message.
- The accumulation and integration of data from multiple messages.

ESQL field references overview
An ESQL field reference is a sequence of period-separated values that identify a specific field (which might be a structure) within a message tree or a database table.

The path from the root of the information to the specific field is traced using the parent-child relationships.

A field reference is used in an ESQL statement to identify the field that is to be referenced, updated, or created within the message or database table. For example, you might use the following identifier as a message field reference:

```
Body.Invoice.Payment
```

You can use an ESQL variable of type REFERENCE to set up a dynamic pointer to contain a field reference. This might be useful in creating a fixed reference to a commonly-referenced point within a message; for example the start of a particular structure that contains repeating fields.

A field reference can also specify element types, XML namespace identifications, indexes and a type constraint; see ESQL field reference overview for further details.

The first name in a field reference is sometimes known as a *Correlation name*.

ESQL operators overview
An ESQL operator is a character or symbol that you can use in expressions to specify relationships between fields or values.

ESQL supports the following groups of operators:

- Comparison operators, to compare one value to another value (for example, "less than"). Refer to ESQL simple comparison operators and ESQL complex comparison operators for details of the supported operators and their use.
- Logical operators, to perform logical operations on one or two terms (for example, AND). Refer to ESQL logical operators for details of the supported operators and their use.
- Numeric operators, to indicate operations on numeric data (for example, +). Refer to ESQL numeric operators for details of the supported operators and their use.

There are some restrictions on the application of some operators to data types; not all lead to a meaningful operation. These are documented where they apply to each operator.

Operators that return a Boolean value (TRUE or FALSE), for example the "greater than" operator, are also known as *predicates*.

ESQL statements overview
An ESQL statement is an instruction that represents a step in a sequence of actions or a set of declarations.

ESQL provides a large number of different statements that perform different types of operation. All ESQL statements start with a keyword that identifies the type of statement and end with a semicolon. An ESQL program consists of a number of statements that are processed in the order they are written.

As an example, consider the following ESQL program:

```
DECLARE x INTEGER;
SET x = 42;
```

This program consists of two statements. The first starts with the keyword DECLARE and ends at the first semicolon. The second statement starts with the keyword SET and ends at the second semicolon. These

two statements are written on separate lines and it is conventional (but not required) that they be so. You will notice that the language keywords are written in capital letters. This is also the convention but is not required; mixed case and lowercase are acceptable.

The first statement declares a variable called x of type INTEGER, that is, it reserves a space in the computer's memory large enough to hold an integer value and allows this space to be subsequently referred to in the program by the name x. The second statement sets the value of the variable x to 42. A number appearing in an ESQL program without decimal point and not within quotation marks is known as an integer literal.

ESQL has a number of data types and each has its own way of writing literal values. These are described in “ESQL data types overview” on page 1608.

For a full description of all the ESQL statements, see ESQL statements.

ESQL nested statements
An ESQL nested statement is a statement that is contained within another statement.

Consider the following ESQL program fragment:

```
IF Size> 100.00 THEN
  SET X = 0;
  SET Y = 0;
  SET REVERSE = FALSE;
ELSE
  SET X = 639;
  SET Y = 479;
  SET REVERSE = TRUE;
END IF;
```

In this example, you can see a single IF statement containing the optional ELSE clause. Both the IF and ELSE portions contain three nested statements. Those within the IF clause are processed if the operator > (greater than) returns the value TRUE (that is, if Size has a value greater than 100.00); otherwise, those within the ELSE clause are processed.

Many statements can have expressions nested within them, but only a few can have statements nested within them. The key difference between an expression and a statement is that an expression calculates a value to be used, whereas a statement performs an action (usually changing the state of the program) but does not produce a value.

ESQL functions overview
A function is an ESQL construct that calculates a value from a number of given input values.

A function usually has input parameters and can, but does not usually have, output parameters. It returns a value calculated by the algorithm described by its statement. This statement is usually a compound statement, such as BEGIN... END, because this allows an unlimited number of nested statements to be used to implement the algorithm.

ESQL provides a number of predefined, or "built-in", functions which you can use freely within expressions. You can also use the CREATE FUNCTION statement to define your own functions.

When you define a function, you must give it a unique name. The name is handled in a non-case sensitive way (that is, use of the name with any combination of uppercase and lowercase letters matches the declaration). This is in contrast to the names that you declare for schemas, constants, variables, and labels, which are handled in a case sensitive way, and which you must specify exactly as you declared them.

Consider the following ESQL program fragment:

```
SET Diameter = SQRT(Area / 3.142) * 2;
```

In this example, the function SQRT (square root) is given the value inside the brackets (itself the result of an expression, a divide operation) and its result is used in a further expression, a multiply operation. Its return value is assigned to the variable Diameter. See Calling ESQL functions for information about all the built-in ESQL functions.

In addition, an ESQL expression can refer to a function in another broker schema (that is, a function defined by a CREATE FUNCTION statement in an ESQL file in the same or in a different dependent project). To resolve the name of the called function, you must take one of the following steps:

- Specify the fully-qualified name (<SchemaName>.<FunctionName>) of the called function.
- Include a PATH statement to make all functions from the named schema visible. Note that this technique only works if the schemas do not contain identically-named functions. The PATH statement must be coded in the same ESQL file, but not within any MODULE.

Note that you cannot define a function within an EVAL statement or an EVAL function.

ESQL procedures overview
An ESQL procedure is a subroutine that has no return value. It can accept input parameters from, and return output parameters to, the caller.

Procedures are very similar to functions. The main difference between them is that, unlike functions, procedures have no return value. Thus they cannot form part of an expression and are invoked by using the CALL statement. Procedures commonly have output parameters

You can implement a procedure in ESQL (an internal procedure) or as a database stored procedure (an external procedure). The ESQL procedure must be a single ESQL statement, although that statement can be a compound statement such as BEGIN END. You cannot define a procedure within an EVAL statement or an EVAL function.

When you define a procedure, give it a name. The name is handled in a non-case sensitive way (that is, use of the name with any combination of uppercase and lowercase letters matches the declaration). That is in contrast to the names that you declare for schemas, constants, variables, and labels, which are handled in a case sensitive way, and which you must specify exactly as you declared them.

An ESQL expression can include a reference to a procedure in another broker schema (defined in an ESQL file in the same or a different dependent project). If you want to use this technique, either fully qualify the procedure, or include a PATH statement that sets the qualifier. The PATH statement must be coded in the same ESQL file, but not within a MODULE.

An external database procedure is indicated by the keyword EXTERNAL and the external procedure name. This procedure must be defined in the database and in the integration node, and the name specified with the EXTERNAL keyword and the name of the stored database procedure must be the same, although parameter names do not have to match. The ESQL procedure name can be different from the external name it defines.

Overloaded procedures are not supported to any database. (An overloaded procedure is one that has the same name as another procedure in the same database schema which has a different number of parameters, or parameters with different types.) If the integration node detects that a procedure has been overloaded, it raises an exception.

Dynamic schema name resolution for stored procedures is supported; when you define the procedure you must specify a wildcard for the schema that is resolved before invocation of the procedure by ESQL. This is explained further in "Invoking stored procedures" on page 1674.

ESQL modules overview
A module is a sequence of declarations that define variables and their initialization, and a sequence of subroutine (function and procedure) declarations that define a specific behavior for a message flow node.

A module must begin with the `CREATE node_type MODULE` statement and end with an `END MODULE` statement. The *node_type* must be one of COMPUTE, DATABASE, DATABASEEVENT, or FILTER. For DatabaseInput nodes, the required *node_type* is DATABASEEVENT. For Compute, Database, and Filter nodes the required *node_type* is the same as the node. For example, you must use the COMPUTE *node_type* in ESQL modules for Compute nodes. For Compute, Database and Filter nodes, the entry point of the ESQL code is the function named MAIN, which has MODULE scope. ESQL modules for DatabaseInput nodes do not contain the MAIN function, but contain three procedures named READEVENTS, BUILDMESSAGE, and ENDEVENT. For more information about these three procedures, see "Configuring a DatabaseInput node" on page 1140.

Each module is identified by a name which follows CREATE *node_type* MODULE. The name might be created for you with a default value, which you can modify, or you can create it yourself. The name is handled in a non-case-sensitive way (that is, use of the name with any combination of uppercase and lowercase letters matches the declaration). This is in contrast to the names that you declare for schemas, constants, variables, and labels, which are handled in a case-sensitive way, and which you must specify exactly as you declared them.

You must create the code for a module in an ESQL file which has a suffix of `.esql`. You must create this file in the same broker schema as the node that references it. There must be one module of the correct type for each corresponding node, and it is specific to that node and cannot be used by any other node.

When you create an ESQL file (or complete a task that creates one), you indicate the integration project and broker schema with which the file is associated and specify a name for the file.

Within the ESQL file, the name of each module is determined by the value of the corresponding property of the message flow node. For example, the property *ESQL Module* for the Compute node specifies the name of the module in the ESQL file for that node. The default value for this property is the name of the node. You can specify a different name, but you must ensure that the value of the property and the name of the module that provides the required function are the same.

For Compute, Database, and Filter nodes, the module must contain the function MAIN, which is the entry point for the module. This function is included automatically if the module is created for you. Within MAIN, you can code ESQL to configure the behavior of the node. If you include ESQL within the module that declares variables, constants, functions, and procedures, these are of local scope only and can be used within this single module.

For DatabaseInput nodes, the module must contain the three procedures READEVENTS, BUILDMESSAGE, and ENDEVENT. These procedures are included automatically, together with comments to describe the procedure, if the module is created for you. Within the three procedures, you can code ESQL to configure the behavior of the node, see "Configuring a DatabaseInput node" on page 1140. If you include ESQL within the module that declares variables, constants, functions, and procedures, these are of local scope only and can be used within this single module.

If you want to reuse ESQL constants, functions, or procedures, you must declare them at broker schema level. You can then refer to these constants, functions or procedures from any resource within that broker schema, in the same or another project. If you want to use this technique, either fully qualify the procedure, or include a PATH statement that sets the qualifier. The PATH statement must be coded in the same ESQL file, but not within any MODULE.

Managing ESQL files

In an application, library, or integration project, manage ESQL files that contain the ESQL code that you provide to modify or customize the behavior of Compute, Database, DatabaseInput, and Filter nodes.

About this task

The ESQL code for a message flow node is contained in a module that is associated with the node. Each module must be created in an ESQL file (file extension `.esql`) . You can change the name of the module in the ESQL file from its default value of *MessageFlow_NodeName*, where *MessageFlow* is the name of the message flow and *NodeName* is the name of the message flow node. The name of the module in the ESQL file must match the name specified for the module in the ESQL `Module` property of the corresponding message flow node.

By default, ESQL files are deployed to the integration server as individual resources, and can be edited and redeployed without redeploying the message flows that reference them. Alternatively, you can include the code from an ESQL file directly in the compiled message flow (`.cmf` file) that references it. Compiled message flows that include ESQL code in this manner must be redeployed each time you change the ESQL code. For more information, see "Adding resources to a BAR file" on page 2470.

The following topics describe how to manage ESQL files.

- "Creating an ESQL file" on page 1616
- "Opening an existing ESQL file" on page 1617

- “Creating ESQL for a node” on page 1618
- “Deploying an ESQL file” on page 1623
- “Modifying ESQL for a node” on page 1620
- “Saving an ESQL file” on page 1621
- “Copying an ESQL file” on page 1623
- “Renaming an ESQL file” on page 1624
- “Moving an ESQL file” on page 1624
- “Changing ESQL preferences” on page 1625
- “Deleting ESQL for a node” on page 1627
- “Deleting an ESQL file” on page 1627

Creating an ESQL file
When you include a node in your message flow that requires ESQL code to customize its function, you must code the ESQL statements that provide the customization in an ESQL module in an ESQL file. The Compute, Database, DatabaseInput, and Filter nodes use ESQL code. You can use the same ESQL file for more than one module.

Before you begin

For background information, see “ESQL overview” on page 1608.

Optional: You can create an application, library, or integration project before you create an ESQL file. Alternatively, you can create the containing project when you create the ESQL file.

About this task

ESQL files are stored in a file system or in a shared repository. If you are using a file system, you can use the local file system or a shared drive. If you store files in a repository, you can use any of the available repositories that are supported by Eclipse, for example CVS.

To create an ESQL file, complete the following steps.

Procedure

1. Click **File** > **New** > **Message Flow ESQL File**.

   You can also click **New** in the Application Development view, then click **Message Flow ESQL File**.

   The **New Message Flow ESQL File** wizard opens.
2. Either select an existing application, library, or integration project in which to create the ESQL file, or click **New** to create a new container.

   When you store ESQL files in a shared library, you must place the ESQL files inside a schema that is not the default empty schema. For more information, see “Shared libraries” on page 1948.
3. Enter a name for the new ESQL file.

   If you enter a name that is already in use for an ESQL file in this project, the error message The `resource <name>.esql already exists` is shown and you must specify a different name.

   When creating ESQL files, the overall file path length must not exceed 256 characters, due to a Windows file system limitation. If you try to add a message flow to a BAR file with ESQL or mapping files with a path length that exceeds 256 characters, the compiled message flow is not generated and cannot be deployed. Therefore, make sure that the names of your ESQL files, mapping files, projects, and broker schema are as short as possible.
4. To define the ESQL file in a specific broker schema, clear **Use default broker schema** and either select a broker schema from the drop-down list, or enter the name of the broker schema.
5. Click **Finish**.

Results

The ESQL file opens in the editor, where you can edit the file, then save it. The ESQL file is shown in the Application Development view, beneath the ESQLs folder of the containing application, library, or integration project.

An ESQL file can also be created automatically for you. You can right-click a Compute, Database, DatabaseInput, or Filter node, then click **Open ESQL**. If the module identified by the appropriate property does not already exist in the broker schema, a module is created automatically. This module is created in the file `<message_flow_name>.esql` in the same broker schema in the same project as the `<message_flow_name>.msgflow` file. If that ESQL file does not already exist, that is also created for you.

The contents of a single ESQL file do not have any specific relationship with message flows and nodes. It is your decision which modules are created in which files (unless the specified module, identified by the appropriate property, is created by default in the file `<message_flow_name>.esql` as described above). Monitor the size and complexity of the ESQL in each file, and split the file if it becomes difficult to view or manage.

If you create reusable subroutines (at broker schema level) in an ESQL file, you might want to refer to these routines from ESQL modules in another project. To refer to the routines, specify that the project that runs the subroutines depends on the project in which the ESQL file containing them is defined. You can specify this behavior when you create the second project, or you can create a project reference; see "Referencing resources in other libraries" on page 1976.

Opening an existing ESQL file
You can add to and modify ESQL code that you have created in an ESQL file.

Before you begin

To complete this task, you must have created an ESQL file, as described in "Creating an ESQL file" on page 1616.

About this task

To open an existing ESQL file, complete the following steps.

Procedure

1. In the Application Development view, expand the appropriate application, library, or integration project, expand the ESQLs folder, then double-click the ESQL file that you want to open.

   The ESQL file opens in the editor.
2. Edit the contents of file to make your changes.

   The file can contain modules that relate to specific nodes in a message flow, PATH statements, and declarations at broker schema level, such as reusable constants and procedures. You can select the content that you want to work with by selecting its name in the Outline view. The code for the selected resource is highlighted.
3. Save and close the ESQL file.

Results

You can also open an ESQL file when you have a message flow open in the editor view by right-clicking an appropriate node (a Compute, Database, DatabaseInput, or Filter node), then clicking **Open ESQL**. In this case, the ESQL file that contains this module is opened, and the module for the selected node is highlighted in the editor view.

Creating ESQL for a node
Create ESQL code to customize the behavior of a Compute, Database, DatabaseInput, or Filter node in an ESQL file.

Before you begin

This topic assumes that you have created an ESQL file. For more information, see "Creating an ESQL file" on page 1616.

About this task

In the ESQL file, create a module that is associated with a node in your message flow. A module can be associated with only one node of a particular type (Compute, Database, DatabaseInput, or Filter). Within the module, you can create and use functions and procedures in addition to the supplied statements and functions. You can also create local constants and variables.

If you have created constants, functions, or procedures at the broker schema level, you can also refer to these in the module. You can define routines at a level at which many different modules can use them, which can save you development time and maintenance effort.

To create ESQL for a node, complete the following steps.

Procedure

1. Open the message flow that includes the node for which you want to create ESQL.

   In the Application Development view, expand the appropriate application, library, or integration project, expand the Flows folder, then double-click the message flow.

   The message flow opens in the Message Flow editor.
2. Right-click a Compute, Database, DatabaseInput, or Filter node, then click **Open ESQL**.

   The default ESQL file for this message flow, *message_flow_name*.esql, opens in the editor view. If the file does not already exist, it is created, containing a skeleton module for this node at the end. The exact content depends on the type of node.

   If you have already created the file, it is opened in the editor view and a new module is created and highlighted.

   The following module is created for a Compute node:

```
CREATE COMPUTE MODULE module_name
       CREATE FUNCTION Main() RETURNS BOOLEAN
       BEGIN
              -- CALL CopyMessageHeaders();
              -- CALL CopyEntireMessage();
              RETURN TRUE;
       END;

       CREATE PROCEDURE CopyMessageHeaders() BEGIN
              DECLARE I INTEGER 1;
              DECLARE J INTEGER CARDINALITY(InputRoot.*[]);
              WHILE I < J DO
                     SET OutputRoot.*[I] = InputRoot.*[I];
                     SET I = I + 1;
              END WHILE;
       END;

       CREATE PROCEDURE CopyEntireMessage() BEGIN
              SET OutputRoot = InputRoot;
       END;
END MODULE;
```

   The module name is determined by the value that you have set for the corresponding node property. The default name is *message_flow_name_node_type*. The main function contains calls to two procedures (described in the following list) that are declared in the Compute node module following

the function Main. These calls are commented out. To include the function that they provide, uncomment the lines and place them at the appropriate point in the ESQL that you create for Main.

CopyMessageHeaders
This procedure loops through the headers contained in the input message and copies each one to the output message.

CopyEntireMessage
This procedure copies the entire contents of the input message, including the headers, to the output message.

If you create an ESQL module for a Database node, the following module is created:

```
CREATE DATABASE MODULE module_name
       CREATE FUNCTION Main() RETURNS BOOLEAN
       BEGIN
                RETURN TRUE;
       END;
END MODULE;
```

For a DatabaseInput node, the module that is created contains three procedures, ReadEvents, BuildMessage, and EndEvent. Each of these procedures contains boilerplate text, which describes how the procedure works. For more information about configuring DatabaseInput nodes, see “Configuring a DatabaseInput node” on page 1140. For a DatabaseInput node, the following first line of the module is created:

```
CREATE DATABASEEVENT MODULE module_name
```

For a Filter node, the module is identical to the module created for the Database node, except for the first line, which reads:

```
CREATE FILTER MODULE module_name
```

3. Add ESQL to this file to customize the behavior of the node.

   For Compute, Database, or Filter nodes, start by adding ESQL statements in the Main function, (after the BEGIN statement, and before RETURN TRUE). For DatabaseInput nodes, add ESQL statements in the ReadEvents, BuildMessage, and EndEvent procedures. You can add DECLARE statements in the module that are not within the Main function. To add a new line into the file, press Enter.

   To help you to code valid ESQL, the editor shows a list of valid statements and functions at the point of the cursor. To start this assistance, click **Edit** > **Content Assist**. On some systems, you can use the key combination Ctrl+Space. Scroll through the list to find and highlight the statement or function that you want, and press Enter. The appropriate code is inserted into your module.

   Content assistance is provided in the following areas:

   - Applicable keywords, based on language syntax.
   - Blocks of code that go together, such as `BEGIN END;`.
   - Constants that you have defined, identifiers, labels, functions, and procedures that can be used, where the routines can be in any projects, even if the current project does not reference them.
   - Database schema and table names after the database correlation name, table column names in INSERT, UPDATE, DELETE, and SELECT statements, and, in most cases, the WHERE clauses of those statements.
   - Elements of message field reference: runtime domain (parser) names, format of type expression, namespace identifiers, namespace-qualified element and attribute names, and format of index expression.
   - Content in the Properties folder under the output message.
   - For the DECLARE NAMESPACE statement, target namespaces of message sets and schema names.

   Content assistance works only if the ESQL can be parsed correctly. Errors such as END missing after BEGIN, and other unterminated block statements, cause parser failures and no content assistance

is provided. Try content assistance in other areas around the statement where it does not work to narrow down the point of error. Alternatively, save the ESQL file; saving the file causes validation, and all syntax errors are written to the Problems view. Refer to the errors reported to understand and correct the ESQL syntax. If you use content assistance to generate most statements (such as block statements), these statements are correctly entered and there is less opportunity for error.

4. When you have finished working with this module, save and close the ESQL file.

Results

You can also open the ESQL file directly and create the module in that file by using the editor:

1. Open the ESQL file in which you want to create the module.
2. In the editor view, position your cursor on a new line and use content assistance to select the appropriate module skeleton for this type of node, for example `CREATE COMPUTE MODULE END MODULE;`. You can also type in this text, but you must ensure that what you type is consistent with the required skeleton, shown earlier. Use content assistance to give you additional help by inserting only valid ESQL, and by inserting matching end statements (for example, `END MODULE;`) where they are required.
3. Complete the coding of the module as appropriate.

Whichever method you use to open the ESQL file, be aware that the editor provides functions to help you to code ESQL. This section refers to content assistance; other functions are available. For information about these functions, see ESQL editor.

Modifying ESQL for a node
To change the customization of a node that requires ESQL (Compute, Database, DatabaseInput, or Filter node), modify the ESQL statements in the module that you created for that node.

Before you begin

This topic assumes that you have created ESQL code for a file. For more information, see “Creating ESQL for a node” on page 1618.

About this task

To modify ESQL code, complete the following steps.

Procedure

1. Open the message flow with which you want to work.

   In the Application Development view, expand the appropriate application, library, or integration project, expand the Flows folder, then double-click the message flow.)

   The message flow is opened in the Message Flow editor.
2. Right-click the node that corresponds to the ESQL module that you want to modify and click **Open ESQL**.

   The ESQL file is opened in the editor view. The module for this node is highlighted.
3. Make the required changes in the module by entering new statements, changing existing statements by over-typing, or deleting statements by using the Delete or backspace keys. You can use Content Assist, available from the **Edit** menu or, on some systems, by pressing Ctrl+Space). To get Content Assist to work with message references, you must set up a project reference from the project containing the ESQL to the project containing the message set. For information about setting up a project reference, see “Referencing resources in other libraries” on page 1976.
4. You can change the name of the module with which you are working by over-typing the current name with the new one. In this case, you must also change the node property ESQL `Module` to reflect the new name, to ensure that the correct ESQL code is deployed with the node.
5. When you have finished working with this module, save and close the ESQL file.

Results

You can also open the ESQL file directly by double-clicking it in the Application Development view. You can select the module with which you want to work from the Outline view.

The editor provides functions that you can use to help you modify your ESQL code. These functions are described in ESQL editor.

You can also modify the ESQL source by clicking **Source** > **Format**. This option formats all selected lines of code (unless only partially selected, when they are ignored), or, if no lines are selected, formats the entire file (correcting alignments and indentation).

Adding comments to ESQL

About this task

You can add and remove comments in your ESQL code.

Procedure

- To change an existing line of code into a comment line, click **Source** > **Comment**.
- To change a comment line to a code line, click **Source** > **Uncomment**.
- To create a new comment line, press Enter to create a new line, then either type the comment identifier `--` or click **Source** > **Comment**. You can enter any text after the identifier; everything that you type is ignored by the ESQL editor.

Saving an ESQL file
When you edit an ESQL file, you can save it to preserve the additions and modifications that you have made, and to force the editor to validate the content of the file.

Before you begin

This task assumes that you have created or opened an ESQL file. For more information, see “Creating an ESQL file” on page 1616 or “Opening an existing ESQL file” on page 1617.

About this task

To save an ESQL file, complete the following steps.

Procedure

1. Change the contents of the ESQL file.

2. Save the file by clicking **File** > **Save** or **File** > **Save All**.

   When you save the file, the validator is called by the editor to check that the ESQL obeys all grammar and syntax rules (specified by the syntax diagrams and explanations in ESQL reference).

   You can request additional validation when you set ESQL preferences:

   a) Click **Window** > **Preferences** > **Integration Development** > **ESQL** > **Validation**.
   The Preferences dialog box is displayed.

   b) Select the level of validation that you require for each category of error:

      i) Unresolved identifiers

      ii) Message references do not match message definitions

      iii) Database references do not match database schema

      iv) Use of deprecated keywords

      The default level is *warning*; you can change this value to *error* or *ignore*.

      Validating message definitions can affect response times in the editor, particularly if you have complicated ESQL that makes many references to a complex message definition. You might choose to delay this validation. Call validation when you have finished developing the message flow and are about to deploy it, to avoid runtime errors.

      For each error found, the editor writes the code line number and the reason for the error; errors are created as entries in the Problems view.

3. If you double-click the error, the editor positions your cursor on the line in which it found that error.

   The line is also highlighted by the error icon  .

   The editor might also find potential error situations, which it highlights as warnings (with the warning icon ); the editor also writes these warnings to the Problems view. For example, you might have included a BROKER SCHEMA statement that references an invalid schema (namespace).

   Check your code, and make the corrections required by that statement or function.

Save As

About this task

You can save a copy of this ESQL file by using **File** > **Save As**.

Procedure

1. Click **File** > **Save As**.
2. Specify the integration project in which you want to save a copy of the ESQL file.

   The project name defaults to the current project. You can accept this name, or choose another name from the valid options that are displayed in the File Save dialog box.
3. Specify the name for the new copy of the ESQL file.

   To save this ESQL file in the same project, either rename it, or confirm that you want to overwrite the current copy (that is, copy the file to itself).

   To save this ESQL file in another project, the project must exist. You can save the file with the same or another name in another project.
4. Click **OK**.

   The message flow is saved and the message flow editor validates its contents. The editor provides a report of all errors that it finds in the Problems view.

Copying an ESQL file
You can copy an ESQL file as a starting point for a new ESQL file that has similar function.

Before you begin

This topic assumes that you have created an ESQL file. For more information, see "Creating an ESQL file" on page 1616.

About this task

To copy an ESQL file, complete the following steps.

Procedure

1. In the Application Development view, right-click the ESQL file that you want to copy, and click **Copy**.

   Alternatively, you can select the ESQL file and click **Edit** > **Copy**.
2. Right-click the integration project into which you want to copy the ESQL file and click **Paste**.

   Alternatively, you can select the integration project and click **Edit** > **Paste**.

   You can copy the ESQL file to the same broker schema within the same integration project, or to a different broker schema within the same integration project, or to a broker schema in a different integration project.

   When you copy an ESQL file, the associated files (message flow, and mapping if present) are not automatically copied to the same target integration project. If you want these files copied as well, you must do so manually.

   To use this ESQL file with another message flow, ensure that the modules in the ESQL file match the nodes that you have in the message flow, and that the node properties are set correctly.

Results

You can also copy an ESQL file by using **File** > **Save As**; for more information, see "Saving an ESQL file" on page 1621.

Deploying an ESQL file
By default, ESQL files are deployed in BAR files as individual resources, and can be edited and redeployed without redeploying the message flows that reference them.

Before you begin

This topic assumes that you have created an ESQL file. For more information, see "Creating ESQL for a node" on page 1618.

About this task

When you create a BAR file and add your message flow, the IBM App Connect Enterprise Toolkit packages any ESQL files that are referenced by the message flow into the BAR file. If the ESQL code references additional ESQL files that are not directly referenced by the message flow, the additional ESQL files must be added to the BAR file manually before it is deployed.

Optionally, you can include the code from an ESQL file directly in the compiled message flow (`.cmf` file) that references it. Compiled message flows that include ESQL code in this manner must be redeployed each time you change the ESQL code. For more information, see "Adding resources to a BAR file" on page 2470.

Deployed ESQL files are displayed in the Integration Explorer view. If your messaging solution uses applications or libraries, deployed ESQL files are displayed under the application or library to which they

were deployed. If your messaging solution does not use applications or libraries, deployed ESQL files are displayed under the integration server to which they were deployed.

For more information, see:

- "Creating a BAR file" on page 2469
- "Adding resources to a BAR file" on page 2470
- "Deploying integration solutions to a production environment" on page 2480

Renaming an ESQL file
You might want to rename an ESQL file if you have renamed the message flow with which it is associated.

Before you begin

This task assumes that you have created an ESQL file, as described in "Creating an ESQL file" on page 1616.

About this task

To rename an ESQL file, complete the following steps.

Procedure

1. Locate the ESQL file that you want to rename by expanding the appropriate application, library, or integration project, then expanding the ESQLs folder.
2. Right-click the ESQL file and click **Rename**.

   Alternatively, you can select the ESQL file, then click **File** > **Rename**.

   The Rename Resource dialog box opens.
3. Enter the new name for the ESQL file, then click **OK**.

   The ESQL file is renamed.

Moving an ESQL file
If you move a message flow from one broker schema to another, or from one project to another, you might want to move all ESQL files that are associated with that message flow.

Before you begin

To complete this task, you must have completed the following task:

- "Creating an ESQL file" on page 1616

About this task

To move an ESQL file:

Procedure

1. Move the ESQL file in one of the following ways:
   - Drag the ESQL file that you want to move from its current location to a broker schema within the same or another integration project.

     If the target location that you have chosen is not valid (for example, if an ESQL file of this name exists in the broker schema), the invalid icon is displayed and the move is not completed. If you have created an empty broker schema for this purpose, it might not be visible in the Application

Development view if category mode is selected. To see an empty schema in the Application Development view, click Hide Categories  .

- Right-click the ESQL file and click **Move**, or click **File** > **Move**. The Move dialog is displayed.

  Select the project and the broker schema from the list of valid targets that is shown in the dialog.

  Click **OK** to complete the move, or **Cancel** to cancel the request.

  If you click **OK**, the ESQL file is moved to its new location.

2. Check the Problems view for errors (indicated by the error icon ) or warnings (indicated by the warning icon ) generated by the move.

   The errors in the Problems view include those errors caused by broken references. When the move is completed, all references to this ESQL file are checked. If you have moved the file within the same named broker schema within the same integration project, all references are still valid. If you have moved the file to another broker schema in the same or another integration project, the references are broken. If you have moved the file to the same named broker schema in another integration project, the references might be broken if the project references are not set correctly to recognize external references in this file. These errors occur because resources are linked by a fully qualified name.

3. Double-click each error or warning to open the message flow that has the error in the editor view, and highlight the node in error.

   You can now correct the error.

Results

When you move an ESQL file, its associated files (for example, the message flow file) are not automatically moved to the same target broker schema. You must move these files yourself.

Changing ESQL preferences
You can modify the way in which ESQL is displayed in the editor and validated by the editor:

Procedure

- “Changing ESQL editor settings” on page 1626
- “Changing ESQL validation settings” on page 1626

Changing ESQL editor settings
When you open an ESQL file in the editor view, you can tailor the editor appearance by changing editor settings.

Procedure

1. **To change ESQL editor settings:**
   a) Click **Window** > **Preferences**.
   The Preferences dialog box opens.
   b) Expand the item for ESQL on the left and click **ESQL Editor**.
   c) Update the settings available for tab width and colors:
   - Click the **General** tab to change the displayed tab width within the ESQL editor.
   - Click the **Colors** tab to change the color of the editor view background, and of the entities displayed in the editor view. These include comments and keywords in your ESQL code.

   d) When you have completed your changes, click either **Apply** (to apply your changes and leave the Preferences dialog box open), or **OK** (to apply your changes and close the dialog box). Alternatively, to close the dialog box and discard your changes, click **Cancel**.
   e) To return the ESQL editor settings to the initial values, click **Restore Defaults**.
   All values are reset to the original settings.

   If you change the editor settings when you have an editor session active, the changes are implemented immediately. If you do not have an editor session open, you see the changes when you next edit an ESQL file.
2. **To change font settings for the ESQL editor:**
   a) Click **Window** > **Preferences**. The Preferences dialog box opens.
   b) Expand the item for Workbench on the left of the Preferences dialog box, and click **Colors and Fonts**.
   c) On the **Colors and Fonts** tab, expand Basic.
   d) Select a font or text color option and click **Change**. The Font dialog box opens.
   e) When you have completed your changes, click either **Apply** (to apply your changes and leave the Preferences dialog box open) or **OK** (to apply your changes and close the dialog box). Alternatively, to close the dialog box and discard your changes, click **Cancel**.
   f) To return the ESQL editor settings to the initial values, click **Restore Defaults**.

Changing ESQL validation settings
You can specify the level of validation that the ESQL editor performs when you save a `.esql` file. If the validation you have requested results in warnings, you can deploy a BAR file containing this message flow. However, if errors are reported, you cannot deploy the BAR file.

About this task

To change ESQL validation settings:

Procedure

1. Switch to the Integration Development perspective.
2. Click **Window** > **Preferences**.
   The Preferences dialog is displayed.
3. Expand the item for ESQL on the left and click Validation.
4. Update the settings for what is validated, and for what warnings or errors are reported.
   See ESQL editor for details of the settings and their values.

5. When you have completed your changes, click **Apply** to close the Preferences dialog, apply your changes and leave the Preferences dialog open. Click **OK** to apply your changes and close the dialog. Click **Cancel** to close the dialog and discard your changes.
6. If you want to return your ESQL editor preferences to the initial values, click **Restore Defaults**.

   All values are reset to the original settings.

Results

If you make changes to the validation settings, the changes are implemented immediately for currently open edit sessions and for subsequent edit sessions.

Deleting ESQL for a node
If you delete a node from a message flow, you can delete the ESQL module that you created to customize its function.

Before you begin

This topic assumes that you have created ESQL code for a node. For more information, see "Creating ESQL for a node" on page 1618.

About this task

To delete ESQL code, complete the following steps.

Procedure

1. Open the message flow with which you want to work.

   Expand the appropriate application, library, or integration project, expand the Flows folder, then double-click the message flow.

   The message flow opens in the Message Flow editor.
2. Right-click the node for which you want to delete the ESQL module, then click **Open ESQL**.

   The ESQL file is opened in the editor view, with the module for this node highlighted.
3. Press the Delete or backspace key to delete the whole module.
4. When you have finished working with this module, save and close the ESQL file.

   Saving the file also validates the ESQL; for more details, see "Saving an ESQL file" on page 1621.

Deleting an ESQL file
If you delete a message flow, or if you have deleted all the ESQL code in an ESQL file, you can delete the ESQL file.

Before you begin

This task assumes that you have created an ESQL file. For more information, see "Creating an ESQL file" on page 1616.

About this task

To delete an ESQL file, complete the following steps.

Procedure

1. In the Application Development view, right-click the ESQL file that you want to delete, and click **Delete**.

   You can also select the file in the Application Development view, and click **Edit** > **Delete**.

   A dialog box is displayed that asks you to confirm the deletion.

2. Click **Yes** to delete the file, or **No** to cancel the delete request.

   If you maintain resources in a shared repository, a copy is retained in that repository. You can follow the instructions provided by the repository supplier to retrieve the file if required.

   If you are using the local file system or a shared file system to store your resources, no copy of the file is retained. Be careful to select the correct file when you complete this task.

Exporting mapping information from Compute nodes
Export information for use by products, such as IBM InfoSphere® Metadata Workbench, that can perform impact analysis and data lineage operations.

The **Data Lineage Documents** wizard can generate the following documents:

Extension mapping documents
Extension mapping documents are comma-separated files that contain information about mapping transformations from Compute nodes in an IBM App Connect Enterprise project. You can generate mapping documents for all message flows, or for a single flow.

Extended data source documents
Extended data source documents describe the data structure of messages from each message set referenced by an IBM App Connect Enterprise project.

Procedure

1. Use one of the following methods to start the **Data Lineage Documents** wizard:
   - Right-click the application, library, or project, and then select **New** > **Data Lineage Documents**.
   - Click **File** > **New** > **Data Lineage Documents**.
2. Complete the wizard as appropriate.

Data lineage CSV files
Comma-separated value (CSV) files for use in impact analysis and data lineage.

You can export all mapping transformations from all Compute nodes in a specified application, library, or IBM App Connect Enterprise project. You can also create extended data source documents for schemas in a message set project.

The resulting CSV files can be imported into products, such as IBM InfoSphere Metadata Workbench, that can perform impact analysis and data lineage operations.

Data lineage
See where the information comes from, and what happens to it as it moves across data integration processes.

Impact analysis
Determine the effects of changing a field in the information flow.

The **Data Lineage Documents** wizard creates the following artifact as CSV files:

Extension Mapping Documents
This artifact contains rows of mappings from IBM App Connect Enterprise transformations between message models in a message flow. One mapping document is created for each flow, containing all mappings done by different Compute nodes in the flow. Each transformation in a node is recorded on its own row:

```
Name,Source Columns,Target Columns,Rule,Function,Specification Description
"Compute","WMBMessageModels.ShipOrderLibLibrary.shipPartRequest.shipPartRequest/
partNo","WMBMessageModels.ShipOrderLibLibrary.shipPartResponse.shipPartResponse/
partNo",,,"{}ProcessShipping_Compute.Main"
"Compute","WMBMessageModels.ShipOrderLibLibrary.shipPartRequest.shipPartRequest/
partQuantity","WMBMessageModels.ShipOrderLibLibrary.shipPartResponse.shipPartResponse/
partQuantity",,,"{}ProcessShipping_Compute.Main"
```

The fields are as follows:

Name
The name of the node in the message flow.

Source Columns
The source of the mappings.

Target Columns
The target of the mappings.

Rule
Not currently used.

Function
A list of user-defined or built-in functions that are being called in the mapping. If the list exceeds 255 characters, it is truncated.

Specification Description
The Compute node module or ESQL procedure or function where the mapping takes place, that is where the target is being mapped. If it is in a function or procedure inside a compute module, it has this form:

```
{broker.schema1}MyMessageFlow2_Compute.Main, {}Compute2.CopyEntireMessage.
```

If it is a procedure or function outside the module scope, the procedure or function name is shown, for example:

```
{broker.schema1}ExternalProcedure1
```

Not all ESQL transformations are supported; see Data Lineage restrictions.

Writing ESQL

How you can use ESQL to customize nodes.

About this task

When you create a message flow, you include input nodes that receive the messages and, optionally, output nodes that send out new or updated messages. If required by the processing that must be performed on the message, you can include other nodes after the input node that complete the actions that your applications need.

Some of the built-in nodes enable you to customize the processing that they provide. The Compute, Database, DatabaseInput, and Filter nodes require you to provide a minimum level of ESQL, and you can provide much more than the minimum to control precisely the behavior of each node. This set of topics discusses ESQL and the ways in which you can use it to customize these nodes.

You can use the Mapping node to customize the processing visually. You can also call ESQL from a map to process or reuse existing or common ESQL routines. For more information, see Using message maps

ESQL provides a rich and flexible syntax for statements and functions that enable you to check and manipulate message and database content. You can:

- Read the contents of the input message
- Modify message content with data from databases
- Modify database content with data from messages
- Construct new output messages created from all, part, or none of the input message (in the Compute node only)

The following topics provide more information about these and other tasks that you can perform with ESQL. Unless otherwise stated, these guidelines apply to messages in all message domains except the BLOB domain, for which you can implement a limited set of actions.

- “Tailoring ESQL code for different node types” on page 1631
- “Manipulating message body content” on page 1632

- “Manipulating other parts of the message tree” on page 1649
- “Transforming from one data type to another” on page 1659
- “Interaction with databases using ESQL” on page 1666
- “Coding ESQL to handle errors” on page 1676
- “Configuring a message flow at deployment time with user-defined properties” on page 1749
- “Accessing a user-defined policy by using ESQL” on page 1750

The following topics provide additional information specific to the parser that you have specified for the input message:

- “Manipulating messages in the DFDL domain” on page 1693
- “Manipulating messages in the XML domain” on page 1727
- “Manipulating messages in the MRM domain” on page 1727
- “Manipulating messages in the JMS domains” on page 1741
- “Manipulating messages in the XMLNS domain” on page 1719
- “Manipulating messages in the XMLNSC domain” on page 1706
- “Manipulating messages in the IDOC domain” on page 1741
- “Manipulating messages in the MIME domain” on page 1742
- “Manipulating messages in the BLOB domain” on page 1744
- “Manipulating messages in the JSON domain” on page 1744

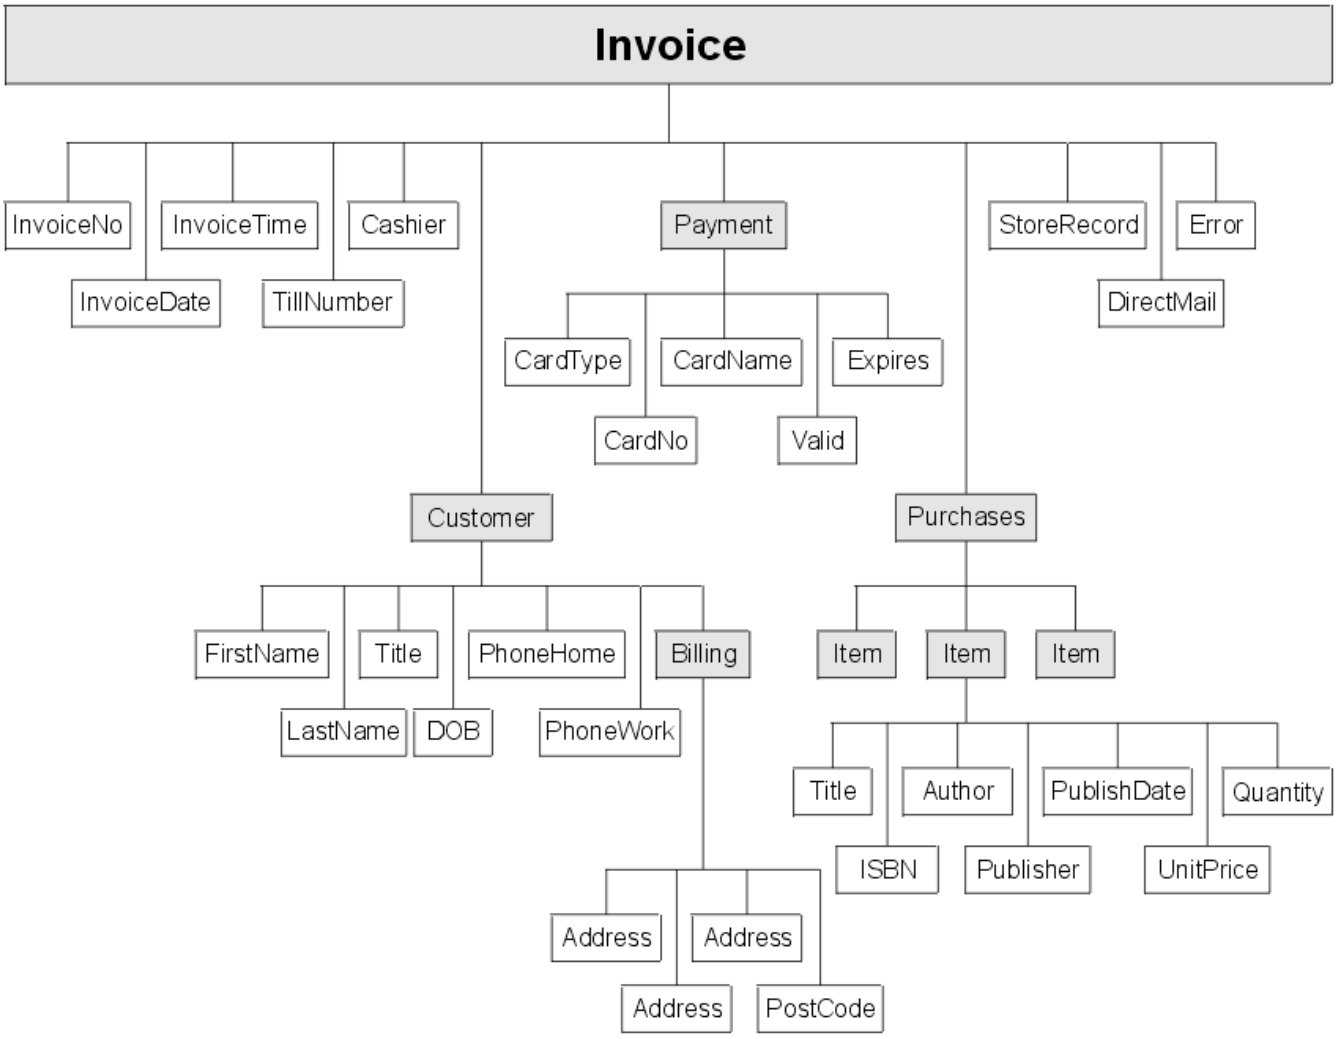
ESQL examples

About this task

Most of the examples included in the topics listed previously show parser-independent ESQL. If examples include a reference to MRM, they assume that you have modeled the message in the MRM and that you have set the names of the MRM objects to be identical to the names of the corresponding tags or attributes in the XML source message. Some examples are also shown for the XML domain. Unless stated otherwise, the principals illustrated are the same for all message domains. For domain-specific information, use the appropriate link in the previous list.

Most of the topics that include example ESQL use the ESQL sample message, Invoice, as the input message to the logic. This message is provided in XML source format (with tags and attributes), see Example message. The example message is shown in the following diagram.

A few other input messages are used to show ESQL that provides function on messages with a structure or content that is not included in the Invoice or Video samples. Where this occurs, the input message is included in the topic that refers to it.



Tailoring ESQL code for different node types
When you code ESQL to configure Compute, Database, DatabaseInput, and Filter node behavior, be aware of the limitations of each type of node.

About this task

Compute node

You can configure the Compute node to do any of the following operations:

- Update data in a database.
- Insert data into a database.
- Delete data from a database.
- Update the environment tree.
- Update the local environment tree.
- Create one or more output messages, with none, some, or all the content of the input message, and propagate these new messages to the next node in the message flow.

  To propagate the input LocalEnvironment to the output LocalEnvironment, remember to set the Compute node property `Compute mode` to an appropriate value. The Environment is always propagated in the output message.

Database node

You can configure the Database node to do any of the following operations:

- Update data in a database.
- Insert data into a database.
- Delete data from a database.
- Update the environment tree.
- Update the local environment tree.
- Propagate the input message to the next node in the message flow.

DatabaseInput node
You can configure the DatabaseInput node to do any of the following operations:

- Respond to updates that are made to the data in a database.
- Create one or more output messages, with none, some, or of all the content retrieved from a database, and propagate these new messages to the next node in the message flow.

Filter node
You can configure the Filter node to do any of the following operations:

- Update data in a database.
- Insert data into a database.
- Delete data from a database.
- Update the environment tree.
- Update the local environment tree.
- Propagate the input message to the next node in the message flow (the terminal through which the message is propagated depends on the result of the filter expression).

View the remaining tasks in this section to find the details of how you can perform these operations.

Manipulating message body content
The message body is always the last child of root, and is identified by its parser name, for example XML or MRM. You can refer to, modify, and create message body data.

About this task

The following topics describe how you can refer to, modify, and create message body data. The information provided here is domain independent.

Referencing field types
Some message parsers have complex models in which it is not enough to identify a field by its name and an array subscript. In these cases, you associate an optional field type with an element of data in the tree format.

About this task

Each element within the parsed tree can be one of three types:

Name element
A name element has a string, which is the name of the element, associated with it. An example of a name element is `XMLElement`, described in XML element.

Value element
A value element has a value associated with it. An example of a value element is `XMLContent`, described in XML content.

Name-value element
A name-value element is an optimization of the case where a name element contains only a value element and nothing else. The element contains both a name and a value. An example of a name-value element is `XMLAttribute`, described in XML attribute.

Accessing elements in the message body
When you want to access the contents of a message, for reading or writing, use the structure and arrangement of the elements in the tree that is created by the parser from the input bit stream.

About this task

Follow the relevant parent and child relationships from the top of the tree downwards, until you reach the required element.

- If you are referring to the input message tree to interrogate its content in a Compute node, use correlation name `InputBody` followed by the path to the element to which you are referring. `InputBody` is equivalent to `InputRoot` followed by the parser name (for example, `InputRoot.MRM`), which you can use if you prefer.
- If you are referring to the output message tree to set or modify its content in the Compute node, use correlation name `OutputRoot` followed by the parser name (for example, `OutputRoot.MRM`).
- If you are referring to the input message to interrogate its contents in a Database or Filter node, use correlation name `Body` to refer to the start of the message. `Body` is equivalent to `Root` followed by the parser name (for example, `Root.XMLNS`), which you can use if you prefer. You cannot use the `Body` correlation name in a DatabaseInput node.

  You must use these different correlation names because there is only one message to which to refer in a Database or Filter node; you cannot create an output message in these nodes. Use a Compute node to create an output message.

When you construct field references, the names that you use must be valid ESQL identifiers that conform to ESQL rules. If you enclose an item in double quotation marks, ESQL interprets it as an identifier. If you enclose an item in single quotation marks, ESQL interprets it as a character literal. You must enclose all strings (character strings, byte strings, or binary (bit) strings) in quotation marks, as shown in the following examples. To include a single or double quotation mark within a string, include two consecutive single or double quotation marks.

Important: For a full description of field reference syntax, see ESQL field reference overview.

For more information about ESQL data types, see ESQL data types in message flows.

Assume that you have created a message flow that handles the message Invoice, shown in the figure in “Writing ESQL” on page 1629. If, for example, you want to interrogate the element `CardType` from within a Compute node, use the following statement:

```
IF InputBody.Invoice.Payment.CardType='Visa' THEN
   DO;
```

```
     -- more ESQL --
END IF;
```

If you want to make the same test in a Database or Filter node (where the reference is to the single input message), code:

```
IF Body.Invoice.Payment.CardType='Visa' THEN
   DO;
     -- more ESQL --
END IF;
```

If you want to copy an element from an input XML message to an output message in the Compute node without changing it, use the following ESQL:

```
SET OutputRoot.XMLNS.Invoice.Customer.FirstName =
              InputBody.Invoice.Customer.FirstName;
```

If you want to copy an element from an input XML message to an output message and update it, for example by folding to uppercase or by calculating a new value, code:

```
SET OutputRoot.XMLNS.Invoice.Customer.FirstName =
              UPPER(InputBody.Invoice.Customer.FirstName);
SET OutputRoot.XMLNS.Invoice.InvoiceNo = InputBody.Invoice.InvoiceNo + 1000;
```

If you want to set a STRING element to a constant value, code:

```
SET OutputRoot.XMLNS.Invoice.Customer.Title = 'Mr';
```

You can also use the equivalent statement:

```
SET OutputRoot.XMLNS.Invoice.Customer.Title VALUE = 'Mr';
```

If you want to update an INTEGER or DECIMAL, for example the element `TillNumber`, with the value 26, use the following assignment (valid in the Compute node only):

```
SET OutputRoot.MRM.Invoice.TillNumber=26;
```

The integer data type stores numbers using the 64-bit twos complement form, allowing numbers in the range -9223372036854775808 to 9223372036854775807. You can specify hexadecimal notation for integers as well as normal integer literal format. The hexadecimal letters A to F can be written in uppercase or lowercase, as can the X after the initial zero, which is required. The following example produces the same result as the example shown earlier:

```
SET OutputRoot.MRM.Invoice.TillNumber= 0x1A;
```

The following examples show SET statements for element types that do not appear in the Example message.

To set a FLOAT element to a non-integer value, code:

```
SET OutputRoot.MRM.FloatElement1 = 1.2345e2;
```

To set a BINARY element to a constant value, code:

```
SET OutputRoot.MRM.BinaryElement1 = X'F1F1';
```

For BINARY values, you must use an initial character X (uppercase or lowercase) and enclose the hexadecimal characters (also uppercase or lowercase) in single quotation marks, as shown.

To set a BOOLEAN element to a constant value (the value 1 equates to true, 0 equates to false), code:

```
SET OutputRoot.MRM.BooleanElement1 = true;
```

or

```
SET OutputRoot.MRM.BooleanElement1 = 1;
```

You can use the SELECT statement to filter records from an input message without reformatting the records, and without any knowledge of the complete format of each record. Consider the following example:

```
-- Declare local variable
DECLARE CurrentCustomer CHAR 'Smith';

-- Loop through the input message
SET OutputRoot.XMLNS.Invoice[] =
    (SELECT I FROM InputRoot.XMLNS.Invoice[] AS I
              WHERE I.Customer.LastName = CurrentCustomer
    );
```

This code writes all records from the input message to the output message if the WHERE condition (LastName = Smith) is met. All records that do not meet the condition are not copied from input message to output message. I is used as an alias for the correlation name InputRoot.XMLNS.Invoice[].

The declared variable CurrentCustomer is initialized on the DECLARE statement: this option is the most efficient way of declaring a variable for which the initial value is known.

You can use this alias technique with other SELECT constructs. For example, if you want to select all the records of the input message, and create an additional record:

```
-- Loop through the input message
SET OutputRoot.XMLNS.Invoice[] =
    (SELECT I, 'Customer' || I.Customer.LastName AS ExtraField
              FROM InputRoot.XMLNS.Invoice[] AS I
    );
```

You could also include an AS clause to place records in a subfolder in the message tree:

```
-- Loop through the input message
SET OutputRoot.XMLNS.Invoice[] =
    (SELECT I AS Order
            FROM InputRoot.XMLNS.Invoice[] AS I
    );
```

If you are querying or setting elements that contain, or might contain, null values, be aware of the following considerations:

Querying null values

When you compare an element to the ESQL keyword NULL, this tests whether the element is present in the logical tree that has been created from the input message by the parser.

For example, you can check whether an invoice number is included in the current invoice message with the following statement:

```
IF InputRoot.XMLNS.Invoice.InvoiceNo IS NULL THEN
   DO;
     -- more ESQL --
END IF;
```

You can also use an ESQL reference, as shown in the following example:

```
DECLARE cursor REFERENCE TO InputRoot.MRM.InvoiceNo;

IF LASTMOVE(cursor) = FALSE THEN
   SET OutputRoot.MRM.Analysis = 'InvoiceNo does not exist in logical tree';
ELSEIF FIELDVALUE(cursor) IS NULL THEN
   SET OutputRoot.MRM.Analysis =
       'InvoiceNo does exist in logical tree but is defined as an MRM NULL value';
ELSE
   SET OutputRoot.MRM.Analysis = 'InvoiceNo does exist and has a value';
END IF;
```

For more information about declaring and using references, see “Creating dynamic field references” on page 1639. For a description of the LASTMOVE and FIELDVALUE functions, see LASTMOVE function and FIELDTYPE function.

If the message is in the MRM domain, there are additional considerations for querying null elements that depend on the physical format. For further details, see “Querying null values in a message in the MRM domain” on page 1734.

Setting null values

You can use two statements to set null values:

1. If you set the element to NULL by using the following statement, the element is deleted from the message tree:

   ```
   SET OutputRoot.XMLNS.Invoice.Customer.Title = NULL;
   ```

   If the message is in the MRM domain, there are additional considerations for null values that depend on the physical format. For further details, see “Setting null values in a message in the MRM domain” on page 1735.

   This technique is called implicit null processing.

2. If you set the value of this element to NULL as follows:

   ```
   SET OutputRoot.XMLNS.Invoice.Customer.Title VALUE = NULL;
   ```

   the element is not deleted from the message tree. Instead, a special value of NULL is assigned to the element.

   ```
   SET OutputRoot.XMLNS.Invoice.Customer.Title = NULL;
   ```

   If the message is in the MRM domain, the content of the output bit stream depends on the settings of the physical format null handling properties. For further details, see “Setting null values in a message in the MRM domain” on page 1735.

   This technique is called explicit null processing.

If you set an MRM complex element or an XML, XMLNS, or JMS parent element to NULL without using the VALUE keyword, that element and all its children are deleted from the logical tree.

Accessing known multiple occurrences of an element

When you refer to or create the content of messages, it is very likely that the data contains repeating fields. If you know how many instances there are of a repeating field, and you want to access a specific instance of such a field, you can use an array index as part of a field reference.

About this task

For example, you might want to filter on the first line of an address, to expedite the delivery of an order. Three instances of the element Billling.Address are always present in the sample message. To test the first line, write an expression such as:

```
IF Body.Invoice.Customer.Billing.Address[1] = 'Patent Office' THEN
   DO;
     -- more ESQL --
END IF;
```

The array index `[1]` indicates that it is the first instance of the repeating field that you are interested in (array indices start at 1). An array index such as this can be used at any point in a field reference, so you could, for example, filter on the following test:

```
IF Body.Invoice."Item"[1].Quantity> 2 THEN
   DO;
     -- more ESQL --
END IF;
```

You can refer to the last instance of a repeating field using the special [<] array index, and to instances relative to the last (for example, the second to last) as follows:

- `Field[<]` indicates the last element.
- `Field[<1]` indicates the last element.
- `Field[<2]` indicates the last but one element (the penultimate element).

You can also use the array index [>] to represent the first element, and elements relative to the first element in a similar way.

- `Field[>]` indicates the first element. This is equivalent to `Field[1]`.

The following examples refer to the Example message using these indexes:

```
IF Body.Invoice.Customer.Billing.Address[<] = 'Hampshire' THEN
      DO;
     -- more ESQL --
END IF;
IF Body.Invoice.Customer.Billing.Address[<2 ] = 'Southampton' THEN
   DO;
     -- more ESQL --
END IF;
```

You can also use these special indexes for elements that repeat an unknown number of times.

Deleting repeating fields

About this task

If you pass a message with several repeats of an element through a message flow and you want to delete some of the repeats, be aware that the numbering of the repeats is reordered after each delete. For example, if you have a message with five repeats of a particular element, and in the message flow you have the following ESQL:

```
SET OutputRoot.MRM.e_PersonName[1] = NULL;
SET OutputRoot.MRM.e_PersonName[4] = NULL;
```

You might expect elements one and four to be deleted. However, because repeating elements are stored on a stack, when you delete one, the one above it takes its place. This means that, in the above example, elements one and five are deleted. To avoid this problem, delete in reverse order, that is, delete element four first, then delete element one.

Accessing unknown multiple occurrences of an element
To access repeating fields in a message, you must use a construct that can iterate over all instances of a repeating field.

About this task

You are likely to deal with messages that contain repeating fields with an unknown number of repeats (such as the `Item` field in Example message).

To write a filter that takes into account all instances of the `Item` field, you need to use a construct that can iterate over all instances of a repeating field. The quantified predicate allows you to execute a predicate against all instances of a repeating field, and collate the results.

For example, you might want to verify that none of the items that are being ordered has a quantity greater than 50. To do this you could write:

```
FOR ALL Body.Invoice.Purchases."Item"[]
    AS I (I.Quantity <= 50)
```

With the quantified predicate, the first thing to note is the brackets [] on the end of the field reference after FOR ALL. These tell you that you are iterating over all instances of the `Item` field.

In some cases, this syntax appears unnecessary because you can get that information from the context, but it is done for consistency with other pieces of syntax.

The AS clause associates the name `I` with the current instance of the repeating field. This is similar to the concept of iterator classes used in some object oriented languages such as C++. The expression in parentheses is a predicate that is evaluated for each instance of the `Item` field.

A description of this example is:

Procedure

Iterate over all instances of the field Item inside `Body.Invoice`.

For each iteration:

a) Bind the name `I` to the current instance of `Item`.

b) Evaluate the predicate `I.Quantity <= 50`.

If the predicate:

- Evaluates to TRUE for all instances of `Item`, return TRUE.
- Is FALSE for any instance of `Item`, return FALSE.
- For a mixture of TRUE and UNKNOWN, return UNKNOWN.

Results

The above is a description of how the predicate is evaluated if you use the ALL keyword. An alternative is to specify SOME, or ANY, which are equivalent. In this case the quantified predicate returns TRUE if the sub-predicate returns TRUE for any instance of the repeating field. Only if the sub-predicate returns FALSE for all instances of the repeating field does the quantified predicate return FALSE. If a mixture of FALSE and UNKNOWN values are returned from the sub-predicate, an overall value of UNKNOWN is returned.

In the following filter expression:

```
FOR ANY Body.Invoice.Purchases."Item"[]
    AS I (I.Title = 'The XML Companion')
```

the sub-predicate evaluates to TRUE. However this next expression returns FALSE:

```
FOR ANY Body.Invoice.Purchases."Item"[]
    AS I (I.Title = 'C Primer')
```

because the `C Primer` is not included on this invoice. If some of the items in the invoice do not include a book title field, the sub-predicate returns UNKNOWN, and the quantified predicate returns the value UNKNOWN.

To deal with the possibility of null values appearing, write this filter with an explicit check on the existence of the field, as follows:

```
FOR ANY Body.Invoice.Purchases."Item"[]
  AS I (I.Book IS NOT NULL AND I.Book.Title = 'C Primer')
```

The predicate IS NOT NULL ensures that, if an `Item` field does not contain a Book, a FALSE value is returned from the sub-predicate.

You can also manipulate arbitrary repeats of fields within a message by using a SELECT expression, as described in “Referencing columns in a database” on page 1666.

You can refer to the first and last instances of a repeating field using the [>] and [<] array indexes, and to instances relative to the first and last, even if you do not know how many instances there are. These indexes are described in “Accessing known multiple occurrences of an element” on page 1636.

Alternatively, you can use the CARDINALITY function to determine how many instances of a repeating field there are. For example:

```
DECLARE I INTEGER CARDINALITY(Body.Invoice.Purchases."Item"[])
```

Using anonymous field references
You can refer to the array of all children of a particular element by using a path element of *.

About this task

For example:

```
InputRoot.*[]
```

is a path that identifies the array of all children of InputRoot. This is often used in conjunction with an array subscript to refer to a particular child of an entity by position, rather than by name. For example:

InputRoot.*[<]
Refers to the last child of the root of the input message, that is, the body of the message.

InputRoot.*[1]
Refers to the first child of the root of the input message, the message properties.

You might want to find out the name of an element that has been identified with a path of this kind. To do this, use the FIELDNAME function, which is described in FIELDNAME function.

Creating dynamic field references
You can use a variable of type REFERENCE as a dynamic reference to navigate a message tree. This acts in a similar way to a message cursor or a variable pointer.

About this task

It is generally simpler and more efficient to use reference variables in preference to array indexes when you access repeating structures. Reference variables are accepted everywhere that field references are accepted, and come with a set of statements and functions to allow detailed manipulation of message trees.

You must declare a dynamic reference before you can use it. A dynamic reference is declared and initialized in a single statement.

All examples in this topic use the Example message as their input message. The following example shows how to create and use a reference.

```
-- Declare the dynamic reference
DECLARE myref REFERENCE TO OutputRoot.XMLNS.Invoice.Purchases.Item[1];

--  Continue processing for each item in the array
WHILE LASTMOVE(myref)=TRUE
DO
-- Add 1 to each item in the array
   SET myref = myref + 1;
-- Move the dynamic reference to the next item in the array
   MOVE myref NEXTSIBLING;
END WHILE;
```

The example works if the message tree was created with typed fields, based on a message model for the Example message. If this is not the case, you can modify the ESQL to work without a model, for example:

```
SET myref = CAST (myref AS INTEGER) + 1;
```

This example declares a dynamic reference, `myref`, which points to the first item in the array within Purchases. The value in the first item is incremented by one, and the pointer (dynamic reference) is moved to the next item. Once again the item value is incremented by one. This process continues until the pointer moves outside the scope of the message array (all the items in this array have been processed) and the LASTMOVE function returns FALSE.

The following examples show further examples.

```
DECLARE ref1 REFERENCE TO InputBody.Invoice.Purchases.Item[1];

DECLARE ref2 REFERENCE TO
 InputBody.Invoice.Purchases.NonExistentField;

DECLARE scalar1 CHARACTER;
DECLARE ref3 REFERENCE TO scalar1;
```

In the second example, `ref2` is set to point to InputBody because the specified field does not exist.

With the exception of the MOVE statement, which changes the position of the dynamic reference, you can use a dynamic reference anywhere that you can use a static reference. The value of the dynamic reference in any expression or statement is the value of the field or variable to which it currently points. For example, using the message in Example message, the value of `Invoice.Customer.FirstName` is Andrew. If the dynamic reference `myref` is set to point at the Customer field as follows:

```
DECLARE myref REFERENCE TO Invoice.Customer;
```

you can then extend this dynamic reference to address children of that field:

```
SET myref.Billing.Address[1] = 'Oaklands';
```

This changes the address in the example to Oaklands Hursley Village Hampshire SO213JR.

The position of a dynamic reference remains fixed even if a tree is modified. To illustrate this point the steps that follow use the message in Example message as their input message and create a modified version of this message as an output message:

Procedure

1. Copy the input message to the output message.
2. To modify the output message, first declare a dynamic reference `ref1` that points at the first item, The XML Companion.

   ```
   DECLARE ref1 REFERENCE TO
    OutputRoot.XMLNS.Invoice.Purchases.Item[1];
   ```

   The dynamic reference is now equivalent to the static reference `OutputRoot.XMLNS.Invoice.Purchases.Item[1].`
3. Use a create statement to insert a new first item for this purchase.

   ```
   CREATE PREVIOUSSIBLING OF ref1 VALUE 'Item';
   ```

   The dynamic reference is now equivalent to the static reference `OutputRoot.XMLNS.Invoice.Purchases.Item[2].`

Creating new fields
You can use a Compute node to create a new output message by adding new fields to an existing input message.

About this task

This topic provides example ESQL code for a Compute node that creates a new output message based on the input message, to which are added a number of additional fields.

The input message received by the Compute node within the message flow is an XML message, and has the following content:

```
<TestCase description="This is my TestCase">
    <Identifier>ES03B305_T1</Identifier>
    <Sport>Football</Sport>
    <Date>01/02/2000</Date>
    <Type>LEAGUE</Type>
</TestCase>
```

The Compute node is configured and an ESQL module is created that includes the following ESQL. The following code copies the headers from the input message to the new output message, then creates the entire content of the output message body.

```
-- copy headers
DECLARE i INTEGER 1;
DECLARE numHeaders INTEGER CARDINALITY(InputRoot.*[]);

WHILE i < numHeaders DO
    SET OutputRoot.*[i] = InputRoot.*[i];
    SET i = i + 1;
END WHILE;

CREATE FIELD OutputRoot.XMLNS.TestCase.description TYPE NameValue VALUE 'This is my TestCase';
CREATE FIRSTCHILD OF OutputRoot.XMLNS.TestCase Domain('XMLNS') NAME 'Identifier'
                               VALUE InputRoot.XMLNS.TestCase.Identifier;
CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase Domain('XMLNS') NAME 'Sport'
                               VALUE InputRoot.XMLNS.TestCase.Sport;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase Domain('XMLNS') NAME 'Date'
                               VALUE InputRoot.XMLNS.TestCase.Date;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase Domain('XMLNS') NAME 'Type'
                               VALUE InputRoot.XMLNS.TestCase.Type;
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Number TYPE NameValue
                               VALUE 'Premiership';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Result[1].Number TYPE NameValue VALUE  '1';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Result[1].Home TYPE Name;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[1].Home NAME 'Team'
                               VALUE 'Liverpool' ;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[1].Home NAME 'Score'
                               VALUE '4';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Result[1].Away TYPE Name;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[1].Away NAME 'Team'
                               VALUE 'Everton';
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[1].Away NAME 'Score'
                               VALUE '0';

 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Result[2].Number TYPE NameValue VALUE '2';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Result[2].Home TYPE Name;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[2].Home NAME 'Team'
                               VALUE 'Manchester United';
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[2].Home NAME 'Score'
                               VALUE '2';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[1].Result[2].Away TYPE Name;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[2].Away NAME 'Team'
                               VALUE 'Arsenal';
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[1].Result[2].Away NAME 'Score'
                               VALUE '3';

 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[2].Number TYPE NameValue
                               VALUE '2';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[2].Result[1].Number TYPE NameValue
                               VALUE  '1';
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[2].Result[1].Home TYPE Name;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[2].Result[1].Home NAME 'Team'
                               VALUE 'Port Vale';
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[2].Result[1].Home NAME 'Score'
                               VALUE '9' ;
 CREATE FIELD OutputRoot.XMLNS.TestCase.Division[2].Result[1].Away TYPE Name;
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[2].Result[1].Away NAME 'Team'
                               VALUE 'Brentford';
 CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Division[2].Result[1].Away NAME 'Score'
                               VALUE '5';
```

The output message that results from the ESQL shown above has the following structure and content:

```
<TestCase description="This is my TestCase">
  <Identifier>ES03B305_T1</Identifier>
  <Sport>Football</Sport>
  <Date>01/02/2000</Date>
  <Type>LEAGUE</Type>
  <Division Number="Premiership">
    <Result Number="1">
      <Home>
        <Team>Liverpool</Team>
        <Score>4</Score>
      </Home>
      <Away>
        <Team>Everton</Team>
        <Score>0</Score>
```

```
      </Away>
    </Result>
    <Result Number="2">
      <Home>
        <Team>Manchester United</Team>
        <Score>2</Score>
      </Home>
      <Away>
        <Team>Arsenal</Team>
        <Score>3</Score>
      </Away>
    </Result>
  </Division>
  <Division Number="2">
    <Result Number="1">
      <Home>
        <Team>Port Vale</Team>
        <Score>9</Score>
      </Home>
      <Away>
        <Team>Brentford</Team>
        <Score>5</Score>
      </Away>
    </Result>
  </Division>
</TestCase>
```

Generating multiple output messages

You can use the PROPAGATE statement to generate multiple output messages in the Compute node. The output messages that you generate can have the same or different content. You can also direct output messages to any of the four alternate output terminals of the Compute node, or to a Label node.

About this task

For example, to create three copies of the input message received by the Compute node, and send one to the standard Out terminal of the Compute node, one to the first alternate Out1 terminal of the Compute node, and one to the Label node ThirdCopy, code the following ESQL:

```
SET OutputRoot = InputRoot;
PROPAGATE;
SET OutputRoot = InputRoot;
PROPAGATE TO TERMINAL 'out1';
SET OutputRoot = InputRoot;
PROPAGATE TO LABEL 'ThirdCopy';
```

In the above example, the content of OutputRoot is reset before each PROPAGATE, because by default the node clears the output message buffer and reclaims the memory when the PROPAGATE statement completes. An alternative method is to instruct the node not to clear the output message on the first two PROPAGATE statements, so that the message is available for routing to the next destination. The code to achieve this result is:

```
SET OutputRoot = InputRoot;
PROPAGATE DELETE NONE;
PROPAGATE TO TERMINAL 'out1' DELETE NONE;
PROPAGATE TO LABEL 'ThirdCopy';
```

If you do not initialize the output buffer, an empty message is generated, and the message flow detects an error and throws an exception.

Also ensure that you copy all required message headers to the output message buffer for each output message that you propagate.

If you want to modify the output message content before propagating each message, code the appropriate ESQL to make the changes that you want before you code the PROPAGATE statement.

If you set up the contents of the last output message that you want to generate, and propagate it as the final action of the Compute node, you do not have to include the final PROPAGATE statement. The default action of the Compute node is to propagate the contents of the output buffer when it terminates. This is implemented by the RETURN TRUE statement, included as the final statement in the module skeleton.

For example, to generate three copies of the input message, and not perform any further action, include this code immediately before the RETURN TRUE statement:

```
SET OutputRoot = InputRoot;
PROPAGATE DELETE NONE;
PROPAGATE DELETE NONE;
```

Alternatively, you can modify the default behavior of the node by changing RETURN TRUE to RETURN FALSE:

```
SET OutputRoot = InputRoot;
PROPAGATE DELETE NONE;
PROPAGATE DELETE NONE;
PROPAGATE;
RETURN FALSE;
```

Three output messages are generated by the three PROPAGATE statements. The final RETURN FALSE statement causes the node to terminate but not propagate a final output message. Note that the final PROPAGATE statement does not include the DELETE NONE clause, because the node must release the memory at this stage.

Using numeric operators with datetime values
The following examples show the ESQL that you can code to manipulate datetime values with numeric operators.

About this task

Adding an interval to a datetime value

The simplest operation that you can perform is to add an interval to, or subtract an interval from, a datetime value. For example, you could write the following expressions:

```
DATE '2000-03-29' + INTERVAL '1' MONTH
TIMESTAMP '1999-12-31 23:59:59' + INTERVAL '1' SECOND
```

The following example shows how to calculate a retirement date by adding the retirement age to the birth date.

```
DECLARE retAge CHARACTER '65';
DECLARE birthDate DATE DATE '1953-06-01';

SET OutputRoot.XML.Test.retirementDate = birthDate + CAST(retAge AS INTERVAL YEAR);
```

The repetition of the word DATE in the above example is intentional. The first occurrence of DATE specifies the data type of the declared variable, birthDate. The second occurrence initializes the same variable with the constant character string that is enclosed in single quotation marks as a DATE.

Adding or subtracting two intervals

You can combine two interval values by using addition or subtraction. The two interval values must be of compatible types. It is not valid to add a year-month interval to a day-second interval as shown in the following example:

```
INTERVAL '1-06' YEAR TO MONTH + INTERVAL '20' DAY
```

The interval qualifier of the resultant interval is sufficient to encompass all the fields that are present in the two operand intervals. For example:

```
INTERVAL '2 01' DAY TO HOUR + INTERVAL '123:59' MINUTE TO SECOND
```

results in an interval with qualifier DAY TO SECOND, because both day and second fields are present in at least one of the operand values.

Subtracting two datetime values

You can subtract two datetime values to return an interval. You must include an interval qualifier in the expression to indicate what precision the result should be returned in. For example:

```
(CURRENT_DATE - DATE '1776-07-04') DAY
```

returns the number of days since the 4th July 1776, whereas:

```
(CURRENT_TIME - TIME '00:00:00') MINUTE TO SECOND
```

returns the age of the day in minutes and seconds.

Scaling intervals

You can multiply or divide an interval value by an integer factor:

```
INTERVAL '2:30' MINUTE TO SECOND / 4
```

Calculating a time interval

You can use ESQL to calculate the time interval between two events, and to set a timer to be triggered after a specified interval.

About this task

This ESQL example calculates the time interval between an input IBM MQ message being put on the input queue, and the time that it is processed in the current Compute node.

(When you make a call to a CURRENT_ datetime function, the value that is returned is identical to the value returned to another call in the same node. This ensures that you can use the function consistently within a single node.)

```
 CALL CopyMessageHeaders();
 Declare PutTime INTERVAL;

 SET PutTime = (CURRENT_GMTTIME - InputRoot.MQMD.PutTime) MINUTE TO SECOND;

 SET OutputRoot.XMLNS.Test.PutTime = PutTime;
```

The output message has the format (although actual values vary):

```
<Test>
 <PutTime>INTERVAL &apos;1:21.862&apos; MINUTE TO SECOND</PutTime>
</Test>
```

Example

The following code snippet sets a timer, to be triggered after a specified interval from the start of processing, in order to check that processing has completed. If processing has not completed within the elapsed time, the firing of the timer might, for example, trigger some recovery processing.

The `StartTime` field of the timeout request message is set to the current time plus the allowed delay period, which is defined by a user-defined property on the flow. (The user-defined property has been set to a string of the form "HH:MM:SS" by the administrator.)

```
DECLARE StartDelyIntervalStr EXTERNAL CHARACTER '01:15:05';

 CREATE PROCEDURE ValidateTimeoutRequest() BEGIN

  -- Set the timeout period
  DECLARE timeoutStartTimeRef REFERENCE TO
         OutputRoot.XMLNSC.Envelope.Header.TimeoutRequest.StartTime;
  IF LASTMOVE(timeoutStartTimeRef)
   THEN
   -- Already set
  ELSE
   -- Set it from the UDP StartDelyIntervalStr
   DECLARE startAtTime TIME CURRENT_TIME
          + CAST(StartDelyIntervalStr AS INTERVAL HOUR TO SECOND);

   -- Convert "TIME 'hh.mm.ss.fff'" to hh.mm.ss format
       -- needed in StartTime field
   DECLARE startAtTimeStr CHAR;
   SET startAtTimeStr = startAtTime;
```

```
   SET startAtTimeStr = SUBSTRING(startAtTimeStr FROM 7 FOR  8);
   SET OutputRoot.XMLNSC.Envelope.Header.TimeoutRequest.StartTime
                            = startAtTimeStr;
  END IF;
 END;
```

Selecting a subfield from a larger field
You might have a message flow that processes a message containing delimited subfields. You can code ESQL to extract a subfield from the surrounding content if you know the delimiters of the subfield.

About this task

If you create a function that performs this task, or a similar one, you can invoke it both from ESQL modules (for Compute, Database, DatabaseInput, and Filter nodes) and from mapping files (used by the Mapping node).

The following function example extracts a particular subfield of a message that is delimited by a specific character.

```
CREATE FUNCTION SelectSubField
       (SourceString CHAR, Delimiter CHAR, TargetStringPosition INT)
d       RETURNS CHAR
-- This function returns a substring at parameter position TargetStringPosition within the
-- passed parameter SourceString.  An example of use might be:
-- SelectSubField(MySourceField,' ',2) which will select the second subfield from the
-- field MySourceField delimited by a blank.  If MySourceField has the value
-- "First Second Third" the function will return the value "Second"
  BEGIN
    DECLARE DelimiterPosition INT;
    DECLARE CurrentFieldPosition INT 1;
    DECLARE StartNewString INT 1;
    DECLARE WorkingSource CHAR SourceString;
    SET DelimiterPosition = POSITION(Delimiter IN SourceString);
    WHILE CurrentFieldPosition < TargetStringPosition
      DO
       IF DelimiterPosition = 0  THEN
      -- DelimiterPosition will be 0 if the delimiter is not found
         -- exit the loop
        SET CurrentFieldPosition = TargetStringPosition;
       ELSE
        SET StartNewString = DelimiterPosition + 1;
        SET WorkingSource = SUBSTRING(WorkingSource FROM StartNewString);
        SET DelimiterPosition = POSITION(Delimiter IN WorkingSource);
        SET CurrentFieldPosition = CurrentFieldPosition + 1;
       END IF;
    END WHILE;
    IF DelimiterPosition> 0 THEN
       -- Remove anything following the delimiter from the string
       SET WorkingSource = SUBSTRING(WorkingSource FROM 1 FOR DelimiterPosition);
       SET WorkingSource = TRIM(TRAILING Delimiter FROM WorkingSource);
    END  IF;
    RETURN WorkingSource;
END;
```

Copying repeating fields
You can configure a node with ESQL to copy repeating fields in several ways.

About this task

Consider an input XML message that contains a repeating structure:

```
...
 <Field_top>
   <field1></field1>
   <field1></field1>
   <field1></field1>
   <field1></field1>
   <field1></field1>
 </Field_top>
.....
```

You cannot copy this whole structure field with the following statement:

```
SET OutputRoot.XMLNS.Output_top.Outfield1 = InputRoot.XMLNS.Field_top.field1;
```

That statement copies only the first repeat, and therefore produces the same result as this statement:

```
SET OutputRoot.XMLNS.Output_top.Outfield1[1] = InputRoot.XMLNS.Field_top.field1[1];
```

You can copy the fields within a loop, controlling the iterations with the CARDINALITY of the input field:

```
SET I = 1;
SET J = CARDINALITY(InputRoot.XMLNS.Field_top.field1[]);
WHILE  I <= J DO
 SET OutputRoot.XMLNS.Output_top.Outfield1[I] = InputRoot.XMLNS.Field_top.field1[I];
 SET I = I + 1;
END WHILE;
```

This might be appropriate if you want to modify each field in the output message as you copy it from the input field (for example, add a number to it, or fold its contents to uppercase), or after it has been copied. If the output message already contained more Field1 fields than existed in the input message, the surplus fields would not be modified by the loop and would remain in the output message.

The following single statement copies the iterations of the input fields to the output fields, and deletes any surplus fields in the output message.

```
SET OutputRoot.XMLNS.Output_top.Outfield1.[] = InputRoot.XMLNS.Field_top.field1[];
```

The following example shows how you can rename the elements when you copy them into the output tree. This statement does not copy across the source element name, therefore each `field1` element becomes a `Target` element.

```
SET OutputRoot.XMLNS.Output_top.Outfield1.Target[] =
    (SELECT I FROM InputRoot.XMLNS.Field_top.field1[] AS I );
```

The next example shows a different way to do the same operation; it produces the same end result.

```
SET OutputRoot.XMLNS.Output_top.Outfield2.Target[]
             = InputRoot.XMLNS.Field_top.field1[];
```

The following example copies across the source element name. Each `field1` element is retained as a `field1` element under the `Target` element.

```
SET OutputRoot.XMLNS.Output_top.Outfield3.Target.[]
             = InputRoot.XMLNS.Field_top.field1[];
```

This example is an alternative way to achieve the same result, with `field1` elements created under the `Target` element.

```
SET OutputRoot.XMLNS.Output_top.Outfield4.Target.*[]
             = InputRoot.XMLNS.Field_top.field1[];
```

These examples show that there are several ways in which you can code ESQL to copy repeating fields from source to target. Select the most appropriate method to achieve the results that you require.

The principals shown here apply equally to all areas of the message tree to which you can write data, not just the output message tree.

Working with elements of type list
The XML Schema specification allows an element, or attribute, to contain a list of values that are based on a simple type, with the individual values separated by white space.

About this task

In the message tree, an `xsd:list` element is represented as a name node, with an anonymous child node for each list item. Repeating lists can be handled without any loss of information.

Consider the following XML input message:

```
<message1>
  <listE1>one two three</listE1>
</message1>
```

This XML element produces the following message tree:

```
MRM
listEl  (Name)
 "one"   (Value)
 "two"   (Value)
 "three" (Value)
```

Individual list items can be accessed as `ElementName.*[n]`.

For example, use the following ESQL to access the third item of listE1:

```
SET X = FIELDVALUE (InputBody.message1.listE1.*[3]);
```

An attribute can also be of type `xsd:list`.

Consider the following XML input message:

```
<message1>
<Element listAttr="one two three"/>
</message1>
```

This XML element produces the following message tree:

```
MRM
Element (Name)
 listAttr (Name)
  "one" (Value)
  "two" (Value)
  "three" (Value)
```

As before, individual list items can be accessed as `AttrName.*[n]`.

For example, use the following ESQL to access the third item of listAttr:

```
SET X = FIELDVALUE (InputBody.message1.Element.listAttr.*[3]);
```

A list element can occur more than once.

Consider the following XML message:

```
<message1>
<listE1>one two three/listE1>
<listE1>four five six/listE1>
</message1>
```

The message tree for this XML message is:

```
MRM
listE1 (Name)
 "one" (Value)
 "two" (Value)
 "three" (Value)
listE1 (Name)
 "four" (Value)
```

```
  "five" (Value)
  "six" (Value)
```

Code the following ESQL to access the first item in the second occurrence of the list:

```
SET X = FIELDVALUE (InputBody.message1.listE1[2].*[1]);
```

Copying data between a list and a repeating element
This task shows how to copy data from a list into a repeating element by using ESQL.

About this task

Consider the form of the following XML input message:

```
<MRM>
  <inner>abcde fghij 12345</inner>
</MRM>
```

where the element inner is of type `xsd:list`, and therefore has three associated string values, rather than a single value.

To copy the three values into an output message, where each value is associated with an instance of repeating elements as shown here:

```
<MRM>
  <str1>abcde</str1>
  <str1>fghij</str1>
  <str1>12345</str1>
</MRM>
```

you might expect that the following ESQL syntax works:

```
DECLARE D INTEGER;
SET D = CARDINALITY(InputBody.str1.*[]);
DECLARE M INTEGER 1;
WHILE M <= D DO
   SET OutputRoot.MRM.str1[M] = InputBody.inner.*[M];
   SET M = M + 1;
END WHILE;
```

However, the statement:

```
SET OutputRoot.MRM.str1[M] = InputBody.inner.*[M];
```

requests a tree copy from input to output. Because the output element does not yet exist, the statement creates it, and its value and type are set from the input.

Therefore, to create the output message with the required format, given an input element which is of type `xsd:list`, use the FIELDVALUE function to explicitly retrieve only the value of the input element:

```
SET OutputRoot.MRM.str1[M] = FIELDVALUE(InputBody.inner.*[M]);
```

Manipulating repeating fields in a message tree
This topic describes the use of the SELECT function, and other column functions, to manipulate repeating fields in a message tree.

About this task

Suppose that you want to perform a special action on invoices that have a total order value greater than a certain amount. To calculate the total order value of an `Invoice` field, you must multiply the `Price` fields by the `Quantity` fields in all the `Items` in the message, and total the result. You can do this using a SELECT expression as follows:

```
(
 SELECT SUM( CAST(I.Price AS DECIMAL) * CAST(I.Quantity AS INTEGER) )
  FROM Body.Invoice.Purchases."Item"[] AS I
)
```

The example assumes that you need to use CAST expressions to cast the string values of the fields `Price` and `Quantity` into the correct data types. The cast of the `Price` field into a decimal produces a decimal value with the *natural* scale and precision, that is, whatever scale and precision is necessary to represent the number. These CASTs would not be necessary if the data were already in an appropriate data type.

The SELECT expression works in a similar way to the quantified predicate, and in much the same way that a SELECT works in standard database SQL. The FROM clause specifies what is being iterated, in this case, all `Item` fields in `Invoice`, and establishes that the current instance of `Item` can be referred to using `I`. This form of SELECT involves a column function, in this case the SUM function, so the SELECT is evaluated by adding together the results of evaluating the expression inside the SUM function for each `Item` field in the `Invoice`. As with standard SQL, NULL values are ignored by column functions, with the exception of the COUNT column function explained later in this section, and a NULL value is returned by the column function only if there are no non-NULL values to combine.

The other column functions that are provided are MAX, MIN, and COUNT. The COUNT function has two forms that work in different ways with regard to NULLs. In the first form you use it much like the SUM function above, for example:

```
SELECT COUNT(I.Quantity)
  FROM Body.Invoice.Purchases."Item"[] AS I
```

This expression returns the number of `Item` fields for which the `Quantity` field is non-NULL. That is, the COUNT function counts non-NULL values, in the same way that the SUM function adds non-NULL values. The alternative way of using the COUNT function is as follows:

```
SELECT COUNT(*)
  FROM Body.Invoice.Purchases."Item"[] AS I
```

Using COUNT(*) counts the total number of `Item` fields, regardless of whether any of the fields is NULL. The preceding example is in fact equivalent to using the CARDINALITY function, as in the following example:

```
CARDINALITY(Body.Invoice.Purchases."Item"[])
```

In all the examples of SELECT given here, just as in standard SQL, you could use a WHERE clause to provide filtering on the fields.

Manipulating other parts of the message tree
You can access message tree headers, the properties tree, the local environment tree, the environment tree and the exception list tree.

About this task

The following topics describe how you can access parts of the message tree other than the message body data. These parts of the logical tree are independent of the domain in which the message exists, and all these topics apply to messages in the BLOB domain in addition to all other supported domains.

- “Accessing headers” on page 1650
- “Accessing the Properties tree” on page 1653
- “Accessing the local environment tree” on page 1654
- “Accessing the environment tree” on page 1657
- “Accessing the ExceptionList tree using ESQL” on page 1658

Accessing headers
If the input message received by an input node includes message headers that are recognized by the input node, the node invokes the correct parser for each header. You can access these headers using ESQL.

About this task

Parsers are supplied for most IBM MQ headers. The following topics provide some guidance for accessing the information in the MQMD, MQRFH2, and MQPCF headers, which you can follow as general guidance for accessing other headers also present in your messages.

Every header has its own correlation name, for example, MQMD, and you must use this name in all ESQL statements that refer to or set the content of this tree:

- "Accessing the MQMD header" on page 1650
- "Accessing the MQRFH2 header" on page 1651
- "Accessing the MQCFH header" on page 1651

For further details of the contents of these and other IBM MQ headers for which IBM App Connect Enterprise provides a parser, see Element definitions for message parsers.

Accessing transport headers

About this task

You can manipulate IBM MQ, HTTP, and JMS transport headers and their properties without writing Compute nodes:

- Use the MQHeader node to add, modify, or delete MQ Message Descriptor (MQMD) and MQ Dead Letter Header (MQDLH) headers.
- Use the HTTPHeader node to add, modify, or delete HTTP headers such as HTTPRequest and HTTPReply.
- Use the JMSHeader node to modify contents of the JMS Header_Values and Application properties so that you can control the node's output without programming.

Accessing the MQMD header
Code ESQL statements to access the fields of the MQMD header.

About this task

IBM MQ and WebSphere MQ Everyplace® messages include an MQMD header.

You can refer to the fields within the MQMD, and you can update them in a Compute node.

For example, you might want to copy the message identifier MSGID in the MQMD to another field in your output message. To do that, code:

```
SET OutputRoot.MRM.Identifier = InputRoot.MQMD.MsgId;
```

If you send a message to an EBCDIC system from a distributed system, you might need to convert the message to a compatible CodedCharSetId and Encoding. To do this conversion, code the following ESQL in the Compute node:

```
SET OutputRoot.MQMD.CodedCharSetId = 500;
SET OutputRoot.MQMD.Encoding = 785;
```

The MQMD properties of CodedCharSetId and Encoding define the code page and encoding of the section of the message that follows (typically this is either the MQRFH2 header or the message body itself).

Differences exist in the way the Properties folder and the MQMD folder are treated with respect to which folder takes precedence for the same fields. For more information, see "Properties versus MQMD folder behavior for various transports" on page 506.

Accessing the MQRFH2 header
Code ESQL statements to access the fields of the MQRFH2 header.

About this task

When you construct an MQRFH2 header in a Compute node, it includes two types of fields:

- Fields in the MQRFH2 header structure; for example, Format and NameValueCCSID.
- Fields in the MQRFH2 NameValue buffer; for example, mcd and psc.

To differentiate between these two field types, insert a value in front of the referenced field in the MQRFH2 field to identify its type; a value for the NameValue buffer is not required because this is the default. The value that you specify for the header structure is `(MQRFH2.Field)`.

For example:

- To create or change an MQRFH2 Format field, specify the following ESQL:

```
SET OutputRoot.MQRFH2.(MQRFH2.Field)Format = 'MQSTR   ';
```

- To create or change the psc folder with a topic:

```
SET OutputRoot.MQRFH2.psc.Topic = 'department';
```

- To add an MQRFH2 header to an outgoing message that is to be used to make a subscription request:

```
DECLARE I INTEGER 1;
DECLARE J INTEGER CARDINALITY(InputRoot.*[]);

WHILE I < J DO
 SET OutputRoot.*[I] = InputRoot.*[I];
 SET I=I+1;
END WHILE;

SET OutputRoot.MQRFH2.(MQRFH2.Field)Version = 2;
SET OutputRoot.MQRFH2.(MQRFH2.Field)Format = 'MQSTR';
SET OutputRoot.MQRFH2.(MQRFH2.Field)NameValueCCSID = 1208;
SET OutputRoot.MQRFH2.psc.Topic = "InputRoot"."MRM"."topel";
SET OutputRoot.MQRFH2.psc.QMgrName = 'DebugQM';
SET OutputRoot.MQRFH2.psc.QName = 'PUBOUT';
SET OutputRoot.MQRFH2.psc.RegOpt = 'PersAsPub';
```

  Variable J is initialized to the value of the cardinality of the existing headers in the message. Using a variable is more efficient than calculating the cardinality on each iteration of the loop, which happens if you code the following WHILE statement:

```
WHILE I < CARDINALITY(InputRoot.*[]) DO
```

The MQRFH2 header can be parsed using either the MQRFH2 parser or the MQRFH2C compact parser. To consume less memory, use the MQRFH2C compact parser by selecting the `Use MQRFH2C compact parser for MQRFH2 Header` check box on the input node of the message flow. This results in paths that contain MQRFH2C instead of MQRFH2; for example: `SET OutputRoot.MQRFH2C.psc.Topic = 'department';`

Target MQRFH2 fields are created only if the headers are copied, and the MQRFH2C parser option is not selected on the MQInput node. In all other circumstances, an MQRFH2C field is created on output.

Accessing the MQCFH header
Code ESQL statements to access the fields of the MQCFH header (root name MQPCF).

About this task

Messages that are of PCF format (MQPCF, MQADMIN, and MQEVENT) include the MQCFH header. You can process the contents of the MQCFH header, accessing parameters, parameter lists, strings, and groups.

The *ParameterCount* field is hidden from view to keep the value synchronized with the true number of parameters. As a result, you cannot directly view, access, or edit the *ParameterCount* field and this applies when you are using:

- ESQL
- The Mapping Node
- Trace, or debugging code.

You can implement your own *ParameterCount* field with a specific value, but this value will be overwritten by the actual number of parameters on the flow exit.

- To access or to construct parameters in the header, use the following syntax:

```
SET OutputRoot.MQPCF.Parameter[nn] =
 Integer parameter ID
```

  If you access a 64-bit parameter, use the following syntax to differentiate from 32-bit parameters:

```
SET OutputRoot.MQPCF.Parameter64[nn] =
 Integer parameter ID
```

  For example:

```
SET OutputRoot.MQPCF.Parameter[1] =
 MQCACF_AUTH_PROFILE_NAME;
```

- For parameter lists, use the following syntax:

```
SET OutputRoot.MQPCF.ParameterList64[nn] =
 Integer parameter ID
SET OutputRoot.MQPCF.ParameterList64[nn].*[xx] =
 Integer parameter values
```

  For example:

```
SET OutputRoot.MQPCF.ParameterList[1] =
 MQIACF_AUTH_ADD_AUTHS;
SET OutputRoot.MQPCF.ParameterList[1].*[1] =
 MQAUTH_SET;
SET OutputRoot.MQPCF.ParameterList[1].*[2] =
 MQAUTH_SET_ALL_CONTEXT;
```

- A byte string is a byte array data type, and is supported with this syntax:

```
SET OutputRoot.MQPCF.Parameter[nn] =
 Integer parameter ID
SET OutputRoot.MQPCF.Parameter[nn].* =
 Integer, String or ByteArray Parameter value
```

- A group is implemented as a folder containing more PCF, and requires the following syntax:

```
SET OutputRoot.MQPCF.Group[xx] =
 Group Parameter ID
```

  For example:

```
SET OutputRoot.MQPCF.Group[1] =
 MQGACF_Q_ACCOUNTING_DATA;
SET OutputRoot.MQPCF.Group[1].Parameter[1] =
 MQCA_CREATION_DATE;
SET OutputRoot.MQPCF.Group[1].Parameter[1].* =
 '2007-02-05';
```

  You can also use nested groups; for example;

```
SET OutputRoot.MQPCF.Group[1].Group[1] =
 MQGACF_Q_ACCOUNTING_DATA;
SET OutputRoot.MQPCF.Group[1].Group[1].Parameter[1] =
 MQCA_CREATION_DATE;
SET OutputRoot.MQPCF.Group[1].Group[1].Parameter[1].* =
```

```
 '2007-02-05';
```

- A filter is almost identical to a parameter, but it also includes an operator. Therefore the syntax is a tree with named values:

```
SET OutputRoot.MQPCF.Filter[xx] =
 Integer parameter ID
SET OutputRoot.MQPCF.Filter[xx].Operator =
 Integer Filter name
SET OutputRoot.MQPCF.Filter[xx].Value =
 Byte, Integer or String Filter Value
```

- The following is sample code that can be used as an example to create an MQPCF message in a Compute node:

```
CREATE NEXTSIBLING OF OutputRoot.Properties DOMAIN 'MQMD';
CREATE NEXTSIBLING OF OutputRoot.MQMD DOMAIN 'MQADMIN'
NAME 'MQPCF';
CREATE FIELD OutputRoot.MQPCF;
SET OutputRoot.MQMD.MsgType = MQMT_REQUEST;
SET OutputRoot.MQMD.ReplyToQ = 'REPLYQ';
DECLARE refRequest REFERENCE TO OutputRoot.MQPCF;
SET refRequest.Type = 16; --MQCFT_COMMAND_XR z/OS
SET refRequest.StrucLength = MQCFH_STRUC_LENGTH;
SET refRequest.Version = 3; -- required for z/OS
SET refRequest.Command = MQCMD_INQUIRE_Q;
SET refRequest.MsgSeqNumber = 1;
SET refRequest.Control = MQCFC_LAST;
/* First parameter: Queue Name. */
SET refRequest.Parameter[1] = MQCA_Q_NAME;
SET refRequest.Parameter[1].* = 'QUEUENAME.*';
SET refRequest.ParameterList[1] = MQIACF_Q_ATTRS;
SET refRequest.ParameterList[1].*  = MQIACF_ALL;
```

Accessing the Properties tree
The Properties tree has its own correlation name, Properties, and you must use this in all ESQL statements that refer to or set the content of this tree.

About this task

The fields in the Properties tree contain values that define the characteristics of the message. For example, the Properties tree contains message template information for model-driven parsers, fields for the encoding and CCSID in which message data is encoded, and fields that hold the security identity of the message. For a full list of fields in this tree, see Data types for elements in the Properties subtree.

You can interrogate and update these fields using the appropriate ESQL statements. If you create a new output message in the Compute node, you must set values for the message properties.

Setting output message properties

About this task

If you use the Compute node to generate a new output message, you must set its properties in the Properties tree. The output message properties do not have to be the same as the input message properties.

For example, to set the output message properties for an output MRM message, set the following properties:

Property	Value
MessageSet	Message set identifier
MessageType	Message name[1]
MessageFormat	Physical format name[2]

Notes:

1. For details of the syntax of Message type, see "Specifying namespaces in the Message property" on page 2160.
2. The name that you specify for the physical format must match the name that you have defined for it. The default physical format names are Binary1, XML1, and Text1.

This ESQL procedure sets message properties to values passed in by the calling statement. You might find that you have to perform this task frequently, and you can use a procedure such as this in many different nodes and message flows. If you prefer, you can code ESQL that sets specific values.

```
CREATE PROCEDURE setMessageProperties(IN OutputRoot REFERENCE, IN setName char,
                 IN typeName char, IN formatName char) BEGIN
 /*********************************************************************
 * A procedure that sets the message properties
 *********************************************************************/
 set OutputRoot.Properties.MessageSet    = setName;
 set OutputRoot.Properties.MessageType   = typeName;
 set OutputRoot.Properties.MessageFormat = formatName;
END;
```

To set the output message domain, you can code ESQL statements that refer to the required domain in the second qualifier of the SET statement, the parser field. For example, the ESQL statement sets the domain to MRM:

```
SET OutputRoot.MRM.Field1 = 'field1 data';
```

This ESQL statement sets the domain to XMLNS:

```
SET OutputRoot.XMLNS.Field1 = 'field1 data';
```

Do not specify more than one domain in the ESQL for any single message. However, if you use PROPAGATE statements to generate several output messages, you can set a different domain for each message.

For information about the full list of elements in the Properties tree, see Data types for elements in the Properties subtree.

Differences exist in the way the Properties folder and the MQMD folder are treated with respect to which folder takes precedence for the same fields. For more information, see "Properties versus MQMD folder behavior for various transports" on page 506.

Accessing the local environment tree
The local environment tree has its own correlation name, `LocalEnvironment`, and you must use this name in all ESQL statements that refer to or set the content of this tree.

About this task

You can refer to and modify the information in the local environment tree. You can also extend the tree to contain information that you create yourself. You can create subtrees of this tree that you can use as a scratchpad or working area.

The message flow sets up information in two subtrees, `Destination` and `WrittenDestination`, below the `LocalEnvironment` root. You can refer to the content of both of these subtrees, and you can write to the `Destination` tree to influence the way in which the message flow processes your message. However, if you write to the `Destination` tree, follow the defined structure to ensure that the tree remains valid.

The `WrittenDestination` subtree contains the addresses to which the message has been written. Its name is fixed and it is created by the message flow when a message is propagated through the Out terminal of a request, output, or reply node. The subtree includes transport-specific information (for example, if the output message has been put to an IBM MQ queue, it includes the queue manager and queue names). You can use the following method to obtain information about the details of a message after it has been sent by the nodes:

- Connect a Compute node to the Out terminal.

The topic for each node that supports WrittenDestination information contains details about the data that it contains.

If you want the local environment tree to be included in the output message that is propagated by the Compute node, you must set the Compute node property Compute mode to a value that includes the local environment (for example, All). If you do not, the local environment tree is not copied to the output message.

The information that you insert into DestinationData or Defaults depends on the characteristic of the corresponding node property:

- If a node property is represented by a check box (for example, New Message ID), set the Defaults or DestinationData element to Yes (equivalent to selecting the check box) or No (equivalent to clearing the check box).
- If a node property is represented by a drop-down list (for example, Transaction Mode), set the Defaults or DestinationData element to the appropriate character string (for example Automatic).
- If a node property is represented by a text entry field (for example, Queue Manager Name), set the Defaults or DestinationData element to the character string that you would enter in this field.

If necessary, configure the sending node to indicate where the destination information is. For example, for the output node MQOutput, set Destination Mode:

- If you set Destination Mode to Queue Name, the output message is sent to the queue identified in the output node properties Queue Name and Queue Manager Name. Destination is not referenced by the node.
- If you set Destination Mode to Destination List, the node extracts the destination information from the Destination subtree. If you use this value you can send a single message to multiple destinations, if you configure Destination and a single output node correctly. The node checks the node properties only if a value is not available in Destination (as described above).
- If you set Destination Mode to Reply To Queue, the message is sent to the reply-to queue identified in the MQMD in this message (field ReplyToQ). Destination is not referenced by the node.

To find more information about ESQL procedures that perform typical updates to the local environment, see "Populating Destination in the local environment tree" on page 1656. Review the ESQL statements in these procedures to see how to modify the local environment. You can use these procedures unchanged, or modify them for your own requirements.

To find more information about how to extend the contents of this tree for your own purposes, see "Using scratchpad areas in the local environment" on page 1655.

Using scratchpad areas in the local environment
The local environment tree includes a subtree called variables. This subtree is always created, but is never populated by the message flow. Use this area for your own purposes; for example, to pass information from one node to another. You can create other subtrees of the local environment tree.

About this task

The advantage of creating your own data in a scratchpad in the local environment is that this data can be propagated as part of the logical tree to subsequent nodes in the message flow. If you create a new output message in a Compute node, you can also include all or part of the local environment tree from the input message in the new output message.

To ensure that the information in the local environment is propagated further down the flow, the Compute mode property of the Compute node must be set to include the local environment as part of the output tree (for example, specify LocalEnvironment and Message). For further details about the Compute mode property, see Setting the mode.

However, any data updates or additions that you make in one node are not retained if the message moves backwards through the message flow (for example, if an exception is thrown). If you create your own data, and want that data to be preserved throughout the message flow, you must use the environment tree.

You can set values in the variables subtree in a Compute node and those values can be used later by another node (Compute, Database, or Filter) for some purpose that you determine when you configure the message flow.

The local environment is not in scope in a Compute node, therefore you must use `InputLocalEnvironment` and `OutputLocalEnvironment` instead. For example, you might use the scratchpad in the local environment to propagate the destination of an output message to subsequent nodes in a message flow. Your first Compute node determines that the output messages from this message flow must go to IBM MQ queues. Include the following ESQL to insert this information into the local environment by setting the value of *OutputLocation* in the OutputLocalEnvironment:

```
SET OutputLocalEnvironment.Variables.OutputLocation = 'MQ';
```

Your second Compute node can access this information from its input message. In the ESQL in this node, use the correlation name InputLocalEnvironment to identify the local environment tree in the input message that contains this data. The following ESQL sets *queueManagerName* and *queueName* based on the content of *OutputLocation* in the local environment, by using InputLocalEnvironment:

```
IF InputLocalEnvironment.Variables.OutputLocation = 'MQ' THEN
   SET OutputLocalEnvironment.Destination.MQ.DestinationData.queueManagerName = 'myQManagerName';
   SET OutputLocalEnvironment.Destination.MQ.DestinationData.queueName = 'myQueueName';
END IF;
```

In the example, *queueManagerName* and *queueName* are set for the Destination subtree in the output message. You must set the `Compute mode` of the second Compute node to include the local environment tree in the output message. Configure the MQOutput node to use the destination list that you have created in the local environment tree by setting the `Destination Mode` property to `Destination List`.

For information about the full list of elements in the DestinationData subtree, see Data types for elements in the MQ DestinationData subtree.

Populating Destination in the local environment tree
Use the Destination subtree to set up the target destinations that are used by output nodes, the HTTPRequest node, the SOAPRequest node, the SOAPAsyncRequest node, and the RouteToLabel node. The following examples show how you can create and use an ESQL procedure to perform the task of setting up values for each of these uses.

About this task

Copy and use these procedures as shown, or you can modify or extend them to perform similar tasks.

If you are creating this ESQL code for a Compute node, you must configure the node by setting the `Compute Mode` property so that it has access to the local environment tree in the output message. You must select one of the three values `LocalEnvironment`, `LocalEnvironment And Message`, or `All`.

Adding a queue name for the MQOutput node with the `Destination Mode` property set to `Destination List`

```
CREATE PROCEDURE addToMQDestinationList(IN LocalEnvironment REFERENCE, IN newQueue char) BEGIN
  /******************************************************************************
  * A procedure that adds a queue name to the MQ destination list in the local environment.
  * This list is used by an MQOutput node that has its mode set to Destination list.
  *
  * IN LocalEnvironment: the LocalEnvironment to be modified.
  * IN queue: the queue to be added to the list
  *
  ******************************************************************************/
DECLARE I INTEGER CARDINALITY(LocalEnvironment.Destination.MQ.DestinationData[]);
  IF I = 0 THEN
   SET OutputLocalEnvironment.Destination.MQ.DestinationData[1].queueName = newQueue;
  ELSE
   SET OutputLocalEnvironment.Destination.MQ.DestinationData[I+1].queueName = newQueue;
  END IF;
 END;
```

For full details of these elements, see Data types for elements in the MQ DestinationData subtree.

Changing the default URL for a SOAPRequest node or a SOAPAsyncRequest node request

```
CREATE PROCEDURE overrideDefaultSOAPRequestURL(IN LocalEnvironment REFERENCE, IN newUrl char) BEGIN
  /**************************************************************************
  * A procedure that changes the URL to which the SOAPRequest node or
  * SOAPAsyncRequest node sends the request.
  *
  * IN LocalEnvironment: the LocalEnvironment to be modified.
  * IN queue:  the URL to which to send the request.
  *
  **************************************************************************/
SET OutputLocalEnvironment.Destination.SOAP.Request.Transport.HTTP.WebServiceURL = newUrl;
END;
```

Changing the default URL for an HTTPRequest node request

```
CREATE PROCEDURE overrideDefaultHTTPRequestURL(IN LocalEnvironment REFERENCE, IN newUrl char) BEGIN
  /**************************************************************************
  * A procedure that changes the URL to which the HTTPRequest node sends the request.
  *
  * IN LocalEnvironment: the LocalEnvironment to be modified.
  * IN queue: the URL to which to send the request.
  *
  **************************************************************************/
  SET OutputLocalEnvironment.Destination.HTTP.RequestURL = newUrl;
END;
```

Adding a label for the RouteToLabel node

```
CREATE PROCEDURE addToRouteToLabelList(IN LocalEnvironment REFERENCE, IN newLabel char) BEGIN
  /**************************************************************************
  * A procedure that adds a label name to the RouteToLabel list in the local environment.
  * This list is used by a RoteToLabel node.
  *
  * IN LocalEnvironment: the LocalEnvironment to be modified.
  * IN label:  the label to be added to the list
  *
  **************************************************************************/
 IF LocalEnvironment.Destination.RouterList.DestinationData is null THEN
     SET OutputLocalEnvironment.Destination.RouterList.DestinationData."label" = newLabel;
  ELSE
     CREATE LASTCHILD OF LocalEnvironment.Destination.RouterList.DestinationData
     NAME 'label' VALUE newLabel;
  END IF;
END;
```

Setting up JMS destination lists

You can configure a JMSOutput node to send to multiple JMS Queues, or to publish to multiple JMS Topics by using a destination list that is created in the local environment tree by a transformation node. The following example shows how to set up JMS destination lists in the local environment tree:

```
CREATE PROCEDURE CreateJMSDestinationList() BEGIN
  SET OutputLocalEnvironment.Destination.JMSDestinationList.DestinationData[1]  = 'jndi://
TestDestQueue1';
  SET OutputLocalEnvironment.Destination.JMSDestinationList.DestinationData[2]  = 'jndi://
TestDestQueue2';
  SET OutputLocalEnvironment.Destination.JMSDestinationList.DestinationData[3]  = 'jndi://
TestDestQueue3';
END;
```

Accessing the environment tree

The environment tree has its own correlation name, Environment, and you must use this name in all ESQL statements that refer to, or set, the content of this tree.

About this task

The environment tree is always created when the logical tree is created for an input message. However, the message flow neither populates it, nor uses its contents. You can use this tree for your own purposes, for example, to pass information from one node to another. You can use the whole tree as a scratchpad or working area.

The advantage of creating your own data in environment is that this data is propagated as part of the logical tree to subsequent nodes in the message flow. If you create a new output message in a Compute node, the environment tree is also copied from the input message to the new output message. (In contrast to the local environment tree, which is only included in the output message if you explicitly request that it is).

Only one environment tree is present for the duration of the message flow. Any data updates, or additions, that you make in one node are retained, and all of the nodes in the message flow have access to the latest copy of this tree. Even if the message flows back through the message flow (for example, if an exception is thrown, or if the message is processed through the second terminal of the FlowOrder node), the latest state is retained. (In contrast to the local environment tree, which reverts to its previous state if the message flows back through the message flow.)

You can use this tree for any purpose you choose. For example, you can use the following ESQL statements to create fields in the tree:

```
SET Environment.Variables =
      ROW('granary' AS bread, 'reisling' AS wine, 'stilton' AS cheese);
SET Environment.Variables.Colors[] =
      LIST{'yellow', 'green', 'blue', 'red', 'black'};
SET Environment.Variables.Country[] = LIST{ROW('UK' AS name, 'pound' AS currency),
     ROW('USA' AS name, 'dollar' AS currency)};
```

This information is now available to all nodes to which a message is propagated, regardless of their relative position in the message flow.

Accessing the ExceptionList tree using ESQL
The ExceptionList tree has its own correlation name, ExceptionList, and you must use this in all ESQL statements that refer to or set the content of this tree.

About this task

This tree is created with the logical tree when an input message is parsed. It is initially empty, and is only populated if an exception occurs during message flow processing. It is possible that more than one exception can occur; if more than one exception occurs, the ExceptionList tree contains a subtree for each exception.

You can access the ExceptionList tree in Compute, Database, and Filter nodes, and you can update it in a Compute node. You must use the appropriate correlation name; ExceptionList for a Database or Filter node, and InputExceptionList for a Compute node.

You might want to access this tree in a node in an error handling procedure. For example, you might want to route the message to a different path based on the type of exception, for example one that you have explicitly generated using an ESQL THROW statement, or one that the integration node has generated.

The following ESQL shows how you can access the ExceptionList and process each child that it contains:

```
-- Declare a reference for the ExceptionList
-- (in a Compute node use InputExceptionList)
DECLARE start REFERENCE TO ExceptionList.*[1];

-- Loop through the exception list children
WHILE start.Number IS NOT NULL DO
   -- more ESQL

   -- Move start to the last child of the field to which it currently points
   MOVE start LASTCHILD;
END WHILE;
```

The following example shows an extract of ESQL that has been coded for a Compute node to loop through the exception list to the last (nested) exception description and extract the error number. This error relates to the original cause of the problem and normally provides the most precise information. Subsequent action taken by the message flow can be decided by the error number retrieved in this way.

```
CREATE PROCEDURE getLastExceptionDetail(IN InputTree reference,OUT messageNumber integer,
OUT messageText char)
    /*****************************************************************************
  * A procedure that will get the details of the last exception from a message
  * IN InputTree:  The incoming exception list
  * IN messageNumber:  The last message numberr.
  * IN messageText: The last message text.
  *****************************************************************************/
   BEGIN
        -- Create a reference to the first child of the exception list
        declare ptrException reference to InputTree.*[1];
        -- keep looping while the moves to the child of exception list work
  WHILE lastmove(ptrException) DO
   -- store the current values for the error number and text
   IF ptrException.Number is not null THEN
          SET messageNumber = ptrException.Number;
          SET messageText = ptrException.Text;
     END IF;
     -- now move to the last child which should be the next exceptionlist
   move ptrException lastchild;
  END WHILE;
 END;
```

The following ESQL example shows how you can convert the exception list to character format:

```
DECLARE tmp ROW;
CREATE LASTCHILD OF tmp DOMAIN('XMLNSC') NAME 'XMLNSC';
SET tmp.XMLNSC.ExceptionList = InputExceptionList;
SET tmp.BLOB = ASBITSTREAM(tmp.XMLNSC.ExceptionList OPTIONS
FolderBitStream CCSID 1208);
DECLARE FULLEXCEPTION CHAR CAST(tmp.BLOB AS CHAR CCSID 1208);
LOG USER TRACE VALUES('FULLEXCEPTION got is ',FULLEXCEPTION);
```

For information on accessing the ExceptionList tree using Java, see “Accessing the ExceptionList tree using Java” on page 1780.

Transforming from one data type to another
Code ESQL functions and statements to transform messages and data types in many ways.

About this task

The following topics provide guidance:

- “Casting data from message fields” on page 1659
- “Converting code page and message encoding” on page 1660
- “Converting EBCDIC NL to ASCII CR LF” on page 1662
- “Changing message format” on page 1665

Casting data from message fields
You can use the CAST function to transform the data type of one value to match the data type of the other. For example, you can use the CAST function when you process generic XML messages. All fields in an XML message have character values, so if you want to perform arithmetic calculations or datetime comparisons, for example, you must convert the string value of the field into a value of the appropriate type using CAST.

About this task

When you compare an element with another element, variable or constant, ensure that the value with which you are comparing the element is consistent (for example, character with character). If the values are not consistent, the integration node generates a runtime error if it cannot provide an implicit casting to resolve the inconsistency. For details of what implicit casts are supported, see Implicit casts.

In the Example message, the field InvoiceDate contains the date of the invoice. If you want to refer to or manipulate this field, you must CAST it to the correct format first. For example, to refer to this field in a test:

```
IF CAST(Body.Invoice.InvoiceDate AS DATE) = CURRENT_DATE THEN
```

This converts the string value of the InvoiceDate field into a date value, and compares it to the current date.

Another example is casting from integer to character:

```
DECLARE I INTEGER 1;
DECLARE C CHARACTER;

-- The following statement generates an error
SET C = I;

-- The following statement is valid
SET C = CAST(I AS CHARACTER);
```

Converting code page and message encoding
You can use ESQL within a Compute node to convert data for code page and message encoding.

About this task

If your message flow is processing IBM MQ messages, you can use IBM MQ facilities (including get and put options and IBM MQ data conversion exits) to provide these conversions. If you are not processing IBM MQ messages, or you choose not to use IBM MQ facilities, you can use IBM App Connect Enterprise facilities by coding the appropriate ESQL in a Compute node in your message flow.

The contents of the MQMD, the MQRFH2, and the message body of a message in the MRM domain that has been modeled with a CWF physical format can be subject to code page and encoding conversion. The contents of a message body of a message in the XML, XMLNS, and JMS domains, and those messages in the MRM domain that have been modeled with an XML or TDS physical format, are treated as strings. Only code page conversion applies; no encoding conversion is required.

For messages in the MRM domain modeled with a CWF physical format, you can set the MQMD CCSID and Encoding fields of the output message, plus the CCSID and Encoding of any additional headers, to the required target value.

For messages in the MRM domain modeled with an XML or TDS physical format, you can set the MQMD CCSID field of the output message, plus the CCSID of any additional headers. XML and TDS data is handled as strings and is therefore subject to CCSID conversion only.

An example IBM MQ message has an MQMD header, an MQRFH2 header, and a message body. To convert this message to a mainframe CodedCharSetId and Encoding, code the following ESQL in the Compute node:

```
SET OutputRoot.MQMD.CodedCharSetId = 500;
SET OutputRoot.MQMD.Encoding = 785;
SET OutputRoot.MQRFH2.CodedCharSetId = 500;
SET OutputRoot.MQRFH2.Encoding = 785;
```

The following example illustrates what you must do to modify a CWF message so that it can be passed from IBM App Connect Enterprise to IMS on z/OS.

Procedure

1. You have defined the input message in XML and are using an MQRFH2 header. Remove the header before passing the message to IMS.
2. The message passed to IMS must have MQIIH header, and must be in the z/OS code page.

   This message is modeled in the MRM and has the name IMS1. Define the PIC X fields in this message as logical type string for conversions between EBCDIC and ASCII to take place. If the fields are binary logical type, no data conversion occurs; binary data is ignored when a CWF message is parsed by the MRM parser.

3. The message received from IMS is also defined in the MRM and has the name IMS2.

   Define the PIC X fields in this message as logical type string for conversions between EBCDIC and ASCII to take place. If the fields are binary logical type, no data conversion occurs; binary data is ignored when a CWF message is parsed by the MRM parser.
4. Convert the reply message to the Windows code page.

   The MQIIH header is retained on this message.
5. You have created a message flow that contains the following nodes:

   :

   a. The outbound flow, **MQInput1 --> Compute1 --> MQOutput1**.

   b. The inbound flow, **MQInput2 --> Compute2 --> MQOutput2**.
6. Code ESQL in Compute1 (outbound) node as follows, specifying the relevant MessageSet ID.

   This code shows the use of the default CWF physical layer name. You must use the name that matches your model definitions. If you specify an incorrect value, the integration node fails with message BIP5431.

```
-- Loop to copy message headers
DECLARE I INTEGER 1;
DECLARE J INTEGER CARDINALITY(InputRoot.*[]);

WHILE I < J - 1 DO
  SET OutputRoot.*[I] = InputRoot.*[I];
  SET I=I+1;
END WHILE;

SET OutputRoot.MQMD.CodedCharSetId = 500;
SET OutputRoot.MQMD.Encoding = 785;
SET OutputRoot.MQMD.Format = 'MQIMS   ';
SET OutputRoot.MQIIH.Version = 1;
SET OutputRoot.MQIIH.StrucLength = 84;
SET OutputRoot.MQIIH.Encoding = 785;
SET OutputRoot.MQIIH.CodedCharSetId = 500;
SET OutputRoot.MQIIH.Format = 'MQIMSVS ';
SET OutputRoot.MQIIH.Flags = 0;
SET OutputRoot.MQIIH.LTermOverride = '        ';
SET OutputRoot.MQIIH.MFSMapName = '        ';
SET OutputRoot.MQIIH.ReplyToFormat = 'MQIMSVS ';
SET OutputRoot.MQIIH.Authenticator = '        ';
SET OutputRoot.MQIIH.TranInstanceId = X'00000000000000000000000000000000';
SET OutputRoot.MQIIH.TranState = ' ';
SET OutputRoot.MQIIH.CommitMode = '0';
SET OutputRoot.MQIIH.SecurityScope = 'C';
SET OutputRoot.MQIIH.Reserved = ' ';
SET OutputRoot.MRM.e_elen08 = 30;
SET OutputRoot.MRM.e_elen09 = 0;
SET OutputRoot.MRM.e_string08 = InputBody.e_string01;
SET OutputRoot.MRM.e_binary02 = X'31323334353637383940';
SET OutputRoot.Properties.MessageSet = 'DHCJOEG072001';
SET OutputRoot.Properties.MessageType = 'IMS1';
SET OutputRoot.Properties.MessageFormat = 'Binary1';
```

   The use of a variable, J, that is initialized to the value of the cardinality of the existing headers in the message, is more efficient than calculating the cardinality on each iteration of the loop, which happens if you code the following WHILE statement:

```
WHILE I < CARDINALITY(InputRoot.*[]) DO
```

7. Create ESQL in Compute2 (inbound) node as follows, specifying the relevant MessageSet ID.

   This code shows the use of the default CWF physical layer name. You must use the name that matches your model definition. If you specify an incorrect value, the integration node fails with message BIP5431.

```
-- Loop to copy message headers
DECLARE I INTEGER 1;
DECLARE J INTEGER CARDINALITY(InputRoot.*[]);

WHILE I < J DO
  SET OutputRoot.*[I] = InputRoot.*[I];
  SET I=I+1;
END WHILE;

SET OutputRoot.MQMD.CodedCharSetId = 437;
SET OutputRoot.MQMD.Encoding = 546;
SET OutputRoot.MQMD.Format = 'MQIMS   ';
SET OutputRoot.MQIIH.CodedCharSetId = 437;
SET OutputRoot.MQIIH.Encoding = 546;
SET OutputRoot.MQIIH.Format = '        ';
SET OutputRoot.MRM = InputBody;
SET OutputRoot.Properties.MessageSet = 'DHCJOEG072001';
SET OutputRoot.Properties.MessageType = 'IMS2';
SET OutputRoot.Properties.MessageFormat = 'Binary1';
```

Results

You do not have to set any specific values for the MQInput1 node properties, because the message and message set are identified in the MQRFH2 header, and no conversion is required.

You must set values for message domain, set, type, and format in the MQInput node for the inbound message flow (MQInput2). You do not need to set conversion parameters.

One specific situation in which you might need to convert data in one code page to another is when messages contain newline characters and are passed between EBCDIC and ASCII systems. The required conversion for this situation is described in “Converting EBCDIC NL to ASCII CR LF” on page 1662.

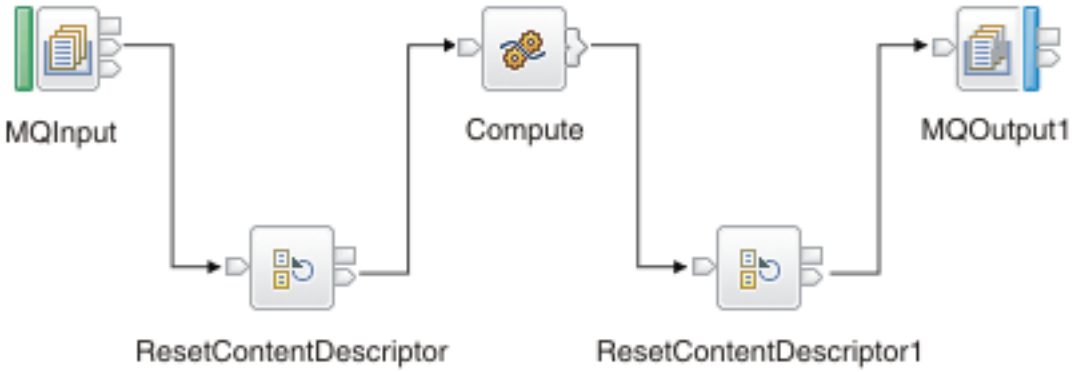
Converting EBCDIC NL to ASCII CR LF

You might want to change newline (NL) characters in a text message to carriage return (CR) and line feed (LF) character pairs. This example shows one way in which you can convert these characters.

About this task

This conversion might be useful if messages from an EBCDIC platform (for example, using CCSID 1047) are sent to an ASCII platform (for example, using CCSID 437). Problems can arise because the EBCDIC NL character hex '15' is converted to the undefined ASCII character hex '7F'. The ASCII code page has no corresponding code point for the NL character.

In this example, a message flow is created that interprets the input message as a message in the BLOB domain. This message is passed into a ResetContentDescriptor node to reset the data to a message in the MRM domain. The message is called msg_nl (a set of repeating string elements delimited by EBCDIC NL characters). A Compute node is then used to create an output based on another message in the MRM domain called msg_crlf (a set of repeating string elements delimited by CR LF pairs). The message domain is then changed back to BLOB in another ResetContentDescriptor node. This message flow is shown in the following diagram.



The following instructions show how to create the messages and configure the message flow.

Procedure

1. Create the message models for the messages in the MRM domain:
   a. Create a message set project called myProj.
   b. Create a message set called myMessageSet with a TDS physical format (the default name is Text1).
   c. Create an element string1 of type xsd:string.
   d. Create a complex type called t_msg_nl and specify the following complex type properties:
      - `Composition` = Ordered Set
      - `Content Validation` = Closed
      - `Data Element Separation` = All Elements Delimited
      - `Delimiter` = <U+0085> (hex '0085' is the UTF-16 representation of an NL character)
      - `Repeat` = Yes
      - `Min Occurs` = 1
      - `Max Occurs` = 50 (the text of the message is assumed to consist of no more than 50 lines)
   e. Add Element string1, and set the following property:
      - `Repeating Element Delimiter` = <U+0085>
   f. Create a Message msg_nl, and set its associated complex type to t_msg_nl
   g. Create a complex type called t_msg_crlf, and specify the following complex type properties:
      - `Composition` = Ordered Set
      - `Content Validation` = Closed
      - `Data Element Separation` = All Elements Delimited
      - `Delimiter` = <CR><LF> (<CR> and <LF> are the mnemonics for the CR and LF characters)
      - `Repeat` = Yes
      - `Min Occurs` = 1
      - `Max Occurs` = 50
   h. Add Element string1, and set the following property:
      - `Repeating Element Delimiter` = <CR><LF>
   i. Create a Message msg_crlf, and set complex type to t_msg_crlf.

2. Configure the message flow shown in the previous figure:
   a. Start with the MQInput node:
      - Set `Message Domain` = BLOB
      - Set `Queue Name` = <Your input message queue name>
   b. Add the ResetContentDescriptor node, connected to the Out terminal of the MQInput node:
      - Set `Message Domain` = MRM
      - Select `Reset Message Domain`
      - Set `Message Set` = <Your Message Set ID> (this field has a maximum of 13 characters)
      - Select `Reset Message Set`
      - Set `Message Type` = msg_nl
      - Select `Reset Message Type`
      - Set `Message Format` = Text1
      - Select `Reset Message Format`
   c. Add the Compute node, connected to the Out terminal of the ResetContentDescriptor node:
      - Enter a name for the ESQL `Module` for this node, or accept the default (<message flow name>_Compute).
      - Right-click the Compute node, and select **Open ESQL**. Add the following ESQL code in the module:

```
-- Declare local working variables
DECLARE I INTEGER 1;
DECLARE J INTEGER CARDINALITY(InputRoot.*[]);

-- Loop to copy all message headers from input to output message
WHILE I < J DO
  SET OutputRoot.*[I] = InputRoot.*[I];
  SET I=I+1;
END WHILE;

-- Set new output message type which uses CRLF delimiter
SET OutputRoot.Properties.MessageType = 't_msg_crlf';

-- Loop to copy each instance of string1 child within message body
SET I = 1;
SET J = CARDINALITY("InputBody"."string1"[]);
WHILE I <= J DO
  SET "OutputRoot"."MRM"."string1"[I] = "InputBody"."string1"[I];
  SET I=I+1;
END WHILE;
```

      The use of a variable, J, initialized to the value of the cardinality of the existing headers in the message, is more efficient than calculating the cardinality on each iteration of the loop, which happens if you code the following WHILE statement:

```
WHILE I < CARDINALITY(InputRoot.*[]) DO
```

   d. Add the ResetContentDescriptor1 node, connected to the Out terminal of the Compute node:
      - Set `Message Domain` = BLOB
      - Select `Reset Message Domain`.
   e. Finally, add the MQOutput node, connected to the Out terminal of the ResetContentDescriptor1 node. Configure its properties to direct the output message to the required queue or queues.

Changing message format
Use the Compute node to copy part of an input message to an output message. The results of such a copy depend on the type of input and output parsers involved.

Before you begin

If you are copying between unlike parsers, some attributes of the original message might be lost. To ensure that you copy every attribute, copy the message to the same parser.

Like parsers

About this task

Where both the source and target messages have the same folder structure at root level, a *like-parser-copy* is performed. For example:

```
SET OutputRoot.MQMD = InputRoot.MQMD;
```

This statement copies all the children in the MQMD folder of the input message to the MQMD folder of the output message.

Another example of a tree structure that supports a like-parser-copy is:

```
SET OutputRoot.XMLNS.Data.Account = InputRoot.XMLNS.Customer.Bank.Data;
```

To transform an input message in the MRM domain to an output message also in the MRM domain, you can use either the Compute or the Mapping node. The Mapping node can interpret the action that is required because it knows the format of both messages. Content Assist in the ESQL module for the Compute node can also use the message definitions for those messages. If the messages are not in the same namespace, you must use the Compute node.

To use Content Assist with message references, you must set up a project reference from the project containing the ESQL to the project containing the message set. For information about setting up a project reference, see “Referencing resources in other libraries” on page 1976.

If both input and output messages are not in the MRM domain, you must use the Compute node and specify the structure of the messages yourself.

Unlike parsers

About this task

Where the source and target messages have different folder structures at root level, you cannot make an exact copy of the message source. Instead, the *unlike-parser-copy* views the source message as a set of nested folders terminated by a leaf name-value pair. For example, copying the following message from XML to MRM:

```
<Name3><Name31>Value31</Name31>Value32</Name3>
```

produces a name element Name3, and a name-value element called Name31 with the value Value31. The second XML pcdata (Value32) cannot be represented and is discarded.

The unlike-parser-copy scans the source tree, and copies folders, also known as name elements, and leaf name-value pairs. Everything else, including elements flagged as *special* by the source parser, is not copied.

An example of a tree structure that results in an unlike-parser-copy is:

```
SET OutputRoot.DFDL.Data.Account = InputRoot.XMLNSC.Data.Account;
```

If the algorithm used to make an unlike-parser-copy does not suit your tree structure, youmust further qualify the source field to restrict the amount of the tree that is copied.

Be careful when you copy information from input messages to output messages in different domains. You might code ESQL that creates a message structure or content that is not consistent with the rules of the parser that processes the output message. This action can result in an output message not being created, or being created with unexpected content. If you believe that the output message generated by a particular message flow does not contain the correct content, or have the expected form, check the ESQL that creates the output message, and look for potential mismatches of structure, field types, field names, and field values.

When copying trees between unlike parsers, it might be necessary to set the MessageSet, MessageType, and MessageFormat fields in the output Properties folder. Which fields need setting is dependent on the target parser. For example, if the target parser is MRM and the message set has been defined with a CWF format, the following commands are required to copy a message body created by the XMLNSC parser to a body owned by the MRM parser:

```
-- Copy message to the output, moving from XMLNSC to MRM domains
SET OutputRoot.MRM = InputRoot.XMLNSC.rootElement;

-- Set the CWF format for output by the MRM domain
SET OutputRoot.Properties.MessageType = '<MessageTypeName>';
SET OutputRoot.Properties.MessageSet = '<MessageSetName>';
SET OutputRoot.Properties.MessageFormat = 'CWF';
```

Interaction with databases using ESQL
Use ESQL statements and functions to read from, write to, and modify databases from your message flows.

About this task

ESQL has a number of statements and functions for accessing databases:

- The CALL statement invokes a stored procedure.
- The DELETE FROM statement removes rows from a database table.
- The INSERT statement adds a row to a database table.
- The PASSTHRU function can be used to make complex selections.
- The PASSTHRU statement can be used to invoke administrative operations (for example, creating a table).
- The SELECT function retrieves data from a table.
- The UPDATE statement changes one or more values stored in zero or more rows.

You can access databases from Compute, Database, DatabaseInput, and Filter nodes. The same ESQL functions and procedures are supported in all these nodes.

You can use the data in the databases to update or create messages, or use the data in the message to update or create data in the databases.

Select **Throw exception on database error** and **Treat warnings as errors**, and set **`Transaction`** to `Automatic` on each node that access a database, to provide maximum flexibility.

For information about configuring the integration node and the database to support access from message flows, see “Accessing databases from ESQL” on page 1135.

Referencing columns in a database

About this task

While the standard SQL SELECT syntax is supported for queries to an external database, there are a number of points to be borne in mind. You must prefix the name of the table with the keyword Database to indicate that the SELECT is to be targeted at the external database, rather than at a repeating structure in the message.

The basic form of database SELECT is:

```
SELECT ...
  FROM Database.TABLE1
  WHERE ...
```

If necessary, you can specify a schema name:

```
SELECT ...
  FROM Database.SCHEMA.TABLE1
  WHERE ...
```

where SCHEMA is the name of the schema in which the table TABLE1 is defined. Include the schema if the user ID under which you are running does not match the schema. For example, if your userID is USER1, the expression Database.TABLE1 is equivalent to Database.USER1.TABLE1. However, if the schema associated with the table in the database is db2admin, you must specify Database.db2admin.TABLE1. If you do not include the schema, and this does not match your current user ID, the integration node generates a runtime error when a message is processed by the message flow.

If, as in the two previous examples, a data source is not specified, TABLE1 must be a table in the default database specified by the node's `data source` property. To access data in a database other than the default specified on the node's `data source` property, you must specify the data source explicitly. For example:

```
SELECT ...
  FROM Database.DataSource.SCHEMA.TABLE1
  WHERE ...
```

Qualify references to column names with either the table name or the correlation name defined for the table by the FROM clause. So, where you could normally execute a query such as:

```
SELECT column1, column2 FROM table1
```

you must write one of the following two forms:

```
SELECT T.column1, T.column2 FROM Database.table1 AS T

SELECT table1.column1, table1.column2 FROM Database.table1
```

This is necessary in order to distinguish references to database columns from any references to fields in a message that might also appear in the SELECT:

```
SELECT T.column1, T.column2 FROM Database.table1
  AS T WHERE T.column3 = Body.Field2
```

You can use the AS clause to rename the columns returned. For example:

```
SELECT T.column1 AS price, T.column2 AS item
  FROM Database.table1 AS T WHERE...
```

The standard select all SQL option is supported in the SELECT clause. If you use this option, you must qualify the column names with either the table name or the correlation name defined for the table. For example:

```
SELECT T.* FROM Database.Table1 AS T
```

When you use ESQL procedure and function names within a database query, the positioning of these within the call affects how these names are processed. If it is determined that the procedure or function affects the results returned by the query, it is not processed as ESQL and is passed as part of the database call.

This applies when attempting to use a function or procedure name with the column identifiers within the SELECT statement.

For example, if you use a CAST statement on a column identifier specified in the Select clause, this is used during the database query to determine the data type of the data being returned for that column.

An ESQL CAST is not performed to that ESQL data type, and the data returned is affected by the database interaction's interpretation of that data type.

If you use a function or procedure on a column identifier specified in the WHERE clause, this is passed directly to the database manager for processing.

The examples in the subsequent topics illustrate how the results sets of external database queries are represented in IBM App Connect Enterprise. The results of database queries are assigned to fields in a message using a Compute node.

A column function is a function that takes the values of a single column in all the selected rows of a table or message and returns a single scalar result.

Selecting data from database columns
You can configure a Compute, Filter, or Database node to select data from database columns and include it in an output message.

About this task

The following example assumes that you have a database table called USERTABLE with two char(6) data type columns (or equivalent), called Column1 and Column2. The table contains two rows:

	Column1	**Column2**
Row 1	value1	value2
Row 2	value3	value4

Configure the Compute, Filter, or Database node to identify the database in which you have defined the table. For example, if you are using the default database (specified on the `data source` property of the node), right-click the node, select **Open ESQL**, and code the following ESQL statements in the module for this node:

```
SET OutputRoot = InputRoot;
DELETE FIELD OutputRoot.*[<];
SET OutputRoot.XML.Test.Result[] =
  (SELECT T.Column1, T.Column2 FROM Database.USERTABLE AS T);
```

This ESQL produces the following output message:

```
<Test>
   <Result>
      <Column1>value1</Column1>
      <Column2>value2</Column2>
   </Result>
   <Result>
      <Column1>value3</Column1>
      <Column2>value4</Column2>
   </Result>
</Test>
```

Figure 4. Output message

To trigger the SELECT, send a trigger message with an XML body that is of the following form:

```
<Test>
   <Result>
      <Column1></Column1>
      <Column2></Column2>
   </Result>
   <Result>
      <Column1></Column1>
      <Column2></Column2>
   </Result>
</Test>
```

The exact structure of the XML is not important, but the enclosing tag must be <Test> to match the reference in the ESQL. If the enclosing tag is not <Test>, the ESQL statements result in top-level enclosing tags being formed, which is not valid XML.

If you want to create an output message that includes all the columns of all the rows that meet a particular condition, use the SELECT statement with a WHERE clause:

```
-- Declare and initialize a variable to hold the
--      test vaue (in this case the surname Smith)
DECLARE CurrentCustomer STRING 'Smith';

-- Loop through table records to extract matching information
SET OutputRoot.XML.Invoice[] =
    (SELECT R FROM Database.USERTABLE AS R
               WHERE R.Customer.LastName = CurrentCustomer
    );
```

The message fields are created in the same order as the columns occur in the table.

If you are familiar with SQL in a database environment, you might expect to code SELECT *. This syntax is not accepted by the integration node, because you must start all references to columns with a correlation name to avoid ambiguities with declared variables. Also, if you code SELECT I.*, this syntax is accepted by the integration node, but the * is interpreted as the first child element, not all elements, as you might expect from other database SQL.

The assignment of the result set of a database into a parser-owned message tree requires the result set to exactly match the message definition. Because the generic XML parser is self-defining, the example creates a new subtree off the Invoice folder, and the parser can parse the new elements in the subtree. If the structure of the result set exactly matches the message definition, the result set can be assigned directly into the `OutputRoot` message body tree.

If the structure of the result set does not exactly match the MRM message definition, you must first assign the result set into a ROW data type, or an Environment tree that does not have a parser associated with it.

The required data can then be assigned to `OutputRoot` to build a message tree that conforms to the message definition.

Selecting data from a table in a case-sensitive database system

About this task

If the database system is case sensitive, you must use an alternative approach. This approach is also necessary if you want to change the name of the generated field to something different:

```
SET OutputRoot = InputRoot;
SET OutputRoot.XML.Test.Result[] =
  (SELECT T.Column1 AS Column1, T.Column2 AS Column2
  FROM Database.USERTABLE AS T);
```

This example produces the output message as shown in Figure 4 on page 1668. Ensure that references to the database columns (in this example, T.Column1 and T.Column2) are specified in the correct case to match the database definitions exactly. If you do not match the database definitions exactly (for example if you specify T.COLUMN1), the integration node generates a runtime error. `Column1` and `Column2` are used in the SELECT statement to match the columns that you have defined in the database, although you can use any values here; the values do not have to match.

Selecting bitstream data from a database

About this task

These samples show how to retrieve XML bitstream data from a database, and include it in an output message. See INSERT statement for examples that show how you can insert bitstream data into a database.

Example

In the following example, bitstream data is held in a database column with a BLOB data type. The database table used in the example (TABLE1) is the one created in the INSERT statement examples, and the table contains the following columns:

- MSGDATA
- MSGCCSID
- MSGENCODING

If the bit stream from the database does not need to be interrogated or manipulated by the message flow, the output message can be constructed in the BLOB domain without any alteration.

In the following example, the message data, along with the MQMD header, is held in a database column with a BLOB data type. To re-create the message tree, including the MQMD header, from the bit stream, you can use a CREATE statement with a PARSE clause and DOMAIN('MQMD'). The output message can then be modified by the message flow:

```
SET Environment.Variables.DBResult = THE( SELECT T.* FROM Database.TABLE1 AS T);
DECLARE resultRef REFERENCE TO Environment.Variables.DBResult;

IF LASTMOVE(resultRef) THEN

  DECLARE outMsg BLOB resultRef.MSGDATA ;
  DECLARE outCCSID INT resultRef.MSGCCSID;
  DECLARE outEncoding INT resultRef.MSGENCODING;
  DECLARE outMsgPriority INT resultRef.MSGPRIORITY;
  DECLARE outMsgSeqNum INT resultRef.MSGSEQNUMBER;

  SET OutputRoot.Properties.CodedCharSetId = outCCSID;
  SET OutputRoot.Properties.Encoding = outEncoding ;

  CREATE LASTCHILD OF OutputRoot DOMAIN('MQMD') PARSE(outMsg, outEncoding, outCCSID);

    SET OutputRoot.MQMD.Version = MQMD_VERSION_2;

  SET OutputRoot.MQMD.Priority = outMsgPriority;
  SET OutputRoot.MQMD.MsgSeqNumber = outMsgSeqNum;

  DECLARE HDRL INT ;
  SET HDRL = LENGTH(BITSTREAM(OutputRoot.MQMD));
  CREATE FIELD OutputRoot."BLOB"."BLOB";
  DECLARE MSGB BLOB;
  SET MSGB = SUBSTRING(outMsg FROM HDRL +1);
  SET OutputRoot."BLOB"."BLOB" = MSGB;

END IF;
```

If you want to interrogate or manipulate a bit stream extracted from a database, you must re-create the original message tree. To re-create the XML message tree from the bit stream, you can use a CREATE statement with a PARSE clause. The output message can then be modified by the message flow.

For example, you might create a database table by using the following statement:

```
INSERT INTO Database.TABLE1(MSGDATA, MSGENCODING, MSGCCSID)
   VALUES (msgBitStream, inEncoding, inCCSID);
```

The following code snippet shows how to re-create the message tree in the XMLNS domain by using the data read from the table:

```
CALL CopyMessageHeaders();
  SET Environment.Variables.DBResult = THE( SELECT T.* FROM Database.TABLE1 AS T);
  DECLARE resultRef REFERENCE TO Environment.Variables.DBResult;
  IF LASTMOVE(resultRef) THEN
    DECLARE outCCSID INT resultRef.MSGCCSID;
    DECLARE outEncoding INT resultRef.MSGENCODING;
    DECLARE outMsg BLOB resultRef.MSGDATA;
    SET OutputRoot.Properties.CodedCharSetId = outCCSID;
    SET OutputRoot.Properties.Encoding = outEncoding;
    CREATE LASTCHILD OF OutputRoot DOMAIN('XMLNS') PARSE(outMsg, outEncoding, outCCSID);
    -- Now modify the message tree fields
```

```
    SET OutputRoot.XMLNS.A.B = 4;
    SET OutputRoot.XMLNS.A.E = 5;
  END IF;
```

In the following example, the data is held in a database column with a character data type, such as CHAR or VARCHAR. A cast is used to convert the data extracted from the database into BLOB format. If the bitstream data from the database does not need to be interrogated or manipulated by the message flow, the output message can be constructed in the BLOB domain, without any alteration.

```
CALL CopyMessageHeaders();
  SET Environment.Variables.DBResult = THE( SELECT T.* FROM Database.TABLE1 AS T);
  DECLARE resultRef REFERENCE TO Environment.Variables.DBResult;
  IF LASTMOVE(resultRef) THEN
    DECLARE outCCSID INT resultRef.MSGCCSID;
    DECLARE outMsg BLOB CAST(resultRef.MSGDATA AS BLOB CCSID outCCSID);
    SET OutputRoot.Properties.CodedCharSetId = outCCSID;
    SET OutputRoot.Properties.Encoding = resultRef.MSGENCODING;
    SET OutputRoot.BLOB.BLOB = outMsg;
  END IF;
```

In the following example, the data is held in a database column with a character data type, such as CHAR or VARCHAR. A cast is used to convert the data extracted from the database into BLOB format. To manipulate or interrogate this data within the message flow, you must re-create the original message tree. In this example, a CREATE statement with a PARSE clause is used to re-create the XML message tree in the XMLNS domain.

```
CALL CopyMessageHeaders();
  SET Environment.Variables.DBResult = THE( SELECT T.* FROM Database.TABLE1 AS T);
  DECLARE resultRef REFERENCE TO Environment.Variables.DBResult;
  IF LASTMOVE(resultRef) THEN
    DECLARE outCCSID INT resultRef.MSGCCSID;
    DECLARE outEncoding INT resultRef.MSGENCODING;
    DECLARE outMsg BLOB CAST(resultRef.MSGDATA AS BLOB CCSID outCCSID);
    SET OutputRoot.Properties.CodedCharSetId = outCCSID;
    SET OutputRoot.Properties.Encoding = outEncoding;
    CREATE LASTCHILD OF OutputRoot DOMAIN('XMLNS') PARSE(outMsg, outEncoding, outCCSID);
    -- Now modify the message tree fields
    SET OutputRoot.XMLNS.A.B = 4;
    SET OutputRoot.XMLNS.A.E = 5;
  END IF;
```

Accessing multiple database tables
You can refer to multiple tables that you have created in the same database. Use the FROM clause on the SELECT statement to join the data from the two tables.

About this task

The following example assumes that you have two database tables called USERTABLE1 and USERTABLE2. Both tables have two char(6) data type columns (or equivalent).

USERTABLE1 contains two rows:

	Column1	**Column2**
Row 1	value1	value2
Row 2	value3	value4

USERTABLE2 contains two rows:

	Column3	**Column4**
Row 1	value5	value6
Row 2	value7	value8

All tables referenced by a single SELECT function must be in the same database. The database can be either the default (specified on the Data Source property of the node) or another database (specified on the FROM clause of the SELECT function).

Configure the Compute, Database, or Filter node that you are using to identify the database in which you have defined the tables. For example, if you are using the default database, right-click the node, select **Open ESQL**, and code the following ESQL statements in the module for this node:

```
SET OutputRoot.XML.Test.Result[] =
         (SELECT A.Column1 AS FirstColumn,
                 A.Column2 AS SecondColumn,
                 B.Column3 AS ThirdColumn,
                 B.Column4 AS FourthColumn
            FROM Database.USERTABLE1 AS A,
                 Database.USERTABLE2 AS B
           WHERE A.Column1 = 'value1' AND
                 B.Column4 = 'value8'
         );
```

This code results in the following output message content:

```
<Test>
  <Result>
    <FirstColumn>value1</FirstColumn>
    <SecondColumn>value2</SecondColumn>
    <ThirdColumn>value7</ThirdColumn>
    <FourthColumn>value8</FourthColumn>
  </Result>
</Test>
```

This example shows how to access data from two database tables. You can code more complex FROM clauses to access multiple database tables (although all the tables must be in the same database). You can also refer to one or more message trees, and can use SELECT to join tables with tables, messages with messages, or tables with messages. “Joining data from messages and database tables” on page 1691 provides an example of how to merge message data with data in a database table.

If you specify an ESQL function or procedure on the column identifier in the WHERE clause, it is processed as part of the database query and not as ESQL.

Consider the following example:

```
  SET OutputRoot.XML.Test.Result =
     THE(SELECT ITEM T.Column1 FROM Database.USERTABLE1 AS T
     WHERE UPPER(T.Column2) = 'VALUE2');
```

This code attempts to return the rows where the value of `Column2` converted to uppercase is `VALUE2`. However, only the database manager can determine the value of `T.Column2` for any given row, therefore it cannot be processed by ESQL before the database query is issued, because the WHERE clause determines the rows that are returned to the message flow.

Therefore, the UPPER is passed to the database manager to be included as part of its processing. However, if the database manager cannot process the token within the SELECT statement, an error is returned.

Changing database content
You can use Compute, Database, and Filter nodes to change the contents of a database by updating, inserting, or deleting data.

About this task

The following ESQL code includes statements that show all three operations. This code is appropriate for a Database and Filter node; if you create this code for a Compute node, use the correlation name InputRoot in place of Root.

```
IF Root.XMLNS.TestCase.Action = 'INSERT' THEN
   INSERT INTO Database.STOCK (STOCK_ID, STOCK_DESC, STOCK_QTY_HELD,
   BROKER_BUY_PRICE, BROKER_SELL_PRICE, STOCK_HIGH_PRICE, STOCK_HIGH_DATE,
   STOCK_HIGH_TIME) VALUES
   (CAST(Root.XMLNS.TestCase.stock_id AS INTEGER),
    Root.XMLNS.TestCase.stock_desc,
    CAST(Root.XMLNS.TestCase.stock_qty_held AS DECIMAL),
    CAST(Root.XMLNS.TestCase.broker_buy_price AS DECIMAL),
    CAST(Root.XMLNS.TestCase.broker_sell_price AS DECIMAL),
    Root.XMLNS.TestCase.stock_high_price,
    CURRENT_DATE,
    CURRENT_TIME);

ELSEIF Root.XMLNS.TestCase.Action = 'DELETE' THEN

        DELETE FROM Database.STOCK WHERE STOCK.STOCK_ID =
                    CAST(Root.XMLNS.TestCase.stock_id AS INTEGER);

   ELSEIF Root.XMLNS.TestCase.Action = 'UPDATE' THEN

           UPDATE Database.STOCK as A SET STOCK_DESC = Root.XMLNS.TestCase.stock_desc
                  WHERE  A.STOCK_ID = CAST(Root.XMLNS.TestCase.stock_id AS INTEGER);
END IF;
```

Checking returns to SELECT
If a SELECT function returns no data, or no further data, this result is handled as a normal situation and no error code is set in SQLCODE, regardless of the setting of the `Throw Exception On Database Error` and `Treat Warnings As Errors` properties on the current node.

About this task

To recognize that a SELECT function has returned no data, include ESQL that checks what has been returned. You can use various methods:

1. EXISTS

   This ESQL returns a Boolean value that indicates if a SELECT function returned one or more values (TRUE), or none (FALSE).

   ```
   IF EXISTS(SELECT T.MYCOL FROM Database.MYTABLE) THEN
   ...
   ```

2. CARDINALITY

   If you expect an array in response to a SELECT, you can use CARDINALITY to calculate how many entries have been received.

   ```
   SET OutputRoot.XMLNS.Testcase.Results[] = (
       SELECT T.MYCOL FROM Database.MYTABLE)
   ......
   IF CARDINALITY (OutputRoot.XMLNS.Testcase.Results[])> 0 THEN
   ........
   ```

3. IS NULL

   If you have used either THE or ITEM keywords in your SELECT function, a scalar value is returned. If no rows have been returned, the value set is NULL. However, it is possible that the value NULL is contained within the column, and you might want to distinguish between these two cases.

   Distinguish between cases by including COALESCE in the SELECT function, for example:

   ```
   SET OutputRoot.XMLNS.Testcase.Results VALUE = THE (
      SELECT ITEM COALESCE(T.MYCOL, 'WAS NULL')
      FROM Database.MYTABLE);
   ```

   If this example returns the character string WAS NULL, it indicates that the column contained NULL, and not that no rows were returned.

In previous releases, an SQLCODE of 100 was set in most cases if no data, or no further data, was returned. An exception was raised by the integration node if you chose to handle database errors in the message flow.

Committing database updates
When you create a message flow that interacts with databases, you can choose whether the updates that you make are committed when the current node has completed processing, or when the current invocation of the message flow has terminated.

About this task

The information in this topic does not apply to the DatabaseInput node. For more information about the DatabaseInput node, see "Event-based database integration" on page 1136.

You must use separate ODBC connections if you want to include nodes with `Automatic` transaction status and nodes with `Commit` transaction status in the same message flow, where the nodes operate on the same external database. Set up one connection for the nodes that are not to commit until the completion of the message flow, and a second connection for the nodes that are to commit immediately.

For each node, select the appropriate option for the `Transaction` property to specify when its database updates are to be committed:

- Choose `Automatic` (the default) if you want updates made in this node to be committed or rolled back as part of the whole message flow. The actions that you define in the ESQL module are performed on the message and it continues through the message flow. If the message flow completes successfully, the updates are committed. If the message flow fails, the message and the database updates are rolled back.
- Choose `Commit` if you want to commit the action of the node on the database, irrespective of the success or failure of the message flow as a whole. The database update is committed when the node processing is successfully completed, that is, after all ESQL has been processed, even if the message flow itself detects an error in a subsequent node that causes the message to be rolled back.

The value that you choose is implemented for the database tables that you have updated. You cannot select a different value for each table.

If you have set `Transaction` to `Commit`, the behavior of the message flow and the commitment of database updates can be affected by the use of the PROPAGATE statement in the node's ESQL.

If you choose to include a PROPAGATE statement that generates one or more output messages from the node, the processing of the PROPAGATE statement is not considered complete until the entire path that the output message takes has completed. This path might include several other nodes, including one or more output nodes. Only then does the node that issues the PROPAGATE statement receive control back and its ESQL terminate. At that point, a database commit is performed, if appropriate.

If one of the nodes on the propagated path detects an error and throws an exception, the processing of the node in which you have coded the PROPAGATE statement never completes. If the error processing results in a rollback, the message flow and the database update in this node are rolled back. This behavior is consistent with the stated operation of the `Commit` option, but might not be the behavior that you expect.

Invoking stored procedures
To invoke a procedure that is stored in a database, use the ESQL CALL statement. The stored procedure must be defined by a CREATE PROCEDURE statement that has a Language clause of DATABASE and an EXTERNAL NAME clause that identifies the name of the procedure in the database and, optionally, the database schema to which it belongs.

About this task

When you invoke a stored procedure with the CALL statement, the integration node ensures that the ESQL definition and the database definition match:

- The external name of the procedure must match a procedure in the database.

- The number of parameters must be the same.
- The type of each parameter must be the same.
- The direction of each parameter (IN, OUT, INOUT) must be the same.

The following restrictions apply to the use of stored procedures:

- Overloaded procedures are not supported. (An overloaded procedure is one that has the same name as another procedure in the same database schema with a different number of parameters, or parameters with different types.) If the integration node detects that a procedure is overloaded, it raises an exception.
- In an Oracle stored procedure declaration, you are not permitted to constrain CHAR and VARCHAR2 parameters with a length, and NUMBER parameters with a precision or scale, or both. Use %TYPE when you declare CHAR, VARCHAR, and NUMBER parameters to provide constraints on a formal parameter.
- Avoid changing the type or number of parameters of a procedure without also changing the name. If changes of this nature cannot be avoided, any integration servers with procedures with changed parameters called by the ESQL must be restarted.

Creating a stored procedure in ESQL

About this task

When you define an ESQL procedure that corresponds to a database stored procedure, you can specify either a qualified name (where the qualifier is a database schema) or an unqualified name.

To create a stored procedure:

Procedure

1. Code a statement similar to this example to create an unqualified procedure:

   ```
   CREATE PROCEDURE myProc1(IN p1 CHAR) LANGUAGE DATABASE EXTERNAL NAME "myProc";
   ```

   The EXTERNAL NAME that you specify must match the definition that you have created in the database, but you can specify any name you choose for the corresponding ESQL procedure.
2. Code a statement similar to this example to create a qualified procedure:

   ```
   CREATE PROCEDURE myProc2(IN p1 CHAR) LANGUAGE DATABASE EXTERNAL NAME "Schema1.myProc";
   ```
3. Code a statement similar to this example to create a qualified procedure in an Oracle package:

   ```
   CREATE PROCEDURE myProc3(IN p1 CHAR) LANGUAGE DATABASE EXTERNAL
                   NAME "mySchema.myPackage.myProc";
   ```

Results

For examples of stored procedure definitions in the database, see the CREATE PROCEDURE statement.

Calling a stored procedure

Procedure

1. Code a statement similar to this example to invoke an unqualified procedure:

   ```
   CALL myProc1('HelloWorld');
   ```

   Because it is not defined explicitly as belonging to any schema, the `myProc1` procedure must exist in the default schema (the name of which is the user name that is used to connect to the data source) or the command fails.

2. The following example calls the myProc procedure in schema Schema1.

```
CALL myProc2('HelloWorld');
```

3. Code a statement similar to this example to invoke an unqualified procedure with a dynamic schema:

```
DECLARE Schema2 char 'mySchema2';
CALL myProc1('HelloWorld') IN Database.{'Schema2'};
```

   This statement calls the myProc1 procedure in database Schema2, overriding the default "username" schema.

Calling a stored procedure that returns two result sets

About this task

To call a stored procedure that takes one input parameter and returns one output parameter and two result sets:

Procedure

1. Define the procedure with a CREATE PROCEDURE statement that specifies one input parameter, one output parameter, and two result sets:

```
CREATE PROCEDURE myProc1 (IN P1 INT, OUT P2 INT)
  LANGUAGE DATABASE
  DYNAMIC RESULT SETS 2
  EXTERNAL NAME "myschema.myproc1";
```

2. To invoke the myProc1 procedure by using a field reference, code:

```
/* using a field reference */
CALL myProc1(InVar1, OutVar2, Environment.ResultSet1[],
            OutputRoot.XMLNS.Test.ResultSet2[]);
```

3. To invoke the myProc1 procedure by using a reference variable, code:

```
/* using a reference variable*/
DECLARE cursor REFERENCE TO OutputRoot.XMLNS.Test;

CALL myProc1(InVar1, cursor.OutVar2, cursor.ResultSet1[],
                     cursor.ResultSet2[]);
```

Coding ESQL to handle errors

When you process messages in a message flow, errors can have a number of different causes and the message flow designer must decide how to handle those errors.

Introduction

When you process messages in message flows, errors can have the following causes:

- External causes; for example, the incoming message is syntactically invalid, a database used by the flow has been shut down, or the power supply to the machine on which the integration node is running fails.
- Internal causes; for example, an attempt to insert a row into a database table fails because of a constraint check, or a character string that is read from a database cannot be converted to a number because it contains alphabetic characters.

  Internal errors can be caused by programs storing invalid data in the database, or by a flaw in the logic of a flow.

The message flow designer must decide how to handle errors.

Using default error-handling

The simplest strategy for handling ESQL errors is to do nothing, and use the integration node's default behavior. The default behavior is to cut short the processing of the failing message, and to proceed to the next message. Input and output nodes provide options to control exactly what happens when processing is cut short.

If the input and output nodes are set to transactional mode, the integration node restores the state before the message is processed:

1. The input message that has apparently been taken from the input queue is put back.
2. Any output messages that the flow has apparently written to output queues are discarded.

If the input and output nodes are not set to transactional mode:

1. The input message that was taken from the input queue is not put back.
2. Any output messages that the flow has written to output queues remain on the output queues.

Each of these strategies has its advantages. The transactional model preserves the consistency of data, while the non-transactional model maximizes the continuity of message processing. In the transactional model, the failing input message is put back onto the input queue, and the integration node attempts to process it again. The most likely outcome of this scenario is that the message continues to fail until the retry limit is reached, at which point the message is placed on a dead letter queue. The reason for the failure to process the message is logged to the system event log (Windows) or syslog (UNIX). Therefore, the failing message holds up the processing of subsequent valid messages, and is left unprocessed by the integration node.

Most databases operate transactionally so that all changes that are made to database tables are committed if the processing of the message succeeds, or rolled back if it fails, therefore maintaining the integrity of data. An exception to this situation is if the integration node itself, or a database, fails (for example, the power to the computers on which they are running is interrupted). In these cases, changes might be committed in some databases, but not in others, or the database changes might be committed but the input and output messages are not committed. If these possibilities concern you, make the flow coordinated and configure the databases that are involved.

Using customized error handling

The following list contains some general tips for creating customized error handlers.

- If you require something better than default error handling, the first step is to use a handler; see DECLARE HANDLER statement. Create one handler per node to intercept all possible exceptions (or all those that you can predict).
- Having intercepted an error, the error handler can use whatever logic is appropriate to handle it. Alternatively, it can use a THROW statement or node to create an exception, which could be handled higher in the flow logic, or even reach the input node, causing the transaction to be rolled back; see “Throwing an exception” on page 1680.
- If a node generates an exception that is not caught by the handler, the flow is diverted to the Failure terminal, if one is connected, or handled by default error-handling if no Failure terminal is connected.

  Use Failure terminals to catch unhandled errors. Attach a simple logic flow to the Failure terminal. This logic flow could consist of a database or Compute node that writes a log record to a database (possibly including the message's bit stream), or writes a record to the event log. The flow could also contain an output node that writes the message to a special queue.

  The full exception tree is passed to any node that is connected to a Failure terminal; see “Exception list tree” on page 516.
- Your error handlers are responsible for logging each error in an appropriate place, such as the system event log.

For a detailed description of the options that you can use to process errors in a message flow, see “Handling errors in message flows” on page 1883. For examples of what you can do, see “Throwing an exception” on page 1680 and “Capturing database state” on page 1680.

Writing code to detect errors

The following sections assume that the integration node detects the error. It is possible, however, for the logic of the flow to detect an error. For example, when coding the flow logic, you could use the following elements:

- IF statements that are inserted specifically to detect situations that should not occur
- The ELSE clause of a case expression or statement to trap routes through the code that should not be possible

As an example of a flow logic-detected error, consider a field that has a range of possible integer values that indicate the type of message. It would not be good practice to leave to chance what would happen if a message were to arrive in which the field's value did not correspond to any known type of message. One way this situation could occur is if the system is upgraded to support extra types of message, but one part of the system is not upgraded.

Using your own logic to handle input messages that are not valid

Input messages that are syntactically invalid (and input messages that appear to be not valid because of erroneous message format information) are difficult to deal with, because the integration node cannot determine the contents of the message. Typically, the best way to deal with these messages is to configure the input node to fully parse and validate the message. However, this configuration applies only to predefined messages; that is, MRM or IDoc.

If the input node is configured in this way, the following results are guaranteed if the input message cannot be parsed successfully:

- The input message never emerges from the node's normal output terminal (it goes to the Failure terminal).
- The input message never enters the main part of the message flow.
- The input message never causes any database updates.
- No messages are written to any output queues.

To deal with a failing message, connect a simple logic flow to the Failure terminal. The only disadvantage to this strategy is that if the normal flow does not require access to all of the message's fields, the forcing of complete parsing of the message affects performance.

Using your own logic to handle database errors

Database errors fall into three categories:

- The database is not working (for example, it is off line).
- The database is working but refuses your request (for example, a lock contention occurs).
- The database is working but it cannot do what you request (for example, read from a non-existent table).

If you require something better than default error handling, the first step is to use a handler (see DECLARE HANDLER statement) to intercept the exception. The handler can determine the nature of the failure from the SQL state that is returned by the database.

A database is not working

If a database is not working at all, and is essential to the processing of messages, there is typically not much that you can do. The handler, having determined the cause, might complete one or more of the following actions:

- Use the RESIGNAL statement to re-throw the original error, therefore allowing the default error handler to take over
- Use a different database

- Write the message to a special output queue

  Be careful if you use an approach similar to this technique; the handler absorbs the exception, therefore all changes to other databases, or writes to queues, are committed.

A database refuses your request
The situation when a lock contention occurs is similar to the "Database not working" case because the database will have backed out *all* the database changes that you have made for the current message, not just the failing request. Therefore, unless you are sure that this was the only update, default error-handling is typically the best strategy, except possibly logging the error or passing the message to a special queue.

Impossible requests
An impossible request occurs when the database is working, but cannot complete the requested action. This type of error covers a wide variety of problems.

If, as discussed in the previous example, the database does not have a table of the name that the flow expects, default error-handling is typically the best strategy, except possibly logging the error or passing the message to a special queue.

Many other errors might be handled successfully, however. For example, an attempt to insert a row might fail because there is already such a row and the new row would be a duplicate. Or an attempt to update a row might fail because there is no such row (that is, the update action updated zero rows). In these cases, the handler can incorporate whatever logic you think appropriate. It might insert the missing row, or use the existing one (possibly making sure the values in it are suitable).

If you want an update of zero rows to be reported as an error, you must set the `Treat warnings as errors` property on the node to `true`, which is not the default setting.

Using your own logic to handle errors in output nodes

Errors that occur in MQOutput nodes report the nature of the error in the SQL state and give additional information in the *SQL native error* variable. Therefore, if something better than default error handling is required, the first step is to use a handler (see DECLARE HANDLER statement) to intercept the exception. Such a handler typically surrounds only a single PROPAGATE statement.

Using your own logic to handle other errors

Besides those errors covered above, a variety of other errors can occur. For example, an arithmetic calculation might overflow, a cast might fail because of the unsuitability of the data, or an access to a message field might fail because of a type constraint. The integration node offers two programming strategies for dealing with these types of error.

- The error causes an exception that is either handled or left to roll back the transaction.
- The failure is recorded as a special value that is tested for later.

In the absence of a type constraint, an attempt to access a non-existent message field results in the value null. Null values propagate through expressions, making the result null. Therefore, if an expression, however complex, does not return a null value, you know that all the values that it needed to calculate its result were not null.

Cast expressions can have a default clause. If there is a default clause, casts fail quietly; instead of throwing an exception, they simply return the default value. The default value could be an innocuous number (for example, zero for an integer), or a value that is clearly invalid in the context (for example, -1 for a customer number). Null might be particularly suitable because it is a value that is different from all others, and it will propagate through expressions without any possibility of the error condition being masked.

Handling errors in other nodes

Exceptions that occur in other nodes (that is, downstream of a PROPAGATE statement) might be caught by handlers in the normal way. Handling such errors intelligently, however, poses a problem: another

node was involved in the original error, therefore another node, and not necessarily the originator of the exception, is likely to be involved in handling the error.

To help in these situations, the Database and Compute nodes have four terminals called Out1, Out2, Out3, and Out4. In addition, the syntax of the PROPAGATE statement includes target expression, message source, and control clauses to give more control over these terminals.

Throwing an exception
If you detect an error or other situation in your message flow in which you want message processing to be ended, you can throw an exception in a message flow in two ways.

About this task

- Use the ESQL THROW EXCEPTION statement.

  Include the THROW statement anywhere in the ESQL module for a Compute, Database, or Filter node. Use the options on the statement to code your own data to be inserted into the exception.
- Include a THROW node in your message flow.

  Set the node properties to identify the source and content of the exception.

By using either statement options or node properties, you can specify a message identifier and values that are inserted into the message text to give additional information and identification to users who interpret the exception. You can specify any message in any catalog that is available to the integration server.

The situations in which you might want to throw an exception are determined by the behavior of the message flow; decide when you design the message flow where this action might be appropriate. For example, you might want to examine the content of the input message to ensure that it meets criteria that cannot be detected by the input node (which might check that a particular message format is received).

The following example uses the Example message to show how you can use the ESQL THROW statement. To check that the invoice number is within a particular range, throw an exception for any invoice message received that does not fall in the valid range.

```
--Check for invoice number lower than permitted range
IF Body.Invoice.InvoiceNo < 100000 THEN
   THROW USER EXCEPTION CATALOG 'MyCatalog' MESSAGE 1234 VALUES
   ('Invoice number too low', Body.Invoice.InvoiceNo);

-- Check for invoice number higher than permitted range
ELSEIF Body.Invoice.InvoiceNo > 500000 THEN
      THROW USER EXCEPTION CATALOG 'MyCatalog' MESSAGE 1235 VALUES
   ('Invoice number too high', Body.Invoice.InvoiceNo);

ELSE DO
  -- invoice number is within permitted range
  -- complete normal processing
ENDIF;
```

Capturing database state
If an error occurs when the integration node accesses an external database, you can either let the integration node throw an exception during message flow node processing or use ESQL statements to process the exception within the message flow node itself.

About this task

Letting the integration node throw an exception during message flow node processing is the default action; ESQL processing in the current message flow node is abandoned. The exception is then propagated backwards through the message flow until an enclosing catch node, or the input node for this message flow, is reached. If the exception reaches the input node, an active transaction is rolled back.

Using ESQL statements to process the exception within the message flow node itself requires an understanding of database return codes and a logical course of action to take when an error occurs. To enable this inline database error processing, you must clear the Filter, Database, or Compute node's `Throw Exception On Database Error` property. If you clear this property, the message flow node

sets the database state indicators SQLCODE, SQLSTATE, SQLNATIVEERROR, and SQLERRORTEXT, with appropriate information from the database manager instead of throwing an exception.

The indicators contain information only when an error (not a warning) occurs, unless you have selected the `Treat Warnings As Errors` property. If a database operation is successful, or returns success with information, the indicators contain their default success values.

You can use the values contained in these indicators in ESQL statements to make decisions about the action to take. You can access these indicators with the SQLCODE, SQLSTATE, SQLNATIVEERROR, and SQLERRORTEXT functions.

If you are attempting inline error processing, check the state indicators after each database statement is executed to ensure that you catch and assess all errors. When processing the indicators, if you meet an error that you cannot handle inline, you can raise a new exception either to deal with it upstream in a catch node, or to let it through to the input node so that the transaction is rolled back, for which you can use the ESQL THROW statement.

You might want to check for the special case in which a SELECT returns no data. This situation is not considered an error and SQLCODE is not set, therefore you must test explicitly for it; see "Checking returns to SELECT" on page 1673.

Using ESQL to access database state indicators

The following ESQL example shows how to use the four database state functions, and how to include the error information that is returned in an exception:

```
DECLARE SQLState1 CHARACTER;
DECLARE SQLErrorText1 CHARACTER;
DECLARE SQLCode1 INTEGER;
DECLARE SQLNativeError1 INTEGER;

-- Make a database insert to a table that does not exist --
INSERT INTO Database.DB2ADMIN.NONEXISTENTTABLE (KEY,QMGR,QNAME)
                              VALUES (45,'REG356','my TESTING 2');

--Retrieve the database return codes --
SET SQLState1 = SQLSTATE;
SET SQLCode1 = SQLCODE;
SET SQLErrorText1 = SQLERRORTEXT;
SET SQLNativeError1 = SQLNATIVEERROR;

--Use the THROW statement to back out the database and issue a user exception--
THROW USER EXCEPTION MESSAGE 2950 VALUES
( 'The SQL State' , SQLState1 , SQLCode1 , SQLNativeError1 ,
SQLErrorText1 );
```

You do not have to throw an exception when you detect a database error; you might prefer to save the error information returned in the local environment tree, and include a Filter node in your message flow that routes the message to error or success subflows according to the values saved.

Using the SELECT function
The SELECT function is a convenient and powerful tool for accessing fields and transforming data in a message tree.

About this task

The following topics show by example how to use the SELECT function to transform a variety of messages. The examples are based on an XML input message that has been parsed in the XMLNS domain. However, the techniques shown in these topics can be applied to any message tree.

- "Transforming a simple message" on page 1682
- "Transforming a complex message" on page 1684
- "Returning a scalar value in a message" on page 1686
- "Joining data in a message" on page 1688
- "Translating data in a message" on page 1689

- "Joining data from messages and database tables" on page 1691

Transforming a simple message
When you code the ESQL for a Compute node, use the SELECT function to transform simple messages.

About this task

This topic provides examples of simple message transformation. Review the examples and modify them for your own use. They are all based on the Example message as input.

Example

Consider the following ESQL:

```
 SET OutputRoot.XMLNS.Data.Output[] =
    (SELECT R.Quantity, R.Author FROM InputRoot.XMLNS.Invoice.Purchases.Item[] AS R
    );
```

When this ESQL code processes the Invoice message, it produces the following output message:

```
<Data>
  <Output>
     <Quantity>2</Quantity>
     <Author>Neil Bradley</Author>
  </Output>
  <Output>
     <Quantity>1</Quantity>
     <Author>Don Chamberlin</Author>
  </Output>
  <Output>
     <Quantity>1</Quantity>
     <Author>Philip Heller, Simon Roberts</Author>
  </Output>
</Data>
```

Three Output fields are present, one for each Item field, because SELECT creates an item in its result list for each item described by its FROM list. Within each Output field, a Field is created for each field named in the SELECT clause. These fields are in the order in which they are specified within the SELECT clause, not in the order in which they appear in the incoming message.

The R that is introduced by the final AS keyword is known as a correlation name. It is a local variable that represents in turn each of the fields addressed by the FROM clause. The name chosen has no significance. In summary, this simple transform does two things:

1. It discards unwanted fields.
2. It guarantees the order of the fields.

You can perform the same transform with a procedural algorithm:

```
DECLARE i INTEGER 1;
DECLARE count INTEGER CARDINALITY(InputRoot.XMLNS.Invoice.Purchases.Item[]);

WHILE (i <= count)
   SET OutputRoot.XMLNS.Data.Output[i].Quantity = InputRoot.XMLNS.Invoice.Purchases.Item[i].Quantity;
   SET OutputRoot.XMLNS.Data.Output[i].Author   = InputRoot.XMLNS.Invoice.Purchases.Item[i].Author;
   SET i = i+1;
END WHILE;
```

These examples show that the SELECT version of the transform is much more concise. It also executes faster.

The following example shows a more advanced transformation:

```
SET OutputRoot.XMLNS.Data.Output[] =
    (SELECT R.Quantity AS Book.Quantity,
            R.Author   AS Book.Author
            FROM InputRoot.XMLNS.Invoice.Purchases.Item[] AS R
    );
```

In this transform, an AS clause is associated with each item in the SELECT clause. This clause gives each field in the result an explicit name rather than a field name that is inherited from the input. These names can be paths (that is, a dot-separated list of names), as shown in the example. The structure of the output message structure can be different from the input message. Using the same Invoice message, the result is:

```
<Data>
  <Output>
    <Book>
      <Quantity>2</Quantity>
      <Author>Neil Bradley</Author>
    </Book>
  </Output>
  <Output>
    <Book>
      <Quantity>1</Quantity>
      <Author>Don Chamberlin</Author>
    </Book>
  </Output>
  <Output>
    <Book>
      <Quantity>1</Quantity>
      <Author>Philip Heller, Simon Roberts</Author>
    </Book>
  </Output>
</Data>
```

The expressions in the SELECT clause can be of any complexity and there are no special restrictions. They can include operators, functions, and literals, and they can refer to variables or fields that are not related to the correlation name. The following example shows more complex expressions:

```
SET OutputRoot.XMLNS.Data.Output[] =
    (SELECT 'Start'                          AS Header,
            'Number of books:' || R.Quantity AS Book.Quantity,
            R.Author || ':Name and Surname'  AS Book.Author,
            'End'                            AS Trailer
            FROM InputRoot.XMLNS.Invoice.Purchases.Item[] AS R
    );
```

Using the same Invoice message, the result in this case is:

```
<Data>
 <Output>
  <Header>Start</Header>
  <Book>
   <Quantity>Number of books:2</Quantity>
   <Author>Neil Bradley:Name and Surname</Author>
  </Book>
  <Trailer>End</Trailer>
 </Output>
 <Output>
  <Header>Start</Header>
  <Book>
   <Quantity>Number of books:1</Quantity>
   <Author>Don Chamberlin:Name and Surname</Author>
  </Book>
  <Trailer>End</Trailer>
 </Output>
 <Output>
  <Header>Start</Header>
  <Book>
   <Quantity>Number of books:1</Quantity>
   <Author>Philip Heller, Simon Roberts:Name and Surname</Author>
  </Book>
  <Trailer>End</Trailer>
 </Output>
</Data>
```

As shown above, the AS clauses of the SELECT clause contain a path that describes the full name of the field that is to be created in the result. These paths can also specify (as is normal for paths) the type of field that is to be created. The following example transform specifies the field types. In this case, XML tagged data is transformed to XML attributes:

```
SET OutputRoot.XMLNS.Data.Output[] =
    (SELECT R.Quantity.* AS Book.(XML.Attribute)Quantity,
            R.Author.*   AS Book.(XML.Attribute)Author
            FROM InputRoot.XMLNS.Invoice.Purchases.Item[] AS R
    );
```

Using the same Invoice message, the result is:

```
<Data>
 <Output>
  <Book Quantity="2" Author="Neil Bradley"/>
 </Output>
 <Output>
  <Book Quantity="1" Author="Don Chamberlin"/>
 </Output>
 <Output>
  <Book Quantity="1" Author="Philip Heller, Simon Roberts"/>
 </Output>
</Data>
```

Finally, you can use a WHERE clause to eliminate some of the results. In the following example a WHERE clause is used to remove results in which a specific criterion is met. An entire result is either included or excluded:

```
SET OutputRoot.XMLNS.Data.Output[] =
    (SELECT R.Quantity AS Book.Quantity,
            R.Author   AS Book.Author
            FROM InputRoot.XMLNS.Invoice.Purchases.Item[] AS R
            WHERE R.Quantity = 2
    );
```

Using the same input message, the result is:

```
<Data>
 <Output>
  <Book>
   <Quantity>2</Quantity>
   <Author>Neil Bradley</Author>
  </Book>
 </Output>
</Data>
```

Transforming a complex message
When you code the ESQL for a Compute node, use the SELECT function for complex message transformation.

About this task

This topic provides examples of complex message transformation. Review the examples and modify them for your own use. They are all based on the Example message as input.

Example

In this example, Invoice contains a variable number of Items. The transform is shown in the following example:

```
SET OutputRoot.XMLNS.Data.Statement[] =
    (SELECT I.Customer.Title                                    AS Customer.Title,
            I.Customer.FirstName || ' ' || I.Customer.LastName  AS Customer.Name,
            COALESCE(I.Customer.PhoneHome,'')                   AS Customer.Phone,
            (SELECT II.Title                          AS Desc,
                    CAST(II.UnitPrice AS FLOAT) * 1.6 AS Cost,
                    II.Quantity                       AS Qty
             FROM I.Purchases.Item[] AS II
             WHERE  II.UnitPrice> 0.0             )     AS Purchases.Article[],
            (SELECT SUM( CAST(II.UnitPrice AS FLOAT) *
                    CAST(II.Quantity  AS FLOAT) *
                    1.6                          )
             FROM I.Purchases.Item[] AS II      )       AS Amount,
            'Dollars'                                   AS Amount.(XML.Attribute)Currency

            FROM InputRoot.XMLNS.Invoice[] AS I
            WHERE I.Customer.LastName <> 'Brown'
    );
```

The output message that is generated is:

```
<Data>
 <Statement>
  <Customer>
   <Title>Mr</Title>
   <Name>Andrew Smith</Name>
   <Phone>01962818000</Phone>
  </Customer>
  <Purchases>

   </Article>
   <Article>
    <Desc Category="Computer" Form="Hardcover" Edition="0">JAVA 2 Developers Handbook</Desc>
    <Cost>9.5984E+1</Cost>
    <Qty>1</Qty>
   </Article>
  </Purchases>
  <Amount Currency="Dollars">2.54144E+2</Amount>
 </Statement>
</Data>
```

This transform has nested SELECT clauses. The outer statement operates on the list of Invoices. The inner statement operates on the list of Items. The AS clause that is associated with the inner SELECT clause expects an array:

```
            (SELECT II.Title                          AS Desc,
                    CAST(II.UnitPrice AS FLOAT) * 1.6 AS Cost,
                    II.Quantity                       AS Qty
             FROM I.Purchases.Item[] AS II
             WHERE  II.UnitPrice> 0.0             )
            -- Note the use of [] in the next expression
               AS Purchases.Article[],
```

This statement tells the outer SELECT clause to expect a variable number of Items in each result. Each SELECT clause has its own correlation name: I for the outer SELECT clause and II for the inner one. Each SELECT clause typically uses its own correlation name, but the FROM clause in the inner SELECT clause refers to the correlation name of the outer SELECT clause:

```
            (SELECT II.Title                          AS Desc,
                    CAST(II.UnitPrice AS FLOAT) * 1.6 AS Cost,
                    II.Quantity                       AS Qty
            -- Note the use of I.Purchases.Item in the next expression
             FROM I.Purchases.Item[] AS II
             WHERE  II.UnitPrice> 0.0             ) AS Purchases.Article[],
```

This statement tells the inner SELECT clause to work with the current Invoice's Items. Both SELECT clauses contain WHERE clauses. The outer one uses one criterion to discard certain Customers, and the inner one uses a different criterion to discard certain Items. The example also shows the use of COALESCE to prevent missing input fields from causing the corresponding output field to be missing. Finally, it also uses the column function SUM to add together the value of all Items in each Invoice. Column functions are discussed in “Referencing columns in a database” on page 1666.

When the fields Desc are created, the whole of the input Title field is copied: the XML attributes and the field value. If you do not want these attributes in the output message, use the FIELDVALUE function to discard them; for example, code the following ESQL:

```
SET OutputRoot.XMLNS.Data.Statement[] =
    (SELECT I.Customer.Title                                AS Customer.Title,
            I.Customer.FirstName || ' ' || I.Customer.LastName AS Customer.Name,
            COALESCE(I.Customer.PhoneHome,'')               AS Customer.Phone,
            (SELECT FIELDVALUE(II.Title)                    AS Desc,
                    CAST(II.UnitPrice AS FLOAT) * 1.6 AS Cost,
                    II.Quantity                         AS Qty
             FROM I.Purchases.Item[] AS II
             WHERE  II.UnitPrice> 0.0              )      AS Purchases.Article[],
            (SELECT SUM( CAST(II.UnitPrice AS FLOAT) *
                    CAST(II.Quantity  AS FLOAT) *
                    1.6                           )
             FROM I.Purchases.Item[] AS II        ) AS Amount,
            'Dollars'                               AS Amount.(XML.Attribute)Currency

    FROM InputRoot.XMLNS.Invoice[] AS I
    WHERE I.Customer.LastName <> 'Brown'
    );
```

That code generates the following output message:

```
<Data>
 <Statement>
  <Customer>
   <Title>Mr</Title>
   <Name>Andrew Smith</Name>
   <Phone>01962818000</Phone>

  <Amount Currency="Dollars">2.54144E+2</Amount>
 </Statement>
</Data>
```

Returning a scalar value in a message
Use a SELECT statement to return a scalar value by including both the **THE** and **ITEM** keywords.

About this task

For example:

```
1 + THE(SELECT ITEM T.a FROM Body.Test.A[] AS T WHERE T.b = '123')
```

Use of the ITEM keyword

About this task

The following example shows the use of the ITEM keyword to select one item and create a single value.

```
SET OutputRoot.MQMD = InputRoot.MQMD;

SET OutputRoot.XMLNS.Test.Result[] =
   (SELECT ITEM T.UnitPrice FROM InputBody.Invoice.Purchases.Item[] AS T);
```

When the Invoice message is received as input, the ESQL shown generates the following output message:

```
<Test>
  <Result>27.95</Result>
  <Result>42.95</Result>
  <Result>59.99</Result>
</Test>
```

When the ITEM keyword is specified, the output message includes a list of scalar values. Compare this message to the one that is produced if the ITEM keyword is omitted, in which a list of fields (name-value pairs) is generated:

```
<Test>
  <Result>
    <UnitPrice>27.95</UnitPrice>
  </Result>
  <Result>
    <UnitPrice>42.95</UnitPrice>
  </Result>
  <Result>
    <UnitPrice>59.99</UnitPrice>
  </Result>
</Test>
```

Effects of the THE keyword

About this task

The THE keyword converts a list containing one item to the item itself.

The two previous examples both specified a list as the source of the SELECT in the FROM clause (the field reference has [] at the end to indicate an array), so typically the SELECT function generates a list of results. Because of this behavior, you must specify a list as the target of the assignment (thus the "Result[]" as the target of the assignment). However, you often know that the WHERE clause that you specify as part of the SELECT returns TRUE for only one item in the list. In this case use the THE keyword.

The following example shows the effect of using the THE keyword:

```
SET OutputRoot.MQMD = InputRoot.MQMD;

SET OutputRoot.XMLNS.Test.Result =
    THE (SELECT T.Publisher, T.Author FROM InputBody.Invoice.Purchases.Item[]
         AS T WHERE T.UnitPrice = 42.95);
```

The THE keyword means that the target of the assignment becomes `OutputRoot.XMLNS.Test.Result` (the "[]" is not permitted). Its use generates the following output message:

```
<Test>
  <Result>
    <Publisher>Morgan Kaufmann Publishers</Publisher>
    <Author>Don Chamberlin</Author>
  </Result>
</Test>
```

Selecting from a list of scalars

About this task

Consider the following sample input message:

```
<Test>
 <A>1</A>
 <A>2</A>
 <A>3</A>
 <A>4</A>
 <A>5</A>
</Test>
```

If you code the following ESQL statements to process this message:

```
SET OutputRoot.XMLNS.Test.A[] =
  (SELECT ITEM A from InputBody.Test.A[]
   WHERE CAST(A AS INTEGER) BETWEEN 2 AND 4);
```

the following output message is generated:

```
      <A>2</A>
      <A>3</A>
      <A>4</A>
```

Joining data in a message

The FROM clause of a SELECT function is not restricted to having one item. Specifying multiple items in the FROM clause produces the typical Cartesian product joining effect, in which the result includes an item for all combinations of items in the two lists.

About this task

Using the FROM clause in this way produces the same joining effect as standard SQL.

The Invoice message includes a set of customer details, payment details, and details of the purchases that the customer makes. Code the following ESQL to process the input Example message:

```
SET OutputRoot.XMLNS.Items.Item[] =
   (SELECT D.LastName, D.Billing,
           P.UnitPrice, P.Quantity
    FROM InputBody.Invoice.Customer[] AS D,
         InputBody.Invoice.Purchases.Item[] AS P);
```

The following output message is generated:

```
<Items>
 <Item>
  <LastName>Smith</LastName>
  <Billing>
   <Address>14 High Street</Address>
   <Address>Hursley Village</Address>
   <Address>Hampshire</Address>
   <PostCode>SO213JR</PostCode>
  </Billing>
  <UnitPrice>27.95</UnitPrice>
  <Quantity>2</Quantity>
 </Item>
 <Item>
  <LastName>Smith</LastName>
  <Billing>
   <Address>14 High Street</Address>
   <Address>Hursley Village</Address>
   <Address>Hampshire</Address>
   <PostCode>SO213JR</PostCode>
  </Billing>
  <UnitPrice>42.95</UnitPrice>
  <Quantity>1</Quantity>
 </Item>
 <Item>
  <LastName>Smith</LastName>
  <Billing>
   <Address>14 High Street</Address>
   <Address>Hursley Village</Address>
   <Address>Hampshire</Address>
   <PostCode>SO213JR</PostCode>
  </Billing>
  <UnitPrice>59.99</UnitPrice>
  <Quantity>1</Quantity>
 </Item>
</Items>
```

Three results are produced, giving the number of descriptions in the first list (one) multiplied by the number of prices in the second (three). The results systematically work through all the combinations of the two lists. You can see this by looking at the *LastName* and *UnitPrice* fields selected from each result:

```
LastName Smith   UnitPrice 27.95
LastName Smith   UnitPrice 42.95
LastName Smith   UnitPrice 59.99
```

You can join data that occurs in a list and a non-list, or in two non-lists, and so on. For example:

```
OutputRoot.XMLNS.Test.Result1[] =
  (SELECT ... FROM InputBody.Test.A[], InputBody.Test.b);
OutputRoot.XMLNS.Test.Result1 =
  (SELECT ... FROM InputBody.Test.A, InputBody.Test.b);
```

The location of the [] in each case is significant. Any number of items can be specified in the FROM clause, not just one or two. If any of the items specify [] to indicate a list of items, the SELECT function returns a list of results (the list might contain only one item, but the SELECT function can return a list of items).

The target of the assignment must specify a list (so must end in []), or you must use the THE function if you know that the WHERE clause guarantees that only one combination is matched.

Translating data in a message
You can translate data from one form to another.

About this task

A typical example of the requirement to translate data is if the items are known in one message by names, and in another message by numbers. For example:

```
Type Name          Type Code

Confectionary      2000
Newspapers         3000
Hardware           4000
```

Consider the following input message:

```
<Data>
  <Items>
    <Item>
      <Cat>1000</Cat>
      <Description>Milk Chocolate Bar</Description>
      <Type>Confectionary</Type>
    </Item>
    <Item>
      <Cat>1001</Cat>
      <Description>Daily Newspaper</Description>
      <Type>NewsPapers</Type>
    </Item>
    <Item>
      <Cat>1002</Cat>
      <Description>Kitchen Sink</Description>
      <Type>Hardware</Type>
    </Item>
  </Items>
  <TranslateTable>
    <Translate>
      <Name>Confectionary</Name>
      <Number>2000</Number>
    </Translate>
    <Translate>
      <Name>NewsPapers</Name>
      <Number>3000</Number>
    </Translate>
    <Translate>
      <Name>Hardware</Name>
      <Number>4000</Number>
    </Translate>
  </TranslateTable>
</Data>
```

This message has two sections; the first section is a list of items in which each item has a catalog number and a type; the second section is a table for translating between descriptive type names and numeric type codes. Include a Compute node with the following transform:

```
SET OutputRoot.XMLNS.Result.Items.Item[] =
   (SELECT M.Cat, M.Description, T.Number As Type
     FROM
       InputRoot.XMLNS.Data.Items.Item[]               As M,
       InputRoot.XMLNS.Data.TranslateTable.Translate[] As T
     WHERE M.Type = T.Name
   );
```

The following output message is generated:

```
<Result>
  <Items>
    <Item>
      <Cat>1000</Cat>
      <Description>Milk Chocolate Bar</Description>
      <Type>2000</Type>
    </Item>
    <Item>
      <Cat>1001</Cat>
      <Description>Daily Newspaper</Description>
      <Type>3000</Type>
    </Item>
    <Item>
      <Cat>1002</Cat>
      <Description>Kitchen Sink</Description>
      <Type>4000</Type>
    </Item>
  </Items>
</Result>
```

In the result, each type name has been converted to its corresponding code. In this example, both the data and the translate table were in the same message tree, although this is not a requirement. For example, the translate table could be coded in a database, or might have been set up in LocalEnvironment by a previous Compute node.

Joining data from messages and database tables
You can use SELECT functions that interact with both message data and databases.

About this task

You can also nest a SELECT function that interacts with one type of data within a SELECT clause that interacts with the other type.

Consider the following input message, which contains invoice information for two customers:

```
<Data>
  <Invoice>
    <CustomerNumber>1234</CustomerNumber>
    <Item>
      <PartNumber>1</PartNumber>
      <Quantity>9876</Quantity>
    </Item>
    <Item>
      <PartNumber>2</PartNumber>
      <Quantity>8765</Quantity>
    </Item>
</Invoice>
  <Invoice>
    <CustomerNumber>2345</CustomerNumber>
    <Item>
      <PartNumber>2</PartNumber>
      <Quantity>7654</Quantity>
    </Item>
    <Item>
      <PartNumber>1</PartNumber>
    <Quantity>6543</Quantity>
    </Item>
</Invoice>
</Data>
```

Consider the following database tables, Prices and Addresses, and their contents:

```
PARTNO      PRICE
----------- ----------------------
          1            +2.50000E+001
          2            +6.50000E+00

PARTNO      STREET                CITY             COUNTRY
------      ------------------    --------------   -------
1234        22 Railway Cuttings   East Cheam       England
2345        The Warren            Watership Down   England
```

If you code the following ESQL transform:

```
-- Create a valid output message
SET OutputRoot.MQMD = InputRoot.MQMD;

-- Select suitable invoices
SET OutputRoot.XMLNS.Data.Statement[] =
   (SELECT I.CustomerNumber                          AS Customer.Number,
           A.Street                                  AS Customer.Street,
           A.City                                    AS Customer.Town,
           A.Country                                 AS Customer.Country,

        -- Select suitable items
          (SELECT II.PartNumber AS PartNumber,
                  II.Quantity   AS Quantity,
                  PI.Price      AS Price
           FROM Database.db2admin.Prices AS PI,
               I.Item[]                  AS II
           WHERE II.PartNumber = PI.PartNo     )    AS Purchases.Item[]

    FROM Database.db2admin.Addresses  AS A,
         InputRoot.XMLNS.Data.Invoice[] AS I

    WHERE I.CustomerNumber = A.PartNo
    );
```

the following output message is generated. The input message is augmented with the price and address information from the database table:

```
<Data>
  <Statement>
    <Customer>
      <Number>1234</Number>
      <Street>22 Railway Cuttings</Street>
      <Town>East Cheam</Town>
      <Country>England</Country>
    </Customer>
    <Purchases>
      <Item>
        <PartNumber>1</PartNumber>
        <Quantity>9876</Quantity>
        <Price>2.5E+1</Price>
      </Item>
      <Item>
        <PartNumber>2</PartNumber>
        <Quantity>8765</Quantity>
        <Price>6.5E+1</Price>
      </Item>
    </Purchases>
  </Statement>
  <Statement>
    <Customer>
      <Number>2345</Number>
      <Street>The Warren</Street>
      <Town>Watership Down</Town>
      <Country>England</Country>
    </Customer>
    <Purchases>
      <Item>
        <PartNumber>1</PartNumber>
        <Quantity>6543</Quantity>
        <Price>2.5E+1</Price></Item>
      <Item>
        <PartNumber>2</PartNumber>
        <Quantity>7654</Quantity>
        <Price>6.5E+1</Price>
      </Item>
    </Purchases>
  </Statement>
</Data>
```

You can nest the database SELECT clause within the message SELECT clause. In most cases, the code is not as efficient as the previous example, but you might find that it is better if the messages are small and the database tables are large.

```
-- Create a valid output message
SET OutputRoot.MQMD = InputRoot.MQMD;

-- Select suitable invoices
SET OutputRoot.XMLNS.Data.Statement[] =
    (SELECT I.CustomerNumber                  AS Customer.Number,

        -- Look up the address
        THE ( SELECT
                  A.Street,
                  A.City    AS Town,
                  A.Country
              FROM Database.db2admin.Addresses AS A
              WHERE A.PartNo = I.CustomerNumber
            )                              AS Customer,

        -- Select suitable items
        (SELECT
            II.PartNumber AS PartNumber,
            II.Quantity   AS Quantity,

            -- Look up the price
            THE (SELECT ITEM P.Price
              FROM Database.db2admin.Prices AS P
              WHERE P.PartNo = II.PartNumber
            )             AS Price

          FROM I.Item[] AS II           ) AS Purchases.Item[]

    FROM InputRoot.XMLNS.Data.Invoice[] AS I
    );
```

Manipulating messages in the DFDL domain
How to use messages that have been modeled by using DFDL schema files, and that are parsed by the DFDL parser.

About this task

The topics in this section provide information about how to write ESQL for processing messages that belong to the DFDL domain, and that are parsed by the DFDL parser. For more information about the DFDL parser and domain, see “DFDL parser and domain” on page 544.

The structure of the message tree that the DFDL parser builds, and the field types that it uses, are defined by the logical model that is defined in your DFDL schema file. For more information about DFDL schema files, see “Working with DFDL schema files” on page 2220. The following topics show you how to deal with messages that have been modeled in the DFDL domain, and that are parsed by the DFDL parser. Use this information in conjunction with the information about manipulating message body content; see “Manipulating message body content” on page 1632.

- Accessing elements in a message
- Accessing multiple occurrences of an element
- Accessing elements within groups
- Accessing elements that have namespace support enabled
- Querying null values
- Setting null values
- Working with bit streams

Accessing elements in a message in the DFDL domain
You can use ESQL to manipulate the logical tree that represents a message in your message flow. This topic describes how to access data for elements that are in a message in the DFDL domain.

About this task

You can populate an element with data by using the SET statement:

```
SET OutputRoot.DFDL.MyMessage.Name = UPPER(InputRoot.DFDL.MyMessage.Name);
```

The field references in the ESQL statement both refer to the element *Name* within the message *MyMessage*, that is modeled in a DFDL schema file. This statement takes the input value for the Name field, converts it to uppercase, and assigns the result to the same element in the output message.

Accessing multiple occurrences of an element in a message in the DFDL domain
You can use specific ESQL code to set the value of one occurrence of an element that has multiple occurrences in a message. You can also use arrow notation to indicate the direction of search when searching for multiple occurrences of an element.

About this task

You can access DFDL domain elements by following the general guidance given in "Accessing known multiple occurrences of an element" on page 1636 and "Accessing unknown multiple occurrences of an element" on page 1637. Further information that is specific to messages in the DFDL domain is provided in this topic.

Consider the following statements:

```
SET OutputRoot.DFDL.MyMessage.Loaned[1].Currency = 'GBP';
SET OutputRoot.DFDL.MyMessage.Loaned[2].Currency = 'USD';
```

The above SET statements operate on two occurrences of the element Loaned. Each statement sets the value of the child Currency. The array index indicates which occurrence of the repeating element you are interested in.

When you define child elements of a complex type in a message set, you can add the same element to the complex type more than once. These instances do not have to be contiguous, but you must use the same method (array notation) to refer to them in ESQL.

For example, if you create a complex type with a `Composition` of `Sequence` that contains the following elements:

- `StringElement1`
- `IntegerElement1`
- `StringElement1`

use the following ESQL to set the value of `StringElement1`:

```
SET OutputRoot.DFDL.MyMessage.StringElement1[1] =
              'This is the first occurrence of StringElement1';
SET OutputRoot.DFDL.MyMessage.StringElement1[2] =
              'This is the second occurrence of StringElement1';
```

You can also use the arrow notation (the greater than (>) and less than (<) symbols) to indicate the direction of search and the index to be specified:

```
SET OutputRoot.DFDL.MyMessage.StringElement1[>] =
               'This is the first occurrence of StringElement1';
SET OutputRoot.DFDL.MyMessage.StringElement1[<2] =
               'This is the last but one occurrence of
 StringElement1';
SET OutputRoot.DFDL.MyMessage.StringElement1[<1] =
               'This is the last occurrence of StringElement1';
```

Refer to "Accessing known multiple occurrences of an element" on page 1636 and "Accessing unknown multiple occurrences of an element" on page 1637 for additional detail.

Accessing elements within groups in a message in the DFDL domain
When an input message is parsed, structures that you have defined as local groups (sequences or choices) in your DFDL schema file are not directly represented in the logical tree, but their child elements are.

About this task

Local groups do not have names in the model, and so do not cause elements to be created in the logical message tree. If you want to refer to the values of elements that are children of a local group, do not include the group in the ESQL path.

Accessing the content of a message in the DFDL domain with namespace support enabled
Use namespaces where appropriate for messages that are parsed by the DFDL parser.

About this task

It is possible to create a DFDL schema file that has a target namespace. All messages defined in that DFDL schema belong to that namespace. When the DFDL parser parses one of the messages, the namespace is included in the elements that are created in the logical message tree. You must include the namespace when you code the ESQL reference to the element. If you do not include the namespace, the integration node searches the `no target` namespace. If the element is not found in the `no target` namespace, the integration node searches all other known namespaces in the message model schema file. For performance and integrity reasons, specify namespaces wherever they apply.

The most efficient way to refer to elements when namespaces are enabled is to define a namespace constant, and use this constant in the appropriate ESQL statements. This technique makes your ESQL code much easier to read and maintain.

Define a constant using the DECLARE NAMESPACE statement:

```
DECLARE ns01 NAMESPACE 'http://www.ns01.com'

SET OutputRoot.DFDL.ns01:MyMessage.ns01:Element1 = InputBody.ns01:MyMessage.ns01:Element1;
```

`ns01` is interpreted correctly as a namespace because of the way that it is declared.

You can also use a CHARACTER variable to declare a namespace:

```
DECLARE ns02 CHARACTER 'http://www.ns02.com'

SET OutputRoot.DFDL.{ns02}:MyMessage.{ns02}:Element1 = InputBody.{ns02}:MyMessage.
{ns02}:Element1;
```

If you use this method, you must surround the declared variable with braces to ensure that it is interpreted as a namespace.

If you are concerned that a CHARACTER variable might get changed, you can use a CONSTANT CHARACTER declaration:

```
DECLARE ns03 CONSTANT CHARACTER 'http://www.ns03.com'

SET OutputRoot.DFDL.{ns03}:MyMessage.{ns03}:Element1 = InputBody.{ns03}:MyMessage.
{ns03}:Element1;
```

You can declare a namespace, constant, and variable within a module or function. However, you can declare only a namespace or constant in schema scope (that is, outside a module scope).

For more information about using namespaces with DFDL, see **Namespaces** in the DFDL v1.0 Specification.

Querying null values in a message in the DFDL domain
You can use an ESQL statement to compare an element to NULL.

About this task

If you want to compare an element to NULL, code the statement:

```
IF InputRoot.DFDL.MyMessage.Elem2.Child1 IS NULL THEN
   DO:
    -- more ESQL --
END IF;
```

If nulls are permitted for this element, this statement tests whether the element exists in the input message, or whether it exists and contains one of the 'nil' values defined for the element in the DFDL schema. The returned result of this test is determined as follows:

- If the element Child1 is not in the bit stream, this test returns TRUE.
- If the element Child1 is in the bit stream and contains one of the 'nil' values, this test returns TRUE.
- If the element Child1 is in the bit stream and does not contain one of the 'nil' values, this test returns FALSE.

If you want to determine if the field is missing, rather than present but with null value, you can use the ESQL CARDINALITY function.

Setting null values in a message in the DFDL domain
You can use implicit or explicit null processing to set the value of an element to NULL in an output message.

About this task

To set a value of an element in an output message, you normally code an ESQL statement, for example:

```
SET OutputRoot.DFDL.MyMessage.Elem2.Child1 = 'xyz';
```

or its equivalent statement:

```
SET OutputRoot.DFDL.MyMessage.Elem2.Child1 VALUE = 'xyz';
```

If you set the element to a non-null value, these two statements give identical results. However, if you want to set the value to null, these two statements do not give the same result:

Procedure

1. If you set the element to NULL using the following statement, the element is deleted from the message tree:

   ```
   SET OutputRoot.DFDL.MyMessage.Elem2.Child1 = NULL;
   ```

   This is called implicit null processing.
2. If you set the value of this element to NULL as follows:

   ```
   SET OutputRoot.DFDL.MyMessage.Elem2.Child1 VALUE = NULL;
   ```

   the element is not deleted from the message tree. Instead, a special value of NULL is assigned to the element.

   This is called explicit null processing.

Results

Setting a complex element to NULL deletes that element and all its children.

Working with DFDL messages and bit streams
Use the ASBITSTREAM function and the CREATE statement to manage DFDL-described message content.

About this task

Note: Note that FolderBitStream is not supported when manipulating messages in the DFDL domain.

The ASBITSTREAM function

If you code an ASBITSTREAM function to parse your message tree to a bit stream, and the `parser mode` option is set to RootBitStream , the result is a DFDL document that is built from the children of the target element in the normal way. This algorithm is identical to the algorithm that is used to generate the normal output bit stream. Because the target element is not included in the output bit stream, you must ensure that the children of the target element follow the constraints for a DFDL document.

One constraint is that there must be only one body element in the message. You can use a well-formed bit stream obtained in this way to re-create the original logical tree by using a CREATE statement that includes a PARSE clause.

For further information about the ASBITSTREAM function, and some examples of its use, see ASBITSTREAM function.

The CREATE statement with a PARSE clause

If you code a CREATE statement with a PARSE clause to parse your bit stream to a message tree, and the `parser mode` option is set to RootBitStream, the expected bit stream is a normal DFDL-described message. An element is created in the logical tree for each element that is identified in the bit stream. This algorithm is identical to the algorithm that is used when parsing a bit stream from an input node.

For further information about the CREATE statement, and examples of its use, see CREATE statement.

Manipulating messages in the XML domains
You can manipulate messages in the XML, XMLNS, and XMLNSC domains.

About this task

The following topics contain instructions about manipulating messages in the XMLNSC, XMLNS, and XML domains.

- “Working with XML messages” on page 1697
- “Manipulating messages in the XMLNSC domain” on page 1706
- “Manipulating messages in the XMLNS domain” on page 1719
- “Manipulating messages in the XML domain” on page 1727

For information about dealing with MRM XML messages, see “Manipulating messages in the MRM domain” on page 1727.

Working with XML messages
The following topics provide information about typical tasks for processing XML messages.

About this task

Some of this information is available publicly in Web pages and online tutorials. If you are new to XML, you will find it useful to also read about the XML standard.

- “Constructing an XML message tree” on page 1698
- “Working with namespaces” on page 1698
- “Working with binary data” on page 1699
- “XMLNSC: Working with CData” on page 1700
- “XMLNSC: Working with XML messages and bit streams” on page 1702

- “Working with large XML messages” on page 1703

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) Web site.

Constructing an XML message tree
When constructing an XML message tree, consider the order of fields in the tree.

About this task

Order of fields in the message tree

When you create an XML output message in a Compute node, the order of your lines of ESQL code is important, because the message elements are created in the order that you code them.

Consider the following XML message:

```
<Order>
  <ItemNo>1</ItemNo>
  <Quantity>2</Quantity>
</Order>
```

If you want to add a DocType Declaration to this, insert the DocType Declaration before you copy the input message to the output message.

For example:

```
SET OutputRoot.XMLNS.(XML.XmlDecl) = '';
SET OutputRoot.XMLNS.(XML.XmlDecl).(XML.Version) = '1.0';
SET OutputRoot.XMLNS.(XML.DocTypeDecl)Order ='';
SET OutputRoot.XMLNS.(XML.DocTypeDecl).(XML.SystemId)   = 'NewDtdName.dtd';
SET OutputRoot = InputRoot;
  -- more ESQL --
```

If you put the last statement to copy the input message before the XML-specific statements, the following XML is generated for the output message.

```
<Order>
  <ItemNo>1</ItemNo>
  <Quantity>2</Quantity>
</Order>
<?xml version="1.0"?>
```

This is not well-formed XML and causes an error when it is written from the message tree to a bit stream in the output node.

Setting the field type

If you copy a message tree from input to output without changing the domain, most of the syntax elements will be created by the parser (XMLNSC or XMLNS) and their field types will be correct. However, if you construct your message tree from a database query, or from another parser's message tree, you must ensure that you identify each syntax element correctly by using its field type. You can find full details of the field type constants used by XMLNSC and XMLNS in the following topics:

- “XMLNSC: Using field types” on page 533
- XML constructs

Working with namespaces
The following example shows how to use ESQL to work with namespaces.

About this task

Namespace constants are declared at the start of the main module so that you can use prefixes in the ESQL statements instead of the full URIs of the namespaces. The namespace constants affect only the ESQL; they do not control the prefixes that are generated in the output message. The prefixes in the generated output message are controlled by namespace declarations in the message tree. You can

include namespace declarations in the tree using the XML.NamespaceDecl field type. These elements are then used to generate namespace declarations in the output message.

When the output message is generated, if the parser encounters a namespace for which it has no corresponding namespace declaration, a prefix is automatically generated using prefixes of the form NSn where n is a positive integer.

```
CREATE COMPUTE MODULE xmlns_doc_flow_Compute
CREATE FUNCTION Main() RETURNS BOOLEAN
BEGIN
CALL CopyMessageHeaders();
-- Declaration of namespace constants --
These are only used by ESQL

DECLARE sp1 NAMESPACE 'http://www.ibm.com/space1';
DECLARE sp2 NAMESPACE 'http://www.ibm.com/space2';
DECLARE sp3 NAMESPACE 'http://www.ibm.com/space3';

-- Namespace declaration for prefix 'space1'
SET OutputRoot.XMLNS.message.(XML.NamespaceDecl)xmlns:space1 = 'http://www.ibm.com/space1';
SET OutputRoot.XMLNS.message.sp1:data1 = 'Hello!';

-- Default namespace declaration ( empty prefix )
SET OutputRoot.XMLNS.message.sp2:data2.(XML.NamespaceDecl)xmlns = 'http://www.ibm.com/space2';
SET OutputRoot.XMLNS.message.sp2:data2.sp2:subData1 = 'Hola!';
SET OutputRoot.XMLNS.message.sp2:data2.sp2:subData2 = 'Guten Tag!';
SET OutputRoot.XMLNS.message.sp3:data3 = 'Bonjour!';
RETURN TRUE;
END;

CREATE PROCEDURE CopyMessageHeaders()
BEGIN
DECLARE I INTEGER 1;
DECLARE J INTEGER CARDINALITY(InputRoot.*[]);
WHILE I < J DO SET OutputRoot.*[I] = InputRoot.*[I];
  SET I = I + 1;
END WHILE;
END;
END MODULE;
```

When this ESQL is processed, the following output message is generated:

```
<message xmlns:space1="http://www.ibm.com/space1">
 <space1:data1>Hello!</space1:data1>
 <data2 xmlns="http://www.ibm.com/space2">
  <subData1>Hola!</subData1>
  <subData2>Guten Tag!</subData2>
 </data2>
 <NS1:data3 xmlns="http://www.ibm.com/space3>Bonjour!</NS1:data3>
</message>
```

Working with binary data
If you need to include binary data or non-valid characters in your XML documents, the safest method is to encode the data as a binary string.

About this task

Binary encodings for XML

There are two methods of encoding binary data in an XML document.

```
hexBinary: <nonXMLChars>000102030405060708B0C0E0F</nonXMLChars>

base64Binary: <nonXMLChars>AAECAwQFBgcICwwODw==</nonXMLChars>
```

The base64Binary encoding makes better use of the available XML characters, and on average a base64-encoded binary field is 2/3 the size of its hexBinary equivalent. Base64Binary is widely used by the MIME format and by various XML-based standards.

You might prefer to use the simpler hexBinary encoding if you are sending data to applications that cannot decode base64 data, and if the increase in message size is not important.

Parsing binary data

The most straightforward way to parse any binary data is to use the XMLNSC parser with a message model:

1. Locate or construct an XML Schema that describes your input XML.
2. In your message flow, set the node properties as follows:
   - On the Default page, set *Message Domain* to XMLNSC.
   - On the Validation page, set *Validation* to Content and Value.
   - In the XMLNSC properties, select the check box option *Build tree using XML Schema types*.

The XMLNSC parser automatically decodes your hexBinary or base64Binary data, being guided by the simple type of the element or attribute that contains the binary data. The message tree will contain the decoded BLOB value.

If you are using the XMLNS domain, you must parse the binary data as a string. It appears in the message tree as a CHARACTER value. If the data is encoded as hexBinary, you can use the ESQL CAST function to convert it to a BLOB value. If the data is encoded as base64Binary, the easiest approach is to use the function **BASE64DECODE**. For more information, see BASE64DECODE function.

Generating binary data

You can generate binary data in your output XML in either hexBinary or base64Binary encoding.

For hexBinary, use the ESQL CAST statement to convert your BLOB data to a hexBinary string.

For base64Binary, you have two options:

- Call the function **BASE64ENCODE**. For more information, see BASE64ENCODE function.
- Use the XMLNSC parser, and modify the type field on the syntax element, as shown in this example:

```
-- ESQL code to generate base64-encoded binary data
DECLARE myBLOB BLOB;
-- Populate myBLOB with your binary data
CREATE LASTCHILD OF OutputRoot.XMLNSC.message
       TYPE BITOR(XMLNSC.Attribute, XMLNSC.base64Binary)
       NAME myBase64Element
       VALUE myBLOB;
```

Note that setting the field type to XMLNSC.base64Binary does not change the logical value in the message tree. In your message flow, it is still a BLOB, and if you ask for its string representation, it is reported as a hexBinary string. However, when the message tree is converted to a bit stream (in an output node, or by a call to ASBITSTREAM) the base64 conversion is performed automatically, and the output XML contains the correct base64 string.

XMLNSC: Working with CData

A CData section can be used to embed an XML document within another XML document.

About this task

What is a CData section?

An XML element can contain text content:

```
<element>text content</element>
```

However, some characters cannot appear in that content. In particular, '<' and '&' both have special meaning to an XML parser. If they are included in the text content of an element, they change the meaning of the XML document.

For example, this is a badly formed XML document:

```
<element><text><content></element>
```

There are two ways to make the XML well-formed:

1. Use character entities:

```
<element>&lt;text&gt;&lt;content&gt;</element>
```

2. Use a CData section:

```
<element><![CDATA[<text><content>]]></element>
```

What can you use a CData section for?

In a CData section, you can include XML markup in the value of an element. However, non-valid XML characters cannot be included. Binary data also cannot be included in a CData section.

The most common use for CData is to embed one XML document within another. For example:

```
<outer>
    <embedXML>
        <![CDATA[<innerMsg></innerMsg>]]>
    </embedXML>
</outer>
```

You can even embed a badly-formed XML document in this way, because the XML parser does not attempt to parse the content of a CData section.

```
<outer>
    <embedXML>
        <![CDATA[<badXML></wrongClosingTag>]]>
    </embedXML>
</outer>
```

The following items are not valid within a CData section:

- Non-valid XML characters (see http://www.w3.org/TR/2006/REC-xml-20060816/#charsets)
- The text string ']]>' (because this terminates the CData section)

Because of these restrictions, do not use a CData section to include arbitrary text in your XML document, and do not try to use a CData section to hold binary data (unless it is encoded as hexBinary or base64Binary).

How do you add a CData section to an output XML message?

Consider the following input message :

```
 <TestCase>
    <Folder>
       <Field1>Value1</Field1>
       <Field2>Value2</Field2>
       <Field3>Value3</Field3>
    </Folder>
 </TestCase>
```

The following ESQL shows how to serialize a whole message:

```
 DECLARE wholeMsgBlob BLOB
   ASBITSTREAM(InputRoot.XMLNSC,
               InputRoot.Properties.Encoding,
               InputRoot.Properties.CodedCharSetId );
  DECLARE wholeMsgChar CHAR
   CAST(wholeMsgBlob AS CHAR CCSID InputRoot.Properties.CodedCharSetId);
 SET OutputRoot.XMLNSC.Output.(XMLNSC.CDataField)Field1 = wholeMsgChar;
```

This example serializes the InputRoot.XMLNSC.TestCase.Folder portion of the message tree.

If the output message tree were examined before an MQOutput node, this would show :

```
(0x01000010):XML        = (
  (0x01000000):Output = (
    (0x01000000):Field1 = (
      (0x02000001): = '<TestCase><Folder><Field1>Value1</Field1><Field2>Value2</Field2>
```

```
                        <Field3>Value3</Field3></Folder><Folder2><Field1>Value1</Field1>
                        <Field2>Value2</Field2><Field3>Value3</Field3><Folder2></TestCase>'
       )
       )
   )
```

As can be seen, each CData section contains a single scalar value that is the character representation of the portion of the XML message that is required.

This tree produces the following XML output message :

```
<Output>
 <Field1><![CDATA[<TestCase><Folder><Field1>Value 1</Field1>
                                    <Field2>Value 2</Field2>
                                    <Field3>Value 3</Field3></Folder>
                            <Folder2><Field1>Value 1</Field1>
                                     <Field2>Value 2</Field2>
                                     <Field3>Value 3</Field3></Folder2>
                  </TestCase>]]</Field1>
 </Output>
```

CData section handling

Use the XMLNSC parser to merge CData sections into a single element in the message tree. Run the following command, where *integrationNodeName* is the name of your integration node and *integrationServerName* is the name of your integration server:

```
mqsichangeproperties integrationNodeName -e integrationServerName  -o
 ComIbmGenericXmlParserFactory  -n cdataFieldMerging -v option
```

option can be one of the following values:

*Table 68. Options for the **-v** flag*

Value	Description
no	Split the CData section in the message tree based on the "]" character and amount of data. This is the default value.
yes	Merge CData section into a single element in the message tree

XMLNSC: Working with XML messages and bit streams
Use the ASBITSTREAM function and the CREATE statement to manage XML message content.

About this task

The ASBITSTREAM function

If you code the ASBITSTREAM function with the parser mode option set to RootBitStream to parse a message tree to a bit stream, the result is an XML document that is built from the children of the target element in the normal way. This algorithm is identical to that used to generate the normal output bit stream. Because the target element is not included in the output bit stream, you must ensure that the children of the element follow the constraints for an XML document.

One constraint is that there must be only one body element in the message. You can use a well-formed bit stream obtained in this way to re-create the original tree using a CREATE statement with a PARSE clause.

If you code the ASBITSTREAM function with the parser mode option set to FolderBitStream to parse a message tree to a bit stream, the generated bit stream is an XML document built from the target element and its children. Any DocTypeDecl or XmlDecl elements are ignored, and the target element itself is included in the generated bit stream.

The advantage of this mode is that the target element becomes the body element of the document, and that body element can have multiple elements nested within it. Use this mode to obtain a bit stream description of arbitrary sub-trees owned by an XML parser. You can use bit streams obtained in

this way to re-create the original tree using a CREATE statement with a PARSE clause, and a mode of FolderBitStream.

For further information about the ASBITSTREAM function, and some examples of its use, see ASBITSTREAM function.

The CREATE statement with a PARSE clause

If you code a CREATE statement with a PARSE clause with the parser mode option set to RootBitStream to parse a bit stream to a message tree, the expected bit stream is a normal XML document. A field in the tree is created for each field in the document. This algorithm is identical to that used when parsing a bit stream from an input node. In particular, an element named 'XML', 'XMLNS', or 'XMLNSC' is created as the root element of the tree, and all the content in the message is created as children of that root.

If you code a CREATE statement with a PARSE clause with the parser mode option set to FolderBitStream to parse a bit stream to a message tree, the expected bit stream is a normal XML document. Any content outside the body element (such as an XML declaration or doctype) is discarded. The first element created during the parse corresponds to the body of the XML document, and from there the parse proceeds as normal.

For further information about the CREATE statement, and examples of its use, see CREATE statement.

Working with large XML messages
The tree representation of an XML message is typically bigger than the input bit stream. Manipulating a large message tree can require much storage but you can code ESQL statements that help to reduce the storage load on the integration node.

About this task

When an input bit stream is parsed and a logical tree is created, the tree representation of an XML message is typically bigger, and in some cases much bigger, than the corresponding bit stream.

The reasons for this expansion include the following factors:

- The addition of the pointers that link the objects together
- Translation of character data into Unicode, which can double the size
- The inclusion of field names that might have been implicit in the bit stream
- The presence of control data that is associated with operation of the integration node

Manipulating a large message tree can require much storage. If you design a message flow that handles large messages that are made up of repeating structures, you can code ESQL statements that help to reduce the storage load on the integration node. These statements support both random and sequential access to the message, but assume that you do not need access to the whole message at one time.

These ESQL statements cause the integration node to perform limited parsing of the message, and to keep in storage at one time, only that part of the message tree that reflects a single record. If your processing requires you to retain information from record to record (for example, to calculate a total price from a repeating structure of items in an order), you can either declare, initialize, and maintain ESQL variables, or you can save values in another part of the message tree; for example, in the local environment.

This technique reduces the memory that is used by the integration node to the memory that is needed to hold the full input and output bit streams, plus the memory that is needed for the message trees of just one record. This technique also provides memory savings when even a few repeats are encountered in the message. The integration node uses partial parsing and the ability to parse specified parts of the message tree, to and from the corresponding part of the bit stream.

To use these techniques in your Compute node, take any of the following steps.

- Copy the body of the input message as a bit stream to a special folder in the output message. This action creates a modifiable copy of the input message that is not parsed and therefore uses a minimum amount of memory.
- Avoid any inspection of the input message, which avoids the need to parse the message.

- Use a loop and a reference variable to step through the message one record at a time. For each record, use the following processes:
  - Use normal transforms to build a corresponding output subtree in a second special folder.
  - Use the ASBITSTREAM function to generate a bit stream for the output subtree. The generated bit stream is stored in a BitStream element that is placed in the position in the output subtree that corresponds to its required position in the final bit stream.
  - Use the DELETE statement to delete both the current input and output record message trees when you have completed their manipulation.
  - When you have completed the processing of all records, detach the special folders so that they do not appear in the output bit stream.

You can vary these techniques to suit the processing that is required for your messages.

The following ESQL code provides an example of one implementation, and is a modification of the ESQL example in "Transforming a complex message" on page 1684. It uses a single SET statement with nested SELECT functions to transform a message that contains nested, repeating structures.

```
-- Copy the MQMD header
  SET OutputRoot.MQMD = InputRoot.MQMD;

-- Create a special folder in the output message to hold the input tree
-- Note : SourceMessageTree is the root element of an XML parser
  CREATE LASTCHILD OF OutputRoot.XMLNS.Data DOMAIN 'XMLNS' NAME 'SourceMessageTree';

-- Copy the input message to a special folder in the output message
-- Note : This is a root to root copy which will therefore not build trees
  SET OutputRoot.XMLNS.Data.SourceMessageTree = InputRoot.XMLNS;

-- Create a special folder in the output message to hold the output tree
  CREATE FIELD OutputRoot.XMLNS.Data.TargetMessageTree;

-- Prepare to loop through the purchased items
  DECLARE sourceCursor REFERENCE TO OutputRoot.XMLNS.Data.SourceMessageTree.Invoice;
  DECLARE targetCursor REFERENCE TO OutputRoot.XMLNS.Data.TargetMessageTree;
  DECLARE resultCursor REFERENCE TO OutputRoot.XMLNS.Data;
  DECLARE grandTotal   FLOAT     0.0e0;

-- Create a block so that it's easy to abandon processing
  ProcessInvoice: BEGIN
  -- If there are no Invoices in the input message, there is nothing to do
    IF NOT LASTMOVE(sourceCursor) THEN
      LEAVE ProcessInvoice;
    END IF;

  -- Loop through the invoices in the source tree
  InvoiceLoop : LOOP
    -- Inspect the current invoice and create a matching Statement
    SET targetCursor.Statement = THE (SELECT 'Monthly' AS (XML.Attribute)Type,
                                          'Full' AS (0x03000000)Style[1],
                                         I.Customer.FirstName AS Customer.Name,
                                         I.Customer.LastName AS Customer.Surname,
                                            I.Customer.Title AS Customer.Title,
                                         (SELECT
                                           FIELDVALUE(II.Title) AS Title,
                                           CAST(II.UnitPrice AS FLOAT) * 1.6 AS Cost,
                                           II.Quantity AS Qty
                                         FROM I.Purchases.Item[] AS II
                                         WHERE II.UnitPrice> 0.0) AS Purchases.Article[],
                                         (SELECT
                                           SUM( CAST(II.UnitPrice AS FLOAT) *
                                                CAST(II.Quantity  AS FLOAT) *
                                                1.6                          )
                                         FROM I.Purchases.Item[] AS II) AS Amount,
                                         'Dollars' AS Amount.(XML.Attribute)Currency
                                       FROM sourceCursor AS I
                                       WHERE I.Customer.LastName <> 'White');

    -- Turn the current Statement into a bit stream
    DECLARE StatementBitStream BLOB
    ASBITSTREAM(targetCursor.Statement OPTIONS FolderBitStream);
    -- If the SELECT produced a result
    -- (that is, it was not filtered out by the WHERE clause),
    -- process the Statement
    IF StatementBitStream IS NOT NULL THEN
```

```
    -- create a field to hold the bit stream in the result tree
       CREATE LASTCHILD OF resultCursor
          Type  XML.BitStream
          NAME  'StatementBitStream'
          VALUE StatementBitStream;

    -- Add the current Statement's Amount to the grand total
    -- Note that the cast is necessary because of the behavior
    -- of the XML syntax element
       SET grandTotal = grandTotal
        + CAST(targetCursor.Statement.Amount AS FLOAT);
    END IF;

    -- Delete the real Statement tree leaving only the bit stream version
    DELETE FIELD targetCursor.Statement;

    -- Step onto the next Invoice,
    -- removing the previous invoice and any
    -- text elements that might have been
    -- interspersed with the Invoices

    REPEAT
      MOVE sourceCursor NEXTSIBLING;
      DELETE PREVIOUSSIBLING OF sourceCursor;
      UNTIL (FIELDNAME(sourceCursor) = 'Invoice')
       OR (LASTMOVE(sourceCursor) = FALSE)
    END REPEAT;

    -- If there are no more invoices to process, abandon the loop
    IF NOT LASTMOVE(sourceCursor) THEN
     LEAVE InvoiceLoop;
    END IF;

  END LOOP InvoiceLoop;
END ProcessInvoice;

-- Remove the temporary source and target folders
DELETE FIELD OutputRoot.XMLNS.Data.SourceMessageTree;
DELETE FIELD OutputRoot.XMLNS.Data.TargetMessageTree;

-- Finally add the grand total
SET resultCursor.GrandTotal = grandTotal;
```

This ESQL code produces the following output message:

```
<Data>
 <Statement Type="Monthly" Style="Full">
  <Customer>
   <Name>Andrew</Name>
   <Surname>Smith</Surname>
   <Title>Mr</Title>
  </Customer>
  <Purchases>
   <Article>
    <Title>The XML Companion</Title>
    <Cost>4.472E+1</Cost>
    <Qty>2</Qty>
   </Article>
   <Article>
    <Title>A Complete Guide to DB2 Universal Database</Title>
    <Cost>6.872E+1</Cost>
    <Qty>1</Qty>
   </Article>
   <Article>
    <Title>JAVA 2 Developers Handbook</Title>
    <Cost>9.5984E+1</Cost>
    <Qty>1</Qty>
   </Article>
  </Purchases>
  <Amount Currency="Dollars">2.54144E+2</Amount>
  </Statement>
  <GrandTotal>2.54144E+2</GrandTotal>
 </Data>
```

Manipulating messages in the XMLNSC domain
If you are writing ESQL to process messages in the XMLNSC domain, it is helpful to learn about the structure of the message tree that the XMLNSC parser builds.

About this task

The topics in this section provide information about how to write ESQL for processing messages that belong to the XMLNSC domain, and that are parsed by the XMLNSC parser. For background information, see "XMLNSC parser" on page 531.

The following topics provide detailed information about the structure of the message tree that the XMLNSC parser builds, and the field types that it uses.

- "XMLNSC: The XML declaration" on page 1706
- "XMLNSC: The inline DTD" on page 1707
- "XMLNSC: The message body" on page 1707
- "XMLNSC: XML Schema support" on page 1715

If you are migrating from XML, XMLNS, or MRM XML, see "Migrating to XMLNSC" on page 1718.

For further information about processing XML messages, see "Working with XML messages" on page 1697.

XMLNSC: The XML declaration
The XML declaration is represented in the message tree by a syntax element with field type XMLNSC.XMLDeclaration.

If an XML declaration is created by the XMLNSC parser, its name is 'XmlDeclaration'. However, when a message tree is being produced, the name is not important: the XMLNSC parser recognizes this syntax element by its field type only. The following example shows a typical declaration:

```
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
<!DOCTYPE s1 PUBLIC "http://www.ibm.com/example.dtd" "example.dtd">
<s1>........</s1>
```

The XML Declaration has three optional attributes; Version, Standalone, and Encoding. The XMLNSC parser does not define special field types for these attributes. Instead, they are identified by their name, and by their position as a child of the XML Declaration element.

ESQL example code to create an XML declaration

To construct the XML declaration that is shown in the previous example, code the following ESQL statements:

```
CREATE FIRSTCHILD OF OutputRoot.XMLNSC TYPE XMLNSC.XmlDeclaration NAME 'XmlDeclaration';
SET OutputRoot.XMLNSC.(XMLNSC.XmlDeclaration)*.(XMLNSC.Attribute)Version = '1.0';
SET OutputRoot.XMLNSC.(XMLNSC.XmlDeclaration)*.(XMLNSC.Attribute)Encoding = 'UTF-8';
SET OutputRoot.XMLNSC.(XMLNSC.XmlDeclaration)*.(XMLNSC.Attribute)StandAlone = 'yes';
```

The first line is optional; if it is omitted, the XMLNSC.XMLDeclaration element is automatically created when it is referenced by the second line.

Java example code to create an XML declaration

To construct the XML declaration that is shown in the previous example, write the following Java code:

```
//Create the XML domain root node
MBElement xmlRoot =
 root.createElementAsLastChild(MbXMLNSC.PARSER_NAME);
//Create the XML declaration parent node
MbElement xmlDecl =
 xmlRoot.createElementAsFirstChild(MbXMLNSC.XML_DECLARATION);

xmlDecl.setName("XmlDeclaration");

MbElement version =
```

```
 xmlDecl.CreateElementAsFirstChild(MbXMLNSC.ATTRIBUTE, "Version", "1.0");
MbElement encoding =
 xmlDecl.CreateElementAsFirstChild(MbXMLNSC.ATTRIBUTE, "Encoding", "utf-8");
MbElement standalone =
 xmlDecl.CreateElementAsFirstChild(MbXMLNSC.ATTRIBUTE, "Standalone", "yes");
```

Note: In both the ESQL example and the Java example, 'Version', 'StandAlone', and 'Encoding' can all be written in lowercase.

XMLNSC: The inline DTD
When you parse an XML document that has an inline DTD, the XMLNSC parser does not put the DTD information into the message tree. However, by using ESQL code, you can add XML entity definitions to the message tree, and these definitions are used when the message tree is produced by the XMLNSC parser.

ESQL example code for entity definition and entity reference

This example assumes that InputRoot.XMLNSC has been created from the following XML message:

```
<BookInfo dtn="BookInfo" edn="author" edv="A.N.Other"/>
```

The following output message is generated:

```
<!DOCTYPE BookInfo [<!ENTITY author "A.N.Other">]>
<BookInfo><entref>&author;</entref></BookInfo>
```

The ESQL to create the output message is:

```
DECLARE cursor REFERENCE TO InputRoot.XMLNSC.BookInfo;
DECLARE docTypeName CHARACTER cursor.dtn;
DECLARE authorRef CHARACTER 'author';
-- Create <!DOCTYPE BOOKInfo …
SET OutputRoot.XMLNSC.(XMLNSC.DocumentType)* NAME = docTypeName;
-- Create  <!ENTITY author "A.N.Other" > …
SET OutputRoot.XMLNSC.(XMLNSC.DocumentType){docTypeName}.(XMLNSC.EntityDefinition) {authorRef} =
cursor.edv;
-- Create the entity reference
SET OutputRoot.XMLNSC.(XMLNSC.Folder){docTypeName}.(XMLNSC.EntityReference)entref = authorRef;
```

XMLNSC: The message body
The XMLNSC parser builds a message tree from the body of an XML document.

The following topics describe how the XMLNSC parser builds a message tree from the body of an XML document:

- “XMLNSC: Using field types” on page 533
- “XMLNSC: Attributes and elements” on page 1710
- “XMLNSC: Namespace declarations” on page 1711
- “XMLNSC: Element values and mixed content” on page 1712
- “XMLNSC: Comments and Processing Instructions” on page 1715

XMLNSC: Using field types
The XMLNSC parser sets the field type on every syntax element that it creates.

The field type indicates the type of XML construct that the element represents. The XMLNSC parser uses the field type when writing a message tree. The field type can be set by using ESQL or Java to control the output XML. The field types that are used by the XMLNSC parser must be referenced by using constants with names that are prefixed by 'XMLNSC.'

Tip: Field type constants that have the prefix 'XML.' are for use with the XMLNS and XML parsers only, and are not valid with the XMLNSC or MRM parsers.

Field types for creating syntax elements

Use the following field type constants to create syntax elements in the message tree. The XMLNSC parser uses these values when creating a message tree from an input message.

XML construct	XMLNSC Field Type constant	Value
Simple Element	XMLNSC.Field XMLNSC.CDataField	0x03000000 0x03000001
Attribute	XMLNSC.SingleAttribute XMLNSC.Attribute	0x03000101 0x03000100
Mixed content	XMLNSC.Value XMLNSC.CDataValue	0x02000000 0x02000001
Namespace Declaration	XMLNSC.SingleNamespaceDecl XMLNSC.NamespaceDecl	0x03000102 0x03000103
Complex element	XMLNSC.Folder	0x01000000
Inline DTD	XMLNSC.DocumentType	0x01000300
XML declaration	XMLNSC.XmlDeclaration	0x01000400
Entity reference	XMLNSC.EntityReference	0x02000100
Entity definition	XMLNSC.SingleEntityDefinition XMLNSC.EntityDefinition	0x03000301 0x03000300
Comment	XMLNSC.Comment	0x03000400
Processing Instruction	XMLNSC.ProcessingInstruction	0x03000401

Field types for path expressions (generic field types)

Use the following field type constants when querying the message tree by using a path expression; for example:

```
SET str = FIELDVALUE(InputRoot.e1.(XMLNSC.Attribute)attr1)
```

It is good practice to specify field types when querying a message tree built by the XMLNSC parser. This makes your ESQL code more specific and more readable, and it avoids incorrect results in some cases. However, care is required when choosing which field type constant to use. When you use the XMLNSC parser, use a generic field type constant when querying the message tree. This allows your path expression to tolerate variations in the input XML.

The generic field type constants are listed in the following table:

XML construct	XMLNSC Field Type constant	Purpose
Tag	XMLNSC.Element	Matches any tag, whether it contains child tags (XMLNSC.Folder) or a value (XMLNSC.Field)

XML construct	XMLNSC Field Type constant	Purpose
Element	XMLNSC.Field	Matches a tag which contains normal text, CData, or a mixture of both. Does not match tags which contain child tags.
Attribute	XMLNSC.Attribute	Matches single-quoted and double-quoted attributes
Mixed content	XMLNSC.Value	Matches normal text, CData, or a mixture of both
XML Declaration	XMLNSC.NamespaceDecl	Matches single- and double-quoted declarations

If you write

```
InputRoot.e1.(XMLNSC.DoubleAttribute)attrName
```

your path expression does not match a single-quoted attribute. If you use the generic field type constant *XMLNSC.Attribute*, your message flow works with either single-quoted or double-quoted attributes.

Note that you should always use the field type constants and not their numeric values.

Field types for controlling output format

The following field types are provided for XML Schema and base64 support. Do not use these field type constants in path expressions; use them in conjunction with XMLNSC.Attribute and XMLNSC.Field to indicate the required output format for DATE and BLOB values. See "XMLNSC: XML Schema support" on page 1715 for further information.

XMLNSC Field Type constant	Purpose	Value
XMLNSC.gYear	The value must be a DATE. If the field type includes this value, the DATE value is produced by using the XML Schema gYear format.	0x00000010
XMLNSC.gYearMonth	The value must be a DATE. If the field type includes this value, the DATE value is produced by using the XML Schema gYearMonth format.	0x00000040
XMLNSC.gMonth	The value must be a DATE. If the field type includes this value, the DATE value is produced by using the XML Schema gMonth format.	0x00000020
XMLNSC.gMonthDay	The value must be a DATE. If the field type includes this value, the DATE value is produced by using the XML Schema gMonthDay format.	0x00000050
XMLNSC.gDay	The value must be a DATE. If the field type includes this value, the DATE value is produced by using the XML Schema gDay format.	0x00000030
XMLNSC.base64Binary	The value must be a BLOB. The value is produced with base64 encoding.	0x00000060
XMLNSC.List	The element must be XMLNSC.Attribute or XMLNSC.Field. If the field type includes this value, the values of all child elements in the message tree are produced as a space-separated list.	0x00000070

Field types for direct output

Use the following field types to produce pre-constructed segments of an XML document. Character escaping is not done; therefore, take extra care not to construct a badly-formed output document. Use these constants only after carefully exploring alternative solutions.

XMLNSC Field Type constant	Purpose	Value
XMLNSC.BitStream	The value of this syntax element must be a BLOB. The value is written directly to the output bit stream. For more information about its usage, see "Working with large XML messages" on page 1703.	0x03000200
XMLNSC.AsisElementContent	The value of this syntax element must be CHARACTER. The value is written directly to the output bit stream. No character substitutions are performed. Use this element with care.	0x03000600

XMLNSC: Attributes and elements

The XMLNSC parser uses field types to represent attributes and elements.

Use the following field type constants when creating your own syntax elements in the message tree.

Table 69. Specific field type constants

XML Construct	XMLNSC Field Type constant	Value
Complex element	XMLNSC.Folder	0x01000000
Simple element	`XMLNSC.Field` `XMLNSC.CDataField`	`0x02000000` `0x02000001`
Attribute	`XMLNSC.SingleAttribute` `XMLNSC.Attribute`	`0x03000100` `0x03000101`

When accessing elements and attributes in the message tree, use generic field type constants which match all of the alternative values. Because there is only one type of Folder element, it is safe to use XMLNSC.Folder when querying the message tree.

Table 70. Generic field type constants

XML Construct	XMLNSC Field Type constant	Purpose
Element	XMLNSC.Field	Matches elements that contain normal text, CData, or a mixture of both
Attribute	XMLNSC.Attribute	Matches both single-quoted and double-quoted attributes

ESQL code examples

The following examples use this XML message:

```
<root id="12345">
    <id>ABCDE</id>
</root>
```

Note that the message contains an attribute and an element with the same name.

Example 1 : Query the value of an XML element

```
SET value = FIELDVALUE(InputRoot.XMLNSC.root.(XMLNSC.Field)id)
```

The result is that value is set to 'ABCDE'.

Example 2 : Query the value of an XML attribute

```
SET value = FIELDVALUE(InputRoot.XMLNSC.root.(XMLNSC.Attribute)id)
```

The result is that value is set to '12345'.

Example 3 : Create the example message by using ESQL

```
CREATE LASTCHILD OF OutputRoot.XMLNSC Type XMLNSC.Folder Name 'root';
-- Note : XMLNSC.Attribute could be used here as well.
SET OutputRoot.XMLNSC.root.(XMLNSC.Attribute)id = '12345';
SET OutputRoot.XMLNSC.root.(XMLNSC.Field)id = 'ABCDE';
```

The first line is optional because the element 'root' is created automatically by the following line if it does not already exist.

XMLNSC: Namespace declarations
The XMLNSC parser provides full support for namespaces.

The XMLNSC parser sets the correct namespace on every syntax element that it creates while parsing a message, and stores namespace declarations in the message tree. The parser uses the namespace declarations to select the appropriate prefixes when outputting the message tree.

The XMLNSC parser uses the following field types to represent namespace declarations. Use the field type constants that are listed in this table when you create namespace declarations in the message tree.

Table 71. Specific field type constants

XML construct	XMLNSC field type constant	Value
Namespace declaration	`XMLNSC.SingleNamespaceDecl` `XMLNSC.DoubleNamespaceDecl`	`0x03000102` `0x03000103`

When accessing elements and attributes in the message tree, do not use the constants that are listed in the previous table; instead, use the generic field type constant that matches both of the values in the table above.

Table 72. Generic field type constants

XML construct	XMLNSC field type constant	Purpose
Namespace declaration	XMLNSC.NamespaceDecl	Matches namespace declarations in both single and double quotation marks

ESQL code examples

Example 1: Declaring a non-empty prefix

```
DECLARE space1 NAMESPACE 'namespace1';
SET OutputRoot.XMLNSC.space1:root.(XMLNSC.NamespaceDecl)xmlns:ns1 = space1;
SET OutputRoot.XMLNSC.space1:root.space1:example = 'ABCDE';
```

This creates the following XML message:

```
<ns1:root xmlns:ns1="namespace1">
    <ns1:example>ABCDE</ns1:example>
</ns1:root>
```

Note that the NAMESPACE constant space1 is just a local variable in the ESQL; it does not affect the namespace prefix ns1 that is defined by the NameSpaceDecl element and appears in the output message.

However, as shown here, space1 can be used to initialize the NameSpaceDecl for ns1. This avoids the need to duplicate the namespace URI ('namespace1' in this example), which in practice is typically a much longer string.

Example 2: Declaring an empty prefix

```
DECLARE space1 NAMESPACE 'namespace1';
SET OutputRoot.XMLNSC.space1:root.(XMLNSC.NamespaceDecl)xmlns = space1;
SET OutputRoot.XMLNSC.space1:root.space1:example = 'ABCDE';
```

This creates the following XML message:

```
<root xmlns="namespace1">
    <example>ABCDE</example>
</root>
```

Note that the syntax elements root and example must have a non-empty namespace. The default namespace declaration means that any child element without a prefix is in the namespace namespace1.

Example 3: Example of incorrect usage

```
DECLARE space1 NAMESPACE 'namespace1';
SET OutputRoot.XMLNSC.root.(XMLNSC.NamespaceDecl)xmlns = space1;
SET OutputRoot.XMLNSC.root.example = 'ABCDE';
```

This example causes the XMLNSC parser to issue the message BIP5014 when it attempts to create the message tree. The elements root and example are both within the scope of the default namespace declaration; therefore, in ESQL, these elements must be qualified by a namespace prefix bound to that namespace.

Example 4: Adding a namespace declaration with a prefix

```
SET OutputRoot.(XMLNSC.DoubleNamespaceDecl)xmlns:ns2 = space1;
```

This example of a SET statement creates a namespace declaration with the name ns2 in the namespace xmlns.

```
CREATE LASTCHILD OF OutputRoot IDENTITY (XMLNSC.DoubleNamespaceDecl)xmlns:ns2 VALUE space1;
```

```
CREATE LASTCHILD OF OutputRoot TYPE XMLNSC.DoubleNamespaceDecl NAMESPACE 'xmlns' NAME 'ns2'
 VALUE space1;
```

These examples of a CREATE statement also create a namespace declaration with the name ns2 in the namespace xmlns.

However, be aware that the following example of a CREATE statement creates a namespace declaration with the name xmlns:ns2 in the default namespace:

```
CREATE LASTCHILD OF OutputRoot TYPE XMLNSC.DoubleNamespaceDecl NAME 'xmlns:ns2' VALUE space1;
```

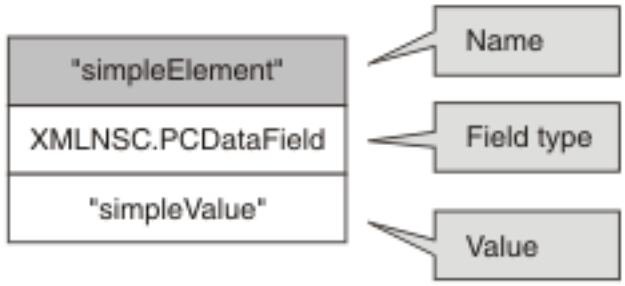
XMLNSC: Element values and mixed content

The XMLNSC parser is a compact parser; therefore, an element with single content is parsed as a single syntax element. When an element has both child elements and some text, the text is called *mixed content*.

Element with simple content

The following XML fragment with a single content is parsed as a single syntax element:

```
<simpleElement>simpleValue</simpleElement>
```



The value of this element can be queried with this ESQL:

```
SET val = FIELDVALUE(InputRoot.XMLNSC.(XMLNSC.Field)simpleElement);
```

To generate an element with simple content in the output:

```
SET OutputRoot.XMLNSC.(PCDataField)simpleElement VALUE = 'simpleValue';
```

Note that XMLNSC.Field is used when querying the message tree, but XMLNSC.PCDataField is specified when constructing the output message. XMLNSC.PCDataField can be used to query the message tree; however, that would not work if the input message used a CData section, as shown in the following example:

```
<simpleElement><![CDATA[simpleValue]]></simpleElement>
```

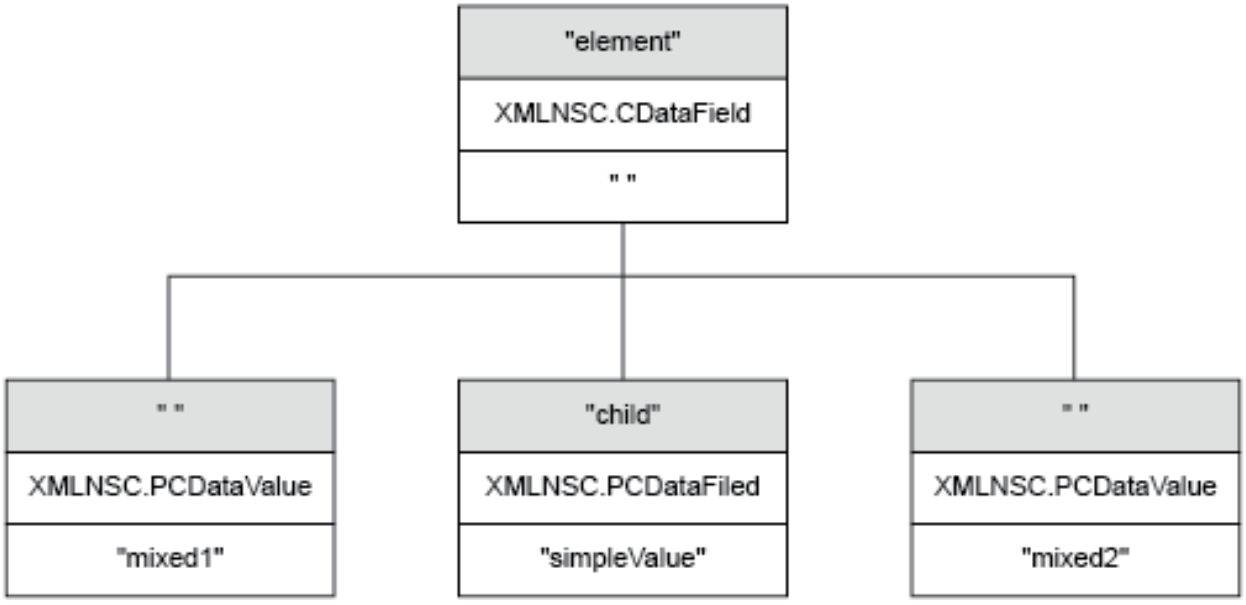
Element with mixed content

If an element has child elements, it is typically a 'folder', and does not have a value. When an element has both child elements and some text, the text is called 'mixed content'.

```
<element>mixed1<child>simpleValue</child>mixed2</element>
```

By default, mixed content is discarded because it is typically just formatting white space and has no business meaning. Mixed content can be preserved if you select the `Retain mixed content` check box on the Parser Options page of the node properties.

If mixed content is being preserved, the XMLNSC parser creates a Value child element for each distinct item of mixed content.



The mixed content can be queried with this ESQL:

```
SET mixed1 = FIELDVALUE(InputRoot.XMLNSC.(element).*[1];
```

The ESQL to construct the above XML fragment is:

```
CREATE ref REFERENCE TO OutputRoot.XMLNSC.element;
CREATE FIRSTCHILD OF ref TYPE XMLNSC.PCDataValue VALUE 'mixed1';
CREATE LASTCHILD OF ref NAME 'child' TYPE XMLNSC.PCDataField  VALUE 'simpleValue';
CREATE LASTSTCHILD OF ref TYPE XMLNSC.PCDataValue VALUE 'mixed2';
```

The following ESQL enables the *Retain mixed content* option:

```
DECLARE X BLOB;
-- assume that X contains an XML document
CREATE LASTCHILD OF OutputRoot
    PARSE(X OPTIONS XMLNSC.MixedContentRetainAll);
```

Element containing a CData section

A CData section is an XML notation that allows XML markup characters to be included in the content of an element.

The following two XML fragments are identical in their meaning:

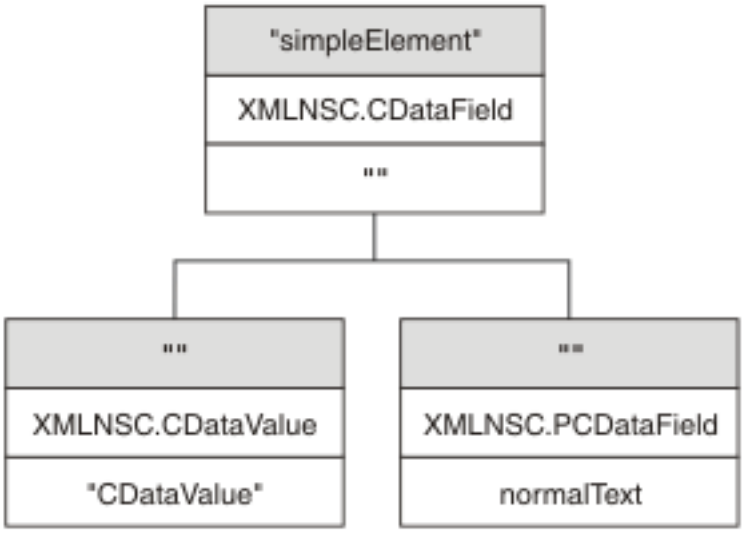
```
<simpleElement>simpleValue</simpleElement>
```

```
<simpleElement><![CDATA[simpleValue]]></simpleElement>
```

If the CData section is the only text content, the XMLNSC parser remembers that the input document contained a CData section by setting the field type to XMLNSC.CDataField instead of XMLNSC.PCDataField.

If the CData section is not the only text content, it is created as a child value element, with other child value elements representing the remaining text content. The following is an example of this:

```
<simpleElement><![CDATA[CDataValue]]>normalText</simpleElement>
```



See “XMLNSC: Working with CData” on page 1700 for more information about the correct use of CData in XML documents.

XMLNSC: Comments and Processing Instructions
The XMLNSC parser discards comments and processing instructions because both comments and processing instructions are auxiliary information with no business meaning.

Comments

Comments can be preserved if you select the *Retain comments* check box on the Parser Options page of the node properties.

If *Retain comments* is selected, each comment in the input document is represented by a single syntax element with field type XMLNSC.Comment. The *Retain comments* option can also be accessed by using the following ESQL:

```
DECLARE X BLOB;
-- assume that X contains an XML document
CREATE LASTCHILD OF OutputRoot.XMLNSC
    PARSE(X DOMAIN XMLNSC
          NAME preserveComments
          OPTIONS XMLNSC.CommentsRetainAll);

-- do it again, this time discarding comments
CREATE LASTCHILD OF OutputRoot.XMLNSC
    PARSE(X DOMAIN XMLNSC
          NAME discardComments
          OPTIONS XMLNSC.CommentsRetainNone);
```

Processing Instructions

Processing instructions can be preserved if you select the *Retain processing instructions* check box on the Parser Options page of the node properties.

If *Retain processing instructions* is selected, each processing instruction the input document is represented by a single syntax element with field type XMLNSC.ProcessingInstruction. The *Retain processing instructions* option can also be accessed by using the following ESQL:

```
DECLARE X BLOB;
-- assume that X contains an XML document
CREATE LASTCHILD OF OutputRoot.XMLNSC
    PARSE(X DOMAIN XMLNSC
          NAME preserveProcessingInstructions
          OPTIONS XMLNSC.ProcessingInstructionsRetainAll);

-- do it again, this time discarding processing instructions
CREATE LASTCHILD OF OutputRoot.XMLNSC
    PARSE(X DOMAIN XMLNSC
          NAME discardProcessingInstructions
          OPTIONS XMLNSC.ProcessingInstructionsRetainNone);
```

XMLNSC: XML Schema support
Use the XMLNSC parser to parse and validate by using an XML Schema.

For information about how to configure the XMLNSC parser to use an XML Schema, see "XMLNSC parser" on page 531.

The following topics describe how the XMLNSC parser uses the field type to hold information about XML Schema simple types. This behavior enables the parser to write dates and binary elements in the same form in which they were parsed, and according to the XML Schema specification. It also allows the message flow developer to write dates, lists, and binary data in the correct XML Schema format.

- "XMLNSC: base64 support" on page 1716
- "XMLNSC: XML Schema date formatting" on page 1716
- "XMLNSC: XML List type support" on page 1717

XMLNSC: base64 support
The XMLNSC parser can produce binary data in base64-encoded format.

If `Validation` is set to `Content and Value`, and `Build tree using schema types` is enabled, the XMLSNC parser automatically decodes base64 data and creates a BLOB value in the message tree. When producing a message tree, the XMLNSC parser will 'base64-encode' a BLOB if the field type includes the constant *XMLNSC.base64Binary*.

ESQL code example to output base64 data

```
DECLARE Base64Data BLOB '0102030405060708090A0B0C0D0E0F';
-- Add in the base64Binary field type
DECLARE base64FieldType INTEGER XMLNSC.Field + XMLNSC.base64Binary;
CREATE LASTCHILD OF OutputRoot DOMAIN 'XMLNSC' NAME 'XMLNSC';
CREATE LASTCHILD OF OutputRoot.XMLNSC TYPE base64FieldType NAME 'myBinaryData' VALUE Base64Data;
```

Result : <myBinaryData>AQIDBAUGBwgJCgsMDQ4P</myBinaryData>

Note that this example does not depend on validation. The XMLNSC parser can produce base64 binary data even if `Validation` is set to `None`.

XMLNSC: XML Schema date formatting
The XMLNSC parser can parse and write all of the XML Schema simple types.

The rarely used types gYear, gYearMonth, gMonth, gMonthDay, and gDay do not map directly to an integration node data type. For these simple types, the XMLNSC parser adds one of the following constant values to the field type. This behavior allows the parser to produce the data for output in the same format as it was received.

Field types for controlling date format

The following field types are provided for XML Schema date format support. Do not use these field type constants in path expressions. Use them in conjunction with constants XMLNSC.Attribute and XMLNSC.Field to indicate the required output format for DATE values.

XMLNSC Field Type constant	Purpose	Value
XMLNSC.gYear	Value must be a DATE. If the field type includes this value, the DATE value is written by using the XML Schema gYear format.	0x00000010
XMLNSC.gYearMonth	Value must be a DATE. If the field type includes this value, the DATE value is written by using the XML Schema gYearMonth format.	0x00000040
XMLNSC.gMonth	Value must be a DATE. If the field type includes this value, the DATE value is written by using the XML Schema gMonth format.	0x00000020
XMLNSC.gMonthDay	Value must be a DATE. If the field type includes this value, the DATE value is written by using the XML Schema gMonthDay format.	0x00000050
XMLNSC.gDay	Value must be a DATE. If the field type includes this value, the DATE value is written by using the XML Schema gDay format.	0x00000030

ESQL code example

```
DECLARE gYear DATE ‘2007-01-01';
-- Add in the gYear field type
DECLARE gYearFieldType INTEGER XMLNSC.Field + XMLNSC.gYear;
CREATE LASTCHILD OF OutputRoot DOMAIN ‘XMLNSC' NAME ‘XMLNSC';
CREATE LASTCHILD OF OutputRoot.XMLNSC TYPE gYearFieldType NAME ‘gYear' VALUE gYear;
```

Result : <gYear>2007</gYear>

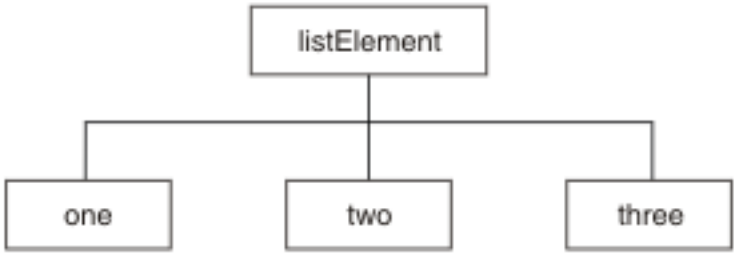
XMLNSC: XML List type support
The XMLNSC parser can automatically parse a space-separated list of values into individual syntax elements in the message tree if you select certain options.

An element or an attribute can have multiple values separated by spaces, as shown in the following examples:

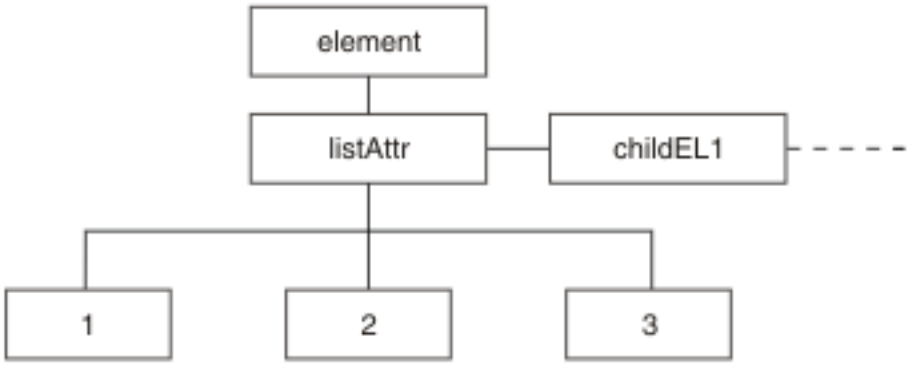
```
<listElement>one two three</listElement>
```

```
<element listAttribute="1 2 3"><childEL1/></element>
```

If your XML schema specifies a list type for an element or an attribute, and `Validation` is set to `Content and Value`, and `Build tree using schema types` is enabled, the XMLNSC parser automatically parses the space-separated list of values into individual syntax elements in the message tree. The resulting message tree looks like this:



and for an attribute with a list value it looks like this:



ESQL code examples

Access the individual values in a list

```
SET val = InputRoot.XMLNSC.listElement.*[1];
```

Result : val = 'one'

```
SET val = InputRoot.XMLNSC.element.(XMLNSC.Attribute)listAttr.*[3];
```

Result : val='3'

Create a list element in the message tree

```
CREATE LASTCHILD OF OutputRoot.XMLNSC
   Name 'listElement'
   Type XMLNSC.List;
DECLARE listEl REFERENCE TO OutputRoot.XMLNSC.listElement;
DECLARE listValType INTEGER XMLNSC.PCDataValue;
CREATE LASTCHILD OF listEl TYPE listValType VALUE 'one';
CREATE LASTCHILD OF listEl TYPE listValType VALUE 'two';
CREATE LASTCHILD OF listEl TYPE listValType VALUE 'three';
```

Migrating to XMLNSC
The XMLNSC parser offers the best combination of features and performance for most applications.

Reasons to migrate

If your message flow uses the XMLNS or XML domain, you might want to migrate a message flow to XMLNSC to take advantage of the XML schema validation. If your message flow uses the MRM domain, you might want to migrate to XMLNSC to obtain standards-compliant validation, and a large reduction in processor usage.

Migrating from the XMLNS or XML domain

The XMLNSC parser differs from the XMLNS parser in the following ways:

- The XMLNSC parser builds a compact message tree.
- It uses different field type constants.
- It discards inline DTDs

In most cases, the compact message tree has no effect on ESQL paths or XPath expressions. Typically, a simple message tree query produces the same results in XMLNSC as in the XMLNS or XML domain. Changing the correlation name from XMLNS to XMLNSC is often sufficient, but care must be taken with the following items:

- Empty elements and null values.

  The XMLNSC parser does not always handle empty elements and null values in the same way as XML and XMLNS.
- Complex XPath expressions that navigate to the value of an element, then to its parent in a single query.

  These expressions might produce different results in the XMLNSC domain.

The field type constants that are used by the XMLNSC parser are different from those constants used by XMLNS or XML. Every occurrence of XML.Attribute, XML.XmlDecl, for example, must be changed to use the equivalent XMLNSC field type constant.

The discarding of inline DTDs only affects message flows that process the DTD.

Migrating from MRM XML

The XMLNSC parser differs from the MRM XML parser in the following ways:

- The XMLNSC parser uses field types to identify the XML constructs in the message tree. The MRM parser distinguishes attributes from elements by matching the message tree against the message definition.
- When writing a message tree, the XMLNSC parser selects namespace prefixes by detecting and using xmlns attributes in the message tree. The MRM XML parser uses a table in the message set properties.
- The MRM parser does not include the root tag of the XML document in the message tree.

Migrating a message flow from MRM to XMLNSC typically requires extensive changes to your message flow. However, the migration usually delivers a large reduction in processor usage, and allows much more accurate control of the output XML.

Manipulating messages in the XMLNS domain
When you write ESQL for processing messages in the XMLNS domain, it is helpful to understand the structure of the message tree that the XMLNS parser builds.

About this task

The topics in this section provide information about how to write ESQL for processing messages that belong to the XMLNS domain, and that are parsed by the XMLNS parser. Most of the information in these topics also applies to the XML domain, unless it refers to features that are not supported in the XML domain.

Refer to "XMLNS parser" on page 541 for background information.

The following topics provided detailed information about the structure of the message tree that the XMLNS parser builds, and the field types that it uses.

- "XMLNS: The XML declaration" on page 1719
- "XMLNS: The DTD" on page 1720
- "XMLNS: The XML message body" on page 1721

You can find more information about processing XML messages in "Working with XML messages" on page 1697.

XMLNS: The XML declaration
The beginning of an XML message can contain an XML declaration.

The following is an example of a declaration:

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<!DOCTYPE s1 PUBLIC "http://www.ibm.com/example.dtd" "example.dtd">
<s1>........</s1>
```

The XML Declaration is represented by the following types of syntax element:

- "XML.XMLDecl" on page 1719
- "XML.version" on page 1719
- "XML.standalone" on page 1720

"XMLNS: XML declaration example" on page 1720 includes another example of an XML declaration and the tree structure that it forms.

XML.XMLDecl
The XML Declaration is represented in the message tree by a syntax element with field type 'XML.XMLDecl'.

If the XML declaration is created by the XMLNS parser its name is 'XMLDecl'. However, when a message tree is being written, the name is not important; only the field type is used by the parser.

The following shows an example of a declaration:

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<!DOCTYPE s1 PUBLIC "http://www.ibm.com/example.dtd" "example.dtd">
<s1>........</s1>
```

XML.version
The XML version attribute in the XML declaration is represented in the message tree by a syntax element with field type 'XML.version'.

The value of the XML version attribute is the value of the version attribute. It is always a child of an XML.XmlDecl syntaxelement. In the following example, the version element contains the string value 1.0:

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<!DOCTYPE s1 PUBLIC "http://www.ibm.com/example.dtd" "example.dtd">
<s1>........</s1>
```

XML.encoding
The encoding attribute is represented by a syntax element with field type ‘XML.encoding', and is always a child of an XML.XmlDecl syntax element.

In the following example, the encoding attribute has a value of UTF-8.

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<!DOCTYPE s1 PUBLIC "http://www.ibm.com/example.dtd" "example.dtd">
<s1>........</s1>
```

You cannot specify IBM MQ encodings in this element.

In your ESQL, (XML,"Encoding") must include quotation marks, because Encoding is a reserved word.

XML.standalone
The XML standalone element defines the existence of an externally-defined DTD. In the message tree it is represented by a syntax element with field type XML.standalone.

The value of the XML standalone element is the value of the standalone attribute in the XML declaration. It is always a child of an XML.XmlDecl syntax element. The only valid values for the standalone element are yes and no. The following is an example of this:

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<!DOCTYPE s1 PUBLIC "http://www.ibm.com/example.dtd" "example.dtd">
<s1>........</s1>
```

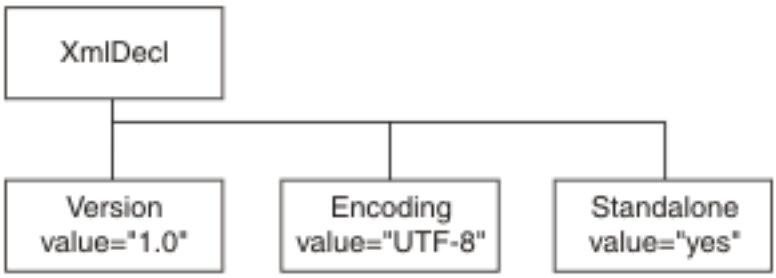
A value of no indicates that this XML document is not standalone, and depends on an externally-defined DTD. A value of yes indicates that the XML document is self-contained. However, because the current release of IBM App Connect Enterprise does not resolve externally-defined DTDs, the setting of standalone is irrelevant, and is ignored.

XMLNS: XML declaration example
The XMLNS parser creates a tree that represents an XML declaration.

The following example shows an XML declaration in an XML document:

```
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
```

The following figure shows the tree structure that the XMLNS parser creates for this declaration:



XMLNS: The DTD
The document type declaration (DTD) of an XML message is represented by a syntax element with field type XML.DocTypeDecl, and its children. These comprise the DOCTYPE construct.

Only internal (inline) DTD subsets are represented in the syntax element tree. An inline DTD is a DTD that is declared within the XML document itself. It can be a complete DTD definition, or it can extend the definition in an external DTD.

External DTD subsets (identified by the SystemID or PublicId elements described later in this section) can be referenced in the message, but those referenced are not resolved by the integration node.

The following field type constants can be used to reference the various parts of a DTD in the message tree:

- XML DocTypeDecl

- XML NotationDecl
- XML entities
- XML ElementDef
- XML AttributeList
- XML AttributeDef
- XML DocTypePI
- XML WhiteSpace and DocTypeWhiteSpace
- XML DocTypeComment

XML DTD example shows an example of an XML DTD.

See XML document type declaration for more information about handling an inline DTD.

XMLNS: The XML message body
Every XML message must have a body. The body consists of a hierarchy of XML elements and other XML constructs that represent the message data.

The XMLNS parser assigns a field type to every syntax element that it creates. The value of the field type indicates the XML construct that it represents. In the following topics, each field type is discussed, with a series of example XML fragments.

The following common element types are discussed:

- “XML.element” on page 1723
- “XML.Attribute” on page 1723

“XML message body example” on page 1727 provides an example of an XML message body and the tree structure that is created from it using the syntax elements types that are listed above.

More complex XML messages might use some of the following syntax element types:

- “XML.CDataSection” on page 1724
- “XML.EntityReferenceStart and XML.EntityReferenceEnd” on page 1725
- “XML.comment” on page 1725
- “XML.ProcessingInstruction” on page 1725
- “XML.AsisElementContent” on page 1726
- “XML.BitStream” on page 1726

Accessing attributes and elements
The XMLNS parser sets the field type on every message tree element that it creates.

The field type indicates the type of XML construct that the element represents. The field types used by the XMLNS parser can be referenced using constants with names prefixed with ‘XML.' Field type constants with prefix ‘XML.' are for use with the XMLNS and XML parsers only; they do not work with the XMLNSC or MRM parsers.

	XMLNS Field Type constant
Tag	XML.Element
Attribute	`XML.Attribute` `XML.Attr`

By using the field type in this way, the XMLNS parser can distinguish between an element and an attribute that have the same name.

Example XML

```
<parent id="12345">
```

```
    <id>ABCDE</id>
</parent>
```

Example ESQL

```
SET value = FIELDVALUE(InputRoot.XMLNS.parent.(XML.Element)id)
Result : value is 'ABCDE'

SET value = FIELDVALUE(InputRoot.XMLNS.parent.(XML.Attr)id)
Result : value is '12345'
```

Example using SELECT to access multiple attributes

In the Example message, the element Title within each Item element has three attributes: Category, Form, and Edition. For example, the first Title element contains:

```
<Title Category="Computer" Form="Paperback" Edition="2">The XML Companion</Title>
```

The element `InputRoot.XML.Invoice.Purchases.Item[1].Title` has four children in the logical tree: Category, Form, Edition, and the element value, which is "The XML Companion".

If you want to access the attributes for this element, you can code the following ESQL. This extract of code retrieves the attributes from the input message and creates them as elements in the output message. It does not process the value of the element itself in this example.

```
-- Set the cursor to the first XML.Attribute of the Title.
-- Note the * after (XML.Attribute) meaning any name, because the name might not be known
DECLARE cursor REFERENCE TO InputRoot.XMLNS.Invoice.Purchases.Item[1].Title.(XML.Attribute)*;
WHILE LASTMOVE(cursor) DO
-- Create a field with the same name as the XML.Attribute
-- and set its value to the value of the XML.Attribute

  SET OutputRoot.XML.Data.Attributes.{FIELDNAME(cursor)} = FIELDVALUE(cursor);
-- Move to the next sibling of the same TYPE to avoid the Title value
-- which is not an XML.Attribute
  MOVE cursor NEXTSIBLING REPEAT TYPE;
END WHILE;
```

When this ESQL is processed by the Compute node, the following output message is generated:

```
<Data>
  <Attributes>
    <Category>Computer</Category>
    <Form>Paperback</Form>
    <Edition>2</Edition>
  </Attributes>
</Data>
```

You can also use a SELECT statement:

```
SET OutputRoot.XMLNS.Data.Attributes[] =
  (SELECT FIELDVALUE(I.Title) AS title,
          FIELDVALUE(I.Title.(XML.Attribute)Category) AS category,
          FIELDVALUE(I.Title.(XML.Attribute)Form) AS form,
          FIELDVALUE(I.Title.(XML.Attribute)Edition) AS edition
     FROM InputRoot.XML.Invoice.Purchases.Item[] AS I);
```

This statement generates the following output message:

```
<Data>
  <Attributes>
    <title>The XML Companion</title>
    <category>Computer</category>
    <form>Paperback</form>
    <edition>2</edition>
  </Attributes>
  <Attributes>
    <title>A Complete Guide to DB2 Universal Database</title>
    <category>Computer</category>
    <form>Paperback</form>
    <edition>2</edition>
  </Attributes>
```

```
  <Attributes>
    <title>JAVA 2 Developers Handbook</title>
    <category>Computer</category>
    <form>Hardcover</form>
    <edition>0</edition>
  </Attributes>
</Data>
```

You can qualify the SELECT with a WHERE statement to narrow down the results to obtain the same output message as the one that is generated by the WHILE statement. This second example shows that you can create the same results with less, and less complex, ESQL.

```
SET OutputRoot.XMLNS.Data.Attributes[] =
  (SELECT FIELDVALUE(I.Title.(XML.Attribute)Category) AS category,
          FIELDVALUE(I.Title.(XML.Attribute)Form) AS form,
          FIELDVALUE(I.Title.(XML.Attribute)Edition) AS edition
     FROM InputRoot.XML.Invoice.Purchases.Item[] AS I)
     WHERE I.Title = 'The XML Companion');
```

This statement generates the following output message:

```
<Data>
  <Attributes>
    <Category>Computer</Category>
    <Form>Paperback</Form>
    <Edition>2</Edition>
  </Attributes>
  </Data>
```

XML.element
This syntax element represents an XML element (a tag).

The name of the syntax element corresponds to the name of the XML element in the message. This element can have many children in the message tree, including attributes, elements, and content.

XML.tag is supported as an alternative to XML.element for compatibility with earlier versions of the product. Use XML.element in any new message flows that you create.

XML.Attribute
The XMLNS parser uses this field type for syntax elements that represent an XML attribute.

Parsing

The name and value of the syntax element correspond to the name and value of the XML attribute that is represented. Attribute elements have no children and must always be children of an element.

Writing

When the XMLNS parser generates a bit stream from a message tree, occurrences of ampersand (&), less than (<), greater than (>), double quotation mark ("), and apostrophe ('), within the attribute value, are replaced by the predefined XML entities &, <, >, ", and '.

The XML.attr field type constant is also supported for compatibility with earlier versions.

XML.content
The XMLNS parser uses this syntax element to represent character data (including an XML attribute).

The name and value of the syntax element correspond to the name and value of the XML attribute that is represented. Attribute elements have no children and must always be children of an element.

Writing

When the XMLNS parser generates a bit stream from a message tree, occurrences of ampersand (&), less than (<), greater than (>), double quotation mark ("), and apostrophe ('), within the attribute value, are replaced by the predefined XML entities &, <, >, ", and '.

XML.CDataSection
CData sections in the XML message are represented by a syntax element with field type XML.CdataSection.

The content of the CDataSection element is the value of the CDataSection element without the <![CDATA[that marks its beginning, and the]]> that marks its end.

For example, the following CData section:

```
<![CDATA[<greeting>Hello, world!</greeting>]]>
```

is represented by a CDataSection element with a string value of:

```
"<greeting>Hello, world!</greeting>"
```

Unlike Content, occurrences of <,>, &, ", and ' are not translated to their XML character entities (<, >, and &) when the CDataSection is produced.

When to use XML.CDataSection

A CData section is often used to embed one XML message within another. By using a CData section, you ensure that the XML reserved characters (<, >, and &) are not replaced with XML character entities.

XML.AsisElementContent also allows the production of unmodified character data, but XML.CDataSection is typically a better choice because it protects the outer message from errors in the embedded message.

Parsing the contents of a CDataSection

A common requirement is to parse the contents of a CData section to create a message tree, which you can achieve by using the ESQL statement CREATE with the PARSE clause; see "XMLNSC: Working with XML messages and bit streams" on page 1702.

XML.NamespaceDecl
A namespace declaration is represented by a syntax element with field type XML.NamespaceDecl.

Namespace declarations take one of two forms in the message tree:

- **Declaration using a namespace prefix**

  ```
  <ns1:e1 xmlns:ns1="namespace1"/>
  ```

  In the message tree, the syntax element for this namespace declaration is shown in the following table:

Namespace	
Name	
Value	

- **Declaration of a default namespace**

  A default namespace declaration is an xmlns attribute that defines an empty prefix

  ```
  <e1 xmlns="namespace1"/>
  ```

  In the message tree, the syntax element for this namespace declaration is shown in the following table:

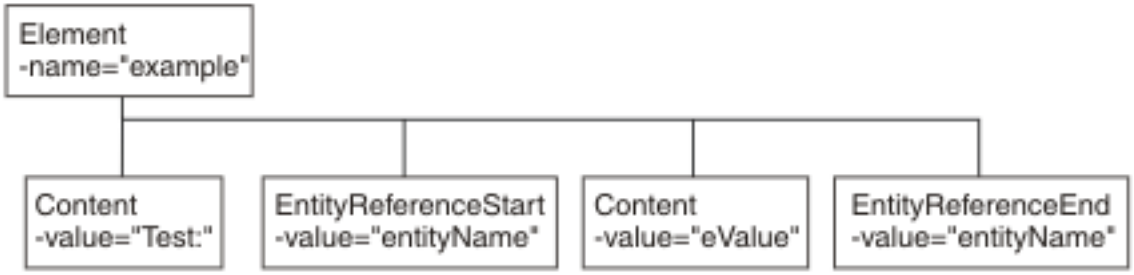
Namespace	""
Name	xmlns
Value	namespace1

  Note that, in both cases, element ‘e1' is in namespace ‘namespace1'.

XML.EntityReferenceStart and XML.EntityReferenceEnd
When an entity reference is encountered in the XML message, both the expanded form and the original entity name are stored in the syntax element tree. The name of the entity is stored as the value of the EntityReferenceStart and EntityReferenceEnd syntax elements, and any syntax elements between contain the entity expansion.

The following examples show the XML entity references in an XML document, and in tree structure form.

```
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
<!DOCTYPE example [ <!ENTITY entityName "eValue"> ]>
<example>Test: &entityName;</example>
```



The XML declaration and the document type declaration are not shown here. Refer to "XMLNS: The XML declaration" on page 1719 and "XMLNS: The DTD" on page 1720 for details of those sections of the syntax element tree.

XML.comment
An XML.comment that is encountered outside the document type declaration is represented by a syntax element with field type XML.comment. The value of the element is the comment text from the XML message.

If the value of the element contains the character sequence `-->`, the sequence is replaced with the text `-->`. This ensures that the contents of the comment cannot prematurely terminate the comment. Occurrences of the following characters are not translated to their escape sequences:

```
< > & " '
```

The following is an example of the XML comment in an XML document:

```
<example><!-- This is a comment --></example>
```

XML.ProcessingInstruction
A processing instruction that is encountered outside the document type declaration is represented by a syntax element with field type XML.ProcessingInstruction.

This is a name-value element; the name of the syntax element is the processing instruction target name, and the value of the syntax element is the character data of the processing instruction. The value of the syntax element must not be empty. The name cannot be XML in either uppercase or lowercase.

If the value of the element contains the character sequence `?>`, the sequence is replaced with the text `?>`. This ensures that the content of the processing instruction cannot prematurely terminate the processing instruction. Occurrences of the following characters are not translated to their escape sequences:

```
< > & " '
```

The following shows an example of the XML processing instruction in an XML document:

```
<example><?target This is a PI.?></example>
```

XML.AsisElementContent
Use the special field type XML.AsisElementContent to precisely control generated XML.

XML.AsisElementContent is a special field type. Use the field type in a message flow to precisely control the XML that is generated in an output message, without the safeguards of the Element, Attribute, and Content syntax elements. The XMLNS parser never creates elements with this field type.

Try to avoid using AsisElementContent; there is typically a safer alternative approach. If you do use AsisElementContent, it is your responsibility to ensure that the output message is well-formed XML.

You might choose to use AsisElementContent if, for example, you want to suppress the usual behavior in which occurrences of ampersand (&), less than (<), greater than (>), double quotation mark ("), and apostrophe (') are replaced by the predefined XML entities &, <, >, ", and '.

The following example illustrates the use of AsisElementContent. The statement:

```
Set OutputRoot.XMLNS.(XML.Element)Message.(XML.Content) = '<rawMarkup>';
```

generates the following XML in an output message:

```
<Message>&lt;rawMarkup&gt;</Message>
```

However, the statement:

```
Set OutputRoot.XMLNS.(XML.Element)Message.(XML.AsisElementContent) = '<rawMarkup>';
```

generates the following XML in an output message:

```
<Message><rawMarkup></Message>
```

This shows that the value of an AsisElementContent syntax element is not modified before it is written to the output message.

XML.BitStream
BitStream is a specialized element designed to aid the processing of very large messages.

XML.Bitstream is a special field type. When writing an XML message, the value of the BitStream element is written directly into the message, and the name is not important. The BitStream element might be the only element in the message tree.

The value of the element must be of type BLOB; any other data type generates an error when writing the element. Ensure that the content of the element is appropriate for use in the output message; pay special attention to the CCSID and the encoding of the XML text in the BLOB.

Use of the BitStream element is similar to the use of the AsisElementContent element, except that the AsisElementContent type converts its value into a string, whereas the BitStream element uses its BLOB value directly. This is a specialized element designed to aid the processing of very large messages.

The following ESQL excerpts demonstrate some typical use of this element. First, declare the element:

```
DECLARE StatementBitStream BLOB
```

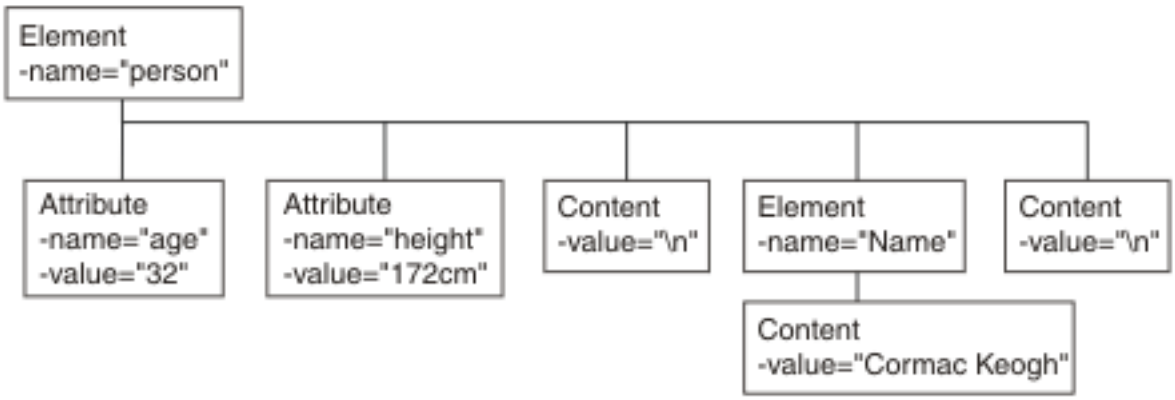
Initialize the contents of StatementBitStream from an appropriate source, such as an input message. If the source field is not of type BLOB, use the CAST statement to convert the contents to BLOB. Then create the new field in the output message; for example:

```
CREATE LASTCHILD OF resultCursor
 Type XML.BitStream
 NAME 'StatementBitStream'
 VALUE StatementBitstream;
```

XML message body example
The XMLNS parser creates a message tree that represents an XML document.

The following example shows the message tree that the XMLNS parser creates for the following snippet from a simple XML document:

```
<Person age="32" height="172cm">
<Name>Cormac Keogh</Name>
</Person>
```



Manipulating messages in the XML domain
The XML parser is like the XMLNS parser, but the XML parser has no support for namespaces or opaque parsing.

About this task

For information about how to work with the XML parser, see "Manipulating messages in the XMLNS domain" on page 1719.

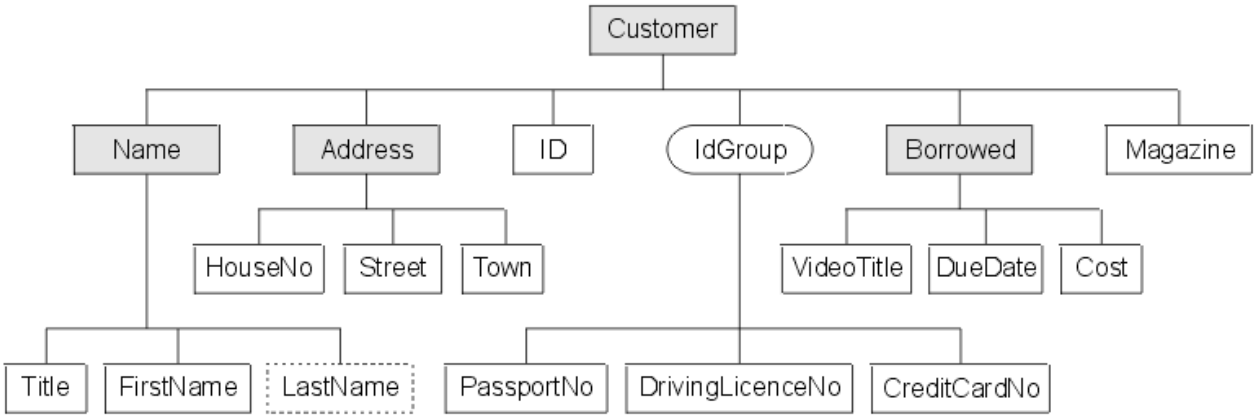
Manipulating messages in the MRM domain
How to use messages that have been modeled in the MRM domain, and that are parsed by the MRM parser.

About this task

The following topics show you how to deal with messages that have been modeled in the MRM domain, and that are parsed by the MRM parser. The physical formats associated with the message models do not affect this information unless specifically stated. Use this information in conjunction with the information about manipulating message body content; see "Manipulating message body content" on page 1632.

- "Accessing elements in a message in the MRM domain" on page 1728
- "Accessing multiple occurrences of an element in a message in the MRM domain" on page 1728
- "Accessing attributes in a message in the MRM domain" on page 1729
- "Accessing elements within groups in a message in the MRM domain" on page 1730
- "Accessing mixed content in a message in the MRM domain" on page 1732
- "Accessing embedded messages in the MRM domain" on page 1733
- "Accessing the content of a message in the MRM domain with namespace support enabled" on page 1734
- "Querying null values in a message in the MRM domain" on page 1734
- "Setting null values in a message in the MRM domain" on page 1735
- "Working with MRM messages and bit streams" on page 1736
- "Handling large MRM messages" on page 1738

The structure of a "Customer" message is shown in the following example.



The message includes a variety of structures that demonstrate how you can classify metadata to the MRM. Within an MRM message set, you can define the following objects: messages, types, groups, elements, and attributes. Folder icons that represent each of these types of objects are displayed for each message definition file in the Integration Development perspective.

Each message definition file can contribute to a namespace. You can combine several message definition files to form a complete message dictionary, which you can then deploy to an integration node.

Accessing elements in a message in the MRM domain
You can use ESQL to manipulate the logical tree that represents a message in the message flow. This topic describes how to access data for elements in a message in the MRM domain.

About this task

You can populate an element with data with the SET statement:

```
SET OutputRoot.MRM.Name = UPPER(InputRoot.MRM.Name);
```

The field reference on the left hand side of the expression refers to the element called Name within the MRM message domain. This statement takes the input value for the Name field, converts it to uppercase, and assigns the result to the same element in the output message.

The Name element is defined in the noTarget namespace. No namespace prefix is specified in front of the Name part of the field reference in the example above. If you have defined an MRM element in a namespace other than the noTarget namespace, you must also specify a namespace prefix in the statement. For example:

```
DECLARE brw NAMESPACE 'http://www.ibm.com/Borrowed';

SET OutputRoot.MRM.brw:Borrowed.VideoTitle = 'MRM Greatest Hits';
```

For more information about using namespaces with messages in the MRM domain, see “Accessing the content of a message in the MRM domain with namespace support enabled” on page 1734.

Accessing multiple occurrences of an element in a message in the MRM domain
You can use specific ESQL code to set the value of one occurrence of an element that has multiple occurrences in a message. You can also use arrow notation to indicate the direction of search when searching for multiple occurrences of an element.

About this task

You can access MRM domain elements following the general guidance given in “Accessing known multiple occurrences of an element” on page 1636 and “Accessing unknown multiple occurrences of an element” on page 1637. Further information specific to MRM domain messages is provided in this topic.

Consider the following statements:

```
DECLARE brw NAMESPACE 'http://www.ibm.com/Borrowed';

SET OutputRoot.MRM.brw:Borrowed[1].VideoTitle = 'MRM Greatest Hits Volume 1';
SET OutputRoot.MRM.brw:Borrowed[2].VideoTitle = 'MRM Greatest Hits Volume 2';
```

The above SET statements operate on two occurrences of the element Borrowed. Each statement sets the value of the child VideoTitle. The array index indicates which occurrence of the repeating element you are interested in.

When you define child elements of a complex type (which has its `Composition` property set to `Sequence`) in a message set, you can add the same element to the complex type more than once. These instances do not have to be contiguous, but you must use the same method (array notation) to refer to them in ESQL.

For example, if you create a complex type with a `Composition` of `Sequence` that contains the following elements:

- `StringElement1`
- `IntegerElement1`
- `StringElement1`

use the following ESQL to set the value of `StringElement1`:

```
SET OutputRoot.MRM.StringElement1[1] =
              'This is the first occurrence of StringElement1';
SET OutputRoot.MRM.StringElement1[2] =
              'This is the second occurrence of StringElement1';
```

You can also use the arrow notation (the greater than (>) and less than (<) symbols) to indicate the direction of search and the index to be specified:

```
SET OutputRoot.MRM.StringElement1[>] =
               'This is the first occurrence of StringElement1';
SET OutputRoot.MRM.StringElement1[<2] =
               'This is the last but one occurrence of
 StringElement1';
SET OutputRoot.MRM.StringElement1[<1] =
               'This is the last occurrence of StringElement1';
```

Refer to “Accessing known multiple occurrences of an element” on page 1636 and “Accessing unknown multiple occurrences of an element” on page 1637 for additional detail.

Accessing attributes in a message in the MRM domain
When an MRM message is parsed into a logical tree, attributes and the data that they contain are created as name-value pairs in the same way that MRM elements are. The ESQL that you code to interrogate and update the data held in attributes refers to the attributes in a similar manner.

About this task

Consider the sample MRM message described in this topic: “Manipulating messages in the MRM domain” on page 1727

The attribute LastName is defined as a child of the Name element in the Customer message. Here is an example input XML message:

```
<Customer xmlns:addr="http://www.ibm.com/AddressDetails"

xmlns:brw="http://www.ibm.com/BorrowedDetails">
   <Name LastName="Bloggs">

```

When the input message is parsed, values are stored in the logical tree as shown in the following section of user trace:

```
(0x0100001B):MRM = (
  (0x01000013):Name = (
    (0x0300000B):LastName = 'Bloggs'
    (0x0300000B):Title = 'Mr'
    (0x0300000B):FirstName = 'Fred'
  )
  (0x01000013)http://www.ibm.com/AddressDetails:Address = (
    (0x0300000B):HouseNo = 13
    (0x0300000B):Street = 'Oak Street'
    (0x0300000B):Town = 'Southampton'
  )
  (0x0300000B):ID = 'P'
  (0x0300000B):PassportNo = 'J123456TT'
  (0x01000013)http://www.ibm.com/BorrowedDetails:Borrowed = (
    (0x0300000B):VideoTitle = 'Fast Cars'
    (0x0300000B):DueDate = TIMESTAMP '2003-05-23 00:00:00'
    (0x0300000B):Cost = 3.50
  )
  (0x01000013)http://www.ibm.com/BorrowedDetails:Borrowed = (
    (0x0300000B):VideoTitle = 'Cut To The Chase '
    (0x0300000B):DueDate = TIMESTAMP '2003-05-23 00:00:00'
    (0x0300000B):Cost = 3.00
  )
  (0x0300000B):Magazine = FALSE
```

The following ESQL changes the value of the LastName attribute in the output message:

```
SET OutputRoot.MRM.Name.LastName = 'Smith';
```

Be aware of the ordering of attributes when you code ESQL. When attributes are parsed, the logical tree inserts the corresponding name-value before the MRM element's child elements. In the previous example, the child elements Title and FirstName appear in the logical message tree after the attribute LastName. In the Integration Development perspective, the Outline view displays attributes after the elements. When you code ESQL to construct output messages, you must define name-value pairs for attributes before any child elements.

Accessing elements within groups in a message in the MRM domain
When an input message is parsed, structures that you have defined as groups in your message set are not represented in the logical tree, but its children are. If you want to refer to or update values for elements that are children of a groups, do not include the group in the ESQL statement. Groups do not have tags that appear in instance messages, and do not appear in user trace of the logical message tree.

About this task

Consider the following Video message:

```
<Customer xmlns:addr="http://www.ibm.com/AddressDetails"
xmlns:brw="http://www.ibm.com/BorrowedDetails">
   <Name LastName="Bloggs">
      <Title>Mr</Title>
      <FirstName>Fred</FirstName>
   </Name>
   <addr:Address>
      <HouseNo>13</HouseNo>
      <Street>Oak Street</Street>
      <Town>Southampton</Town>
   </addr:Address>
            <ID>P</ID>
   <PassportNo>J123456TT</PassportNo>
   <brw:Borrowed>
      <VideoTitle>Fast Cars</VideoTitle>
      <DueDate>2003-05-23T01:00:00</DueDate>
      <Cost>3.50</Cost>
   </brw:Borrowed>
   <brw:Borrowed>
      <VideoTitle>Cut To The Chase</VideoTitle>
      <DueDate>2003-05-23T01:00:00</DueDate>
      <Cost>3.00</Cost>
   </brw:Borrowed>
   <Magazine>0</Magazine>
</Customer>
```

When the input message is parsed, values are stored in the logical tree as shown in the following section of user trace:

```
(0x0100001B):MRM = (
  (0x01000013):Name = (
    (0x0300000B):LastName = 'Bloggs'
    (0x0300000B):Title = 'Mr'
    (0x0300000B):FirstName = 'Fred'
  )
  (0x01000013)http://www.ibm.com/AddressDetails:Address = (
    (0x0300000B):HouseNo = 13
    (0x0300000B):Street = 'Oak Street'
    (0x0300000B):Town = 'Southampton'
  )
  (0x0300000B):ID = 'P'
  (0x0300000B):PassportNo = 'J123456TT'
  (0x01000013)http://www.ibm.com/BorrowedDetails:Borrowed = (
    (0x0300000B):VideoTitle = 'Fast Cars'
    (0x0300000B):DueDate = TIMESTAMP '2003-05-23 00:00:00'
    (0x0300000B):Cost = 3.50
  )
  (0x01000013)http://www.ibm.com/BorrowedDetails:Borrowed = (
    (0x0300000B):VideoTitle = 'Cut To The Chase '
    (0x0300000B):DueDate = TIMESTAMP '2003-05-23 00:00:00'
    (0x0300000B):Cost = 3.00
  )
  (0x0300000B):Magazine = FALSE
```

Immediately following the element named ID, the MRM message definition uses a group which has a *Composition* of Choice. The group is defined with three children: PassportNo, DrivingLicenceNo, and CreditCardNo. The choice composition dictates that instance documents must use only one of these three possible alternatives. The example shown above uses the PassportNo element.

When you refer to this element in ESQL statements, you do not specify the group to which the element belongs. For example:

```
SET OutputRoot.MRM.PassportNo = 'J999999TT';
```

If you define messages within message sets that include XML and TDS physical formats, you can determine from the message data which option of a choice has been taken, because the tags in the message represent one of the choice's options. However, if your messages have CWF physical format, or are non-tagged TDS messages, it is not clear from the message data, and the application programs processing the message must determine which option of the choice has been selected. This is known

as *unresolved choice handling*. For further information, see the description of the value of `Choice` in Message Sets: Complex type logical properties.

Accessing mixed content in a message in the MRM domain
When you define a complex type in a message model, you can optionally specify its content to be mixed. This setting, in support of mixed content in XML Schema, allows you to manipulate data that is included between elements in the message.

About this task

Consider the following example:

```
<MRM>
  <Mess1>
    abc
    <Elem1>def</Elem1>
    ghi
    <Elem2>jkl</Elem2>
    mno
    <Elem3>pqr</Elem3>
  </Mess1>
</MRM>
```

The strings abc, ghi, and mno do not represent the value of a particular element (unlike def, for example, which is the value of element Elem1). The presence of these strings means that you must model Mess1 with mixed content. You can model this XML message in the MRM using the following objects:

Message
The message *Name* property is set to `Mess1` to match the XML tag.

The *Type* property is set to `tMess1`.

Type
The complex type *Name* property is set to `tMess1`.

The *Composition* property is set to `OrderedSet`.

The complex type has mixed content.

The complex type contains the following objects:

Element
The *Name* property is set to `Elem1` to match the XML tag.

The *Type* property is set to simple type `xsd:string`.

Element
The *Name* property is set to `Elem2` to match the XML tag.

The *Type* property is set to simple type `xsd:string`.

Element
The *Name* property is set to `Elem3` to match the XML tag.

The *Type* property is set to simple type `xsd:string`.

If you code the following ESQL:

```
SET OutputRoot.MRM.*[1] = InputBody.Elem3;
SET OutputRoot.MRM.Elem1 = InputBody.*[5];
SET OutputRoot.MRM.*[3] = InputBody.Elem2;
SET OutputRoot.MRM.Elem2 = InputBody.*[3];
SET OutputRoot.MRM.*[5] = InputBody.Elem1;
SET OutputRoot.MRM.Elem3 = InputBody*[1];
```

the mixed content is successfully mapped to the following output message:

```
<MRM>
  <Mess1>
    pqr
    <Elem1>mno</Elem1>
    jkl
    <Elem2>ghi</Elem2>
    def
    <Elem3>abc</Elem3>
  </Mess1>
</MRM>
```

Accessing embedded messages in the MRM domain
If you have defined a multipart message, you have at least one message embedded within another. Within the overall complex type that represents the outer messages, you can model the inner message in two ways.

About this task

You can model the inner message in the following ways:

- An element (named E_outer1 in the following example) with its *Type* property set to a complex type that has been defined with its *Composition* property set to `Message`
- A complex type with its *Composition* property set to `Message` (named t_Embedded in the following example)

The ESQL that you need to write to manipulate the inner message varies depending on which of the above models you have used. For example, assume that you have defined:

- An outer message M_outer that has its *Type* property set to t_Outer.
- An inner message M_inner1 that has its *Type* set to t_Inner1
- An inner message M_inner2 that has its *Type* set to t_Inner2
- Type t_Outer that has its first child element named E_outer1 and its second child defined as a complex type named t_Embedded
- Type t_Embedded that has its *Composition* property set to `Message`
- Type t_Inner1 that has its first child element named E_inner11
- Type t_Inner2 that has its first child element named E_inner21
- Type t_outer1 that has its *Composition* property set to `Message`
- Element E_outer1 that has its *Type* property set to t_outer1

If you want to set the value of E_inner11, code the following ESQL:

```
SET OutputRoot.MRM.E_outer1.M_inner1.E_inner11 = 'FRED';
```

If you want to set the value of E_inner21, code the following ESQL:

```
SET OutputRoot.MRM.M_inner2.E_inner21 = 'FRED';
```

If you copy message headers from the input message to the output message, and your input message type contains a path, only the outermost name in the path is copied to the output message type.

When you configure a message flow to handle embedded messages, you can specify the path of a message type in either an MQRFH2 header (if one is present in the input message) or in the input node *Message Type* property in place of a name (for example, for the message modeled above, the path could be specified as M_Outer/M_Inner1/M_Inner2 instead of just M_Outer).

If you have specified that the input message has a physical format of either CWF or XML, any message type prefix is concatenated in front of the message type from the MQRFH2 or input node, giving a final path to use (for more information refer to “Message Sets: Multipart messages” on page 2175). The MRM uses the first item in the path as the outermost message type, then progressively works inwards when it finds a complex type with its *Composition* property set to `Message`.

If you have specified that the input message has a physical format of TDS, a different process that uses message keys is implemented. This is described in "MRM TDS format: Multipart messages" on page 2197.

For more information about path concatenations, see Message Sets: Message set properties.

Accessing the content of a message in the MRM domain with namespace support enabled
Use namespaces where appropriate for messages that are parsed by the MRM parser.

About this task

When you want to access elements of a message and namespaces are enabled, you must include the namespace when you code the ESQL reference to the element. If you do not do so, the integration node searches the `no target` namespace. If the element is not found in the `no target` namespace, the integration node searches all other known namespaces in the message dictionary (that is, within the deployed message set). For performance and integrity reasons, specify namespaces wherever they apply.

The most efficient way to refer to elements when namespaces are enabled is to define a namespace constant, and use this in the appropriate ESQL statements. This technique makes your ESQL code much easier to read and maintain.

Define a constant using the DECLARE NAMESPACE statement:

```
DECLARE ns01 NAMESPACE 'http://www.ns01.com'
.
.
SET OutputRoot.MRM.ns01:Element1 = InputBody.ns01:Element1;
```

`ns01` is interpreted correctly as a namespace because of the way that it is declared.

You can also use a CHARACTER variable to declare a namespace:

```
DECLARE ns02 CHARACTER 'http://www.ns02.com'
.
.
SET OutputRoot.MRM.{ns02}:Element2 = InputBody.{ns02}:Element2;
```

If you use this method, you must surround the declared variable with braces to ensure that it is interpreted as a namespace.

If you are concerned that a CHARACTER variable might get changed, you can use a CONSTANT CHARACTER declaration:

```
DECLARE ns03 CONSTANT CHARACTER 'http://www.ns03.com'
.
.
SET OutputRoot.MRM.{ns03}:Element3 = InputBody.{ns03}:Element3;
```

You can declare a namespace, constant, and variable within a schema, module, or function.

Querying null values in a message in the MRM domain
You can use an ESQL statement to compare an element to NULL.

About this task

If you want to compare an element to NULL, code the statement:

```
IF InputRoot.MRM.Elem2.Child1 IS NULL THEN
   DO:
    -- more ESQL --
END IF;
```

If nulls are permitted for this element, this statement tests whether the element exists in the input message, or whether it exists and contains the MRM-supplied null value. The behavior of this test depends on the physical format:

- For an XML element, if the XML tag or attribute is not in the bit stream, this test returns TRUE.

- For an XML element, if the XML tag or attribute is in the bit stream and contains the MRM null value, this test returns TRUE.
- For an XML element, if the XML tag or attribute is in the bit stream and does not contain the MRM null value, this test returns FALSE.
- For a delimited TDS element, if the element has no value between the previous delimiter and its delimiter, this test returns TRUE.
- For a delimited TDS element, if the element has a value between the previous delimiter and its delimiter that is the same as the MRM-defined null value for this element, this test returns TRUE.
- For a delimited TDS element, if the element has a value between the previous delimiter and its delimiter that is not the MRM-defined null value, this test returns FALSE.
- For a CWF or fixed length TDS element, if the element's value is the same as the MRM-defined null value for this element, this test returns TRUE.
- For a CWF or fixed length TDS element, if the element's value is not the same as the MRM-defined null value, this test returns FALSE.

If you want to determine if the field is missing, rather than present but with null value, you can use the ESQL CARDINALITY function.

Setting null values in a message in the MRM domain
You can use implicit or explicit null processing to set the value of an element to NULL in an output message.

About this task

To set a value of an element in an output message, you normally code an ESQL statement similar to the following one:

```
SET OutputRoot.MRM.Elem2.Child1 = 'xyz';
```

The equivalent statement is as follows:

```
SET OutputRoot.MRM.Elem2.Child1 VALUE = 'xyz';
```

If you set the element to a non-null value, these two statements give identical results. However, if you want to set the value to null, these two statements do not give the same result:

Procedure

1. If you use the following statement to set the element to NULL, the element is deleted from the message tree:

   ```
   SET OutputRoot.MRM.Elem2.Child1 = NULL;
   ```

   The content of the output bit stream depends on the physical format:

   - For an XML element, neither the XML tag or attribute nor its value are included in the output bit stream.
   - For a Delimited TDS element, neither the tag (if appropriate) nor its value are included in the output bit stream. The absence of the element is typically conveyed by two adjacent delimiters.
   - For a CWF or Fixed Length TDS element, the content of the output bit stream depends on whether you set the `Default Value` property for the element. If you set this property, the default value is included in the bit stream. If you did not set the property, an exception is raised.

   This behavior is called implicit null processing.

2. If you set the value of this element to NULL as follows, the element is not deleted from the message tree. Instead, a special value of NULL is assigned to the element. The content of the output bit stream depends on the settings of the physical format null-handling properties.

```
SET OutputRoot.MRM.Elem2.Child1 VALUE = NULL;
```

   This behavior is called explicit null processing.

Results

Setting a complex element to NULL deletes that element and all its child elements.

Working with MRM messages and bit streams
When you use the ASBITSTREAM function or the CREATE FIELD statement with a PARSE clause you must consider various restrictions.

About this task

The ASBITSTREAM function

If you code the ASBITSTREAM function with the parser mode option set to *RootBitStream*, to parse a message tree to a bit stream, the result is an MRM document in the format specified by the message format that is built from the children of the target element in the normal way.

The target element must be a predefined message defined within the message set, or can be a self-defined message if you are using an XML physical format. This algorithm is identical to that used to generate the normal output bit stream. A well-formed bit stream obtained in this way can be used to re-create the original tree by using a CREATE statement with a PARSE clause.

If you code the ASBITSTREAM function with the parser mode option set to *FolderBitStream*, to parse a message tree to a bit stream, the generated bit stream is an MRM element built from the target element and its children. Unlike *RootBitStream* mode the target element does not have to represent a message; it can represent a predefined element within a message or self-defined element within a message.

So that the MRM parser can correctly parse the message, the path from the message to the target element within the message must be specified in the *Message Type*. The format of the path is the same as that used by message paths except that the message type prefix is not used.

For example, suppose the following message structure is used:

```
          Message
              elem1
                   elem11
                   elem12
```

To serialize the subtree representing element `elem12` and its children, specify the message path `'message/elem1/elem12'` in the *Message Type*.

If an element in the path is qualified by a namespace, specify the namespace URI between {} characters in the message path. For example if element `elem1` is qualified by namespace `'http://www.ibm.com/temp'`, specify the message path as `'message/{http://www.ibm.com/temp}elem1/elem12'`

This mode can be used to obtain a bit stream description of arbitrary sub-trees owned by an MRM parser. When in this mode, with a physical format of XML, the XML bit stream generated is not enclosed by the 'Root Tag Name' specified for the Message in the Message Set. No XML declaration is created, even if not suppressed in the message set properties.

Bit streams obtained in this way can be used to re-create the original tree by using a CREATE statement with a PARSE clause (by using a mode of *FolderBitStream*).

The CREATE statement with a PARSE clause

If you code a CREATE statement with a PARSE clause, with the parser mode option set to *RootBitStream*, to parse a bit stream to a message tree, the expected bit stream is a normal MRM document. A field in the

tree is created for each field in the document. This algorithm is identical to that used when parsing a bit stream from an input node

If you code a CREATE statement with a PARSE clause, with the parser mode option set to *FolderBitStream*, to parse a bit stream to a message tree, the expected bit stream is a document in the format specified by the Message Format, which is either specified directly or inherited. Unlike *RootBitStream* mode the root of the document does not have to represent an MRM message; it can represent a predefined element within a message or self-defined element within a message.

So that the MRM parser can correctly parse the message the path from the message to the target element within the message must be specified in the *Message Type*. The format of the message path is the same as that used for the ASBITSTREAM function described above.

Example of using the ASBITSTREAM function and CREATE statement with a PARSE clause in FolderBitStream mode

The following ESQL uses the message definition described above. The ESQL serializes part of the input tree by using the ASBITSTREAM function, then uses the CREATE statement with a PARSE clause to re-create the subtree in the output tree. The Input message and corresponding Output message are shown below the ESQL.

```
CREATE COMPUTE MODULE DocSampleFlow_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  CALL CopyMessageHeaders();

  -- Set the options to be used by ASBITSTREAM and CREATE ... PARSE
  -- to be FolderBitStream and enable validation
  DECLARE parseOptions INTEGER BITOR(FolderBitStream, ValidateContent,
                       ValidateValue, ValidateLocalError);

  -- Serialise the elem12 element and its children from the input bitstream
  -- into a variable
       DECLARE subBitStream BLOB
         ASBITSTREAM(InputRoot.MRM.elem1.elem12
           OPTIONS parseOptions
           SET 'DocSample'
           TYPE 'message/elem1/elem12'
           FORMAT 'XML1');

       -- Set the value of the first element in the output tree
       SET OutputRoot.MRM.elem1.elem11 = 'val11';

       -- Parse the serialized sub-tree into the output tree
       IF subBitStream IS NOT NULL THEN
           CREATE LASTCHILD OF OutputRoot.MRM.elem1
               PARSE ( subBitStream
                       OPTIONS parseOptions
                       SET 'DocSample'
                       TYPE 'message/elem1/elem12'
                       FORMAT 'XML1');
       END IF;

  -- Convert the children of elem12 in the output tree to uppercase
  SET OutputRoot.MRM.elem1.elem12.elem121 =
   UCASE(OutputRoot.MRM.elem1.elem12.elem121);

  SET OutputRoot.MRM.elem1.elem12.elem122 =
   UCASE(OutputRoot.MRM.elem1.elem12.elem122);

       -- Set the value of the last element in the output tree
       SET OutputRoot.MRM.elem1.elem13 = 'val13';

  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;
```

```
END MODULE;
```

Input message :

```
<message>
    <elem1>
        <elem11>value11</elem11>
        <elem12>
            <elem121>value121</elem121>
            <elem122>value122</elem122>
        </elem12>
        <elem13>value13</elem13>
    </elem1>
</message>
```

Output message :

```
<message>
    <elem1>
        <elem11>val11</elem11>
        <elem12>
            <elem121>VALUE121</elem121>
            <elem122>VALUE122</elem122>
        </elem12>
        <elem13>val13</elem13>
    </elem1
</message
```

Handling large MRM messages
When an input bit stream is parsed, and a logical tree is created, the tree representation of an MRM message is typically larger, and in some cases much larger, than the corresponding bit stream.

About this task

The reasons for this large size include:

- The addition of the pointers that link the objects together
- Translation of character data into Unicode that can double the original size
- The inclusion of field names that can be contained implicitly within the bit stream
- The presence of control data that is associated with the integration node's operation

Manipulation of a large message tree can, therefore, demand a great deal of storage. If you design a message flow that handles large messages that are made up of repeating structures, you can code specific ESQL statements that help to reduce the storage load on the integration node. These statements support both random and sequential access to the message, but assume that you do not need access to the whole message at one time.

These ESQL statements cause the integration node to perform limited parsing of the message, and to keep only that part of the message tree that reflects a single record in storage at a time. If your processing requires you to retain information from record to record (for example, to calculate a total price from a repeating structure of items in an order), you can either declare, initialize, and maintain ESQL variables, or you can save values in another part of the message tree, for example LocalEnvironment.

This technique reduces the memory that is used by the integration node to that needed to hold the full input and output bit streams, plus that required for one record's trees. It provides memory savings when even a few repeats are encountered in the message. The integration node makes use of partial parsing, and the ability to parse specified parts of the message tree, to and from the corresponding part of the bit stream.

To use these techniques in your Compute node apply these general techniques:

- Copy the body of the input message as a bit stream to a special folder in the output message. This creates a modifiable copy of the input message that is not parsed and therefore uses a minimum amount of memory.
- Avoid any inspection of the input message; this avoids the need to parse the message.

- Use a loop and a reference variable to step through the message one record at a time. For each record:
  - Use normal transforms to build a corresponding output subtree in a second special folder.
  - Use the ASBITSTREAM function to generate a bit stream for the output subtree that is stored in a *BitStream* element, placed in the position in the tree, that corresponds to its required position in the final bit stream.
  - Use the DELETE statement to delete both the current input and the output record message trees when you complete their manipulation.
  - When you complete the processing of all records, detach the special folders so that they do not appear in the output bit stream.

You can vary these techniques to suit the processing that is required for your messages. The following ESQL provides an example of one implementation.

The ESQL is dependent on a message set called `LargeMessageExanple` that has been created to define messages for both the Invoice input format and the Statement output format. A message called `AllInvoices` has been created that contains a global element called `Invoice` that can repeat one or more times, and a message called `Data` that contains a global element called `Statement` that can repeat one or more times.

The definitions of the elements and attributes have been given the correct data types, therefore, the CAST statements used by the ESQL in the XML example are no longer required. An XML physical format with name `XML1` has been created in the message set which allows an XML message corresponding to these messages to be parsed by the MRM.

When the `Statement` tree is serialized using the ASBITSTREAM function the *Message Set*, *Message Type*, and *Message Format* are specified as parameters. The *Message Type* parameter contains the path from the message to the element being serialized which, in this case, is `Data/Statement` because the `Statement` element is a direct child of the `Data` message.

The input message to the flow is the same Invoice example message used in other parts of the documentation except that it is contained between the tags:

```
       <AllInvoices> ....  </AllInvoices>
```

Example

```
CREATE COMPUTE MODULE LargeMessageExampleFlow_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  CALL CopyMessageHeaders();
    -- Create a special folder in the output message to hold the input tree
    -- Note : SourceMessageTree is the root element of an MRM parser
    CREATE LASTCHILD OF OutputRoot.MRM DOMAIN 'MRM' NAME 'SourceMessageTree';

    -- Copy the input message to a special folder in the output message
    -- Note : This is a root to root copy which will therefore not build trees
    SET OutputRoot.MRM.SourceMessageTree = InputRoot.MRM;

    -- Create a special folder in the output message to hold the output tree
    CREATE FIELD OutputRoot.MRM.TargetMessageTree;

    -- Prepare to loop through the purchased items
    DECLARE sourceCursor REFERENCE TO OutputRoot.MRM.SourceMessageTree.Invoice;
    DECLARE targetCursor REFERENCE TO OutputRoot.MRM.TargetMessageTree;
    DECLARE resultCursor REFERENCE TO OutputRoot.MRM;
    DECLARE grandTotal   FLOAT     0.0e0;

    -- Create a block so that it's easy to abandon processing
    ProcessInvoice: BEGIN
     -- If there are no Invoices in the input message, there is nothing to do
     IF NOT LASTMOVE(sourceCursor) THEN
        LEAVE ProcessInvoice;
     END IF;

     -- Loop through the invoices in the source tree
     InvoiceLoop : LOOP
        -- Inspect the current invoice and create a matching Statement
        SET targetCursor.Statement =
```

```
        THE (
           SELECT
             'Monthly'                        AS Type,
             'Full'                           AS Style,
             I.Customer.FirstName             AS Customer.Name,
             I.Customer.LastName              AS Customer.Surname,
             I.Customer.Title                 AS Customer.Title,
             (SELECT
                FIELDVALUE(II.Title)    AS Title,
                II.UnitPrice * 1.6    AS Cost,
                II.Quantity                   AS Qty
             FROM I.Purchases.Item[] AS II
             WHERE II.UnitPrice> 0.0               ) AS Purchases.Article[],
             (SELECT
                SUM( II.UnitPrice *
                        II.Quantity  *
                     1.6                          )
              FROM I.Purchases.Item[] AS II                    ) AS Amount,
              'Dollars'                                  AS Amount.Currency
            FROM sourceCursor AS I
            WHERE I.Customer.LastName <> 'White'
          );

      -- Turn the current Statement into a bit stream
      -- The SET parameter is set to the name of the message set
       -- containing the MRM definition
      -- The TYPE parameter contains the path from the from the message
       -- to element being serialized
      -- The FORMAT parameter contains the name of the physical format
       -- name defined in the message
      DECLARE StatementBitStream BLOB
        ASBITSTREAM(targetCursor.Statement
         OPTIONS FolderBitStream
         SET 'LargeMessageExample'
         TYPE 'Data/Statement'
         FORMAT 'XML1');

      -- If the SELECT produced a result (that is, it was not filtered
       -- out by the WHERE clause), process the Statement
      IF StatementBitStream IS NOT NULL THEN
        -- create a field to hold the bit stream in the result tree
        -- The Type of the element is set to MRM.BitStream to indicate
         -- to the MRM Parser that this is a bitstream
        CREATE LASTCHILD OF resultCursor
           Type  MRM.BitStream
           NAME  'Statement'
           VALUE StatementBitStream;

```

Manipulating messages in the JMS domains
This topic provides information specific to dealing with messages that belong to the JMSMap and JMSStream domains. These messages are parsed by the generic XML parser.

About this task

Messages that belong to the JMS domains are processed by the XML parser, so you can follow the guidance provided for XML messages in "Manipulating messages in the XML domain" on page 1727, in conjunction with the information in "Manipulating message body content" on page 1632.

The JMSMap and JMSStream domains support MapMessage and StreamMessage messages. Other kinds of JMS message are supported by other domains. For further information about using JMS messages with IBM App Connect Enterprise, see "Using JMS in IBM App Connect Enterprise" on page 852.

Manipulating messages in the IDOC domain
Use ESQL from a Compute node to copy the incoming IDoc to the outgoing IDoc, and manipulate the message.

About this task

Note: The IDOC domain is deprecated and is not recommended for developing new message flows. Instead use the MRM domain with a TDS physical format. See "MRM parser and domain" on page 545.

A valid IDoc message flows out of SAP and is sent to the MQSeries link for R/3.

When this IDoc has been committed successfully to the outbound IBM MQ queue, the input node of the message flow reads it from that queue and generates the syntax element tree.

The Compute node manipulates this syntax element tree and, when it has finished, passes the output message to subsequent nodes in the message flow. When the message reaches the output node, the IDOC parser is called to rebuild the bit stream from the tree.

The message flow must create an output message in a similar format to the input message.

See Field names of the IDOC parser structures for the field names in the DC (Control Structure) and DD (Data Structure) that are recognized by the IDOC parser

Procedure

Use the following ESQL example from a Compute node:

```
SET OutputRoot = InputRoot;
SET OutputRoot.IDOC.DC[1].tabnam = 'EDI_DC40  ';
SET OutputRoot.IDOC.DD[2].sdatatag.MRM.maktx = 'Buzzing all day';
```

Results

The first line of the code copies the incoming IDoc to the outgoing IDoc.

The second line sets the *tabname* of the first DC.

The third line uses the second DD segment, which in this example is of type E2MAKTM001, and sets the *maktx* field.

Accessing fields of the IDoc using ESQL

About this task

Use the ESQL editor Content Assist to complete the SAP-defined fields of the IDoc.

After the sdatatag tag in an ESQL statement, the next tag is MRM, which you must enter manually, followed by the field name that is to be manipulated. Specify the name of the field within the message segment here, not the name of the message segment.

For example, the following code sets the segment name of the IDoc:

```
SET OutputRoot.IDOC.DD[I].segnam  = 'E2MAKTM001';
```

The following example sets the msgfn field within the E2MAKTM001 segment:

```
SET OutputRoot.IDOC.DD[I].sdatatag.MRM.msgfn = '006';
```

Manipulating messages in the MIME domain

A MIME message does not need to be received over a particular transport. For example, a message can be received over HTTP by using an HTTPInput node, or over IBM MQ by using an MQInput node. The MIME parser is used to process a message if the message domain is set to MIME in the input node properties, or if you are using IBM MQ, and the MQRFH2 header has a message domain of MIME.

This topic explains how to deal with messages that belong to the MIME domain, and are parsed by the MIME parser. Use this information in conjunction with the information in "Manipulating message body content" on page 1632.

You can manipulate the logical tree using ESQL before passing the message on to other nodes in the message flow. A message flow can also create a MIME domain tree using ESQL. When a MIME domain message reaches an output node, the MIME parser is called to rebuild the bit stream from the logical tree.

The following examples show how to manipulate MIME messages:

- "Creating a new MIME tree" on page 1742
- "Modifying an existing MIME tree" on page 1743
- "Managing Content-Type" on page 1743

Creating a new MIME tree

A message flow often receives, modifies, and returns a MIME message. In this case, you can work with the valid MIME tree that is created when the input message is parsed. If a message flow receives input from another domain, such as XMLNS, and returns a MIME message, you must create a valid MIME tree. Use the following ESQL example in a Compute node to create the top-level structure for a single-part MIME tree:

```
CREATE FIELD OutputRoot.MIME TYPE Name;
DECLARE M REFERENCE TO OutputRoot.MIME;
CREATE LASTCHILD OF M TYPE Name NAME 'Data';
```

The message flow must also ensure that the MIME Content-Type is set correctly, as explained in "Managing Content-Type" on page 1743. The flow must then add the message data into the MIME tree. The following ESQL examples show how you can do this. In each case, a Data element is created with the domain BLOB.

- A bit stream from another part of the tree is used. This example shows how a bit stream could be created from an XML message that is received by the message flow. The flow then invokes the BLOB parser to store the data under the Data element.

  ```
  DECLARE partData BLOB ASBITSTREAM(InputRoot.XMLNS);
  ```

```
CREATE LASTCHILD OF M.Data DOMAIN('BLOB') PARSE(partData);
```

- Instead of parsing the bit stream, create the new structure, then attach the data to it, as shown in this ESQL example:

```
DECLARE partData BLOB ASBITSTREAM(InputRoot.XMLNS);
CREATE LASTCHILD OF M.Data DOMAIN('BLOB') NAME 'BLOB';
CREATE LASTCHILD OF M.Data.BLOB NAME 'BLOB' VALUE partData;
```

Both of these approaches create the same tree structure. The first approach is better because explicit knowledge of the tree structure that the BLOB parser requires is not built into the flow.

More commonly, the Compute node must build a tree for a multipart MIME document. The following ESQL example shows how you can do this, including setting the top-level Content-Type property.

```
DECLARE part1Data BLOB ASBITSTREAM(InputRoot.XMLNS, InputProperties.Encoding,
 InputProperties.CodedCharSetId);

SET OutputRoot.Properties.ContentType = 'multipart/related; boundary=myBoundary';

CREATE FIELD OutputRoot.MIME TYPE Name;
DECLARE M REFERENCE TO OutputRoot.MIME;
CREATE LASTCHILD OF M TYPE Name NAME 'Parts';
CREATE LASTCHILD OF M.Parts TYPE Name NAME 'Part';
DECLARE P1 REFERENCE TO M.Parts.Part[1];
CREATE FIELD P1."Content-Type" TYPE NameValue VALUE 'text/plain';
CREATE FIELD P1."Content-Id"   TYPE NameValue VALUE 'part one';
CREATE LASTCHILD OF P1 TYPE Name NAME 'Data';
CREATE LASTCHILD OF P1.Data DOMAIN('BLOB') PARSE(part1Data);

CREATE LASTCHILD OF M.Parts TYPE Name NAME 'Part';
DECLARE P2 REFERENCE TO M.Parts.Part[2];
CREATE FIELD P2."Content-Type" TYPE NameValue VALUE 'text/plain';
CREATE FIELD P2."Content-Id"   TYPE NameValue VALUE 'part two';
CREATE LASTCHILD OF P2 TYPE Name NAME 'Data';
CREATE LASTCHILD OF P2.Data DOMAIN('BLOB') PARSE(part2Data);
```

Modifying an existing MIME tree

This ESQL example adds a new MIME part to an existing multipart MIME message. If the message is not multipart, it is not modified.

```
SET OutputRoot = InputRoot;

-- Check to see if the MIME message is multipart or not.
IF LOWER(InputProperties.ContentType) LIKE 'multipart/%'
THEN
  CREATE LASTCHILD OF OutputRoot.MIME.Parts NAME 'Part';

  DECLARE P REFERENCE TO OutputRoot.MIME.Parts.[<];
  CREATE FIELD P."Content-Type" TYPE NameValue VALUE 'text/xml';
  CREATE FIELD P."Content-ID"   TYPE NameValue VALUE 'new part';
  CREATE LASTCHILD OF P TYPE Name NAME 'Data';

  -- This is an artificial way of creating some BLOB data.
  DECLARE newBlob BLOB '4f6e652074776f2074687265650d0a';
  CREATE LASTCHILD OF P.Data DOMAIN('BLOB') PARSE(newBlob);
END IF;
```

If you receive a MIME message, for example; through an EmailInput node, and you know the format of your message, you might want to reparse the message. For example:

```
CREATE LASTCHILD OF OutputRoot.XMLNSC.emailData  DOMAIN('XMLNSC')
PARSE(InputRoot.MIME.Data.BLOB.BLOB,InputProperties.Encoding,
InputProperties.CodedCharSetId);
```

Managing Content-Type

When you create a new MIME message tree, or when you modify the value of the MIME boundary string, make sure that the MIME Content-Type header is set correctly by setting the ContentType value in the

integration node Properties subtree. The following example shows how to set the ContentType value for a MIME part with simple content:

```
SET OutputRoot.Properties.ContentType = 'text/plain';
```

Do not set the Content-Type value directly in the MIME tree or HTTP trees because the value is ignored or used inconsistently.

When you receive a MIME message, you can filter or route the message content based on the content-Type. The following example shows an XPath query that can be used in a Route node to filter the content based on whether the message contains an attachment or not:

```
starts-with($Root/MIME/Content-Type,"multipart")
```

Manipulating messages in the BLOB domain
How to deal with messages that belong to the BLOB domain, and that are parsed by the BLOB parser.

About this task

You cannot manipulate the contents of a BLOB message, because it has no predefined structure. However, you can refer to its contents using its known position within the bit stream, and process the message with a minimum of knowledge about its contents.

The BLOB message body parser does not create a tree structure in the same way that other message body parsers do. It has a root element BLOB, that has a child element, also called BLOB, that contains the data.

You can refer to message content using substrings if you know the location of a particular piece of information within the BLOB data. For example, the following expression identifies the tenth byte of the message body:

```
InputBody.BLOB.BLOB[10]
```

The following expression references 10 bytes of the message data starting at offset 10:

```
SUBSTRING(InputBody.BLOB.BLOB from 10 for 10)
```

You can use the Mapping node to map to and from a predefined BLOB message, and to map to and from items of BLOB data.

Simple example to write a string in the output message

About this task

The following simple example allows you to write some character data in your ESQL (for example, if you have read some character fields from a database) out as a BLOB:

```
CALL CopyMessageHeaders();
 -- CALL CopyEntireMessage();
 DECLARE mystring CHARACTER;
 SET mystring='hello';
 SET OutputRoot.BLOB.BLOB=CAST (mystring AS BLOB CCSID 1208);
```

Manipulating messages in the JSON domain
You can use the Graphical Data Mapping editor, Java, or ESQL to manipulate JSON messages.

You can create JSON messages that contain JSON objects, JSON arrays, or both, by creating elements in the logical message tree, under the Data element that is owned by the JSON parser root. For more information, see “Creating a JSON message” on page 1745.

You can modify JSON messages. For more information, see “Modifying a JSON message” on page 1746.

Use this information in conjunction with the information in “Manipulating message body content” on page 1632.

Creating a JSON message
You can create JSON message data that contains JSON objects, JSON arrays, or both, by creating elements in the logical message tree, under the `Data` element that is owned by the JSON parser root.

A JSON message can have either an anonymous object or an anonymous array as the root of the data. It is not possible to put a JSON string literal, number, boolean, or null value as the root of the data using the JSON parser. When you create a JSON array in the logical message tree, the JSON array name is placed in a tree element that has a type that is set to the JSON parser element type `JSON.Array`.

The items in the JSON array are placed in the logical tree as `NameValue` elements, as children of the `JSON.Array` element, with the required value. The names of these array item elements are not used by the JSON serializer because JSON array items are anonymous. However, for consistency with the name that is used by the JSON parser, use the name `Item` when you define the array item elements.

Creating a JSON object message

The following example shows how to create a JSON message that is formatted with an object at the root level, with the form `{ --- }`.

This example shows how to create a simple JSON object message with one name-value pair:

```
{"Message":"Hello World"}
```

The following ESQL code can be used to create the message:

```
SET OutputRoot.JSON.Data.Message = 'Hello World';
```

The following Java code can also be used to create the message:

```
MbElement outRoot =
   outMessage.getRootElement();
MbElement outJsonRoot =
   outRoot.createElementAsLastChild(MbJSON.PARSER_NAME);
MbElement outJsonData =
   outJsonRoot.createElementAsLastChild(MbElement.TYPE_NAME, MbJSON.DATA_ELEMENT_NAME, null);
MbElement outJsonTest =
   outJsonData.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Message", "Hello World");
```

Creating a JSON array message

The following example shows how to create a message that is formatted with an array at the root level, in the form `[ --- ]`.

This example shows how to create a JSON array message:

```
["valueA","valueB"]
```

The following ESQL code can also be used to create the array:

```
CREATE FIELD OutputRoot.JSON.Data IDENTITY (JSON.Array)Data;
CREATE LASTCHILD OF OutputRoot.JSON.Data TYPE NameValue NAME 'Item' VALUE 'valueA';
CREATE LASTCHILD OF OutputRoot.JSON.Data TYPE NameValue NAME 'Item' VALUE 'valueB';
```

The following Java code can also be used to create the array:

```
MbElement outJsonRoot =
   outRoot.createElementAsLastChild("JSON");
MbElement outJsonData =
   outJsonRoot.createElementAsLastChild(MbJSON.ARRAY, "Data", null);
   outJsonData.createElementAsLastChild(MbElement.TYPE_NAME_VALUE,
                                        "Item", "valueA");
   outJsonData.createElementAsLastChild(MbElement.TYPE_NAME_VALUE,
                                        "Item", "valueB");
```

The message is created in the integration node logical message tree in the following form:

```
Message: ( ['json' : 0xc552990]
```

```
  (0x01001000:Array     ):Data    = (
    (0x03000000:NameValue):Item = 'valueA' (CHARACTER)
    (0x03000000:NameValue):Item = 'valueB' (CHARACTER)
 )
```

Creating a JSON object array message

The following example shows how to create a message that is formatted with an array of objects at the root level, in the form `[{--},{--},...]`.

This example shows how to create the JSON object array message:

```
[{"Nam1":"val1","Num1":1},{"Nam2":"val2","Num2":2}]
```

The following ESQL code can also be used to create the array:

```
CREATE FIELD OutputRoot.JSON.Data IDENTITY(JSON.Array)Data;
SET OutputRoot.JSON.Data.Item[1].Nam1 = 'val1';
SET OutputRoot.JSON.Data.Item[1].Num1 = 1;
SET OutputRoot.JSON.Data.Item[2].Nam2 = 'val2';
SET OutputRoot.JSON.Data.Item[2].Num2 = 2;
```

The following Java code can also be used to create the array:

```
MbElement jsonData =

 outMessage.getRootElement().createElementAsLastChild(MbJSON.PARSER_NAME).createElementAsLastChild
                                        (MbJSON.ARRAY,MbJSON.DATA_ELEMENT_NAME, null);
MbElement jsonFirstArrayItem =
   jsonData.createElementAsLastChild(MbElement.TYPE_NAME, MbJSON.ARRAY_ITEM_NAME, null);
   jsonFirstArrayItem.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE, "Nam1", "val1");
   jsonFirstArrayItem.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Num1", new
 Integer(1));

MbElement jsonSecondArrayItem =
   jsonData.createElementAsLastChild(MbElement.TYPE_NAME, MbJSON.ARRAY_ITEM_NAME, null);
   jsonSecondArrayItem.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE, "Nam2", "val2");
   jsonSecondArrayItem.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Num2", new
 Integer(2));
```

The message is created in the integration node logical message tree in the following form:

```
Message: ( ['json' : 0xc673900]
  (0x01001000:Array):Data = (
    (0x01000000:Object):Item = (
      (0x03000000:NameValue):nam1 = 'val1' (CHARACTER)
      (0x03000000:NameValue):num1 = 1 (INTEGER)
    )(0x01000000:Object):Item = (
      (0x03000000:NameValue):nam2 = 'val2' (CHARACTER)
      (0x03000000:NameValue):num2 = 2 (INTEGER)
    )
  )
)
```

Modifying a JSON message
You can modify JSON objects and JSON arrays.

JSON data streams are parsed into the logical message tree and placed under the `Data` element that is owned by the JSON parser root. The JSON data objects and arrays can be accessed and modified from each supported language as follows:

- ESQL as `OutputRoot.JSON.Data.`*`path to required object or array`*
- Java as `/JSON/Data/`*`path to required object or array`*

You can also manipulate JSON messages in the Graphical Data Mapping editor. For more information, see Creating or transforming a JSON output message by using a message map.

The following example shows a possible JSON message:

```
{
    "name" : "John Doe",
```

```
    "age" : -1,
    "known" : false,
    "address" : { "street" : null,
                  "city" : "unknown" },
    "belongings" : ["this", "that", "the other"]
}
```

The JSON parser parses the input JSON bit stream, to produce the following integration node logical message tree:

```
(Message):JSON     = ( ['json' : 0xhhhhhh]
    (0x01000000:Object):Data      = (
      (0x03000000:NameValue): name    = 'John Doe' (CHARACTER)
      (0x03000000:NameValue): age     = -1 (INTEGER)
      (0x03000000:NameValue): known   = FALSE (BOOLEAN)
      (0x01000000:Object     ): address = (
        (0x03000000:NameValue): street = NULL (UNKNOWN)
        (0x03000000:NameValue): city = 'unknown' (CHARACTER)
      )
      (0x01001000:Array     ): belongings = (
        (0x03000000:NameValue): Item = 'this' (CHARACTER)
        (0x03000000:NameValue): Item = 'that' (CHARACTER)
        (0x03000000:NameValue): Item = 'the other' (CHARACTER)
      )
    )
  )
```

This message tree can be modified through ESQL as:

```
SET OutputRoot.JSON.Data.age =  InputRoot.JSON.Data.age + 22;   -- Set age to 21
SET OutputRoot.JSON.Data.belongings.Item[4] = 'an other';
SET OutputRoot.JSON.Data.belongings.Item[5] = 'and another';
```

The message tree can be modified through Java as:

```
MbElement ageEl = message.getRootElement().getLastChild().getFirstElementByPath("/JSON/Data/
age");
int age = ((Integer)ageEl.getValue()).intValue();
ageEl.setValue(age + 22);       // Set age to 21
inMessage.getRootElement().getLastChild().getFirstElementByPath("/JSON/Data/belongings/
Item[3]").setValue('an other');
```

JSON with a multidimensional array

The following example shows JSON input containing a multidimensional array:

```
{
    "customer" : "Joe",
    "orders" : [ [ "thing1", 1, 10.1 ],
                 [ "thing2", 2, 20.2 ]  ]
}
```

The following integration node message tree is produced:

```
(Message):JSON   = ( ['json' : 0xhhhhhh]
    (0x01000000:Object):Data   = (
      (0x03000000:NameValue):customer = 'Joe' (CHARACTER)
      (0x01001000:Array):orders = (
        (0x01001000:Array):Item   = (
          (0x03000000:NameValue):Item = 'thing1' (CHARACTER)
          (0x03000000:NameValue):Item = 1 (INTEGER)
          (0x03000000:NameValue):Item = 1.01E+1 (FLOAT)
        )
        (0x01001000:Array):Item   = (
          (0x03000000:NameValue):Item = 'thing2' (CHARACTER)
          (0x03000000:NameValue):Item = 2 (INTEGER)
          (0x03000000:NameValue):Item = 2.02E+1 (FLOAT)
        )
      )
    )
  )
```

This message tree is accessed through ESQL in the following way (you can use either the name *Item* or an asterisk (*) as a wildcard):

```
InputRoot.JSON.Data.orders.Item[1].Item[1]   -- 'thing1'
InputRoot.JSON.Data.orders.*[2].*[3]         -- 2.02E+1
```

The message tree is accessed through Java in the following way (you can use either the name *Item*, which the JSON parser gives to array items, or an asterisk (*) as a wildcard):

```
inMessage.getRootElement().getFirstElementByPath("/JSON/Data/orders/Item[1]/Item[1]");  //
 'thing1'
inMessage.getRootElement().getFirstElementByPath("/JSON/Data/orders/*[2]/*[3]");  // '2.02'
```

Using the CALL statement to call a user-written routine
The ESQL CALL statement calls routines that have been created and implemented in different ways.

About this task

A routine is a user-defined function or procedure that has been defined by one of the following statements:

- CREATE FUNCTION
- CREATE PROCEDURE

You can use the CALL statement to call a routine that has been implemented in any of the following ways:

- ESQL
- Java
- As a stored procedure in a database
- As a function that is provided by IBM App Connect Enterprise

  You can use CALL to call built-in functions and user-defined SQL functions, but typically you use their names directly in expressions .

For details of the syntax and parameters of the CALL statement, see CALL statement. For an example of the use of CALL, see the examples in CREATE PROCEDURE statement.

Calling an ESQL routine

About this task

A routine is called as an ESQL method if the routine's definition specifies a LANGUAGE clause of ESQL or if the routine is a built-in function. An exact one-to-one matching of the data types and directions of each parameter, between the definition and the CALL, is required. An ESQL routine is allowed to return any ESQL data type, excluding List and Row.

Calling a Java routine

About this task

A routine is called as a Java method if the routine's definition specifies a LANGUAGE clause of JAVA. An exact one-to-one matching of the data types and directions of each parameter, between the definition and the CALL, is required. If the Java method has a void return type, the INTO clause cannot be used because no value exists to return.

A Java routine can return any data type in the ESQL-to-Java data-type mapping table, excluding List and Row.

Calling a database stored procedure

About this task

A routine is called as a database stored procedure if the routine's definition has a LANGUAGE clause of DATABASE.

When a call is made to a database stored procedure, the integration node searches for a definition (created by a CREATE PROCEDURE statement) that matches the procedure's local name. The integration node then uses the following sequence to resolve the name by which the procedure is known in the database and the database schema to which it belongs:

1. If the CALL statement specifies an IN clause, the name of the data source, the database schema, or both, is taken from the IN clause.
2. If the name of the data source is not provided by an IN clause on the CALL statement, it is taken from the DATASOURCE attribute of the node.
3. If the database schema is not provided by an IN clause on the CALL statement, but is specified on the EXTERNAL NAME clause of the CREATE PROCEDURE statement, it is taken from the EXTERNAL NAME clause.
4. If no database schema is specified on the EXTERNAL NAME clause of the CREATE PROCEDURE statement, the database's user name is used as the schema name. If a matching procedure is found, the routine is called.

The chief use of the CALL statement's IN clause is that it allows the data source, the database schema, or both, to be chosen dynamically at run time. (The EXTERNAL SCHEMA clause also allows the database schema which contains the stored procedure to be chosen dynamically, but it is not as flexible as the IN clause and is retained only for compatibility with earlier versions. Its use in new applications is deprecated.)

If the called routine has any DYNAMIC RESULT SETS specified in its definition, the number of expressions in the CALL statement's *ParameterList* must match the number of parameters to the routine, plus the number of DYNAMIC RESULT SETS. For example, if the routine has three parameters and two DYNAMIC RESULT SETS, the CALL statement must pass five parameters to the called routine. The parameters passed for the two DYNAMIC RESULT SETS must be list parameters; that is, they must be field references qualified with array brackets [ ]; for example, Environment.ResultSet1[].

A database stored procedure is allowed to return any ESQL data type, excluding Interval, List, and Row.

Configuring a message flow at deployment time with user-defined properties
Use user-defined properties (UDPs) to configure message flows at deployment and run time, without modifying program code. You can give a UDP an initial value when you declare it in your program, or when you use the Message Flow editor to create or modify a message flow.

Before you begin

For an overview of user-defined properties, see “User-defined properties” on page 569.

For an example of how to code a UDP statement, see DECLARE statement.

About this task

In ESQL, you can define UDPs at the module or schema level. After a UDP has been defined in the Message Flow editor, you can modify the value before you deploy it. You can also modify the value of a UDP dynamically at run time by using the administration REST API, as described in “Setting message flow user-defined properties at run time by using the administration REST API” on page 436.

To configure UDPs, complete the following steps.

Procedure

1. Open the BAR file.

   The contents of the BAR file are shown on the **Manage** tab of the BAR File editor. On this tab, you can expand a flow to show the individual nodes that it contains.
2. Click the relevant message flow or subflow (not the `.cmf` compiled message flow file).

   The UDPs that are defined in that flow are displayed with their values in the **Properties** view.
3. If the value of the UDP is unsuitable for your current environment or task, change it to an appropriate value.

   The value of the UDP is set at the flow level, and is the same for all eligible nodes that are contained in the flow.

   Note: If a subflow includes a UDP that has the same name as a UDP in the main flow, the value of the UDP in the subflow is not changed.
4. Save your BAR file.

What to do next

Deploy the message flow by following the instructions in "Deploying integration solutions to a production environment" on page 2480.

Accessing a user-defined policy by using ESQL
Use ESQL to query properties dynamically at run time, in user-defined policies.

Before you begin

Complete the following tasks:

- "Creating a message flow" on page 574
- User Defined policy (UserDefined)

About this task

If you created a user-defined policy, and created properties for that policy, you can query those properties by using a Java class method that can be called from ESQL. For example, you can create a user-defined policy to set timeouts for processing HTTP messages.

Procedure

1. Create a Java class with a static method that can be called from the ESQL `mypolicyaccessclass.getpolicyproperty()`.

   In this method, you can access the policy by using the provided Java class `mbpolicy`, as shown in "Accessing a user-defined policy from a JavaCompute node" on page 1785.
2. Right-click the Compute node and click **Open ESQL** to create and open an ESQL file in the Editor view, or open an existing file.
3. Create a Java class called `MyPolicyAccessClass` with a static method called `getPolicyProperty()`.

   This method uses the MbPolicy Java class to return a Java string that contains the policy property. For more information, see "Policies overview" on page 324.
4. Add user code as shown below. In the example shown, a user-defined policy called MyUDCS has been defined in a policy project called PP1.

```
CREATE FUNCTION getPolicyProperty( IN policyName CHARACTER, IN propertyName CHARACTER )
  RETURNS CHARACTER
  LANGUAGE JAVA
  EXTERNAL NAME "MyPolicyAccessClass.getPolicyProperty";

DECLARE Property2 CHARACTER;
```

```
SET Property2=getPolicyProperty('{PP1}:MyUDCS', 'prop2');
```

This lookup syntax can be qualified by policy project. If no policy project is qualified, the policy project that is defined on the *defaultPolicyProject* property in the `node.conf.yaml` configuration file is used. Null is returned if either the property or the policy does not exist.

5. Create and deploy the Java class that is called from the ESQL code that you added in step 2, to access and return the policy property.
For example:

```
import com.ibm.broker.plugin.MbPolicy;
public class MyPolicyAccessClass {
  public static String getPolicyProperty(String policyName, String propertyName ) {
    String resultPropertyValue = null;
    try {
      MbPolicy myPol = MbPolicy.getPolicy("UserDefined", policyName);
      if (myPol != null) {
        resultPropertyValue = myPol.getPropertyValueAsString(propertyName);
        if (resultPropertyValue == null) {
          System.out.println("Unable to find property '"+propertyName+"' in UserDefined
 policy with name '"+policyName+"'");
        } else {
          System.out.println("Found property '"+propertyName+"' with value
 '"+resultPropertyValue+"' in UserDefined policy with name '"+policyName+"'");
        }
      } else {
        System.out.println("Unable to find UserDefined policy with name '"+policyName+"'");
      }
    } catch (MbException mbe) {
      System.out.println("Exception caught trying to find UserDefined policy with name
 '"+policyName+"'. Exception details: '"+mbe.toString()+"'");
    }
    return resultPropertyValue;
} }
```

Developing Java

When you use the JavaCompute node, you customize it to determine the exact processing that it provides.

About this task

You can add any valid Java code to a JavaCompute node, making full use of the Java user-defined node API to process an incoming message. You can use the Java editing facilities of the Eclipse platform to develop your Java code. These facilities include:

- Code completion
- Integrated Javadoc documentation
- Automatic compilation

The Java user-defined node API includes some extra methods that simplify tasks that involve message routing and transformation. These tasks include accessing named elements in a message tree, setting their values, and creating elements, without the need to navigate the tree explicitly.

Use the Debug perspective to debug a message flow that contains a JavaCompute node. When control passes to a JavaCompute node during debugging, the perspective opens the Java debugger, and you can step through the Java class code for the node.

Developers can use any of the following programming styles:

- Java Plugin API
- Java Architecture for XML Binding (JAXB)
- Document Object Model (DOM)

This section provides the following information on developing Java:

- “Java overview” on page 1752
- “Writing Java” on page 1755

Java overview

The Java code that you provide to modify or customize the behavior of a JavaCompute node is stored in a Java project. IBM App Connect Enterprise uses the Eclipse Java perspective for developing and administering Java files.

The topics in this section introduce the following Java concepts:

- Java isolation
- “Java shared classloader” on page 1752
- “JavaCompute node class loading” on page 1754
- “JavaCompute node class loading by using a policy” on page 1754

Java shared classloader

The Java shared classloader loads all the JAR files that are located within the shared-classes directories. For integration servers that are associated with an integration node, the precedence order of loading is dictated by the directories in which the JAR files are located. For independent integration servers, the JAR files are placed in the shared-classes directory under the integration server work directory for the integration server.

The way in which the JAR files are loaded depends on whether the integration server is associated with an integration node or is independent of an integration node:

- **Integration servers associated with an integration node:**

  JAR files are loaded in the following precedence order:

  1. JAR files placed in the integration server `shared-classes` directory allow only a single defined integration server to access them. Files placed in here are loaded first. No other integration servers can use them.

     Add the JAR files to the following directory:

     – For Windows

       workpath\config\<*my_int_node_name*>\<*my_int_server_label*>\shared-classes

     – For Linux

       workpath/config/<*my_int_node_name*>/<*my_int_server_label*>/shared-classes

     Ensure that the integration node name, and any integration servers created, contain only characters that are valid on your file system. You may also need to create the required directory structure.

     All files placed into the integration server `shared-classes` directory that have a `.jar` extension, are loaded and made available in the Java environment for that integration server. JAR files in this directory take precedence over JAR files in the integration node `shared-classes` directory.

     Note: If the integration server `shared-classes` directory is empty when the integration server is deleted, the directory is automatically removed.

  2. JAR files placed in the integration node `shared-classes` directory allow only a single defined integration node to access them. Files placed in here are loaded after any files placed in the integration server `shared-classes` directory. No other integration node can use them.

     Add the JAR files to the following directory:

     – For Windows

       workpath\config\<*my_int_node_name*>\shared-classes

     – For Linux

       workpath/config/<*my_int_node_name*>/shared-classes

       Ensure that the integration node name contains only characters that are valid on your file system. You may also need to create the required directory structure.

       All files placed into the integration node `shared-classes` directory that have a `.jar` extension, are loaded and made available in the Java environment for all integration servers in that integration node. JAR files in this directory take precedence over JAR files in the top level `shared-classes` directory.

       Note: If the integration node `shared-classes` directory is empty when the integration node is deleted, the directory is automatically removed.

  3. JAR files placed in the top level `shared-classes` directory are made available to all integration node and all integration servers. Files placed in here are loaded after any files placed in the integration node `shared-classes` directory.

     Add the JAR files to the following directory:

     – For Windows

       workpath\shared-classes

     – For Linux

       workpath/shared-classes

- **Independent integration servers:**

  The Java shared classloader loads all the JAR files that are located within the shared-classes directories. JAR files are placed in the shared-classes directory under the integration server work directory for the integration server. For example, if the work directory passed to the command on

startup is `/Users/user1/workDir1`, the shared-classes directory is `/Users/user1/workDir1/shared-classes`.

JavaCompute node class loading
The JavaCompute node loads and runs a Java class that is defined as the `Java class` property on the node. This class is deployed, with any other required classes, in a Java archive (JAR) file.

You can deploy this JAR file in several ways; for example:

- You can deploy the JAR file in a BAR file with the container of the message flow that contains the JavaCompute node.
- You can deploy the JAR file directly to an integration server in a shared library that is referenced by one or more applications or shared libraries.
- You can deploy the JAR file in a BAR file in a shared library that is referenced by one or more applications or shared libraries.

Java classes in shared libraries

You can use a shared library to share the Java classes between multiple solutions, or to provide isolation.

Java classes that are deployed in a shared library are not available to the integration server-wide class loader. When you deploy a shared library that contains Java files, a new class loader is created for that shared library. This class loader contains all Java classes in the shared library, as well as the Java classes from all referenced shared libraries. Delegation does not exist from one shared library class loader to another shared library class loader. Java classes in shared library class loaders are isolated from Java classes in the integration server-wide class loader. Similarly, Java classes in the integration server-wide class loader are isolated from the Java classes in any shared library class loaders.

A Java class can exist in multiple class loaders if that Java class is contained in a shared library that is referenced by other shared libraries. When you update that Java class by redeploying the shared library that contains it, all class loaders for all shared libraries that contain that Java class are deleted and re-created.

Integration server-wide class loader

Java classes that are deployed in a BAR file in the container of the flow that includes the JavaCompute node are loaded by an integration server-wide class loader. Whenever a new or changed JAR file is deployed, the integration server-wide class loader is deleted and re-created with all the currently deployed JAR files. At the same time, all JavaCompute nodes refresh the Java classes that are being used within them, as well as re-creating all the Java static variables. You can modify this behavior by using the `Java classloader service` property on the node, which allows alternative class loaders to be used. For more information, see "JavaCompute node class loading by using a policy" on page 1754.

The integration server-wide class loader first searches all the deployed JAR files for a required class. If a required class cannot be found, it defers to the shared class loader. The shared class loader looks in a set of directories on the integration node machine and loads any JAR files found. It can be used to install any required JAR files that do not need to be repeatedly deployed, such as client libraries that the JavaCompute nodes need to use.

If the required class cannot be found in any of the deployed JAR files, or in the JAR files that are installed in the shared classes directories, a class loader that contains all the integration node supplied classes is checked (for example: this class loader contains the `jplugin2.jar`), followed by the class path, and then finally the Java virtual machine (JVM) system class loader.

Delegation from one class loader to another can occur in one direction only. If a class is resolved in the shared class loader, it cannot create classes directly in the integration server-wide class loader.

JavaCompute node class loading by using a policy
The JavaCompute node loads and runs a Java class that is defined as the `Java class` property on the node. Normally, this class is deployed, along with any other required classes, in a Java archive (JAR) file that is contained in a BAR file. Any Java classes that are deployed in this way are loaded by an integration

server-wide class loader. You can override this behavior by setting the `Javaclass loader service` property on the node to the name of a Java Class Loader policy.

As an alternative to using a policy you can use shared libraries to provide isolation for deployed Java classes. Java classes that are deployed in a shared library are not available to the integration server-wide class loader. When you deploy a shared library that contains Java files, a new class loader is created for that shared library (see "JavaCompute node class loading" on page 1754).

The class loader that is defined by the Java Class Loader policy has a list of JAR files (defined by the `JAR files to be loaded` property), which it owns and uses. Whenever these JAR files are deployed, the policy class loader receives the JAR files and uses them for resolving classes. The JAR files are no longer available to the integration server class loader, and any node that uses that class loader does not have access to any classes that are contained in those JAR files.

The policy class loader first searches all the deployed JAR files that it has received for a required class. If a required class cannot be found, the policy class loader defers to the shared class loader. The shared class loader looks in a set of directories on the integration server machine and loads any JAR files that are found. The shared class loader can be used to install required JAR files that do not need to be deployed repeatedly, such as client libraries that the JavaCompute nodes need to use. You can override this mechanism by setting the `Shared JAR file path` property on the policy to use a specified directory to find installed JAR files, rather than the shared classes directories.

If the required class cannot be found in any of the deployed JAR files, or in the JAR files that are installed in the shared classes directories, a class loader that contains all the integration server-supplied classes is checked (for example, this class loader contains the `jplugin2.jar`), followed by the classpath, and then the Java virtual machine (JVM) system class loader.

Properties of the Java Class Loader policy are defined in Java Class Loader policy (JavaClassLoader).

Writing Java

When you create a message flow, you include input nodes that receive messages and, optionally, output nodes that send out new or updated messages. If the message processing requires it, you can include other nodes after the input node that are customized in Java to complete the actions that your applications need.

About this task

You can customize the processing that some of the built-in nodes provide. In a JavaCompute node, you can provide Java code that controls precisely the behavior of the node. This set of topics discusses how you can use Java to customize the JavaCompute node.

You can use a JavaCompute node to check and manipulate message content. The node can read the contents of the input message, then construct new output messages that are created from all, part, or none of the input message.

You can also use a JavaCompute node to interact with a global cache. You can write Java code that stores data in a global cache, or retrieves data for further processing or routing.

Use the Debug perspective to debug a message flow that contains a JavaCompute node. When control passes to a JavaCompute node during debugging, the perspective opens the Java debugger, allowing you to step through the Java class code for the node.

This section provides more information about writing Java:

Creating Java code for a JavaCompute node
You can associate Java code with your JavaCompute node by using a wizard, setting node properties, or creating a Java project.

Before you begin

Before you complete this task, create a JavaCompute node in your message flow.

About this task

You can store the Java code for a JavaCompute node in the same application as the message flow that contains the JavaCompute node. Alternatively, if you want to share Java classes across multiple solutions, you can store Java code in a shared library and refer to that library from one or more applications that contain message flows with JavaCompute nodes. In this case, if you already have Java classes, you can add them to a shared library before you create your message flows. Alternatively, you can specify a shared library to contain the classes when you create the JavaCompute node.

To associate Java code with a JavaCompute node, use one of the following methods.

- "Use the New Java Compute Node Class wizard to create template code" on page 1756
- "Associate a JavaCompute node with an existing Java class" on page 1757
- "Create a Java project from scratch" on page 1757

*Use the **New Java Compute Node Class** wizard to create template code*

About this task

Use the **New Java Compute Node Class** wizard to create template code.

Procedure

1. In the IBM App Connect Enterprise Toolkit, right-click the JavaCompute node and click **Open Java**.
2. Follow the instructions in the **New Java Compute Node Class** wizard.
   a) On the **Java Compute Node Class** page, set **Source folder** to the application or library that contains the Java classes. Click **Next**.
   b) On the **Java Compute Node Class Template** page, choose one of the following options:
      - For a filter node template, select **Filtering message class**.
      - To change an incoming message, select **Modifying message class**.
      - To create a new message, select **Creating message class**.
      - To process messages by using the JAXB template, select **Process via JAXB class**. If you want to use the **Generate JAXB Java object classes** wizard to create your JAXB Java object classes, or

to update the template code to reference your existing JAXB Java object classes, click **Next**. For more information, see "Creating JAXB Java object classes by using a wizard" on page 1774.

- To execute business rules, select **Process via Operational Decision Manager ruleset**. If you want to use the wizard, click **Next**.

c) Optional: If necessary, change the default Java build settings. Click **Next**.

d) Optional: If necessary, change the default JavaCompute node project name.

3. Click **Finish**.

Results

The Java class file opens in the editor. If you view the basic properties for the JavaCompute node, the **Java class** field is populated with the location of the specified Java class. If your Java classes are stored in a shared library, the **Java classloader service** field contains a qualifier for the shared library that contains the Java class in the form {*sharedLibraryName*}.

Associate a JavaCompute node with an existing Java class

About this task

You can associate a JavaCompute node with an existing Java class that the wizard has generated previously. You can use this method to share the same Java code between multiple nodes.

To associate a JavaCompute node with an existing Java class, complete the following steps:

Procedure

1. In the IBM App Connect Enterprise Toolkit, right-click the JavaCompute node and click **Properties**.
2. In the **Java Class** field, click **Browse** and start to type the name of the required Java class.
   As you type, matching classes are displayed.
3. Select the appropriate class and click **OK**.

Results

The **Java class** field is populated with the location of the specified Java class. If your Java classes are stored in a shared library, the **Java classloader service** field contains a qualifier for the shared library that contains the Java class in the form {*sharedLibraryName*}. View the Java class by double-clicking the JavaCompute node.

Create a Java project from scratch

About this task

You can create a Java project from scratch. Before you add one or more classes to the project, complete the following steps.

Procedure

1. Open the `.project` file in the text editor, and ensure that the following builders and natures are set:

```
<buildSpec>
  <buildCommand>
   <name>org.eclipse.jdt.core.javabuilder</name>
   <arguments>
   </arguments>
  </buildCommand>
  <buildCommand>
   <name>com.ibm.etools.mft.java.builder.javabuilder</name>
   <arguments>
   </arguments>
  </buildCommand>
  <buildCommand>
   <name>com.ibm.etools.mft.jcn.jcnbuilder</name>
```

```
    <arguments>
    </arguments>
   </buildCommand>
   <buildCommand>
    <name>com.ibm.etools.mft.bar.barbuilder</name>
    <arguments>
    </arguments>
   </buildCommand>
  </buildSpec>
  <natures>
   <nature>org.eclipse.jdt.core.javanature</nature>
   <nature>com.ibm.etools.mft.bar.barnature</nature>
   <nature>com.ibm.etools.mft.jcn.jcnnature</nature>
  </natures>
```

2. Add the following plug-ins to the build path of the Java project:
   a. Open the properties of the Java project.
   b. Select **Java Build Path** and open the **Libraries** tab.
   c. Click **Add Variable**.
   d. Select the variable `JCN_HOME` and click **OK**.
   e. Double-click the variable you added to open the **Edit Variable Entry** dialog.
   f. Click **Extension** and select `javacompute.jar`.
   g. Repeat the previous four steps to add the variable `JCN_HOME/jplugin2.jar`.
3. Create the appropriate Java class and ensure that it extends from `com.ibm.broker.javacompute.MbJavaComputeNode`.

Results

You have created your Java project.

What to do next

You can now complete the following tasks:

- “Opening an existing Java file” on page 1758
- “Saving a Java file” on page 1759
- “Adding Java code dependencies” on page 1759

Opening an existing Java file
You can add to and modify Java code that you have created in a Java project.

Before you begin

Before you start this task, complete the following tasks:

- Add a node to your message flow.
- “Creating Java code for a JavaCompute node” on page 1756

About this task

To open an existing Java file:

Procedure

1. Switch to the Java perspective.
2. In the Package Explorer view, double-click the Java file that you want to open.
   The file is opened in the editor view.
3. Work with the contents of the file to make your changes.

Results

You can also open a Java file when you have a message flow open in the editor view. Right-click the JavaCompute node, then select **Open Java**.

What to do next

You can now perform the following tasks:

- "Saving a Java file" on page 1759
- "Adding Java code dependencies" on page 1759

Saving a Java file

When you edit your Java files, save them to preserve the additions and modifications that you have made.

Before you begin

To complete this task, you must have completed the following tasks:

- Add a node to your message flow.
- "Creating Java code for a JavaCompute node" on page 1756

About this task

To save a Java file:

Procedure

1. Switch to the Java perspective.
2. Create a new Java file or open an existing Java file.
3. Make the changes to the contents of the Java file.
4. When you have finished working, click **File** > **Save** or **File** > **Save All** to save the file and retain all your changes.

What to do next

You can now perform the following task:

- "Adding Java code dependencies" on page 1759

Adding Java code dependencies

When you write Java code for a JavaCompute node, you can include references to other Java projects and JAR files.

Before you begin

To complete this task, you must have completed the following tasks:

- Add a node to your message flow.
- Create Java code for a JavaCompute node.

About this task

The Java code in a JavaCompute node might contain references to other Java projects in the Eclipse workspace (internal dependencies), or to external JAR files, for example the JavaMail API (external dependencies), or a set of JAXB Java object classes (internal or external). If other JAR files are referenced, you must add the files to the project class path.

See "Using JAXB with a JavaCompute node" on page 1772 for an example of a project using Java objects generated by the JAXB binding compiler.

Procedure

1. Right-click the project folder for the project on which you are working, and click **Properties**.
2. Click **Java Build Path** in the left pane.
3. Click the **Libraries** tab.
4. Complete one of the following steps:
   - To add an internal dependency, click **Add JARs**, select the JAR file that you want to add, then click **OK**.
   - To add an external dependency, click **Add External JARs**, select the JAR file that you want to add, then click **Open**. Copy the JAR file to the `shared-classes` directory required. If you do not copy the JAR file to a valid `shared-classes` directory, `ClassNotFoundException` exceptions are generated at run time.

Results

You have now added a code dependency.

Deploying JavaCompute node code
You can deploy Java code for a JavaCompute node in a BAR file or independently in another container, such as a shared library.

Before you begin

Complete the following tasks:

1. Create a message flow that contains a JavaCompute node.
2. Create the Java code for the JavaCompute node.

About this task

After you create a JavaCompute node and the Java code that it uses, you can deploy your resources. The method of deployment depends on where you store your resources.

You can store the Java code for a JavaCompute node in the same application as the message flow that contains the JavaCompute node. Alternatively, to share Java classes across multiple solutions, store Java code in a shared library and refer to that library from one or more applications that contain JavaCompute nodes.

Use one of the following methods to deploy your Java code.

Procedure

- If your Java code is in the same application as the JavaCompute node, deploy the application by adding it to a BAR file or by dragging it to an integration server. When you deploy an application that contains a JavaCompute node, the IBM App Connect Enterprise Toolkit packages the compiled Java code and its dependencies into the BAR file.
- If your Java code is contained in a referenced shared library, deploy the shared library by dragging it onto the integration server or adding it to a BAR file. You must deploy the shared library before or with the applications that reference it.

Results

Your resources are deployed to the integration server. You can view them in the Integration nodes view.

When you update and redeploy the Java code in a shared library, those updates are available automatically to all the applications that reference that shared library. In this case, you do not need to redeploy those applications.

Manipulating message body data by using a JavaCompute node
You can manipulate message body data by using a JavaCompute node.

About this task

The message body is always the last child of root, and its parser name identifies it, for example XML or MRM.

The following topics describe how to refer to, modify, and create message body data. The information provided here is domain independent:

- "Accessing elements in a message tree from a JavaCompute node" on page 1761
- "Transforming a message by using a JavaCompute node" on page 1764
- "Creating a simple filter by using a JavaCompute node" on page 1769
- "Propagating a message to the JavaCompute node Out and Alternate terminals" on page 1770
- "Extracting information from a message by using XPath 1.0 and a JavaCompute node" on page 1770

Accessing elements in a message tree from a JavaCompute node
Access the contents of a message, for reading or writing, using the structure and arrangement of the elements in the tree that the parser creates from the input bit stream.

About this task

Follow the relevant parent and child relationships from the top of the tree downwards until you reach the required element.

The message tree is passed to a JavaCompute node as an argument of the `evaluate` method. The argument is an MbMessageAssembly object. MbMessageAssembly contains four message objects:

- Message
- Local Environment
- Global Environment
- Exception List

These objects are read-only, except for Global Environment. If you try to write to the read-only objects, an MbReadOnlyException is issued.

Alternatively, use JAXB Java objects with getter and setter methods; see "Using JAXB with a JavaCompute node" on page 1772.

This topic contains the following information about accessing elements in a message tree:

- "Traversing the element tree" on page 1761
- "Accessing information about an element" on page 1763

Traversing the element tree

About this task

The following table shows the Java methods that you can use to access element trees, and the equivalent ESQL field type constant for each point in the tree.

Java accessor from MbMessageAssembly	ESQL field type constant
getMessage().getRootElement()	InputRoot
getMessage().getRootElement().getLastChild()	InputBody
getLocalEnvironment().getRootElement()	InputLocalEnvironment
getGlobalEnvironment().getRootElement()	Environment

Java accessor from MbMessageAssembly	ESQL field type constant
getExceptionList().getRootElement()	InputExceptionList

Use the following methods to traverse a message tree from an element of type MbElement:

getParent()
returns the parent of the current element

getPreviousSibling()
returns the previous sibling of the current element

getNextSibling()
returns the next sibling of the current element

getFirstChild()
returns the first child of the current element

getLastChild()
returns the last child of the current element

Alternatively, use a Document Object Model (DOM) object, and use the DOM API to navigate and manipulate the elements.

MBMessage provides the following methods:

getDOMDocument()
obtains a W3C `org.w3c.dom.Document` object for the message body.

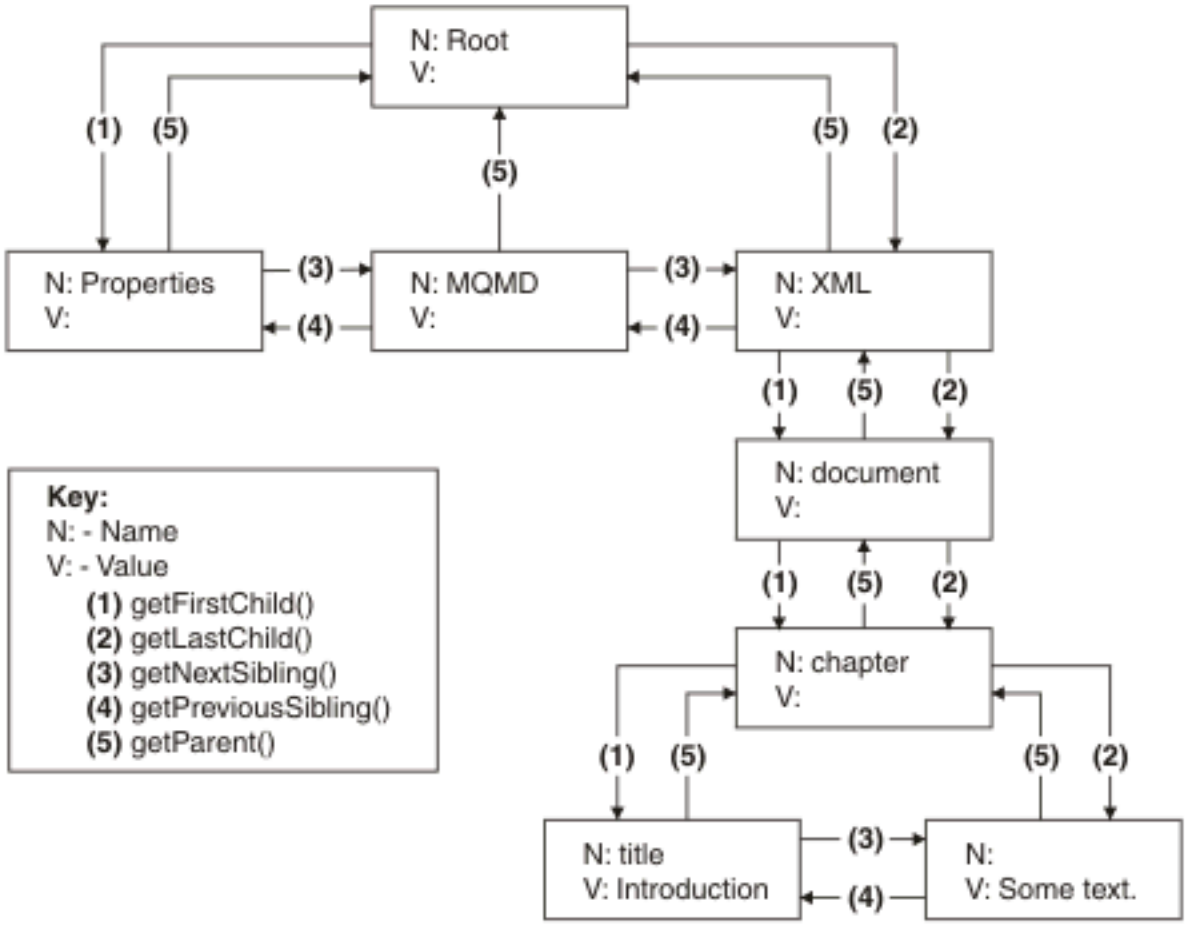
createDOMDocument()
obtains a W3C `org.w3c.dom.Document` object for the message body.

MbElement provides the following method:

getDOMNode()
obtains a W3C `org.w3c.dom.Node` object for the message element.

The following example shows a simple XML message and the logical tree that would be created from the message. The message has been sent using IBM MQ. The logical tree diagram also shows the methods to call in order to navigate around the tree.

```
<document>
  <chapter title='Introduction'>
    Some text
  </chapter>
</document>
```



The tree used in this diagram is the one that is created by parsing the previous XML example.

- From the Root part of the tree, calling **`getFirstChild()`** navigates to Properties. Also from Root, calling **`getLastChild()`** returns XML.
- From Properties, calling **`getParent()`** returns Root, and calling **`getNextSibling()`** returns MQMD.
- From MQMD, calling **`getPreviousSibling()`** returns Properties, calling **`getParent()`** returns Root, and calling **`getNextSibling()`** returns XML.
- From XML, calling **`getPreviousSibling()`** returns MQMD, calling **`getParent()`** returns Root, calling **`getFirstChild()`** returns document, and calling **`getLastChild()`** also returns document.
- From document, calling **`getParent()`** returns XML, calling **`getFirstChild()`** returns chapter, and calling **`getLastChild()`** also returns chapter.
- From chapter, calling **`getParent()`** returns document, calling **`getFirstChild()`** returns title, and calling **`getLastChild()`** returns the child that contains the message data "Some text.".

The following Java code accesses the chapter element in the logical tree for an XML message that does not contain white spaces. The XML parser retains white space in the parsed tree, but the XMLNS and XMLNSC parsers do not.

```
MbElement root = assembly.getMessage().getRootElement();
MbElement chapter = root.getLastChild().getFirstChild().getFirstChild();
```

Accessing information about an element

About this task

Use the following methods to return information about the referenced element:

getName()
returns the element name as a java.lang.String

getValue()
returns the element value

getType()
returns the generic type, which is one of the following types:

- NAME: an element of this type has a name, but no value.
- VALUE: an element of this type has a value, but no name.
- NAME/VALUE: an element of this type has both a value and a name.

getSpecificType()
returns the parser-specific type of the element

getNamespace()
returns the namespace URI of this element

Transforming a message by using a JavaCompute node
You can transform a message by using the JavaCompute node.

The following topics describe how to transform messages by using the JavaCompute node:

- “Creating a new message by using a JavaCompute node” on page 1764
- “Copying and modifying a message by using a JavaCompute node” on page 1765
- “Setting, copying, and moving message elements by using a JavaCompute node” on page 1765
- “Creating new elements by using a JavaCompute node” on page 1766
- “Using JAXB with a JavaCompute node” on page 1772
- “Processing message body data by using JAXB Java object classes” on page 1775
- “Working with large input messages to propagate multiple output messages” on page 1767

Creating a new message by using a JavaCompute node
Many message transformation scenarios require a new outgoing message to be built. The *Create Message Class* template in the **JavaCompute node** wizard generates template code for this.

About this task

In the template code, the default constructor of MbMessage is called to create a blank message, as shown in the following Java code:

```
MbMessage outMessage = new MbMessage();
```

The headers can be copied from the incoming message by using the supplied utility method, copyMessageHeaders(), as shown in this Java code:

```
copyMessageHeaders(inMessage, outMessage);
```

The new message body can now be created. First, add the top level parser element. For XML, this is:

```
MbElement outRoot = outMessage.getRootElement();
MbElement outBody = outRoot.createElementAsLastChild(MbXMLNSC.PARSER_NAME);
```

The remainder of the message can then be built up by using the **createElement** methods and the extended syntax of the integration node XPath implementation.

When you want to create a BLOB message, that is handled as a single byte string by using the BLOB parser domain. The message data is added as a byte array to the single element named "BLOB" under the parser level element, described as follows:

```
String myMsg = "The Message Data";
MbElement outRoot = outMessage.getRootElement();
```

```
// Create the Integration Bus Blob Parser element
MbElement outParser = outRoot.createElementAsLastChild(MbBLOB.PARSER_NAME);
// Create the BLOB element in the Blob parser domain with the required text
MbElement outBody = outParser.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB",
 myMsg.getBytes());
```

You can use the following code to create a BLOB message in a JavaCompute node:

```
MbElement outMsgRootEl = outMessage.getRootElement();

String parserName = MbBLOB.PARSER_NAME;
String messageType = "";
String messageSet = "";
String messageFormat = "";
int encoding = 0;
int ccsid = 0;
int options = 0;
outMsgRootEl.createElementAsLastChildFromBitstream(responseBodyXmlData,
  parserName, messageType, messageSet, messageFormat, encoding, ccsid,
  options);
```

To add a JSON message in a JavaCompute node, see “Creating a JSON message” on page 1745.

Copying and modifying a message by using a JavaCompute node
You can use the *Modify Message Class* template in the JavaCompute node wizard to generate a copied or modified version of an input message

About this task

The incoming message and message assembly are read-only. To modify a message, a copy of the incoming message must be made. The *Modifying Message Class* template in the JavaCompute node wizard generates this copy. In the template code, the copy constructor of *MBMessage* is called to create a message that is populated by copying the input, as shown in the following Java code:

```
MbMessage outMessage = new MbMessage(inAssembly.getMessage());
MbMessageAssembly outAssembly = new MbMessageAssembly(inAssembly, outMessage);
```

The new outAssembly, outMessage objects, or both, can now be modified and propagated to the next node.

Setting, copying, and moving message elements by using a JavaCompute node
Transform elements in the message as it passes through a JavaCompute node in the message flow.

Before you begin

The incoming message and message assembly are read-only. Therefore, to modify a message, you must make a copy of it first. For more information, see “Copying and modifying a message by using a JavaCompute node” on page 1765.

About this task

- “Setting information about an element” on page 1765
- “Moving and copying elements” on page 1766

The Java API reference information provides details about each of the methods used in the following sections:

Setting information about an element

About this task

Use these methods to set information about the referenced element:

setName()
Sets the name of the element

setValue()
Sets the value of the element

setSpecificType()
Sets the parser-specific type of the element

setNamespace()
Sets the namespace URI of the element

Moving and copying elements

About this task

Use a JavaCompute node to copy or detach an element from a message tree by using the following methods:

`detach()`
The element is detached from its parent and siblings, but any child elements are left attached

`copy()`
A copy of the element and its attached children is created

Use one of four methods to attach an element or subtree that you have copied on to another tree:

`addAsFirstChild(`*element*`)`
Adds an unattached element as the first child of *element*

`addAsLastChild(`*element*`)`
Adds an unattached element as the last child of *element*

`addBefore(`*element*`)`
Adds an unattached element as the previous sibling of *element*

`addAfter(`*element*`)`
Adds an unattached element as the next sibling of *element*

Creating new elements by using a JavaCompute node
You can use a JavaCompute node to create new elements.

About this task

Use the following methods in a JavaCompute node to create new elements in a message tree:

- createElementAsFirstChild()
- createElementAsLastChild()
- createElementBefore()
- createElementAfter()

The method returns a reference to the newly-created element. Each method has three overloaded forms:

createElement...(int type)
Creates a blank element of the specified type. Valid generic types are:

- MbElement.TYPE_NAME. This type of element has only a name, for example an XML element.
- MbElement.TYPE_VALUE. This type of element has only a value, for example XML text that is not contained in an XML element.
- MbElement.TYPE_NAME_VALUE. This type of element has both a name and a value, for example an XML attribute.

Specific type values can also be assigned. The meaning of this type information is dependent on the parser. Element name and value information must be assigned by using the setName() and setValue() methods.

createElement...(int type, String name, Object value)
Method for setting the name and value of the element at creation time.

createElement...(String parserName)
A special form of createElement...() that is only used to create top-level parser elements.

This example Java code adds a new chapter element to the XML example given in "Accessing elements in a message tree from a JavaCompute node" on page 1761:

```
MbElement root = outMessage.getRootElement();
MbElement document = root.getLastChild().getFirstChild();
MbElement chapter2 = document.createElementAsLastChild(MbElement.TYPE_NAME,"Chapter",null);

// add title attribute
MbElement title2 = chapter2.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE,
 "title", "Message Flows");
```

This produces the following XML output:

```
<document>
 <chapter title="Introduction">
  Some text.
 </chapter>
 <chapter title="Message Flows"/>
</document>
```

Working with large input messages to propagate multiple output messages
The tree representation of a message is typically bigger than the input bit stream. Manipulating a large message tree can require much storage but you can code Java methods that help to reduce the storage load on the integration node.

About this task

When an input bit stream is parsed and a logical tree is created, the tree representation of a message is typically bigger, and in some cases much bigger, than the corresponding bit stream.

The reasons for this expansion include the following factors:

- The addition of the pointers that link the objects together
- Translation of character data into Unicode, which can double the size
- The inclusion of field names that might have been implicit in the bit stream
- The presence of control data that is associated with operation of the integration node

Manipulating a large message tree can require much storage. If you design a message flow that handles large messages that are made up of repeating structures, you can code Java methods that help to reduce the storage load on the integration node. These methods support both random and sequential access to the message, but assume that you do not need access to the whole message at one time.

These Java methods cause the integration node to complete limited parsing of the message, and to keep in storage at one time, only that part of the message tree that reflects a single record. If your processing requires you to retain information from record to record (for example, to calculate a total price from a repeating structure of items in an order), you can either declare, initialize, and maintain Java variables, or you can save values in another part of the message tree; for example, in the local environment.

This technique reduces the memory that is used by the integration node to the memory that is needed to hold the full input and output bit streams, plus the memory that is needed for the message trees of just one record. This technique also provides memory savings when even a few repeats are encountered in the message. The integration node uses partial parsing and the ability to parse specified parts of the message tree, to and from the corresponding part of the bit stream.

To use these techniques in your JavaCompute node (or Java user-defined node), take any of the following steps.

- Copy the input MbMessage by using the copy constructor. This action creates a modifiable copy of the input message that is not parsed and therefore uses a minimum amount of memory.
- Avoid any inspection of the input message, which avoids the need to parse the message.

- Use a loop and an MbElement variable to step through the message one record at a time. For each record, use the following processes:
  - Use normal transforms to build a corresponding output subtree in an output MbMessage.
  - Use the MbElement.delete() method to delete the current input record message tree when you have completed the record manipulation.
  - Use the following code to propagate the output message for the current record.

    ```
    MbOutputTerminal.propagate(MbMessageAssembly, true)
    ```

    This process allows message tree resources and parsers to be recovered and reused for the next output message iteration.

You can vary these techniques to suit the processing that is required for your messages.

The following example Java code demonstrates how to parse a large input message with many repeating records, where each record is propagated as an individual output message.

The input XMLNSC messages are in the following form, where there are many repeating `Record` elements.

```
<TestCase>
  <Record><Field1>A</Field1><Field2>B</Field2><Field3>C</Field3><Field4>D</Field4><Field5>EA</Field5></
Record>
  <Record><Field1>A</Field1><Field2>B</Field2><Field3>C</Field3><Field4>D</Field4><Field5>EA</Field5></
Record>
  <Record><Field1>A</Field1><Field2>B</Field2><Field3>C</Field3><Field4>D</Field4><Field5>EA</Field5></
Record>
  <Record><Field1>A</Field1><Field2>B</Field2><Field3>C</Field3><Field4>D</Field4><Field5>EA</Field5></
Record>
  ....
</TestCase>
```

The following example shows the Java code that can be used to parse this large message, one record at a time, and propagate each record.

```
//Make a modifiable MbMessage based on the input message passed in on the inAssembly.
MbMessage clonedInMessage = new MbMessage(inAssembly.getMessage());
//Now partially parse the cloned input message one record at a time.
MbElement inputRootElement = clonedInMessage.getRootElement();
MbElement inputPropertiesElement = inputRootElement.getFirstElementByPath("Properties");
MbElement inputMQMDElement = inputRootElement.getFirstElementByPath("MQMD");
MbElement inputXMLNSCElement = inputRootElement.getFirstElementByPath("XMLNSC");

MbElement inputXMLNSCRootTagElement = inputXMLNSCElement.getFirstChild(); //Move to the TestCase tag
MbElement currentInputRecord = inputXMLNSCRootTagElement.getFirstChild(); //Move to the Record tag

while(currentInputRecord != null)
{
  // Create a new output message for the record that we are going to be propagate.
  MbMessage outputMessage = new MbMessage();
  MbMessageAssembly outAssembly = new MbMessageAssembly(inAssembly, outputMessage);

  //Create new parsers folders in the output message.
  MbElement outputRootElement = outputMessage.getRootElement();
  MbElement outputPropertiesElement =
 outputRootElement.createElementAsLastChild(inputPropertiesElement.getParserClassName());
  MbElement outputMQMDElement =
 outputRootElement.createElementAsLastChild(inputMQMDElement.getParserClassName());
  MbElement outputXMLNSCElement =
 outputRootElement.createElementAsLastChild(inputXMLNSCElement.getParserClassName());
  //Create the root tag in the output XMLNSC folder that will be used for this output record.
  MbElement outputXMLNSCRootTag = outputXMLNSCElement.createElementAsLastChild(MbElement.TYPE_NAME,
 "TestCase", null);
  //Create the record tag for this output message instance.
  MbElement currentOutputRecord = outputXMLNSCRootTag.createElementAsLastChild(MbElement.TYPE_NAME,
 "Record", null);

  //Copy the Properties Folder, MQMD header, and the current record.
  outputPropertiesElement.copyElementTree(inputPropertiesElement);
  outputMQMDElement.copyElementTree(inputMQMDElement);
  currentOutputRecord.copyElementTree(currentInputRecord);

  //Propagate this message, requesting that the output message assembly be cleared after propagation.
```

```
  out.propagate(outAssembly, true);
  //Note: You do not need to call clearMessage on outputMessage because it was cleared after the
 propagation.

  //Take a reference to the current record so that it can be deleted.
  MbElement previousInputRecord = currentInputRecord;
  //Now move to the next input record ready for processing.
  currentInputRecord = currentInputRecord.getNextSibling();
  //Now that we have moved to the next sibling, delete the input record that has already been processed.
  previousInputRecord.delete();

}
```

This Java code produces a message for each repeating Record subtree in the input XMLNSC message:

```
<Record>
  <Field1>A</Field1>
  <Field2>B</Field2>
  <Field3>C</Field3>
  <Field4>D</Field4>
  <Field5>E</Field5>
</Record>
```

Creating a simple filter by using a JavaCompute node
The JavaCompute node has two output terminals: Out and Alternate. To use the JavaCompute node as a filter node, propagate a message to either the Out or Alternate terminal based on the message content.

Before you begin

To complete this task, you must have added a node to your message flow.

About this task

Use the **JavaCompute node creation** wizard to generate template code for a filter node:

Procedure

Select the *Filtering Message Class* template in the **JavaCompute node creation** wizard to create a filter node.

The following template code is produced. It passes the input message to the Out terminal without doing any processing on the message.

```
public class jcn2 extends MbJavaComputeNode {

  public void evaluate(MbMessageAssembly assembly) throws MbException {
    MbOutputTerminal out = getOutputTerminal("out");
    MbOutputTerminal alt = getOutputTerminal("alternate");

    MbMessage message = assembly.getMessage();

    // ----------------------------------------------------------
    // Add user code below

    // End of user code
    // ----------------------------------------------------------

    // The following should only be changed
    // if not propagating message to the 'out' terminal

    out.propagate(assembly);
  }
}
```

The template produces a partial implementation of a method called `evaluate()`. The integration node calls `evaluate()` once for each message that passes through the node. The parameter that is passed to `evaluate()` is the message assembly. The message assembly encapsulates the message that is passed on from the previous node in the message flow.

Add custom code to the template, and propagate messages to both the Out and Alternate terminals to create a message filter.

Propagating a message to the JavaCompute node Out and Alternate terminals
The JavaCompute node has two output terminals, Out and Alternate. Therefore, you can use the node both as a filter node and as a message transformation node. After you process the message, propagate the message to an output terminal by using a `propagate()` method.

About this task

To propagate the message assembly to the Out terminal use the following method:

```
out.propagate(assembly);
```

To propagate the message assembly to the Alternate terminal, use the following method:

```
alt.propagate(assembly);
```

To propagate the same MbMessage object multiple times, call the `finalizeMessage()` method on the MBMessage object, so that any changes made to the message are reflected in the bit stream that is generated downstream of the JavaCompute node; for example:

```
MbMessage outMessage = new MbMessage(inMessage);
MbMessageAssembly outAssembly = new MbMessageAssembly(inAssembly, outMessage);
...
newMsg.finalizeMessage(MbMessage.FINALIZE_NONE);
out.propagate(outAssembly);
...
newMsg.finalizeMessage(MbMessage.FINALIZE_NONE);
out.propagate(outAssembly);
```

When you propagate many times from a JavaCompute node, where a new MbMessage is created each time, use the following code:

```
MbOutputTerminal.propagate(MbMessageAssembly, true)
```

This code recovers the message tree and parser resources after the propagation so that these resources can be used when the next MbMessage is constructed for propagation. You can see an example in "Working with large input messages to propagate multiple output messages" on page 1767.

When you use this code, the message tree resources are reclaimed for the non-read-only MbMessages in the MbMessageAssembly. As a result, the method MbMessage.clearMessage(true) is called on each modifiable MbMessage; therefore, these MbMessages cannot be used again.

If message tree fields were local to each MbMessage, or were only detached or attached between the three MbMessages in the MbMessageAssembly, the parsers are also recovered for reuse. However, if elements were detached and attached to an MbMessage that was not propagated, the parsers cannot be reused on the next iterations of input records.

For such MbMessage objects that were not propagated, call the method MbMessage.clearMessage(true) explicitly before the next input record is processed. This method allows parsers to be reused.

Extracting information from a message by using XPath 1.0 and a JavaCompute node
XPath is a query language designed for use with XML documents, but you can use it with any tree structure to query contents.

IBM App Connect Enterprise uses XPath to select elements from the logical message tree regardless of the format of the bit stream. The terminology used in this topic is based on the terminology used in the W3C definition of XPath 1.0. For more information about XPath, see "Using XPath" on page 626; and for more information about the W3C definition of the XPath 1.0 standard, see W3C XPath 1.0 Specification. For examples of XPath use, see the MbXPath topic in the Java user-defined node API documentation.

This topic contains the following information:

- “XPath variable binding” on page 1771
- “XPath namespace support” on page 1771
- “Updating a message by using XPath extensions” on page 1772

Using the evaluateXPath method to extract message information

The `evaluateXPath()` method is included in the Java user-defined node API. It supports XPath 1.0, with the following exceptions:

- Namespace axis and namespace node type. The namespace axis returns the actual XML namespace declaration nodes for a particular element. You can therefore manipulate XML prefix or URI declarations within an XPath expression. This axis returns an empty node set for bit streams that are not XML.
- If you use the **`id()`** function, it throws an MbRecoverableException.

The `evaluateXPath()` method can be called on a MbMessage object (for absolute paths), or on a MbElement object (for relative paths). The XPath expression is passed to the method as a string parameter. A second form of this method is provided that takes an MbXPath object. This object encapsulates an XPath expression along with variable bindings and namespace mappings, if these are required.

The `evaluateXPath()` method returns an object of one of these four types, depending on the expression return type:

- java.lang.Boolean, representing the XPath Boolean type
- java.lang.Double, representing the XPath number type
- java.lang.String, representing the XPath string type
- java.util.List, representing the XPath node set. The List interface represents an ordered sequence of objects, in this case MbElements. It allows direct access to the elements, or the ability to get an Iterator or an MbElement array.

XPath variable binding

XPath 1.0 supports the ability to refer to variables that have been assigned before the expression that contains them is evaluated. The MbXPath class has three methods for assigning and removing these variable bindings from user Java code. The value must be one of the four XPath 1.0 supported types:

- Boolean
- node set
- number
- string

XPath namespace support

For XML messages, namespaces are referred to by using a mapping from an abbreviated namespace prefix to the full namespace URI, as shown in the following XML example:

```
<ns1:aaa xmlns:ns1='http://mydomain.com/namespace1'
         xmlns:ns2='http://mydomain.com/namespace2'>
  <ns2:aaa>
    <ns1:bbb/>
  </ns2:aaa>
</ns1:aaa>
```

The namespace prefix is convenient for representing the namespace, but is meaningful only within the document that defines that mapping. The namespace URI defines the global meaning. Also, the concept of a namespace prefix is not meaningful for documents that are generated in a message flow, because a namespace URI can be assigned to a syntax element without an XMLNS mapping having been defined.

For this reason, the XMLNSC and MRM parsers expose only the namespace URI to the integration node and to user code (ESQL or user-defined code). By using ESQL, you can set up your own mappings to

create abbreviations to these potentially long URIs. These mappings are not related in any way to the prefixes that are defined in the XML document (although they can be the same name).

By using the XPath processor you can map namespace abbreviations on to URIs that are expanded at evaluation time. The MbXPath class contains methods to assign and remove these namespace mappings. For example:

```
MbNamespaceBindings ns = new MbNamespaceBindings();
ns.addBinding("other", "http://mydomain.com/namespace2");
ns.setDefaultNamespace("http://mydomain.com/namespace2");
MbXPath xp = new MbXPath("/aaa/other:aaa/bbb", ns);
List<MbElement> nodeset = (List<MbElement>)message.evaluateXPath(xp);
```

Updating a message by using XPath extensions

The XPath implementation in IBM App Connect Enterprise provides the following extra functions for modifying the message tree:

set-local-name(*object*)
Sets the local part of the expanded name of the context node to the value specified in the argument. *object* can be any valid expression, and is converted to a string as if a call to the string function is used.

set-namespace-uri(*object*)
Sets the namespace URI part of the expanded name of the context node to the value specified in the argument. *object* can be any valid expression, and is converted to a string as if a call to the string function is used.

set-value(*object*)
This function sets the string value of the context node to the value specified in the argument. *object* can be any valid expression, and is converted to a string as if a call to the string function is used.

To allow for syntax element trees to be built as well as modified, the following axis is available in addition to the 13 that are defined in the XPath 1.0 specification:

select-or-create::*name* or ?*name*
?*name* is equivalent to select-or-create::*name*. If *name* is @name, an attribute is created or selected. This selects child nodes matching the specified name, or creates new nodes according to the following rules:

- ?*name* selects children called *name* if they exist. If a child called *name* does not exist, ?*name* creates it as the last child, then selects it.
- ?$*name* creates *name* as the last child, then selects it.
- ?^*name* creates *name* as the first child, then selects it.
- ?>*name* creates *name* as the next sibling, then selects it.
- ?<*name* creates *name* as the previous sibling, then selects it.

Using JAXB with a JavaCompute node
Java Architecture for XML Binding (JAXB) enables Java applications to work with a model of message data as Java object classes. This Java object model can be accessed and manipulated by using getter and setter methods.

About this task

Developing messaging solutions by using JAXB programming provides an alternative to using the IBM App Connect Enterprise Java plug-in API, or the Document Object Model API, and does not require detailed knowledge of the IBM App Connect Enterprise tree representation of the message data.

You can use Java Architecture for XML Binding (JAXB) with a JavaCompute node to process your messages by accessing, creating, and manipulating JAXB Java object classes that you generate from your message model schema files. JAXB Java object classes are a Java object representation of your message, and can be used with Java code completion.

The following topics describe how to use Java Architecture for XML Binding (JAXB) in your IBM App Connect Enterprise messaging solutions:

- “Creating a Java project” on page 1773
- “Creating JAXB Java object classes” on page 1773
- “Processing message body data by using JAXB Java object classes” on page 1775

Creating a Java project
Java projects are used in the IBM App Connect Enterprise Toolkit to contain Java object classes.

About this task

To create a Java project in the Integration Development perspective, complete the following steps:

Procedure

1. Click **File** > **New** > **Other**.
   A window opens in which you can select a wizard.
2. Expand **Java**, select **Java Project**, and click **Next**.
   The **New Java Project** wizard opens.
3. Enter a name for your data design project, and then click **Finish**.
   The **Open associated perspective** dialog is displayed.
4. Click **No**.
   Your Java project is created, and is displayed in the Application Development view, under **Independent resources**.

What to do next

Before you can use your Java project in a messaging solution, you must complete one of the following tasks:

- Include your Java project in an application or library; see “Adding a project to an application, integration service, or library” on page 1979.
- Refer to your Java project from an integration project; see “Referencing resources in other libraries” on page 1976.

After you include your Java Project in an application, library, or integration project, you can complete the following task:

- Create Java object classes by using the JAXB 2.0 schema compiler that is provided with IBM App Connect Enterprise; see “Creating JAXB Java object classes by using the JAXB 2.0 schema compiler” on page 1774.

Creating JAXB Java object classes
Java Architecture for XML Binding (JAXB) Java object classes provide a Java object representation of your message data, and can be used in JavaCompute nodes to build messaging solutions. JAXB support in IBM App Connect Enterprise includes Java code completion for discovery of the object model, getter methods, and setter methods.

About this task

You can create JAXB Java object classes from your message model schema files by using the JAXB 2.0 schema compiler that is provided with IBM App Connect Enterprise.

If you want to use JAXB Java object classes that you generated by using a JAXB 2.0 schema compiler outside of IBM App Connect Enterprise, you must reference them from your application or integration project before you can use them in a JavaCompute node; see “Adding Java code dependencies” on page 1759.

The following topics describe how to create JAXB Java object classes by using IBM App Connect Enterprise Toolkit:

- Creating JAXB Java object classes by using a wizard
- Creating JAXB Java object classes by using the command line

Creating JAXB Java object classes by using a wizard
Create Java Architecture for XML Binding (JAXB) Java object classes by using the **Generate JAXB Java object classes** wizard.

Before you begin

- You must create a message model schema file; see "Constructing message models" on page 2133.

About this task

You can create your JAXB Java object classes when you create a Java class for a JavaCompute node in your message flow. Alternatively, you can create your JAXB Java object classes first, to be used in one or more JavaCompute node Java classes later. The same **Generate JAXB Java object classes** wizard is used whether you call the wizard interdependently or from within the **New Java Compute Node Class** wizard.

To generate JAXB Java object classes from your message model schema files by using the **Generate JAXB Java object classes** wizard, complete the following steps:

Procedure

1. Optional: In the Application Development view, click the view menu (shown by a white arrow in the Application Development view toolbar), and select **Hide Namespaces**.

   This step is required if you want to create your JAXB Java object classes from a folder that contains multiple message model schema files.
2. Right-click the message model schema file that you want to use, and click **Generate JAXB Java object classes**. To create JAXB Java object classes from multiple message model schema files at the same time, right-click a folder that contains the message model schema files that you want to use, and click **Generate JAXB Java object classes**.

   The **Generate JAXB Java object classes** wizard is displayed.
3. Complete the fields as required, then click **Finish**.

Results

Your JAXB Java object classes are visible in the Application Development view, under the **src** folder of the Java project that you selected in the wizard.

What to do next

- For information about how to process message body data by using your JAXB Java object classes, see "Processing message body data by using JAXB Java object classes" on page 1775.

Creating JAXB Java object classes by using the JAXB 2.0 schema compiler
Create Java Architecture for XML Binding (JAXB) Java object classes by using the JAXB 2.0 schema compiler from a command window.

Before you begin

- You must create a message model schema file; see "Constructing message models" on page 2133.
- You might need to add the `bin` folder of the IBM Java SDK to your system path. The `bin` folder of the IBM Java SDK that is included with IBM App Connect Enterprise at *`install_dir`*`\common\jdk\bin`.

About this task

To generate JAXB Java object classes from your message model schema files by using an IBM App Connect Enterprise command window, complete the following steps:

Procedure

1. In the Application Development view, right-click the message model schema file that you want to use to generate your JAXB Java object classes and select **Properties**.

   A window opens that shows the properties for your selected message model schema file.
2. Note the *Location* of your message model schema file, then click **OK** to close the properties window.
3. In the Application Development view, expand the Java project that you want to contain your JAXB Java object classes, then Right-click the **src** folder and select **Properties**.

   A window opens that shows the properties for your selected **src** folder.
4. Note the *Location* of your selected **src** folder, then click **OK** to close the properties window.
5. Open an IBM App Connect Enterprise command window. If you have not added the `bin` folder of the IBM Java SDK to your system path, change directory to this folder. The `bin` folder of the IBM Java SDK that is included with the IBM App Connect Enterprise Toolkit is located at *`install_dir`*`\common\jdk\bin`
6. Optional: To view a full list of commands for the JAXB 2.0 schema compiler, enter the following command:

   ```
   xjc -help
   ```
7. Enter the following command to create your JAXB Java object classes:

   ```
   xjc MessageModelSchema -d JavaProject -p JavaPackage
   ```

   Where *MessageModelSchema* is the location of your message model schema file, *JavaProject* is the location of the **src** folder of your Java project, and *JavaPackage* is the Java package where the generated classes are placed.

   The JAXB 2.0 schema compiler generates JAXB Java object classes from your message model schema file, and saves them to the **src** folder of the Java project that you specified in the command.
8. In the IBM App Connect Enterprise Toolkit, open the **Package Explorer** view:

   a) Click **Window** > **Show view** > **Other...**

   b) In the **Show View** window, expand **Java** and select **Package Explorer**, then click **OK**.
9. In the **Package Explorer** view, right-click the Java project that you selected to contain your JAXB Java object classes and select **Refresh**.

Results

Your JAXB Java object classes are visible in the Application Development view, under the **src** folder of your Java project.

What to do next

- For information about how to process message body data by using your JAXB Java object classes, see “Processing message body data by using JAXB Java object classes” on page 1775.

Processing message body data by using JAXB Java object classes

Use the JAXB object classes generated by a Java Architecture for XML Binding (JAXB) compiler by using the JAXB class template.

Before you begin

- Create your JAXB Java object classes; see “Creating JAXB Java object classes” on page 1773.

- Add a JavaCompute node to your message flow; see node.

About this task

You can use Java Architecture for XML Binding (JAXB) with a JavaCompute node to process your messages by accessing, creating, and manipulating JAXB Java object classes that you generate from your message model schema files.

JAXB Java object classes are a Java object representation of your message, and can be used with Java code completion. The **Process via JAXB class** template in the **New Java Compute Node Class** wizard generates template code for processing your messages by using JAXB Java object classes. If you also used the **New Java Compute Node Class** wizard either to generate your JAXB Java object classes, or to reference your existing JAXB Java object classes, step 1 might be completed for you.

To process message body data by using JAXB Java object classes, complete the following steps:

Procedure

1. Optional: Modify the `onInitialize ()` method to reference the package or packages that contain your Java object binding classes.

   ```
   public void onInitialize() throws MbException {
    try {
     // TODO Update context path "com.example.jaxb" to be the package of your
     // Java object classes that were generated by a Java Architecture for XML
     // Binding (JAXB) binding compiler
     jxbcntxt = JAXBContext.newInstance("com.example.jaxb");
   ```

   Replace `com.example.jaxb` with your JAXB Java object bindings classes package.

   Note: When you deploy or restart your message flow, the `onInitialize ()` method is called only once, and initializes JAXB context for all processing threads.

   If an error is thrown by the generation of the JAXB context, the code that is provided in the "Process via JAXB class" template throws an `MbUserException`, and the deployment operation fails. If the deployment operation fails, inspect the error message that is recorded in the host system event log to determine the cause. The most likely cause is that one or more package names cannot be resolved, or that one or more of the packages you specified do not contain the required JAXB object factory or bindings properties.

2. Modify the `evaluate()` method to process each message that is passed in a `MbMessageAssembly` object. The `MbMessageAssembly` object is defined in the Java user-defined node API.

   a) The first section of the `evaluate()` method extracts the message data from the assembly, creates an output assembly and copies message headers.

   ```
   public void onInitialize() throws MbException {
   try {
   // TODO Update context path "com.example.jaxb" to be the package of your
   // Java object classes that were generated by a Java Architecture for XML
   // Binding (JAXB) binding compiler
   jaxbContext = JAXBContext.newInstance("com.example.jaxb");
   } catch (JAXBException e) {
   // This exception will cause the deploy of this Java compute node to fail
   // Typical cause is the JAXB package above is not available
   MbUserException mbue = new MbUserException(this, "onInitialize()",
   "", "", e.toString(), null);
   throw mbue;
   }
   }
   ```

   b) The next part in the `evaluate()` method *unmarshals* the input message data into the set of Java objects that are bound from the message schema. Unmarshalling creates a Java object model copy of the message data that is in memory.

   ```
   try {
   // unmarshal the input message data from the message tree into your Java object classes
   ```

```
Object inMsgJavaObj =
 jaxbContext.createUnmarshaller().unmarshal(inMessage.getDOMDocument());
```

c) The next part in the `evaluate()` method is where you insert your own JAXB code to create or update the output message by processing message data. See external resources for details of how to program transformations by using JAXB Java object classes. For information about debugging in Java, see Java Debugger.

```
// ------------------------------------------------------
// Add user code below to build the new output data by updating
// your Java objects or building new Java objects
Object outMsgJavaObj = inMsgJavaObj;
// End of user Java object processing
// ------------------------------------------------------
```

The following example shows some JAXB code that adds a record to a CSV message, and sets the value of the three fields in that record:

```
// Example: add a record of fixed data
CsvMsg outMsgJavaObj = (CsvMsg) inMsgJavaObj;
Record additionalCsvRecord = new Record();
additionalCsvRecord.setField1("My new field 1 text");
additionalCsvRecord.setField2("My new field 2 text");
additionalCsvRecord.setField3("My new field 3 text");
outMsgJavaObj.getRecord().add(additionalCsvRecord);
// end example
```

d) The next part in the `evaluate()` method *marshals* the processed Java object classes back into the message tree. Modify this code to pass the relevant Java object in place of the template default. If your JAXB transformation code updated the input message, pass the Java object class that was created during unmarshalling into the marshalling code. If you are creating an output message, pass the Java object class for your new output message into the marshalling code.

The template sets the output domain to XMLNSC; if you require the output message to be in the DFDL or SOAP domains, you must modify this code.

```
// TODO set the required
 domain for the output message, eg XMLNSC
Document outDocument = outMessage.createDOMDocument(MbXMLNSC.PARSER_NAME);
// marshal the new or updated output Java object class into the message tree
jaxbContext.createMarshaller().marshal(outMsgJavaObj, outDocument);
```

What to do next

- You can use the Flow Exerciser to check that your message flow processes messages as expected; see “Testing your message flow by using the Flow Exerciser” on page 648.

Manipulating other parts of the message tree by using a JavaCompute node

You can access parts of the message tree other than the message body data. These parts of the logical tree are independent of the domain in which the message exists, and all these topics apply to messages in all supported domains, including the BLOB domain. You can access all parts of the message tree by using a JavaCompute node.

About this task

Elements of the message tree can be accessed in the same way as the message body data, by using a JavaCompute node.

- “Accessing headers by using a JavaCompute node” on page 1778
- “Updating the local environment with the JavaCompute node” on page 1779
- “Updating the Global Environment with the JavaCompute node” on page 1779

Accessing headers by using a JavaCompute node
You can access headers by using a JavaCompute node.

About this task

If an input node receives an input message that includes message headers that the input node recognizes, the node starts the correct parser for each header. Parsers are supplied for most IBM MQ headers. The following topics provide guidance for accessing the information in the MQMD and MQRFH2 headers that you can follow when accessing other headers that are present in your messages.

- "Copying message headers by using a JavaCompute node" on page 1778
- "Accessing the MQMD header by using a JavaCompute node" on page 1778
- "Accessing the MQRFH2 header by using a JavaCompute node" on page 1778

For further details of the contents of these and other IBM MQ headers for which IBM App Connect Enterprise provides a parser, see Element definitions for message parsers.

Copying message headers by using a JavaCompute node
You can copy message headers by using a JavaCompute node.

The *Modifying Message Class* template in the JavaCompute node wizard generates the following code to copy message headers using a JavaCompute node:

```
public void copyMessageHeaders(MbMessage inMessage, MbMessage outMessage) throws MbException
{
 MbElement outRoot = outMessage.getRootElement();
 MbElement header = inMessage.getRootElement().getFirstChild();

 while(header != null && header.getNextSibling() != null)
 {
  outRoot.addAsLastChild(header.copy());
  header = header.getNextSibling();
 }
}
```

Accessing the MQMD header by using a JavaCompute node
IBM MQ and WebSphere MQ Everyplace messages include an MQMD header. You can use a JavaCompute node to refer to the fields in the MQMD, and to update them.

About this task

The following Java code shows how to add an MQMD header to your message:

```
public void addMqmd(MbMessage msg) throws MbException
{
 MbElement root = msg.getRootElement();

 // create a top level 'parser' element with parser class name
 MbElement mqmd = root.createElementAsFirstChild("MQHMD");

 // specify next parser in chain
 mqmd.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE,
  "Format",
  "XMLNS");
}
```

Accessing the MQRFH2 header by using a JavaCompute node
You can use a JavaCompute node to add an MQRFH2 header to an outgoing message.

About this task

When you construct MQRFH2 headers in a JavaCompute node, two types of field exist:

- Fields in the MQRFH2 header structure (for example, Format and NameValueCCSID)
- Fields in the MQRFH2 NameValue buffer (for example mcd and psc)

The following code adds an MQRFH2 header to an outgoing message that is to be used to make a subscription request:

```
public void addRfh2(MbMessage msg) throws MbException
{
 MbElement root = msg.getRootElement();
 MbElement body = root.getLastChild();

 // insert new header before the message body
 MbElement rfh2 = body.createElementBefore("MQHRF2");

 rfh2.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE, "Version", new Integer(2));
 rfh2.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE, "Format", "MQSTR");
 rfh2.createElementAsFirstChild(MbElement.TYPE_NAME_VALUE, "NameValueCCSID", new Integer(1208));

 MbElement psc = rfh2.createElementAsFirstChild(MbElement.TYPE_NAME, "psc", null);
 psc.createElementAsFirstChild(MbElement.TYPE_NAME, "Topic", "department");
 psc.createElementAsFirstChild(MbElement.TYPE_NAME, "QMgrName", "QM1");
 psc.createElementAsFirstChild(MbElement.TYPE_NAME, "QName", "PUBOUT");
 psc.createElementAsFirstChild(MbElement.TYPE_NAME, "RegOpt", "PersAsPub");

 MbXPath xp = new MbXPath("/MQMD/Format" + "[set-value(´MQHRF2´)]", root);
 root.evaluateXPath(xp);
}
```

In this example, the MQHRF2 parameter is the parser class name, which is different from the parser element name (MQRFH2). For a list of the parsers, root element names, and class names for different headers, see Available parsers.

Updating the local environment with the JavaCompute node
The local environment tree is part of the logical message tree in which you can store information while the message flow processes the message.

About this task

The following information shows how to update the local environment:

Procedure

1. Make a new copy of the local environment to update it. Use the full version of the copy constructor to create a new MbMessageAssembly object, as shown in the following example:

```
MbMessage env = assembly.getLocalEnvironment();
MbMessage newEnv = new MbMessage(env);

newEnv.getRootElement().createElementAsFirstChild(
  MbElement.TYPE_NAME_VALUE,
  "Status",
  "Success");

MbMessageAssembly outAssembly = new MbMessageAssembly(
  assembly,
  newEnv,
  assembly.getExceptionList(),
  assembly.getMessage());

getOutputTerminal("out").propagate(outAssembly);
```

2. Edit the copy to update the local environment.

Updating the Global Environment with the JavaCompute node
The Global Environment tree is always created when the logical tree is created for an input message. However, the message flow neither populates it nor uses its contents. You can use this tree for your own

purposes, for example to pass information from one node to another. You can use the whole tree as a scratchpad or working area.

About this task

The Global Environment can be altered across the message flow, therefore do not make a copy of it to alter. The following Java code shows how to alter the Global Environment:

```
MbMessage env = assembly.getGlobalEnvironment();
env.getRootElement().createElementAsFirstChild(MbElement.TYPE_NAME_VALUE, "Status", "Success");

getOutputTerminal("out").propagate(assembly);
```

Accessing the ExceptionList tree using Java
The ExceptionList tree is created with the logical tree when an input message is parsed.

About this task

The tree is initially empty, and is only populated if an exception occurs during message flow processing. It is possible that more than one exception can occur; if more than one exception occurs, the ExceptionList tree contains a subtree for each exception.

You can access the ExceptionList tree in JavaCompute nodes from the `MbMessageAssembly` parameter of your `evaluate()` method.

You can access the ExceptionList tree in a node in an error handling procedure. For example, you might want to route the message to a different path based on the type of exception.

You can use the querying capabilities within XPath to carry out this task. The descendant axis (`//`) of XPath gives you the ability to search for an element by name regardless of its depth in the tree. For example:

```
    //ParserException
```

returns all elements in the tree named `ParserException`.

If you are specifically interested in a particular message, you can use a predicate (see predicates for further information) to narrow down the result set. For example:

```
    //ParserException[Number=5016]
```

returns only the exception that contains `Number=5016`.

If you only want to extract the text message associated with this exception, the following XPath expression returns this as a `java.lang.String`:

```
    string(//ParserException[Number=5016]/Text)
```

The following Java code extracts this text from your code:

```
String text =
(String)inAssembly.getExceptionList().evaluateXPath("string(//ParserException[Number=5016]/Text)");
```

For information on accessing the ExceptionList tree using ESQL, see “Accessing the ExceptionList tree using ESQL” on page 1658.

Accessing the global cache by using a JavaCompute node
You can use a JavaCompute node to interact with a map in a global cache or an external WebSphere eXtreme Scale grid.

Before you begin

You can also access the global cache by using a Mapping node; see Accessing the global cache by using a Mapping node.

- Read the concept information in "Data caching overview" on page 272.
- Ensure that the global cache or external grid is available. The cache is disabled by default. To use the cache, configure it as described in "Configuring the embedded global cache" on page 285.
- If you are connecting to an external grid, create a WXSServer policy to define how the connection is made. See "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327.
- To use your own Java classes with the global cache, put the JAR files that contain the Java classes in one of the shared-classes directories. These Java classes must be available to all integration servers that participate in the global cache. For more information about the shared-classes directories, see "Java shared classloader" on page 1752.

About this task

You can use a JavaCompute node to store data in a global map. You can then create another JavaCompute node that can get data from the global cache for processing or routing. The JavaCompute node uses the MbGlobalMap object to access the global cache or external grid. This class can be used to get a map, and to put or get data in a map. You cannot create a map explicitly, but if you get a map that does not exist, the map is created automatically. When you get a global map from an external grid, the getGlobalMap method makes a connection to the grid if one does not exist.

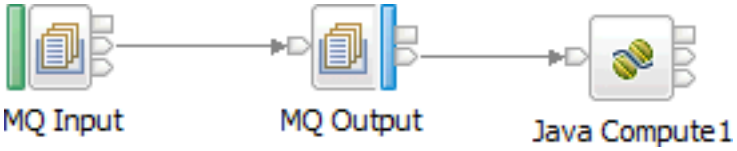
Interactions with the cache happen outside the message flow transaction, and are committed immediately. If an exception is thrown downstream of the node that interacts with the cache, the cache interactions are not rolled back.

The following steps describe how one message flow adds data to a map, and another flow gets the data from that map.

Procedure

1. Create a message flow that contains a JavaCompute node.

   You can place the JavaCompute node before or after an MQOutput node. In the following example, the JavaCompute node is placed after an MQOutput node so that the JavaCompute node can use the message ID of the output message.

2. Double-click the JavaCompute node.

   The **New Java Compute Node Class** wizard opens.

3. On the **Java Compute Node Class** pane, provide the appropriate information, then click **Next**.

   You can accept the default values by clicking **Next**.

4. On the **Java Compute Node Class Template** pane, select the appropriate template for your scenario, then click **Finish**.

   The template Java file opens in the editor, indicating where you can add your own code.

5. To get a map from the embedded cache, or create the map if it does not exist, add the MbGlobalMap object, as shown in the following example.

   The MbGlobalMap object is also described in the Java Plugin API documentation.

   ```
   MbGlobalMap globalMap = MbGlobalMap.getGlobalMap("MyMap");
   ```

   This example gets the map called "MyMap". If the map does not exist, it is created. Alternatively, when you are using the embedded cache, you can use the default map by not specifying a map name, as shown in the following example. When you are connecting to an external grid, no default map exists. You must specify a valid map name on the external grid.

   ```
   MbGlobalMap globalMap = MbGlobalMap.getGlobalMap();
   ```

   The cache uses WebSphere eXtreme Scale dynamic maps. Any map name is allowed, apart from names that begin with SYSTEM.BROKER, which is reserved for use by the integration node. The default map is named SYSTEM.BROKER.DEFAULTMAP; you can use or clear this map.

   To get a map from an external grid, add the MbGlobalMap object, specifying the name of the map on the external grid and the name of the policy that is used to connect to the grid:

   ```
   MbGlobalMap remoteCacheServerMap =
    MbGlobalMap.getGlobalMap("MyMap.LUT","remoteCacheServer");
   ```

   In this example, the map, `MyMap.LUT`, is on an external grid. The policy that is used to connect to the grid is called "remoteCacheServer".
6. Optional: Specify how long, in seconds, the data remains in the global cache before it is removed automatically.

   This time is known as the *time to live* and is counted from when that map entry is last updated. You specify this time when you get an MbGlobalMap object. The value applies to all cache entries that are created by using that MbGlobalMap object. For detailed instructions, see “Specifying how long data remains in the global cache by using the JavaCompute node” on page 1783.
7. To put data in the map, you must create a key and value pair in the map, as shown in the following example.

   For keys and values, Java primitive types and strings are supported. Java objects are supported as values. For the embedded grid only, keys can also be arrays of primitives or strings. (To use your own Java classes with the global cache, put the JAR files that contain the Java classes in one of the shared-classes directories.)

   ```
   globalMap.put(key, val);
   ```
8. Save the message flow.
9. To access the stored data from another message flow, create a flow that contains a JavaCompute node.

   For example, the following message flow contains a JavaCompute node that retrieves the appropriate information from the map, then sends a response message through an MQReply node.

10. Repeat steps 2, 3, and 4 to create a Java file for your new JavaCompute node.
11. Use the MbGlobalMap object to get the map that you created in step 5, then get the data that you added to the map in step 6. If you know that the data that you are retrieving is a string, for example, specify string when you get the data, as shown in the following example.

    ```
    MbGlobalMap globalMap = MbGlobalMap.getGlobalMap("MyMap");
    ...
    ```

```
String val = (String)globalMap.get(key);
```

The following example shows how to get the data that you added to a map on an external grid:

```
MbGlobalMap remoteCacheServerMap =
 MbGlobalMap.getGlobalMap("MyMap.LUT","remoteCacheServer");
...
String val = (String)remoteCacheServerMap.get(key);
```

To prevent the cache from becoming too big, when you have finished with a key and value pair, use the `remove()` method to delete that data from the map.

You can use content assist to list available options when you are constructing Java code. To access content assist, place the cursor at the point of insertion, then either click **Edit** > **Content Assist** or press Ctrl+Space. For example, if you type "myMap", then press Ctrl+Space, you can choose from a list of options, including the following actions.

- *remove*, which removes a single object from a global cache
- *containsKey*, which indicates whether a key exists in a map
- *update*, which updates an existing object

All available options are documented in the Javadoc for the Java Plugin API (see IBM Integration API).

12. Save your message flow.
13. Deploy your message flows.

Specifying how long data remains in the global cache by using the JavaCompute node
Specify when data is removed automatically from the global cache.

Before you begin

Create a message flow that contains a Mapping node or a JavaCompute node that is configured to access the global cache. For more information, see Accessing the global cache by using a Mapping node or “Accessing the global cache by using a JavaCompute node” on page 1781.

About this task

When you get an MbGlobalMap object, you can specify how long the data remains in the global cache before it is removed automatically. This time is known as the *time to live* and is counted from when that map entry is last updated. The value applies to all cache entries that are created by using that MbGlobalMap object in that instance of the message flow. Data that is already in the map that you specify, or that is created by another MbGlobalMap object, is not affected by the time to live value.

By default, the time to live is set to zero so that the data is never removed. To set a specific time to live, create a session policy, which you can reference from the MbGlobalMap object.

You can specify the time to live value in two ways. The following examples both demonstrate how to set a time to live of 60 seconds for cache entries in the map "myMap".

Example 1

```
MbGlobalMap myMap = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(60));
```

Example 2

```
MbGlobalMapSessionPolicy sessionPol = new MbGlobalMapSessionPolicy(60);
MbGlobalMap myMap = MbGlobalMap.getGlobalMap("myMap", sessionPol);
```

Data in the map "myMap" is removed automatically 60 seconds after it is last updated.

You can create multiple MbGlobalMap objects in different flows, integration servers, or integration nodes, all resolving to the same map in the global cache, but with different time to live values. However, you must

structure the code in a specific way when you want to put multiple cache entries, with different time to live values, into the same map in the same message flow.

In the following example, the MbGlobalMap objects are all created before the put statements are made. All three MbGlobalMap objects resolve to the same underlying map. The time to live value of each subsequent MbGlobalMap object replaces the value that was set for the previous object. Therefore, for each put statement, data is removed after 20 seconds.

```
MbGlobalMap m1 = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(60));
MbGlobalMap m2 = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(40));
MbGlobalMap m3 = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(20));
m1.put("k1","v1");
m2.put("k2","v2");
m3.put("k3","v3");
```

In the following example, each put statement is made directly after the associated MbGlobalMap object is created. Therefore, the cache entry that is made by each put statement assumes a different time to live value.

```
MbGlobalMap m1 = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(60));
m1.put("k1","v1");
m1 = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(40));
m1.put("k2","v2");
m1 = MbGlobalMap.getGlobalMap("myMap", new MbGlobalMapSessionPolicy(20));
m1.put("k3","v3");
```

Accessing message flow user-defined properties from a JavaCompute node
Customize a JavaCompute node to access properties that you have associated with the message flow in which the node is included.

About this task

To access these properties from a JavaCompute node, use the `getUserDefinedAttribute(`*name*`)` method, where *name* is the name of the property that you are accessing. The type of the object that is returned depends on the type of the property that you are accessing. The object has one of a set of types:

- MbDate
- MbTime
- MbTimestamp
- Boolean
- byte[]
- String
- Integer 32-bit values
- Long 64-bit values
- Double
- BigDecimal
- BitSet

You cannot access user-defined properties in the constructor. To access them at initialization time, implement the following method, and use it to access the user-defined properties.

```
public void onInitialize() throws MbException
{
   // access the user-defined properties here
}
```

You can use the administration REST API to modify the values of user-defined properties at run time, as described in “Setting message flow user-defined properties at run time by using the administration REST API” on page 436.

You can use the IBM Integration API to change the value of user-defined properties. The `getUserDefinedAttribute()` method is not supported for User-Defined Nodes (UDN). Use the `getUserDefinedPropertyNames()`, `getUserDefinedProperty()`, and `setUserDefinedProperty()` methods to query, discover, and set user-defined properties.

Accessing a user-defined policy from a JavaCompute node
Use a JavaCompute node to query properties dynamically at run time, in user-defined policies.

Before you begin

Complete the following tasks:

- "Creating a message flow" on page 574
- User Defined policy (UserDefined)

About this task

If you created a user-defined policy, and created properties for that policy, you can query those properties in a JavaCompute node. For example, you can create a user-defined policy to set timeouts for processing HTTP messages.

Procedure

1. Right-click the JavaCompute node and click **Open Java** to create and open a Java file in the Editor view, or open an existing file.
2. Create the Java class for the JavaCompute node from which you want to access the user-defined policy.
3. Add user code as shown below to the Java class to define the user-defined policy. In the example shown, a user-defined policy called MyUDCS has been defined in a policy project called PP1.

```
MbPolicy myPol = getPolicy("UserDefined", "{PP1}:MyUDCS");
```

4. Use the following code to access the policy.

```
if (myPol != null) {
System.out.println("Found policy: "+myPol.getName());
System.out.println(" with type: "+myPol.getType());
System.out.println(" and properties:");
System.out.println(" prop1: "+myPol.getPropertyValueAsString("prop1"));
System.out.println(" prop2: "+myPol.getPropertyValueAsString("prop2"));
System.out.println(" prop3: "+myPol.getPropertyValueAsString("prop3"));
}
```

   This lookup syntax can be qualified by policy project. If no policy project is qualified, the policy project that is defined on the *defaultPolicyProject* property in the `node.conf.yaml` configuration file is used. Null is returned if either the property or the policy does not exist.

   If you created a user-defined policy, and created properties for that policy, you can query those properties by using a Java class method that can be called from ESQL.

Interacting with databases by using the JavaCompute node
Access databases from Java code included in the JavaCompute node.

About this task

Choose from the following options for database interaction:

- MbSQLStatement
- JDBC API in an unmanaged environment
- SQLJ

If you use JDBCProvider for type 4 connections or MbSQLStatement, the databases that you access can participate in globally coordinated transactions. In all other cases, database access cannot be globally coordinated.

MbSQLStatement

About this task

The MbSQLStatement class provides full transactional database access by using ESQL and ODBC. Global coordination is provided by IBM MQ on distributed systems, and by RRS on z/OS.

Create instances of the MbSQLStatement class by using the createSQLStatement() method of MbNode, passing to the method the ODBC data source, an EQSL statement, and, optionally, the transaction mode.

- Calling select() on this object returns the results of the query.
- Calling execute() on this object runs a query where no results are returned, such as updating a table.

The following Java code shows how to access a database by using MbSQLStatement:

```
MbMessage newMsg = new MbMessage(assembly.getMessage());
MbMessageAssembly newAssembly = new MbMessageAssembly(assembly, newMsg);

String table = "dbTable";

MbSQLStatement state = createSQLStatement( "dbName",
 "SET OutputRoot.XMLNS.integer[] = PASSTHRU('SELECT * FROM " + table + "');" );

state.setThrowExceptionOnDatabaseError(false);
state.setTreatWarningsAsErrors(true);
state.select( assembly, newAssembly );

int sqlCode = state.getSQLCode();
if(sqlCode != 0)
{
 // Do error handling here
}

getOutputTerminal("out").propagate(assembly);
```

JDBC API in an unmanaged environment

About this task

You can access standard Java APIs in the code that you write for your JavaCompute nodes, including JDBC calls. You can therefore use JDBC APIs to connect to a database, write to or read from the database, and disconnect from the database. On operating systems other than z/OS, your JDBC connection code can call both type 2 and type 4 JDBC drivers in this environment, but they are not supplied. You must obtain these drivers from your database vendor. On z/OS, type 2 drivers are not supported.

If you choose this method to access databases, managing the transactions is not supported; your code must manage the local commit and rollback of database changes. Your code must also manage the connection lifecycle, connection thread affinity, and connection pooling. You must also monitor the access to databases when you use this technique to ensure that these connections do not cause interference with connections made by the integration server. In particular, be aware that type 2 drivers bridge to an ODBC connection that might be in use in message flows that access databases from ESQL.

SQLJ

About this task

SQLJ is a Java extension that you can use to embed static SQL statements within Java code. Create SQLJ files by using the IBM App Connect Enterprise Toolkit. The resource manager does not coordinate database access when using SQLJ.

Procedure

1. Enable SQLJ capability in the IBM App Connect Enterprise Toolkit:
   a) Select **Window** > **Preferences**.
   b) Expand **General**.
   c) Select **Capabilities**.
   d) Select **Data**.
   e) Click **OK**.
2. Create an SQLJ file within a Java project:
   a) Right-click the ***Java project*** in which you want to create the file.
   b) Select **New** > **Other**.
   c) Expand **Data**.
   d) Expand **SQLJ Applications**.
   e) Select **SQLJ File**.
   f) Click **Next**.
   g) Follow the directions given by the **New SQLJ File** wizard to generate the SQLJ file.

Results

You can now reference the class in this SQLJ file from a JavaCompute node class in this project or in another referenced project.

Calling an Enterprise Java Bean
You can call an Enterprise Java Bean (EJB) from a JavaCompute node.

Before you begin

- Ensure that all required Java classes are in the IBM App Connect Enterprise shared-classes directories, or are referenced in the CLASSPATH environment variable. You can use the wildcard character (*) at the end of a directory path specifier to load all JARs in that directory path.
- Ensure that the user JAR files that are needed for EJB access are referenced in CLASSPATH. For more information, see the documentation for the application server that is hosting the EJB.

Example

The following example shows how to call an EJB from a JavaCompute node:

```
public class CallAckNoAckEJB_JavaCompute extends MbJavaComputeNode {

   public void evaluate(MbMessageAssembly inAssembly) throws MbException {
                MbOutputTerminal out = getOutputTerminal("out");
                MbOutputTerminal alt = getOutputTerminal("alternate");

                MbMessage inMessage = inAssembly.getMessage();

                // create new message
                MbMessage outMessage = new MbMessage(inMessage);
                MbMessageAssembly outAssembly = new MbMessageAssembly(inAssembly,outMessage);

                try {
                        // ----------------------------------------------------------
                        // Add user code below

                        String response = null;
                        String responseMessage = null;

                        Properties properties = new Properties();
                        properties.put(Context.PROVIDER_URL, "iiop://localhost:2809");
                        properties.put(Context.INITIAL_CONTEXT_FACTORY, "com.ibm.websphere.naming.
WsnInitialContextFactory");

                        try {
```

```
                           Context initialContext = new InitialContext(properties);
                                Object obj = initialContext.lookup("ejb/com/acme/ejbs/AckNoAckHome");
                                AckNoAckHome ejbHome = (AckNoAckHome)javax.rmi.PortableRemoteObject.
narrow(obj,AckNoAckHome.class);

                                AckNoAck ackNoAck = ejbHome.create();
                                responseMessage = ackNoAck.getAck();
                                response = "Ack";
                           } catch(Exception e) {
                                responseMessage = e.getMessage();
                                response = "NoAck";
                           }

                           MbElement cursor = outMessage.getRootElement().getFirstElementByPath("/XML/
AckNoAck");
                           cursor.createElementAsLastChild(MbElement.TYPE_NAME,"Response",null);

 cursor.getLastChild().createElementAsLastChild(MbElement.TYPE_NAME,response,null);

 cursor.getLastChild().getLastChild().createElementAsLastChild(MbElement.TYPE_VALUE,null,
responseMessage);

                           // End of user code
                           // ------------------------------------------------------------

                           // The following should only be changed
                           // if not propagating message to the 'out' terminal
                           out.propagate(outAssembly);

                } finally {
                           // clear the outMessage
                           outMessage.clearMessage();
                }
   }
}
```

JavaCompute node exception handling
The `evaluate()` method throws an `MbException`.

If your code throws other classes of checked exceptions, they must be caught and rethrown as `MbException`. Typically, you use the `MbUserException` class, as shown in the example code. `MbUserException` is a subclass of `MbException`, and has a public constructor. IBM App Connect Enterprise utility functions can throw other subclasses of MbException that have private constructors.

About this task

Exceptions can occur during message flow processing (during the `evaluate()` method) and during the `onInitialize()` method. If you have implemented the `onInitialize()` method, and you detect an unrecoverable error in the node configuration, an exception of class `MBException` is issued and the flow fails to initialize. Either your flow fails to deploy, and error message BIP4157 is issued, or the flow does not start and does not appear in the list of running flows.

Do not run code in an `onInitialize()` method that depends on another external resource that might not be there because the calls to that method will not be retried. If you need to initialize an external connection, for example, initialize it during the first call to the `evaluate()` method. If the initialization does not work, you can throw an exception that will be handled like any other flow exception.

The following example code shows a simple implementation of a JavaCompute node that routes a CSV message to the `out` or `alt` terminals, based on a header field that contains a positive or negative number. If the text in the field is not numeric, a `NumberFormatException` is thrown. The example code shows how this exception can be caught and thrown as a `MbUserException` so that the handling of `MbException` built into IBM App Connect Enterprise from JavaCompute nodes can be used.

```
public void evaluate(MbMessageAssembly assembly) throws MbException {
  MbOutputTerminal out = getOutputTerminal("out");
  MbOutputTerminal alt = getOutputTerminal("alternate");

  MbMessage message = assembly.getMessage();
  int routeTo = 0;
  try {
    // ------------------------------------------------------
```

```
    // Add user code below
    String routingValue = (String)message.evaluateXPath("string(/csv/header/route_to)");
    routeTo = Integer.parseInt(routingValue);

    // End of user code
    // -----------------------------------------------------------
  } catch (java.lang.NumberFormatException e ) {
    // Example Exception handling
    MbUserException mbue = new MbUserException(this, "evaluate()", "","", e.toString(), null);
    throw mbue;
  }

  // The following should only be changed
  // if not propagating message to the 'out' terminal
  if ( routeTo > 0 )
    out.propagate(assembly);
  else
    alt.propagate(assembly);
}
```

Logging errors with the JavaCompute node
The MbService class contains a number of static methods for writing to the Administration log or syslog. Define message catalogs by using Java resource bundles to store the message text.

About this task

Three levels of severity are supported:

- Information
- Warning
- Error

Using XSL Transform

Use the XSLTransform node to transform an XML message to another form of message, according to the rules provided by an XSL (Extensible Stylesheet Language) style sheet.

About this task

Use the XSLTransform node to transform an input XML message into another format using XSLT style sheets and to set the message domain, message model, message type, and message format for the generated message. It is imperative that the data can be parsed into a XML message. The style sheet, using the rules that are defined within it, can perform the following actions:

- Sort the data
- Select data elements to include or exclude based on some criteria
- Transform the data into another format

The Xalan-Java transformation engine (Apache Xalan-java XSLT processor) is used as the underlying transformation engine. For more information about XML Transformations, the W3C specification of the syntax, and semantics of the XSL Transformations language for transforming XML documents into other XML documents, see W3C XSL Transformations.

You can deploy style sheets and XML files to integration servers, to help with style sheet and XML file maintenance.

You can specify the location of the style sheet to apply to this transformation in three ways:

- Use the content of the XML data within the message itself to transform the message according to a style sheet that the message itself defines.
- Set a value in the `LocalEnvironment` folder. You must set this value in a node that precedes the XSLTransform node (for example, a Compute node). You can therefore use various inputs to determine which style sheet to use for this message, such as the content of the message data, or a value in a database.

- Use node properties to ensure that the transformation that is defined by this single style sheet is applied to every message that is processed by this node.

An XSLT (Extensible Stylesheet Language for Transformations) compiler is used for the transformation if the style sheet is not embedded within the message, and the node cache level (node property Stylesheet Cache Level) is greater than zero. If the XSLT is cached, the performance is improved because the XSLT is not parsed every time it is used.

If the prologue of the input message body contains an XML encoding declaration, the XSLTransform node ignores the encoding, and always uses the CodedCharSetId in the message property folder to decode the message.

The XSLT capability that is provided by the XSLTransform node requires XML processing APIs that are included in Xalan-Java and Xerces JAR files. The XSLTransform node provides Xalan-Java and Xerces JAR files that work correctly with the node. The Java JRE also includes Xalan-Java and Xerces JAR files, but you might experience unpredictable results when these Java XML processing methods are invoked by using an external Java method from a style sheet. Therefore, the calling of Java methods from a style sheet that directly or indirectly reference Java JRE XML processing methods is unsupported.

To find out more about the XSLTransform node and how to configure it, refer to the following topics:

- node
- Using local environment variables to set properties
- Deployed and non-deployed style sheets

Using .NET

You can use .NET applications on Windows integration nodes to create, route, and transform messages by using the .NETCompute and .NETInput nodes.

About this task

.NET nodes use any Common Language Runtime (CLR) compliant language to create or modify the message, such as C#, Visual Basic (VB), F#, and C++/CLI (Common Language Infrastructure).

You configure a .NET node with a .NET assembly that contains the code of the node. The code consists of a class that is derived from the abstract class that is provided in the `IBM.Broker.Plugin.dll` assembly, for example, NBComputeNode.

The .NET assembly is run inside a .NET application domain. For more information, read “.NET application domains” on page 1791.

This section describes the following tasks:

.NET application domains

A .NET application domain is a run time container for .NET assemblies and associated resources used by the .NET code in your message flows.

You can call .NET assemblies in your message flows from the .NETCompute node, .NETInput node or from an ESQL procedure. You can also include .NET assemblies as dependencies of a library. These assemblies run in a .NET application domain and can be packaged in a BAR file. Application domains are shown in the navigator view as peers of applications and libraries.

A named .NET application domain can be associated with IBM App Connect Enterprise applications. Assemblies, or associated resources, contained in the .NET application domain are deployed along with the referencing message flow or application. You can associate more than one application with the same .NET application domain. This means that data and other resources can be shared at run time between multiple applications.

Implicit application domains

Creating a .NET application domain in the IBM App Connect Enterprise Toolkit allows you to package your .NET assemblies and associated resources as desired to run on the CLR (Common Language Runtime). However, you do not have to explicitly create a .NET application domain in the IBM App Connect Enterprise Toolkit.

If you do not explicitly create a .NET application domain, and do not set a value for the **AppDomain** property on the .NET node, .NET assemblies can also be contained in an implicit .NET application domain. If you do not set the **AppDomain** node property, an implicit application domain is shown in the navigator when a message flow in your workspace calls a .NET assembly, or when a library in your workspace includes .NET assemblies. At run time the implicit application domain is automatically created by the integration node and takes the name of the referencing application, or the name of the integration server if the message flow is not contained in an application.

This means that the name of the application domain at run time is dependent on the name of the owning application or integration server, and changes if the application or integration server is renamed. Additionally, if an assembly is included in one library that is referenced by two different applications, the application domain under which that assembly runs has a different name dependent on the owning application.

Consider the following example: A library MyLib includes a .NET assembly and is referenced from application App1. When App1 is deployed, a copy of the library is made and the .NET assembly runs in a .NET application domain that takes the name of the application: App1. However, If MyLib is also referenced from application App2, a separate copy of the library is made, and the application domain in which the second copy of the assembly runs takes the name App2.

Deploying .NET code

When you deploy a message flow or application that uses .NET assemblies, there are two ways of working with the assemblies. These typically correspond with the application development, and test or production stages of the software development life cycle:

- You can choose to not package the .NET application domain in the BAR file. In this case, the .NET assembly is loaded directly from your integration node file system. This means that you do not have to redeploy the message flow when the assembly is rebuilt on the file system, because the integration node reloads the application domain with the rebuilt assembly. However, the assembly must always be available on the integration node file system. Use this method for application development systems.
- You can package the .NET application domain in the BAR file. This allows greater portability of message flows on different integration nodes and servers, but means that you must redeploy the BAR file if the .NET assembly is rebuilt. Use this method for test and production systems.

Creating a .NET application domain
Create a .NET application domain as a run time container for .NET assemblies used in your message flows. You can associate .NET application domains with one or more applications as a dependent resource.

Before you begin

Read the concept information ".NET application domains" on page 1791.

About this task

Use this process to create a .NET application domain, in which you can contain .NET assemblies and other resources that will run within that execution scope at run time. You can associate a .NET application domain with one or more applications as a dependent resource.

To create a .NET application domain, complete the following steps.

Procedure

1. To open the New .NET Project wizard, click **File** > **New** > **.NET Project**.

   Alternatively, in the Application Development view, right-click within the navigator and click **New** > **.NET Project**.
2. Specify the name of the application domain to create.
3. Click **Finish** to create an empty application domain, or click **Next** to import .NET assemblies or other resources into the application domain from the file system.

   You also can drag and drop assemblies from the file system onto the application domain after closing the wizard.
4. To import .NET assemblies into the application domain, select a root directory and choose the assemblies or other resources that you want to import.
5. Click **Finish**.

Results

The new application domain is displayed in the Application Development view, as a peer of applications and libraries.

Importing resources into a .NET application domain

Import .NET assemblies and other resources into a .NET application domain.

Before you begin

Create a .NET application domain. For more information, see "Creating a .NET application domain" on page 1792.

About this task

When you import a .NET assembly into an application domain, the import stores a link to the original location of the file on the file system. Changes made to the assembly on the file system are picked up when you refresh the application domain object.

The import additionally makes a copy of the imported file in the application domain, and so you can deploy your .NET application from your workspace even if you remove the original source file from the file system.

Deploying .NET assemblies

.NET assemblies can be included in a BAR file, or loaded directly from your integration node file system.

About this task

Include the .NET assembly in the BAR file by packaging it in a .NET application domain. The application domain is packaged as a `.appdomainzip` at the root level of the BAR file. The .NET assembly is deployed with any other resources in the application domain.

If the .NET application domain is associated with an application, you can deploy the referencing application. The .NET assemblies in the application domain are deployed with the application. Alternatively, you can deploy the .NET application domain separately.

Deploy the application domain by right-clicking on the object in the Application Development view, or by dragging and dropping the application domain onto an integration server in the Integration Explorer view.

If the .NET assembly is not included in the BAR file, and is loaded directly from the integration node file system, the assembly is found in one of the following ways:

- The absolute directory path specified on a .NET node **Assembly name** property, or specified on an ESQL function or procedure.
- An override to the absolute directory path in a BAR file for the .NET node.
- A DotNet Application Domain policy that overrides the absolute directory path.
- Using advanced properties to search the global assembly cache (GAC).

Identifying the .NET assembly at run time

The rules that govern how the .NET assembly is loaded from the integration node file system if it is not packaged in the BAR file.

About this task

The .NET configuration for an integration server is controlled by properties on the .NET node or the ESQL Procedure signature. Optionally, a DotNet Application Domain policy can also be defined for further configuration options. A message flow can invoke assemblies that run within an integration server that uses the Microsoft Common Language Runtime (CLR). Flow developers can control the .NET framework assemblies that are loaded, and the .NET application domains which are used. Assemblies are invoked either from a .NET node in a message flow, or by calling an ESQL procedure.

Application domains

About this task

The .NET framework separates application assemblies to run in a particular application domain that provides a scope for the resources for an application. In IBM App Connect Enterprise, the integration server operating system process (DataFlowEngine) hosts the CLR. Within this process, .NET assemblies can be executed within multiple application domains if required.

- The **AppDomain name** property of a .NET node specifies the application domain in which the assembly is to be loaded. If a DotNet Application Domain policy is defined with the same name as the **AppDomain name** property of the node, the policy properties take precedence when the assembly is loaded. Such properties include the **Application Base directory** property.
- When an ESQL procedure invokes a .NET assembly, the signature of the procedure can specify the application domain in which the assembly must be loaded. If a DotNet Application Domain policy is defined with the name that is specified for the application domain in the signature of the ESQL procedure, the policy properties (for example the **Application Base directory**) take precedence when the assembly is loaded.

If no application domain is specified by the preceding methods, the application domain in which the assembly is loaded is determined by:

- The name of the application, if deployed within an IBM App Connect Enterprise application
- The name of the integration server, if deployed in a flow which is not defined within an IBM App Connect Enterprise application

If the application domain is determined by the name of the application or the name of the integration server, and a DotNet Application Domain policy is defined with the same name, the policy properties (for example, the **Application Base directory**) take precedence when the assembly is loaded. If the application name or integration server name includes space characters, these characters are ignored when the application name or integration server name is compared to the name of the policy.

Application base directory

About this task

To understand which copy of an assembly will be loaded, first determine the Application Base directory.

1. If the `Application domain` property refers to a policy, the **Application base** property of the policy is used. Use this approach in production environments.

   Note: The policy properties, including **Application base**, always take precedence even if you have deployed a .NET application domain that contains the assemblies to the run time. In this situation, to ensure that the .NET assembly is loaded from the `.appdomainzip` and not from the Application Base directory, ensure that the **Application base** property of the policy is blank.
2. If the Assembly name property of the .NET node (or equivalent part of the ESQL procedure signature) specifies an absolute location in the file system, this full directory path is used as the `Application Base directory`.
3. If the Assembly name property of the .NET node (or equivalent part of the ESQL procedure signature) specifies just the name of the .dll file with no path, the integration node uses a subdirectory of the runtime integration node's work path for the Application Base directory. This directory might change; consider using one of the alternative approaches.

Assembly loading and the Global Assembly Cache

About this task

The integration node expects to find the required .NET assembly in the Application Base directory. However, you can place assemblies in a machine-wide cache, which is known as the Global Assembly Cache (GAC). To place an assembly into the GAC, it must be *Strong-Named*: when it is compiled, the assembly is given the properties of a version, a culture, and a public key token. When configuring the .NET

node or an invocation from ESQL, you can specify the version, culture, and public key token of the *Strong-Named* assembly to be used.

You have to restart the integration server if you want to reload or update a *Strong-Named* assembly.

Creating and transforming messages using a .NETCompute node

You can use the .NETCompute node to create, route, and copy messages, and to create and manipulate message elements.

About this task

This section describes the following tasks:

Creating a message with a .NETCompute node

Write appropriate code in the UserCode region of a CreateNode class.

Procedure

1. In Microsoft Visual Studio, add an instance of the **Class to create a Message Broker message** to your project.
2. Add the appropriate code to the UserCode region of the class that you created.
   The following example creates a simple message:

```
outputRoot.CreateLastChildUsingNewParser(NBParsers.XMLNSC.ParserName);
outputRoot["XMLNSC"].CreateFirstChild(null, "Message");
outputRoot["XMLNSC"]["Message"].CreateFirstChild(null, "Element").SetValue("Some Data");
```

3. Build your project, and then associate the `.dll` file with a .NETCompute node.
   If the example code is associated with a .NETCompute node between an MQInput node and an MQInput node, the following message is created:

```
<Message><Element>Some Data</Element></Message>
```

Copying a message with a .NETCompute node

Copy an existing message using the .NETCompute node.

About this task

Transformation nodes, such as the .NETCompute node, can modify the logical tree structure that is passed through a message flow from one node to the next. This tree structure, or *message assembly*, contains four trees to represent the message, the environment, the local environment, and the exception list. To send data from the input terminal of the .NETCompute node to the output terminal, the class associated with the node must contain an Evaluate method that either propagates the input message assembly, or creates an output message assembly. To copy a message from the input terminal to the output terminal, propagate the whole input message assembly. The template code provided for you when

you create a FilterNode class in C# propagates the message. As you can see in the following code, the inputAssembly is passed to the Propagate method:

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("Out");

            NBMessage inputMessage = inputAssembly.Message;
            NBElement root = inputMessage.RootElement;

            #region UserCode
            // Add user code in this region to filter the message
            #endregion UserCode

            // Change the following if not propagating message to the 'Out' terminal
            outTerminal.Propagate(inputAssembly);
        }
```

If you plan to copy the message and then also update it in the .NETCompute node, it is better to use the CreateNode template. This template creates an output assembly. You copy the input assembly to this output assembly by adding just one line of code to the UserCode region:

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("out");

            NBMessage inputMessage = inputAssembly.Message;

            // Create a new empty message, ensuring it is disposed after use
            using (NBMessage outputMessage = new NBMessage())
            {
                NBMessageAssembly outAssembly = new NBMessageAssembly(inputAssembly,
 outputMessage);
                NBElement inputRoot = inputMessage.RootElement;
                NBElement outputRoot = outputMessage.RootElement;

                // Optionally copy message headers, remove if not needed
                CopyMessageHeaders(inputRoot, outputRoot);

                #region UserCode
                // Add user code in this region to create a new output message
                outputRoot.AddLastChild(inputRoot.LastChild);
                #endregion UserCode

                // Change the following if not propagating message to the 'Out' terminal
                outTerminal.Propagate(outAssembly);
            }
        }
```

Routing a message using a .NETCompute node
Route a message by using the .NETCompute node as a filter node.

Before you begin

Add a .NETCompute node to your message flow.

About this task

By default, the output message assembly is propagated to the Out terminal after the evaluate method in the .NET code has been processed. However, the .NETCompute node supports dynamic terminals. You can create extra terminals, and use the .NETCompute as a filter node by propagating a message to the appropriate terminal, based on the message content.

The following snippet of C# code shows how you might filter a message, depending on the content of an element in the message:

```
            #region UserCode
            // Add user code in this region to filter the message

            if (root[NBParsers.XMLNSC.ParserName].LastChild.Name.Equals("LoyaltyProgram"))
            {
```

```
            outTerminal.Propagate(assembly);
        }

        if (root[NBParsers.XMLNSC.ParserName].LastChild.Name.Equals("SaleEnvelope"))
        {
            altTerminal.Propagate(assembly);
        }
        else
        {
            failureTerminal.Propagate(assembly);
        }
        #endregion UserCode
```

Setting and moving message elements using a .NETCompute node
You can transform elements in the message as it passes through a .NETCompute node in the message flow.

About this task

The following sections show the methods that you can use to set, move, and remove elements:

- "Setting information about an element" on page 1797
- "Moving elements" on page 1797
- "Removing elements" on page 1798

Setting information about an element

About this task

Use these properties and methods to set information about the referenced element:

Name
This property sets the name of the current element

ValueType
This property sets the specific type of the current element.

Namespace
This property sets the namespace URI of the current element

SetValue
This method sets the value of the current element

Moving elements

About this task

Use the following methods to copy or detach an element from a message tree:

Detach
This method detaches the current element from the tree.

DetachAllChildren
This method detaches all children of the current element from the tree.

Use one of the following methods to attach an element or subtree that you have copied on to another tree:

AddBefore
This method adds an element before the referenced element.

AddAfter
This method adds an element after the referenced element.

AddFirst
This method adds an element as the first child of the referenced element.

AddLast
This method adds an element as the last child of the referenced element.

Removing elements

About this task

Use these properties and methods to remove elements from the message tree:

Delete
This method deletes the referenced element from the tree.

DeleteAllChildren
This method deletes all children of the referenced element from the tree.

Creating elements using a .NETCompute node
The NBElement class represents a single parsed element in the message tree. The class provides four different creation methods that you can use to create a new element in the message tree.

About this task

- CreateFirstChild
- CreateLastChild
- CreateBefore
- CreateAfter

The method names indicate where the element is to be created in the hierarchy in relation to the NBElement on which they are called. The following C# Evaluate method contains example code for a ..NETCompute node:

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("Out");
            NBMessage inputMessage = inputAssembly.Message;

            // Create a new empty message, ensuring it is disposed after use
            using (NBMessage outputMessage = new NBMessage())
            {
                NBMessageAssembly outAssembly = new NBMessageAssembly(inputAssembly,
outputMessage);
                NBElement inputRoot = inputMessage.RootElement;
                NBElement outputRoot = outputMessage.RootElement;

                // Optionally copy message headers, remove if not needed
                CopyMessageHeaders(inputRoot, outputRoot);

                #region UserCode
                // Add user code in this region to create a new output message
                NBElement msg =
outputRoot.CreateLastChildUsingNewParser(NBParsers.XMLNSC.ParserName).CreateFirstChild(null,"Message");
                NBElement el4 = msg.CreateLastChild("Element4");
                NBElement el1 = msg.CreateFirstChild("Element1");
                el1.SetValue("Data Value for Element1");
                el4.SetValue("Data Value for Element4");
                el1.CreateAfter("Element2").SetValue("Data Value for Element2");
                el4.CreateBefore("Element3").SetValue("Data Value for Element3");

                #endregion UserCode

                // Change the following if not propagating message to the 'Out' terminal
                outTerminal.Propagate(outAssembly);
            }
        }
```

When the node is wired to a suitable output node (such as an MQOutput node), the code produces an XML message that looks like this:

```
<Message>
     <Element1>Data Value for Elememt1</Element1>
     <Element2>Data Value for Elememt2</Element2>
     <Element3>Data Value for Elememt3</Element3>
     <Element4>Data Value for Elememt4</Element4>
</Message>
```

Writing code for a .NETCompute node
Create code for message flows containing a .NETCompute node by double-clicking the node to start Microsoft Visual Studio.

Before you begin

- Install Microsoft Visual Studio 2010 or 2012.
- Create a message flow that contains a .NETCompute node.

Tip: If the IBM App Connect Enterprise Toolkit is installed after Microsoft Visual Studio, the integration node Project templates will be automatically installed ready for you to use. However, if the IBM App Connect Enterprise Toolkit is installed first, you must manually install the Microsoft Visual Studio templates. This installation can be achieved by running the file `IBM.Broker.DotNet.vsix` and stepping through the wizard (accepting the license file as part of the process). If the default installation location was used for IBM App Connect Enterprise Toolkit, the file can be found at the location `C:\Program Files\IBM\ACE\12.0.`*n*`.0\tools\iibt`.

About this task

You write and compile your code in Microsoft Visual Studio. The following IBM App Connect Enterprise templates are provided to get you started in C#, Visual F#, and Visual Basic:

- **Create an IBM Integration message**. This class also provides a method to copy message headers from an incoming message.
- **Filter an IBM Integration message**.
- **Modify an IBM Integration message**.

Procedure

1. Double-click the .NETCompute node.
2. In Microsoft Visual Studio 2010 or 2012, navigate to your project, and add the appropriate class from the **IBM Integration** templates.
3. Expand the `UserCode` region, and write your code.

   Content assist is available in this region. Press `Ctrl+Space` to invoke it.
4. Save the class and build the solution, making a note of the path to the assembled file.

What to do next

Associate your assembly with the .NETCompute node.

Associating code with a .NETCompute node
To associate your compiled code assembly with a .NETCompute node, complete the **`Assembly name`** and **`Class name`** properties on the node.

About this task

Tip: Your message flows can call .NET assemblies. You write and maintain your .NET code in Microsoft Visual Studio. You develop your message flows in the IBM App Connect Enterprise Toolkit, which runs in an Eclipse framework. It is suggested that you keep the assemblies in the Visual Studio framework; do not import them into the IBM App Connect Enterprise Toolkit.

Tip: You can also drag an existing .NET assembly or .NETCompute node onto the canvas, and then follow the prompts to create this association. The assembly must contain an implementation of a .NETCompute node.

Procedure

1. Create a message flow that contains a .NETCompute node.
   For example, create a message flow containing an MQInput node, a .NETCompute node, and an MQOutput node.
2. On the **Basic** tab of the .NETCompute node, set the **`Assembly name`** property to point to the assembly that contains your compiled code.

   You can either type the full path name of the file into the field, or select **Browse** to navigate to `.exe` and `.dll` files stored on the file system.
3. Optional: Specify the name of the class within the assembly.
4. Save the message flow.

Traversing the element tree by using a .NETCompute node
Use .NETCompute node NBElement properties and methods (in C# for example) to access element trees.

About this task

Use the following statements to traverse a message tree from an NBElement:

Parent
This property returns the parent of the current element.

PreviousSibling
This property returns the previous sibling of the current element.

NextSibling
This property returns the next sibling of the current element.

Children()
This method returns all the child elements of the current element as an array of NBElements.

FirstChild
This property returns the first child of the current element.

LastChild
This property returns the last child of the current element.

Iterating over elements by using a .NETCompute node
Use the **`Where`** method to provide a sequential iteration over elements in the message tree.

About this task

You can use the resulting array in a foreach() statement to iterate over the children of an NBElement. The foreach() loop allows a developer to act on each NBElement in turn. The example below shows how this can be used to create a similar shape output message to the input message. Consider a simple XML input message:

```
<MessageEnvelope>
 <Element>1</Element>
 <Element>2</Element>
 <Element>3</Element>
</MessageEnvelope>
```

The following C# code in a .NETCompute node iterates over the elements:

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("out");

            NBMessage inputMessage = inputAssembly.Message;

            // Create a new empty message, ensuring it is disposed after use
            using (NBMessage outputMessage = new NBMessage())
            {
                NBMessageAssembly outAssembly = new NBMessageAssembly(inputAssembly,
 outputMessage);
                NBElement inputRoot = inputMessage.RootElement;
```

```
                NBElement outputRoot = outputMessage.RootElement;

                // Optionally copy message headers, remove if not needed
                CopyMessageHeaders(inputRoot, outputRoot);

                #region UserCode
                // Add user code in this region to create a new output message
                outputRoot.CreateLastChildUsingNewParser("XMLNSC");
                outputRoot["XMLNSC"].CreateLastChild("OutputMessageEnvelope");
                string notargetnamespace = "";
                NBElement env = inputRoot["XMLNSC"]["MessageEnvelope"];
                var elementlist = env.Where(t => t.Name == "Element");
                foreach (NBElement element in elementlist)
                {
                    int currentvalue = (Int32)element;
                    NBElement outelement = outputRoot["XMLNSC"]
["OutputMessageEnvelope"].CreateLastChild(notargetnamespace, "OutElement");
                    outelement.SetValue("After adding 1 to input value we get " + (currentvalue
 + 1).ToString());
                }
                #endregion UserCode

                // Change the following if not propagating message to the 'Out' terminal
                outTerminal.Propagate(outAssembly);
            }
        }
```

The output is an XML message:

```
<OutputMessageEnvelope>
 <OutElement>After adding 1 to input value we get value 2</OutElement>
 <OutElement>After adding 1 to input value we get value 3</OutElement>
 <OutElement>After adding 1 to input value we get value 4</OutElement>
</OutputMessageEnvelope>
```

Accessing other parts of the message tree using a .NETCompute node
Use the .NETCompute node to access headers, integration node properties, user-defined properties, the local environment, and the global environment.

About this task

The message tree is passed to a .NETCompute node as an argument of the evaluate method. The argument is an NBMessageAssembly object. The message assembly contains four message objects:

- Parsed message
- LocalEnvironment
- GlobalEnvironment
- ExceptionList

The following topics describe how to access parts of the message tree:

- “Accessing headers with a .NETCompute node” on page 1801
- “Updating the local environment with a .NETCompute node” on page 1802
- “Updating the global environment by using a .NETCompute node” on page 1802
- “Accessing user-defined properties from a .NETCompute node” on page 1803

Accessing headers with a .NETCompute node
Use a .NETCompute node to access headers in the message assembly.

About this task

Two of the most common headers encountered in messaging scenarios are the MQMD and MQRFH2. If an input node receives an input message that includes message headers that the input node recognizes, the node invokes the correct parser for each header. Parsers are supplied for most IBM MQ headers. This topic provides guidance for accessing the information in the MQMD and MQRFH2 headers that you can follow when accessing other headers that are present in your messages.

For more information about the contents of these and other IBM MQ headers for which IBM App Connect Enterprise provides a parser, see Element definitions for message parsers.

The following C# code shows how to add an MQMD header and an MQRFH2 header to your message using a .NETCompute node:

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("out");

            NBMessage inputMessage = inputAssembly.Message;

            // Create a new empty message, ensuring it is disposed after use
            using (NBMessage outputMessage = new NBMessage())
            {
                NBMessageAssembly outAssembly = new NBMessageAssembly(inputAssembly,
outputMessage);
                NBElement inputRoot = inputMessage.RootElement;
                NBElement outputRoot = outputMessage.RootElement;

                #region UserCode
                // Add user code in this region to create a new output message
                NBElement MQMD =
outputRoot.CreateLastChildUsingNewParser(NBParsers.NBHeaderParsers.MQMD.ParserName);

                NBElement MQRFH2 =
outputRoot.CreateLastChildUsingNewParser(NBParsers.NBHeaderParsers.MQRFH2.ParserName);
                #endregion UserCode

                // Change the following if not propagating message to the 'Out' terminal
                outTerminal.Propagate(outAssembly);
            }
        }
```

Updating the local environment with a .NETCompute node
The local environment tree is part of the logical message tree where you can store information while the message flow processes the message.

About this task

In the following example, the C# Evaluate method, which is executed by a .NETCompute node, creates an output message assembly based on the input message assembly. The local environment that enters the .NETCompute node is copied and then updated with the name of a queue which can be used as a DestinationList to dynamically control the behavior of a later MQOutput node.

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("Out");
            // This code creates an output Assembly based on the input Assembly
            // The Local Environment is copied and editted to provide a dynamic override for the
MQOutput node
            NBMessage inputLocalEnvironment = inputAssembly.LocalEnvironment;
            NBMessage outputLocalEnvironment = new NBMessage(inputLocalEnvironment);
            NBElement mqLE = outputLocalEnvironment.RootElement.CreateFirstChild(null,
"Destination").CreateFirstChild(null, "MQ");
            mqLE.CreateFirstChild(null, "DestinationData").CreateFirstChild(null, "queueName",
"DOTNET.OUT");
            NBMessageAssembly outAssembly = new NBMessageAssembly(inputAssembly,
inputAssembly.Message, outputLocalEnvironment, inputAssembly.ExceptionList);

            outTerminal.Propagate(outAssembly);
        }
```

Updating the global environment by using a .NETCompute node
Change the global environment by using code in your .NETCompute node.

About this task

The global environment tree is always created when the logical tree is created for an input message. However, a message flow does not populate it or use its contents. You can use this tree for your own purposes, for example to pass information from one node to another. You can use the whole tree as a scratchpad or working area.

The Global Environment can be altered at any point during the message flow; therefore you do not make a copy of it to alter. The following C# code shows how to change the global environment in a .NETCompute node:

```
        public override void Evaluate(NBMessageAssembly inputAssembly)
        {
            NBOutputTerminal outTerminal = OutputTerminal("Out");
            NBMessage inputMessage = inputAssembly.Message;
            // Create a new empty message, ensuring it is disposed after use
            using (NBMessage outputMessage = new NBMessage())
            {
                NBMessageAssembly outAssembly = new NBMessageAssembly(inputAssembly,
 outputMessage);
                NBElement inputRoot = inputMessage.RootElement;
                NBElement outputRoot = outputMessage.RootElement;

                // Optionally copy message headers, remove if not needed
                CopyMessageHeaders(inputRoot, outputRoot);

                #region UserCode
                // Add user code in this region to create a new output message
                NBMessage env = outAssembly.Environment;
                env.RootElement.CreateFirstChild(null, "Status", "Success");

                #endregion UserCode

                // Change the following if not propagating message to the 'Out' terminal
                outTerminal.Propagate(outAssembly);
            }
        }
```

Accessing user-defined properties from a .NETCompute node
You can customize a .NETCompute node to access properties that you have associated with the message flow in which the node is included.

About this task

To access these properties from a .NETCompute node, use the GetUserDefinedProperty or GetUserDefinedPropertyAsString methods. The following sample C# code below shows how the methods can be used:

```
                #region UserCode
                // Add user code in this region to create a new output message
                int intProperty = (int)this.GetUserDefinedProperty("intProperty");
                string stringProperty = this.GetUserDefinedPropertyAsString("stringProperty");
                NBElement msg =
 outputRoot.CreateLastChildUsingNewParser(NBParsers.XMLNSC.ParserName).CreateFirstChild(null,
 "Message");
                NBElement el2 = msg.CreateFirstChild("Element2");
                NBElement el1 = msg.CreateFirstChild("Element1");
                el1.SetValue("The message flow user defined property named intProperty has the
 value "+intProperty.ToString());
                el2.SetValue("The message flow user defined property named stringProperty has
 the value "+stringProperty);
                #endregion UserCode
```

This code produces the following message (where the integer and string flow properties are set to the values 23 and "Hello World!" respectively):

```
<Message>
 <Element1>The message flow user defined property named intProperty has the value 23</Element1>
 <Element2>The message flow user defined property named stringProperty has the value Hello
 World!</Element2>
</Message>
```

Serializing .NET custom exceptions
To make .NET custom exceptions visible in IBM App Connect Enterprise, you must serialize them.

About this task

To be visible in IBM App Connect Enterprise, you must make .NET custom exceptions serializable, which means converting them into a state that can be persisted. For more information about serialization, see the Microsoft .NET framework documentation.

Creating messages by using a .NETInput node

You can use the .NETInput node to create, route, and copy messages, and to create and manipulate message elements.

About this task

This section describes the following features and tasks associated with the .NETInput node:

- "Writing code for a .NETInput node" on page 1804
- "Associating code with a .NETInput node" on page 1805
- "Accessing .NETInput node properties at run time" on page 1806
- "Adding dynamic output terminals to a .NETInput node" on page 1806
- "Adding local environment entries from a .NETInput node" on page 1807
- ".NETInput node exception handling" on page 1808

Writing code for a .NETInput node
Create code for message flows containing a .NETInput node by double-clicking the node to start Microsoft Visual Studio.

Before you begin

- Install Microsoft Visual Studio 2010 or 2012.
- Create a message flow that contains a .NETInput node.

Tip: If the IBM App Connect Enterprise Toolkit is installed after Microsoft Visual Studio, the integration node Project templates will be automatically installed ready for you to use. However, if the IBM App Connect Enterprise Toolkit is installed first, you must manually install the Microsoft Visual Studio templates. This installation can be achieved by running the file `IBM.Broker.DotNet.vsix` and stepping through the wizard, accepting the license file as part of the process. If the default installation location was used for IBM App Connect Enterprise Toolkit, the file can be found at the location `C:\Program Files \IBM\ACE\12.0.n.0\tools\iibt`.

About this task

You write and compile your code in Microsoft Visual Studio. The following IBM App Connect Enterprise templates are provided for C#, Visual F#, and Visual Basic:

- **Create a polling-based IBM Integration input node**.
- **Create an event-driven IBM Integration input node**.

Procedure

1. Double-click the .NETInput node. Alternatively, right-click the node and select **Open Microsoft Visual Studio**.

   If there is a Microsoft Visual Studio project or solution name on the **Visual Studio** panel, the project or solution automatically loads when Microsoft Visual Studio opens.

2. In Microsoft Visual Studio, select **New Project**.

   You can then select an **IBM Integration project** from beneath the language of your choice; C#, F# and Visual Basic.
3. Select a project from the list. For the .NETInput node, you can choose:

   - **Create a polling-based IBM Integration input node**
   - **Create an event-driven IBM Integration input node**

   The project then generates skeleton code that matches the selected type. This skeleton code then displays in the corresponding .NET language editor, for example; C#.
4. Expand the `UserCode` region, and write your code.

   Content assist is available in this region. Press `Ctrl+Space` to invoke it.
5. Optional: Use the methods available for your .NETInput node.

   See "Methods for a .NETInput node" on page 1808.
6. Save the class and build the solution, making a note of the path to the assembled file.

What to do next

- You might want to debug your .NET code.

  To debug a.NETInput node that is running inside the integration server, place the `.pdb` file for the assembly that implements the node in the same directory as the assembly for the node, and attach Microsoft Visual Studio to the `DataFlowEngine.exe` process. You can then place breakpoints in your code and examine variables, for example; when the breakpoint is hit.
- Associate your code with the .NETInput node.

Associating code with a .NETInput node
To associate your compiled code assembly with a .NETInput node, complete the **`Assembly name`** and **`Class name`** properties on the node.

About this task

Tip: Your message flows can call .NET assemblies. You write and maintain your .NET code in Microsoft Visual Studio. You develop your message flows in the IBM App Connect Enterprise Toolkit, which runs in an Eclipse framework. It is suggested that you keep the assemblies in the Microsoft Visual Studio framework; do not import them into the IBM App Connect Enterprise Toolkit.

Tip: You can also drag an existing .NET assembly or .NETInput node onto the canvas, and then follow the prompts to create this association. The assembly must contain an implementation of a .NETInput node.

Procedure

1. Create a message flow that contains a .NETInput node.
   For example, create a message flow that contains an MQInput node, a .NETInput node, and an MQOutput node.
2. On the **Basic** tab of the .NET node, set the **`Assembly name`** property to point to the assembly that contains your compiled code.

   You can either type the full path name of the file into the field, or select **Browse** to navigate to `.exe` and `.dll` files that are stored on the file system.
3. Optional: Specify the name of the class within the assembly.
4. Save the message flow.

Accessing .NETInput node properties at run time
When you add a .NETInput node to a message flow, you can use the **User Defined Properties** tab of the node to specify properties that can be accessed by the .NET connector code, which implements the logic of the input node at run time.

About this task

The .NET framework provides a class in the namespace `System.Collections.Generic` named `Dictionary<TKey, TValue>`, which represents a collection of keys and their associated values. When you write code for a .NETInput node, the templates that are provided in Microsoft Visual Studio helps you initialize a new instance of the `EventInputConnector` or the `PollingInputConnector` class. The template code includes the definition of the subclass for the `EventInputConnector` or `PollingInputConnector` class, which contains a **`properties`** parameter, which is of the data type `Dictionary<string,string>`. This parameter carries user-defined properties for the node, and any flow-level user-defined properties.

The individual property names are case-sensitive. For example, you can define a flow-level user-defined property named `property1`, which would be independent of a .NETInput node **User Defined Property** named `Property1`. If you specify a flow-level user-defined property and a .NETInput node user-defined property with the same name and case, then the value of the .NETInput node property takes precedence.

The following code snippet demonstrates a simple example:

```
public PollingInputConnector(NBConnectorFactory connectorFactory, string name,
 Dictionary<string, string> properties) : base(connectorFactory, name, properties)
{
// Check the Dictionary of user defined properties defined on the node.
// If there is a property named queueName then take its value for use later:
if (properties.ContainsKey("queueName"))
{
queueName = properties["queueName"];
}
}
```

Adding dynamic output terminals to a .NETInput node
You can add, rename, and remove dynamic output terminals on a .NETInput in the Message Flow editor.

Before you begin

- Add a .NETInput node to your message flow that supports dynamic terminals. For more information, see “Adding a message flow node” on page 618, “Message flow node terminals” on page 497, and “Writing code for a .NETInput node” on page 1804.

About this task

The .NETInput node can support dynamic output terminals. When you have added the .NETInput node to the flow editor, you can add, remove, or rename dynamic terminals.

Procedure

- **Adding a dynamic terminal**
  a) Right-click the node and click **Add Output Terminal**.
  b) Enter a name for the new terminal and click **OK**.
  The name must be unique for the terminal type. For example, if an output terminal called *Out* already exists, you cannot create a dynamic output terminal with the name *Out*.

  The new terminal is displayed on the node. If a node has five or more terminals, they are displayed as a terminal group: 

  To connect a particular output terminal, click the terminal group to open the Terminal Selection dialog box, or right-click the node and select **Create Connection**.
- **Renaming a dynamic terminal**
  a) Right-click the node and click **Rename Output Terminal**.
  These options are available only if you have added one or more appropriate terminals to the node.
  b) Select from the list the name of the terminal that you want to change.
  Only dynamic terminals are listed because you cannot change the name of a static terminal.
  c) Enter a new name for the terminal and click **OK**.
  Do not rename a dynamic terminal if one of the node properties is configured to use that name.
- **Removing a dynamic terminal**
  a) Right-click the node and click **Remove Output Terminal**.
  These options are available only if you have added one or more appropriate terminals to this node.
  b) Select from the list the name of the terminal that you want to remove and click **OK**.
  Only dynamic terminals are listed because you cannot remove a static terminal. Do not remove a dynamic terminal if one of the node properties is configured to use that terminal.

What to do next

When you have added dynamic output terminals to the .NETInput node, connect them to other nodes in the message flow. For more information, see “Connecting message flow nodes” on page 636.

Adding local environment entries from a .NETInput node
Add information into the local environment by using the connector code for a .NETInput node.

About this task

When developing for a .NETInput node, the content of the local environment can be populated from within the connector code for the .NETInput node as each message is created. The updated local environment allows metadata about the specific `Event` or `PollingResult` to be stored for use by later nodes in the flow.

The data is put in a section of the local environment that is called `DotNet` by default. Under `DotNet` in the folder structure is an `Input` folder. You can create further folders and elements under the `Input` folder.

You can change the top-level `DotNet` folder name by setting the **Name** property of the factory from within the connectors `Constructor()`, `Initialize()` or `Start()` methods.

You cannot change the `Input` folder name.

To create folders and elements below the `Input` folder, override the `BuildProperties` method on a subclass of `NBPollingResult` or `NBByteArrayPollingResult`. In this method, return a Dictionary that is populated with keys and values that become **Name** or **NameValue** elements under the `Input`

folder. If the key has multiple parts that are separated by / characters, then a local environment tree is created, as shown by the following code examples.

This code snippet is from a user-defined `NBPollingResult` subclass:

```
public override Dictionary<string, string> BuildProperties()
    {
      var result = new Dictionary<string, string>();
      result.Add("a/b/c/d", "Hello");
      result.Add("a/e/f", "World!");
      return result;
    }
```

The previous code results in a Local Environment tree that looks like this:

```
  (0x01000000:Name):DotNet = (
    (0x01000000:Name):Input = (
      (0x01000000:Name):a = (
        (0x01000000:Name):b = (
          (0x01000000:Name):c = (
            (0x03000000:NameValue):d = 'Hello' (CHARACTER)
          )
        )
        (0x01000000:Name):e = (
          (0x03000000:NameValue):f = 'World!' (CHARACTER)
        )
      )
    )
  )
```

The next code snippet shows how to change the name of the top-level `DotNet` folder to the example name `MyConnectorFactory`:

```
    public override void Initialize()
    {
      NBConnectorFactory factory = ConnectorFactory;
      factory.Name = "MyConnectorFactory";
      //Other code here.    }
```

.NETInput node exception handling
The .NETInput node can send exceptions to the Windows event log.

About this task

If the `ValidateData` method input record throws an exception, the exception is written to the **Failure** terminal, if it is wired. If the **Failure** terminal is not wired, then the exception is written to the Windows event log. Exceptions that are thrown in a .NETInput node before `ValidateData` is called (such as the `ReadData` method or the user Delegate) are written to the Windows event log, and an error message is not sent to the **Failure** terminal.

Unhandled exceptions that are thrown by nodes that are wired downstream of the output terminal of the .NETInput node are returned to the .NETInput node and directed to its **Catch** terminal, if wired. If the **Catch** terminal is not wired, the exception is written to the Windows event log.

Methods for a .NETInput node
The methods that you can implement in a .NETInput node depends on if you are using polling or event style message flows.

The API for the .NETInput node is called the **Connector API**. This API is in the `IBM.Broker.Plugin.Connector` namespace.

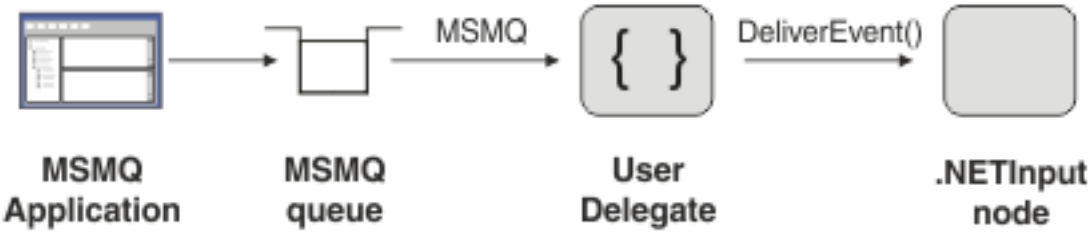
`Initialize`
The `Initialize` method is called when a message flow that contains the .NETInput node is deployed to an integration server. If an exception is thrown from `Initialize`, it rolls back the deployment of the flow.

Start

Use the Start method to create any required connections to the end system from which the .NETInput node retrieves data. This method is called after the Initialize method, when a message flow that contains the .NETInput node is successfully deployed.

If the Start method throws an exception, then it does not influence the result of the deployment of the message flow. Such an exception reports an error to the system log, and the Start method is called again after a short wait.

Event Connectors



If you are using the event-driven style of .NETInput node, then you must register a user-defined delegate with the application that is the source of the events, which drive the .NETInput node. If you use the event-driven style and do not register a delegate in the Start method, then there is no way for the .NETInput node to propagate data to the message flow threads. The User Delegate method is responsible for creating NBEvent objects and passing them to the DeliverEvent method provided on the NBEventConnector class. The DeliverEvent method puts data on an in-memory queue, which the message flow threads access to pass the data in the NBEvent object.

ReadData

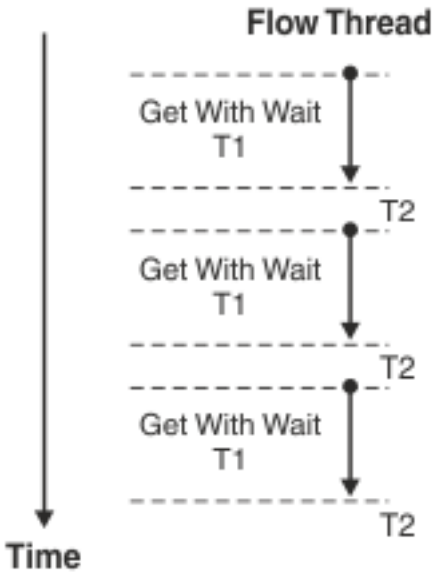
Polling-driven Connectors

If you are using the polling style of .NETInput node, you must implement the ReadData method from the NBPollingConnector base class. Your ReadData method is called by the internal code of the integration node, so a .NETInput node developer implements the method only, and is not responsible for providing code that actually calls the method. Therefore, the .NETInput is not responsible for implementing any recursive polling logic, and so it is not necessary or suitable to code a loop or use a Sleep method as part of ReadData.

The integration node runs the ReadData method automatically after the message flow finishes deploying, when the Start method returns without an exception.

The ReadData method is responsible for taking data from the data source, if available, and returns an instance of the NBPollingResult object. If data is available, the returned NBPollingResult object is either a built-in NBByteArrayPollingResult, which creates the output message directly from the byte array, or a user-defined subclass, from which you can create the message tree manually.

See the following diagram for an example of using polling with the ReadData method.



If no data is available, the node developer returns an `NBTimeoutPollingResult`. When the `ReadData` method has finished waiting for the passed in timeout duration (T1), use the single-argument constructor for `NBTimeoutPollingResult`. If the data source does not allow a timed wait, use the two-argument constructor to return a timeout value back to the integration node. In this case, the integration node waits for this timeout interval (T2) before it calls `ReadData` again. This use of the method allows a developer for the .NETInput node to control the duration of the interval between polls (T2).

For example, you can implement a batch style of operation, requesting that the `ReadData` method is only called once per hour, or once per day.

`Finish`
The `Finish` method is called when the .NETInput node that is using the connector must stop receiving data. When you remove a message flow that contains a .NETInput node that is deployed to an integration server, the `Finish` method is called before the `Terminate` method. If the `Finish` method throws an exception, then the error is reported to the system log, and the connector is placed into stopped state. This method is a good place to close connections or handles, or similar.

`Terminate`
The `Terminate` method is called when a message flow containing the .NETInput node is removed from an integration server. This method always provides a way for your code to end cleanly if you want to do anything before you remove a deployed message flow that contains a .NETInput node.

Cloning a .NETInput node
You can reproduce parameters and attributes that you customized for a .NETInput node by creating a Cloned node from it.

Before you begin

- To create a Cloned node, you must have administrator privileges.
- Add a .NETInput node to a message flow and configure the node.

About this task

The Cloned node has no special properties of its own, and cannot be created from the palette drawer. You can create it only from an existing, configured .NETInput node.

To create a Cloned node, complete the following steps.

Procedure

1. Open the message flow that contains your configured .NETInput node.
2. Right-click the .NETInput node and select **Create Cloned Node**.
3. Enter a name for the cloned node, and provide tooltip text that is displayed when you hover a mouse over the node on the palette.
4. Import node icons to represent the cloned node on the palette and in the Message Flow editor.
5. Click **Finish**.

Results

Your Cloned node is saved in the **.NET** drawer of the palette with the name that you gave it, and is represented in the IBM App Connect Enterprise Toolkit by your chosen node icon.

What to do next

When you create an instance of a Cloned node, it is configured with the properties and values that you specified for the .NETInput node from which it was cloned. To modify properties or values of a Cloned node, configure them by following the instructions in "Configuring a message flow node" on page 624.

You can configure an instance of a Cloned node when the node is dragged into a graphical data map. To configure the node, drag an assembly file from a file explorer to the node. The properties of the node are displayed in the Properties view.

All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

Calling .NET assemblies from ESQL

Use the CREATE FUNCTION or CREATE PROCEDURE statements in a node that supports ESQL.

About this task

You can call .NET code from any of the nodes that support ESQL; see "ESQL overview" on page 1608.

Tip: To associate .NET code with an ESQL node, drag an existing .NET assembly onto the canvas, or a node that supports ESQL, and then follow the prompts.

Procedure

1. In Microsoft Visual Studio, create and build your project.
2. In the IBM App Connect Enterprise Toolkit, drag one of the nodes that support ESQL onto the message flow.
3. Double-click the node to open the ESQL editor.
4. Define a CREATE FUNCTION or CREATE PROCEDURE statement, specifying the language as either .NET or CLR.
   See CREATE FUNCTION statement and CREATE PROCEDURE statement for details, including examples.

Combining a result message with an input message when fetching data from external systems

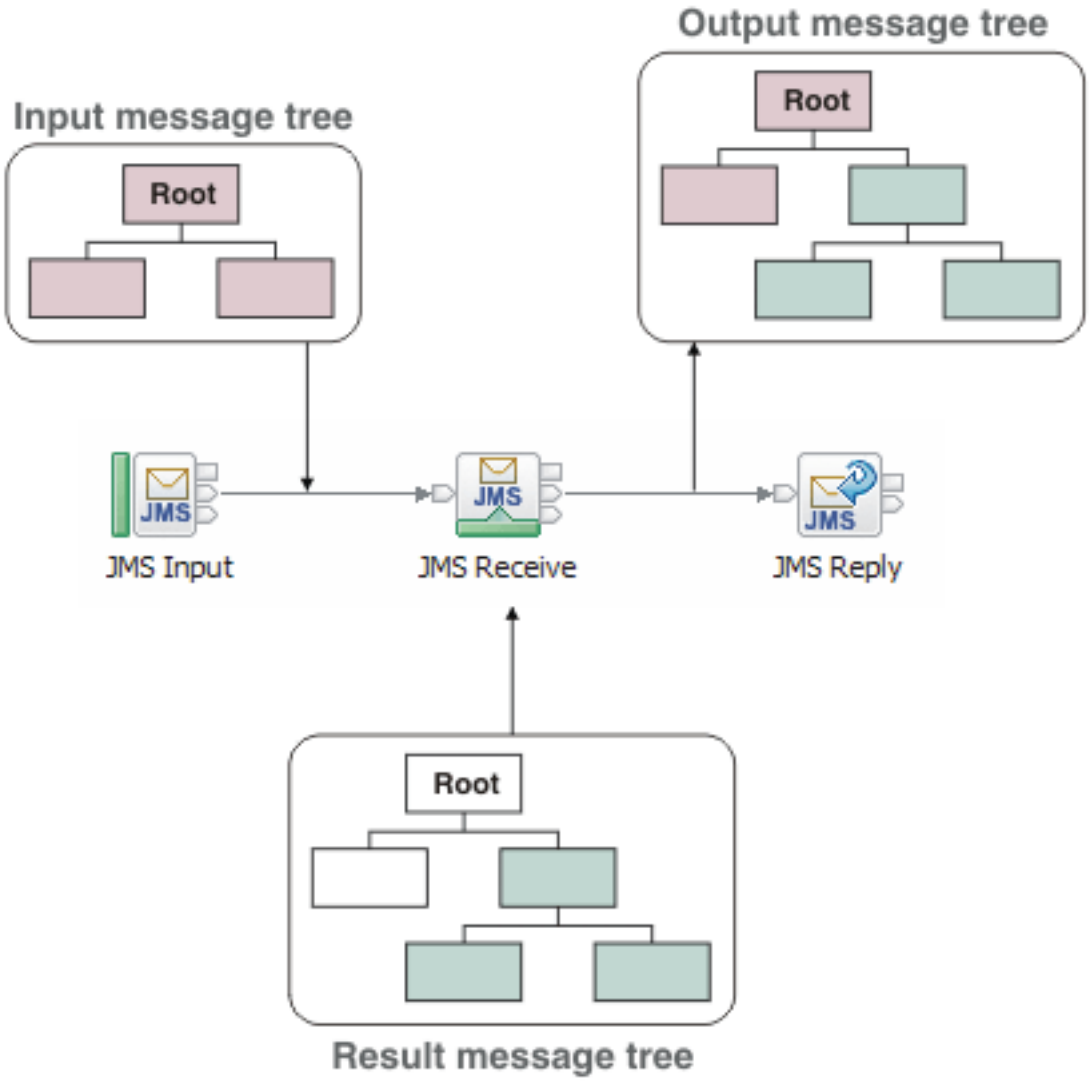
Some nodes can fetch data in the middle of a message flow, and merge the result data with the input message to augment or overwrite sections of the input message.

The following nodes can fetch data in the middle of a message flow and merge the result with the input message:

- Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications protocol (IPIC).

- Use the CORBARequest node to call an external CORBA application over Internet Inter-Orb Protocol (IIOP).
- Use the FileRead node to read one record, or the entire contents of a file, from within a message flow.
- Use the IMSRequest node to send a request to run a transaction on a local or remote IMS system, and wait for a response.
- Use the JMSReceive node to consume or browse JMS messages from a JMS queue in the middle of a message flow.
- Use the LoopBackRequest node to issue synchronous requests through a LoopBack connector, to create, retrieve, update, and delete data in a backend data source.
- Use the RESTAsyncRequest node with the RESTAsyncResponse node to construct a pair of message flows that interact asynchronously with an external REST API.
- Use the RESTRequest node to issue synchronous requests to external REST APIs.
- Use the SalesforceRequest node to send a request to a Salesforce system, to create, update, retrieve, and delete Salesforce data.
- Use the TCPIPClientReceive node to receive data over a client TCP/IP connection.
- Use the TCPIPServerReceive node to receive data over a server TCP/IP connection.

When you use one of these nodes in the middle of a message flow, you can fetch data from external resources. The result data is merged with the input message according to the values of the `Output data location` and, if it exists on the node, the `Result data location` properties.



The input root is first copied to the output root, and the result data is then copied to the location on the output tree specified by `Output data location`. The default value is `$OutputRoot`, which replaces the copied message tree with the result data, and propagates none of the input message.

The default value for `Result data location`, if it exists on the node, is `$ResultRoot`, which copies the entire result message to the output data location. If you specify a value underneath `$ResultRoot`, the specified subtree of the result message is inserted into the output tree.

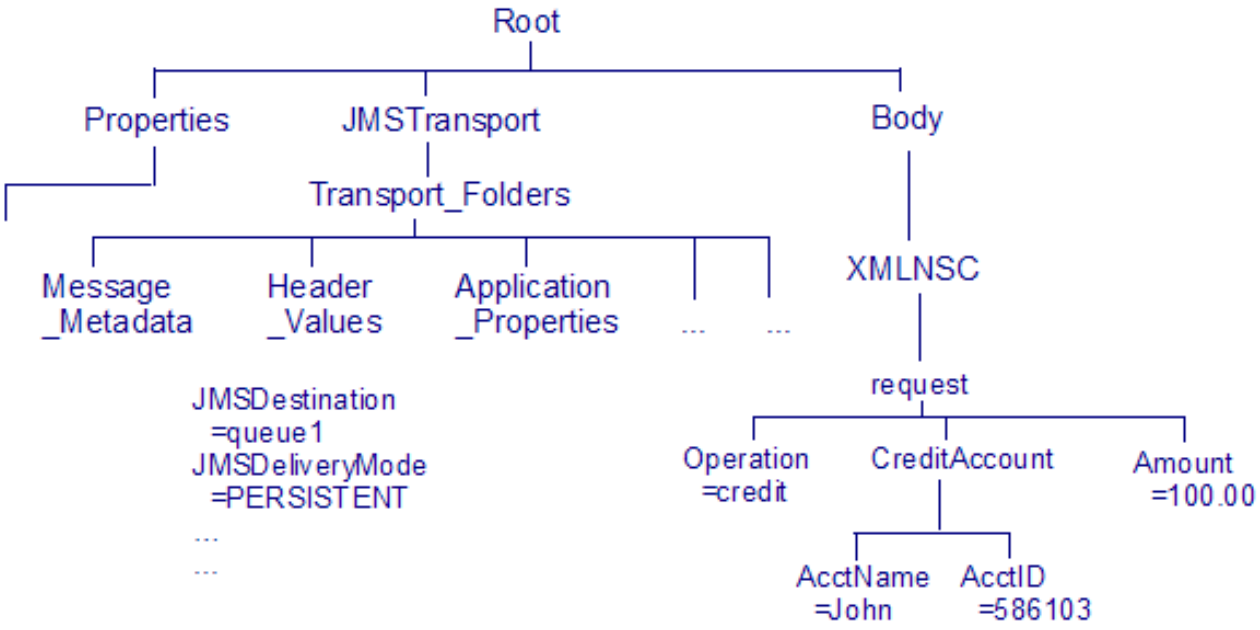
The following examples use the JMSReceive node and show the effect of possible different values specified for `Output data location` and `Result data location`.

Example 1: Replacing the whole message tree

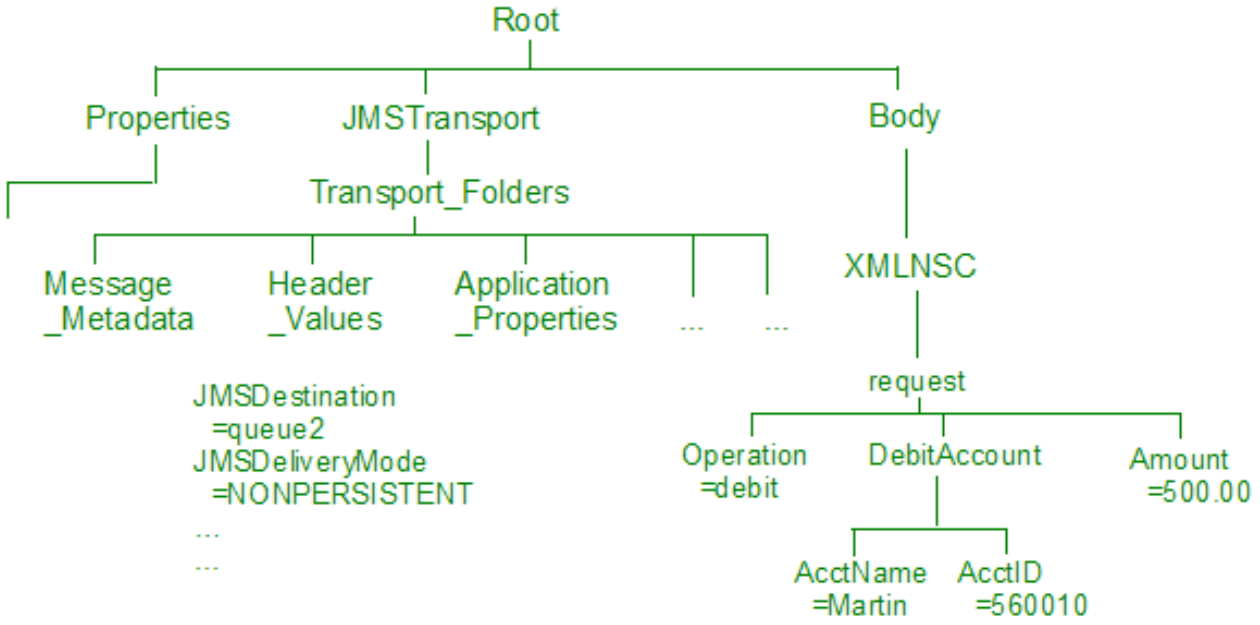
- `Output data location` = `$OutputRoot`
- `Result data location` = `$ResultRoot`

These values are the default values, and cause the input message to be overwritten with the result message.

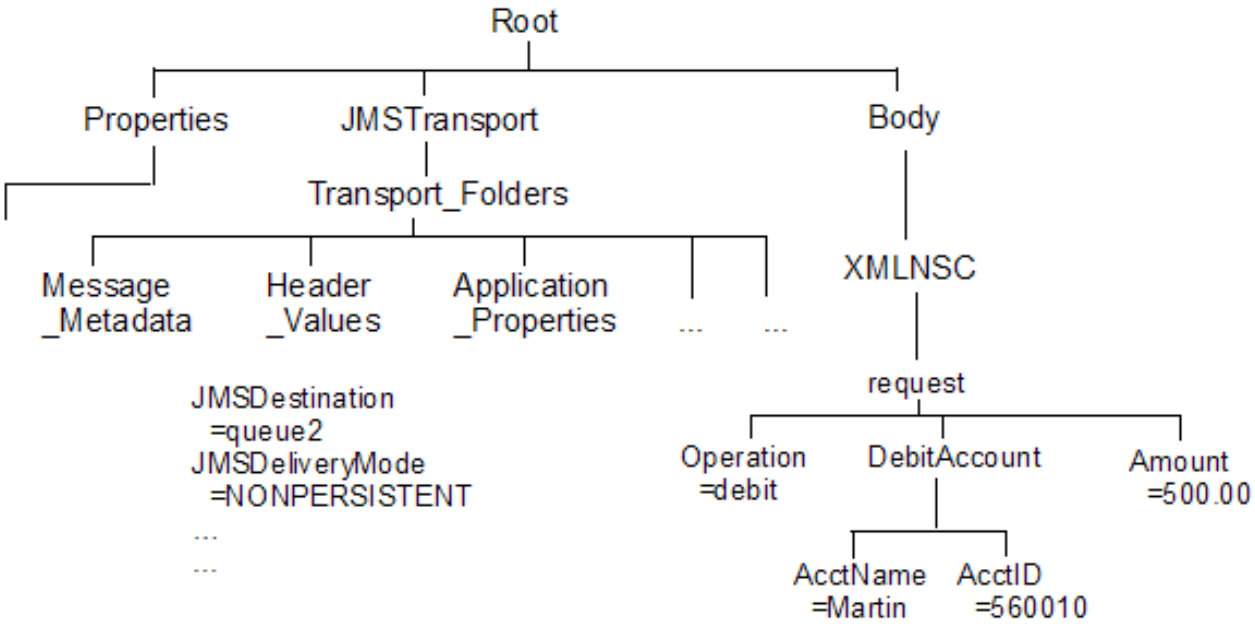
The input message tree is shown. The root element is selected to be overwritten:



The result message tree is shown. The root element is selected for insertion:



The output message tree is shown. The output root has been replaced by the result root tree:

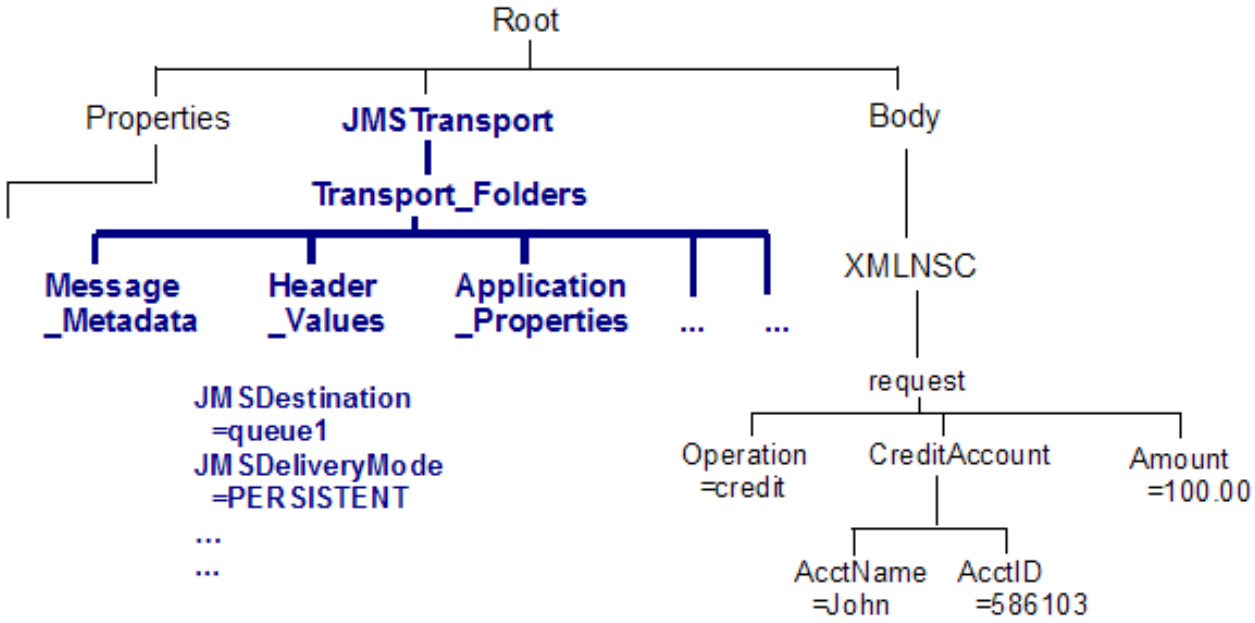


Example 2: Replacing the message headers

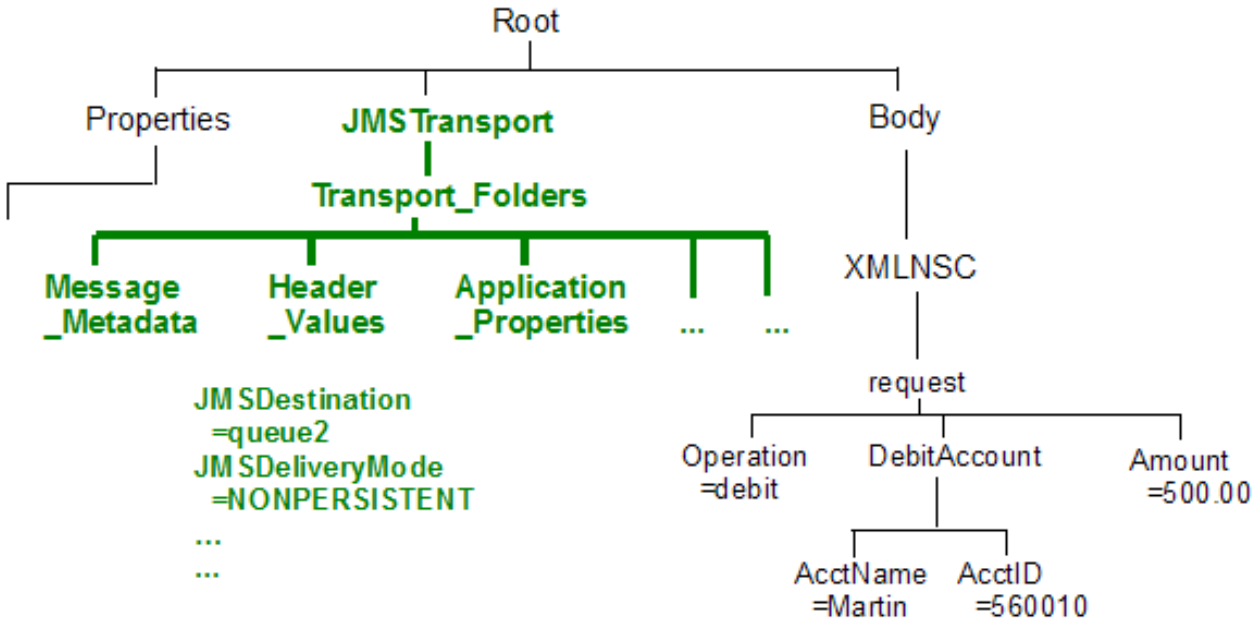
- `Output data location` = `$OutputRoot/JMSTransport`
- `Result data location` = `$ResultRoot/JMSTransport`

The input root is copied to the output root, and then the headers are overwritten by the headers of the result message.

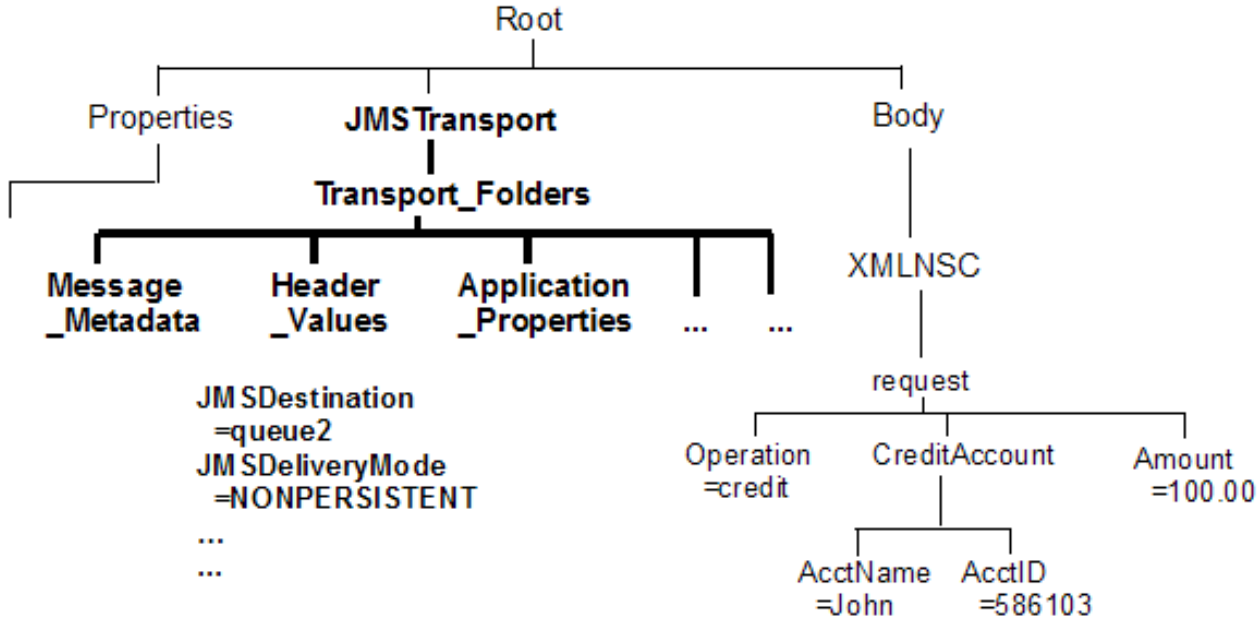
In the input message tree, the JMSTransport subtree is selected to be overwritten:



In the result message tree, the JMSTransport subtree is selected for insertion:



In the output message tree, the output JMSTransport subtree is replaced by the result JMSTransport subtree:

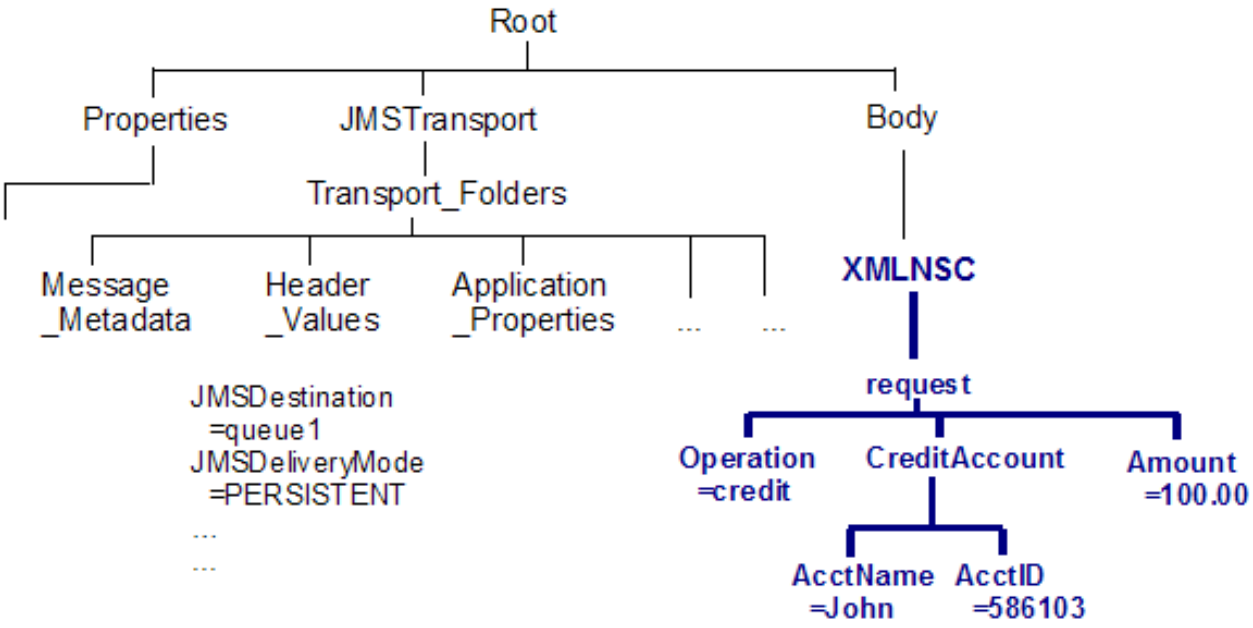


Example 3: Replacing the message body

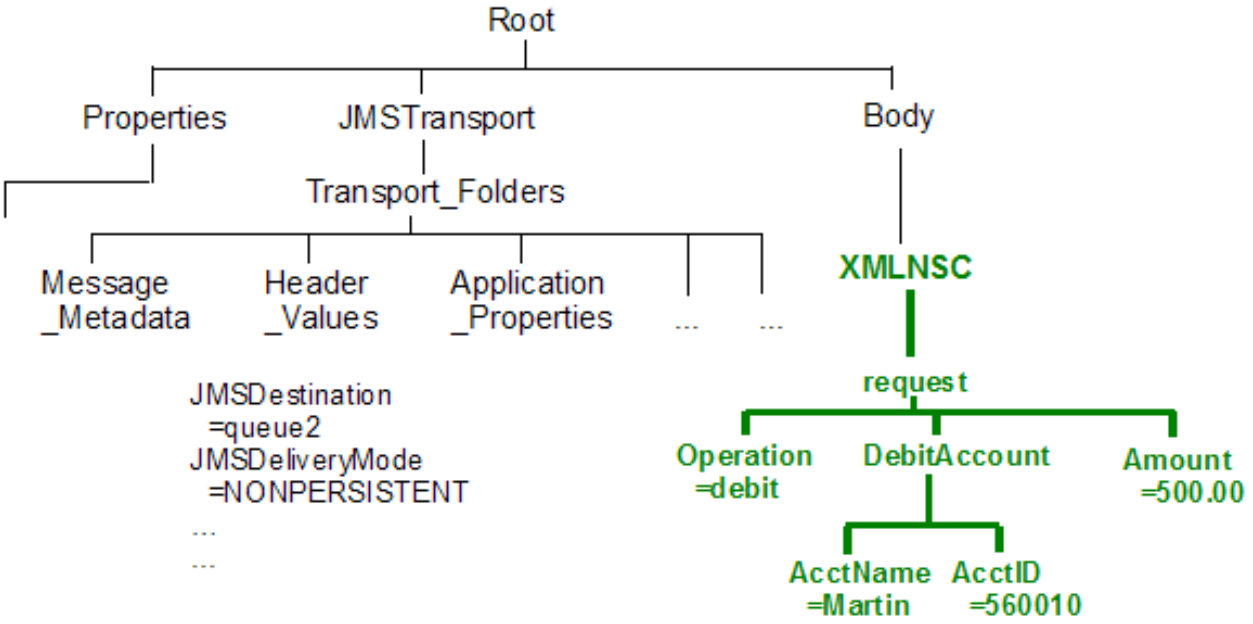
- `Output data location` = `$OutputRoot/XMLNSC`
- `Result data location` = `$ResultRoot/XMLNSC`

The input root is copied to the output root, and then the message body is overwritten by the body of the result message.

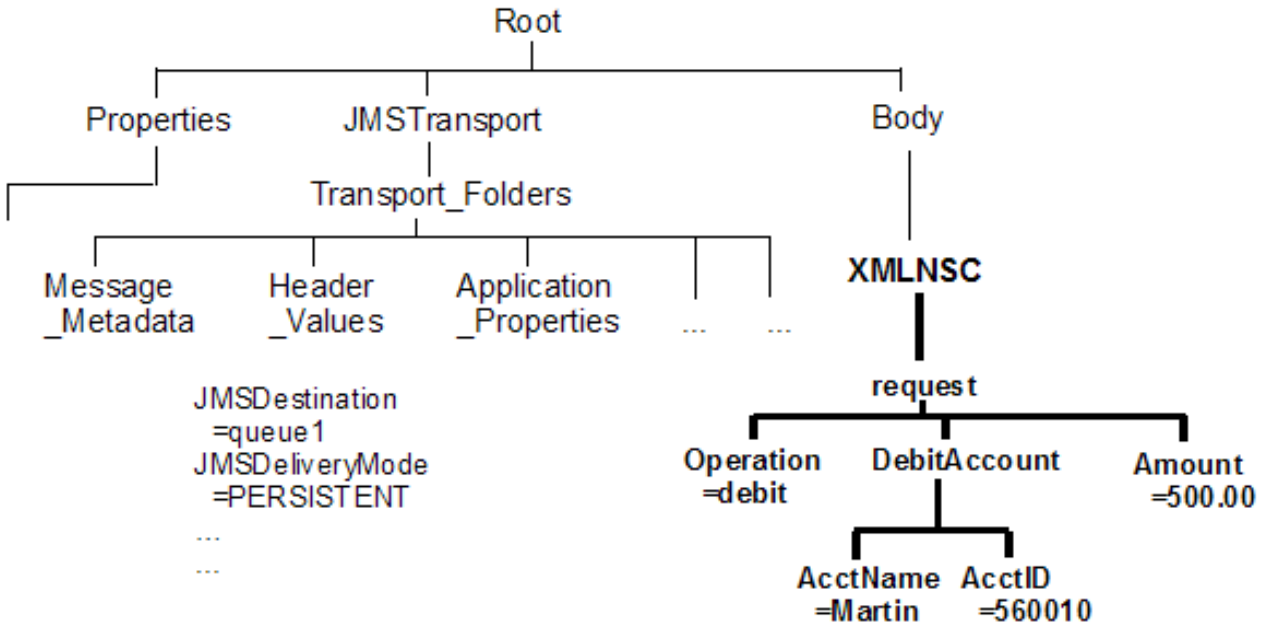
In the input message tree, the XMLNSC element is selected to be overwritten:



In the result message tree, the XMLNSC element is selected for insertion:



In the output message tree, the XMLNSC element has been replaced by the result XMLNSC element:

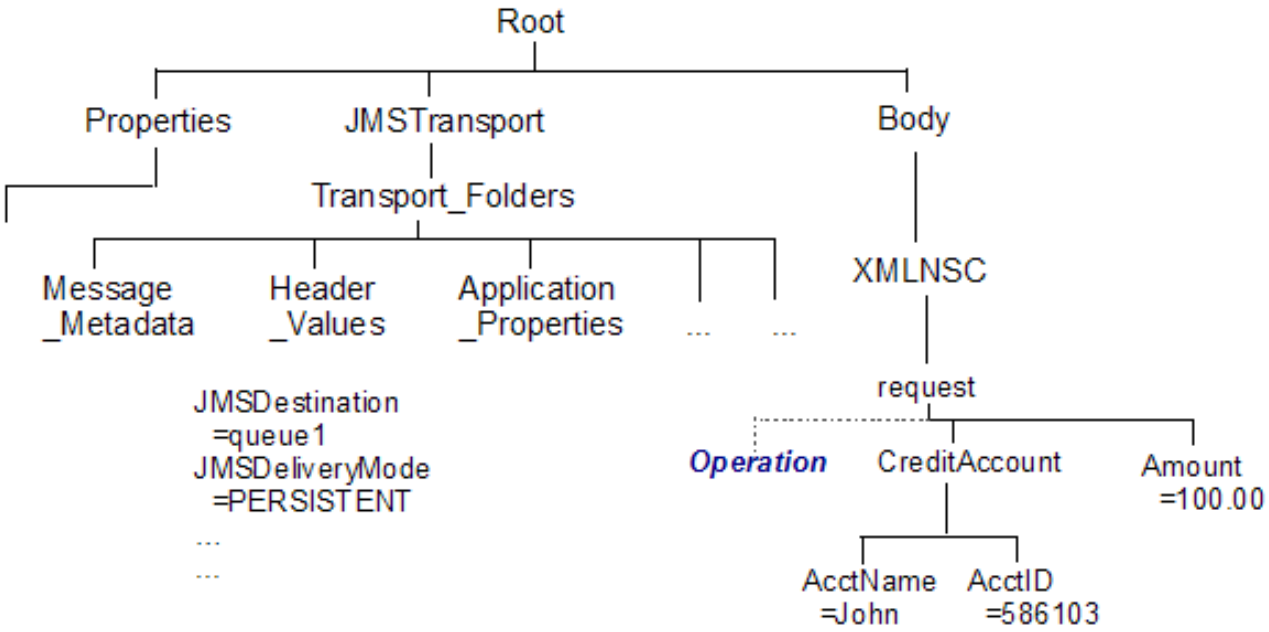


Example 4: Inserting a subtree of the result message

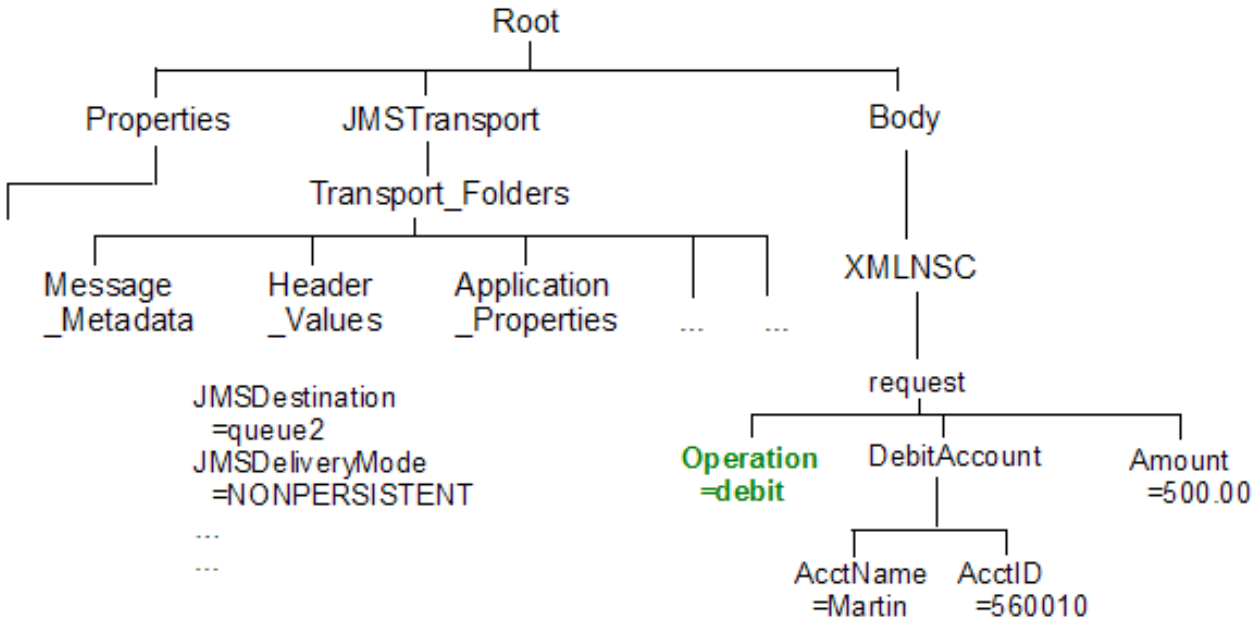
- `Output data location` = `$OutputRoot/XMLNSC/request/Operation`
- `Result data location` = `$ResultRoot/XMLNSC/request/Operation`

The input root is copied to the output root, and then the Operation subtree of the result message is inserted into the output tree underneath the request element. The input message tree does not contain an Operation element, but its location is determined by the `Output data location` value.

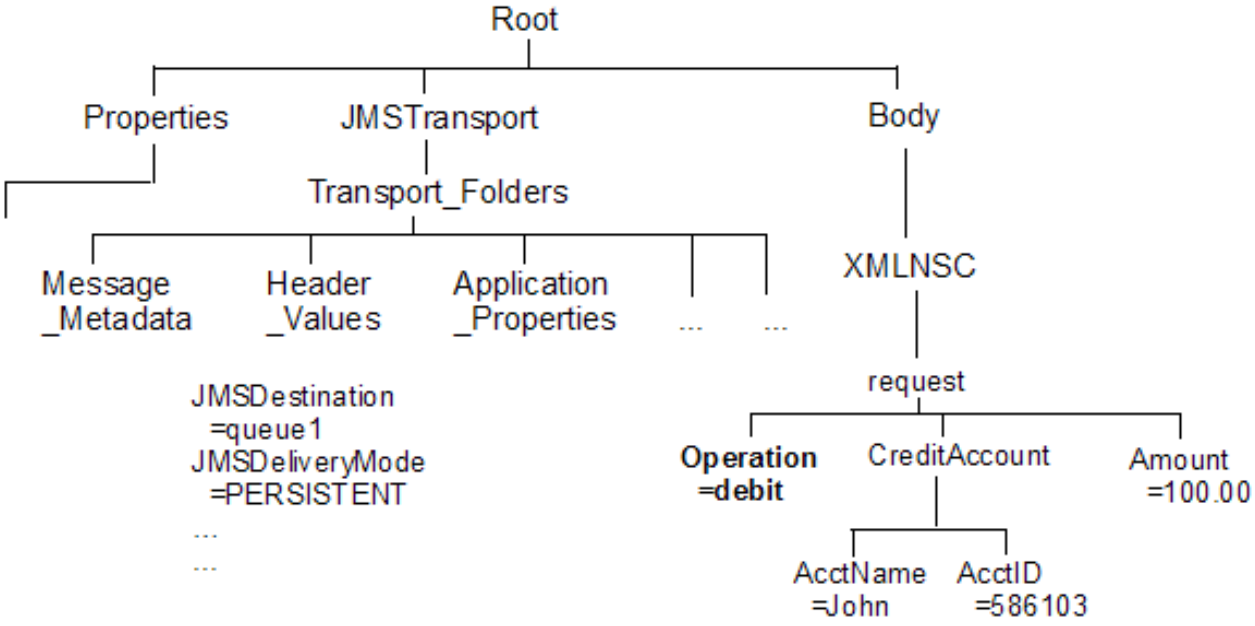
In the input message tree, the location is selected to be written to. This location does not yet exist:



In the result message tree, the Operation element is selected for insertion:



In the output message tree, the Operation element from the result message tree is inserted under the existing request element:



Processing events

You can use event driven message processing to control the flow of messages through your message flows, by using aggregation, message collections, message sequences, and timeout flows. Information about the state of in-flight messages is held on system queues that are controlled by IBM MQ queue managers.

About this task

If you want to use event driven processing on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node. The system queues that hold the state information are owned by the queue manager that is specified on the integration server. You associate a queue manager with the integration server by specifying the queue manager name on the

defaultQueueManager property in the `server.conf.yaml` configuration file; for more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

If you want to use event driven processing with an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as IBM App Connect Enterprise. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

You must create the system queues by running the **iib_createqueues** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

The following topics contain information about using aggregation, message collections, message sequencing, and timeout flows:

- "Using aggregation" on page 1820
- "Using message collections" on page 1840
- Using message sequences
- "Configuring timeout flows" on page 1875

IBM MQ is not provided as part of the IBM App Connect Enterprise installation package, but your license for IBM App Connect Enterprise entitles you to install and use IBM MQ. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96 and "Enhanced flexibility in interactions with IBM MQ " on page 26. For more information about IBM MQ, see IBM MQ product information.

Using aggregation

Use aggregation to generate multiple requests from a single input message, and coordinate the multiple responses to provide a single consolidated response to that input message. Information about the state of in-flight messages is held on system queues that are controlled by IBM MQ.

About this task

If you want to use aggregation on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node. The system queues that hold the state information are owned by the queue manager that is specified on the integration server. You associate a queue manager with the integration server by specifying the queue manager name on the **defaultQueueManager** property in the `server.conf.yaml` configuration file; for more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

You must create the system queues by running the **iib_createqueues** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

If you want to use aggregation with an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

The following topics describe the benefits of message flow aggregation, and explain how to configure your message flows to support message aggregation:

- "Message flow aggregation" on page 1821
- "Configuring aggregation flows" on page 1822

Message flow aggregation

Aggregation is the generation and fan-out of related requests that are derived from a single input message, and the fan-in of the corresponding replies to produce a single aggregated reply message.

The initial request that is received by the message flow, representing a collection of related request items, is split into the appropriate number of individual requests to satisfy the subtasks of the initial request. This process is known as *fan-out*, and it is provided by a message flow that includes aggregation nodes.

Replies from the subtasks are combined and merged into a single reply, which is returned to the original requester (or another target application) to indicate completion of the processing. This process is known as *fan-in*, and it is also provided by a message flow that includes aggregation nodes.

A message aggregation is initiated by a message flow that contains the AggregateControl node followed by an AggregateRequest node. The responses are aggregated back together using a flow that contains the AggregateReply node. The aggregation nodes work correctly only for transports that use a request/reply model; for example, IBM MQ Enterprise Transport.

IBM App Connect Enterprise provides three message flow nodes that support aggregation:

- The AggregateControl node
- The AggregateRequest node
- The AggregateReply node

When you include these nodes in your message flows, the multiple fan-out requests are issued in sequence from one thread in the integration server process.

If you use IBM MQ Enterprise Transport, the responses that are received by the fan-in flow must be valid reply messages that contain the reply identifier. You must set the reply identifier to the value of the message identifier field (MsgId) in the request message's message descriptor (MQMD), then store the reply identifier in the correlation identifier field (CorrelId) of the MQMD. If the CorrelId is set to MQCI_NONE, the AggregateReply node issues an error because the reply message is not valid, and cannot be matched to a request message.

You can also use these aggregation nodes to issue requests to applications outside the integration server environment. Messages can be sent asynchronously to external applications or services; the responses are retrieved from those applications, and the responses are combined to provide a single response to the original request message.

These nodes can help to improve response time because slow requests can be performed in parallel, and they do not need to follow each other sequentially. If the subtasks can be processed independently, and they do not need to be handled as part of a single unit of work, they can be processed by separate message flows.

You can design and configure a message flow that provides a similar function without using the aggregation nodes, by issuing the subtask requests to another application (for example, using the HTTPRequest node), and recording the results of each request in the local environment. After each subtask has completed, merge the results from the LocalEnvironment in a Compute node, and create the combined response message for propagating to the target application. However, all the subtasks are performed sequentially, and they do not provide the performance benefits of parallel operation that you can achieve if you use the aggregation nodes.

The aggregation nodes store state for aggregations on IBM MQ queues. By default, the following storage queues are used:

- SYSTEM.BROKER.AGGR.CONTROL
- SYSTEM.BROKER.AGGR.REPLY
- SYSTEM.BROKER.AGGR.REQUEST
- SYSTEM.BROKER.AGGR.UNKNOWN
- SYSTEM.BROKER.AGGR.TIMEOUT

By default, the timeout on the AggregateControl node is set to 0. If you do not specify a timeout (or if you leave it set to 0), aggregation requests that IBM MQ stores are never deleted unless all reply messages

are returned. This situation might lead to a gradual build up of messages on the internal queues. Set the timeout to a value greater than zero to ensure that requests are removed and that queues do not fill up with redundant requests. It is good practice to set the timeout value to a large value, for example, 86400 seconds (24 hours), so that the queues clear old aggregation messages even if timeouts are not required or expected.

You can set the timeout either by setting the `Timeout` property on the AggregateControl node, or by using an Aggregation policy and specifying the `Aggregation timeout` property. For more information, see "Setting timeout values for aggregation" on page 1831.

The aggregation nodes use IBM MQ message expiry to manage timeout of messages. For message expiry to work, the aggregation nodes must browse the message queues. The aggregation nodes browse the queues automatically to ensure that expired messages are processed.

Configuring aggregation flows

Use aggregation message flows to generate and fan-out a number of related requests, fan-in the corresponding replies, and compile those replies into a single aggregated reply message, by using the AggregateControl, AggregateRequest, and AggregateReply nodes.

Before you begin

- Read the concept topic on "Message flow aggregation" on page 1821.
- If you are using aggregation on an integration server that is managed by an integration node, ensure that you have installed IBM MQ. Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ, and you must install IBM MQ on the same computer as your integration node if you want to use the capabilities provided by the aggregation nodes. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

  If you are using aggregation on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

About this task

By default, the messages are put onto a set of default storage queues (beginning SYSTEM.BROKER.AGGR) for processing, but you can use an Aggregation policy to specify alternative queues. You can also use the Aggregation policy to set a timeout for the aggregation.

For an overview of using aggregation in message flows, see "Message flow aggregation" on page 1821.

To configure aggregation flows see the following topics:

- "Creating the aggregation fan-out flow" on page 1823
- "Creating the aggregation fan-in flow" on page 1826
- "Associating fan-out and fan-in aggregation flows" on page 1829
- "Setting timeout values for aggregation" on page 1831
- "Processing timed out aggregation messages" on page 1833
- "Using multiple AggregateControl nodes" on page 1833
- "Correlating input request and output response aggregation messages" on page 1834
- "Using control messages in aggregation flows" on page 1835
- "Handling exceptions in aggregation flows" on page 1837
- "Configuring the storage of events for aggregation nodes " on page 229

Creating the aggregation fan-out flow
The aggregation fan-out flow receives the initial input message and restructures it to present a number of requests to a number of target applications.

Before you begin

- For background information, see "Message flow aggregation" on page 1821.

About this task

You can include the fan-out and fan-in flow in the same message flow. However, you might prefer to create two separate flows. For more information about the benefits of configuring separate message flows, see "Associating fan-out and fan-in aggregation flows" on page 1829.

To create the fan-out flow:

Procedure

1. Create a message flow to provide the fan-out processing.
   For more information, see "Creating a message flow" on page 574.
2. Add the following nodes to the message flow, then configure and connect them as described.

   Input node
   The input node receives an input message from which multiple request messages are generated. This node can be any one of the built-in nodes, or a user-defined input node.

   a. Select the input node to open the Properties view. The node properties are displayed.
   b. Specify the source of input messages for this node. For example, specify the name of an IBM MQ queue in the `Queue name` property. The MQInput node retrieves messages from this queue.
   c. Optional: set values for any other properties that you want to configure for this node. For example, to ensure that aggregate request messages are put under sync point, set the `Transaction mode` property to `Yes`. This option avoids the situation where the AggregateReply node receives response messages before it has received the control message that informs it of the aggregation instance. Putting the fan-out flow under transactional control ensures that the fan-out flow completes before any response messages get to the AggregateReply.
   d. Connect the input node's Out terminal to the In terminal of an AggregateControl node. This option represents the simplest configuration; if appropriate, you can include other nodes between the input node and the AggregateControl node. For example, store the request for audit purposes (in a Database node), or add a unique identifier to the message (in a Compute node).
   e. Optional: if your fan-out and fan-in flows are combined in one message flow, modify the `Order mode` property on the `Advanced` tab. Select the `By Queue Order` option and ensure that the `Logical Order` property is also selected. These options force the input node to be single threaded to maintain the logical order of the messages that arrive on the queue. Any additional instance threads that you make available are then shared among only the fan-in input nodes to improve the performance of aggregation. If your fan-in and fan-out flows are in separate message flows this step is not required because you can make additional threads available specifically to the fan-in flow.

   AggregateControl node
   The AggregateControl node updates the local environment that is associated with the input message with information required by the AggregateRequest node. The AggregateControl node creates the `LocalEnvironment.ComIbmAggregateControlNode` folder. This folder and the

fields in it are for internal use by IBM App Connect Enterprise and you should not rely on their existence or values when developing your message flows.

a. Select the AggregateControl node to open the Properties view. The node properties are displayed.

b. Set the `Aggregate name` property of the AggregateControl node to identify this particular aggregation. It is used later to associate this AggregateControl node with a specific AggregateReply node. The `Aggregate name` that you specify must be contextually unique in an integration node.

c. Optional: set the `Timeout` property to specify how long the integration node waits for replies to arrive before taking action (described in "Setting timeout values for aggregation" on page 1831). If a timeout is not set on the AggregateControl node then aggregate requests stored internally will not be removed unless all aggregate reply messages return. This situation might lead to a gradual build-up of messages on the internal queues. To avoid this situation, set the timeout to a value other than zero (zero means that a timeout never occurs) so that when the timeout is reached the requests are removed and the queues do not fill up with redundant requests. Even if timeouts are not required or expected, it is good practice to set the timeout value to a large value; for example, 86400 seconds (24 hours) so that the queues occasionally get cleared of old aggregations.

d. Connect the Out terminal of the AggregateControl node to the In terminal of one or more Compute nodes that provide the analysis and breakdown of the request in the input message that is propagated on this terminal.

Compute node

The Compute node extracts information from the input message and constructs a new output message.

If the target applications that handle the subtask requests can extract the information that they require from the single input message, you do not need to include a Compute node to split the message. You can pass the whole input message to all target applications.

If your target applications expect to receive an individual request, not the whole input message, you must include a Compute node to generate each individual subtask output message from the input message. Configure each Compute node in the following way, copying the appropriate subset of the input message to each output message:

a. Select the Compute node to open the Properties view. The node properties are displayed.

b. Select a value for the Basic property `Compute mode`. This property specifies which sections of the message tree are modified by the node. The AggregateControl node inserts elements into the local environment tree in the input message that the AggregateRequest node reads when the message reaches it. Ensure that the local environment is copied from the input message to the output message in the Compute node. This configuration happens automatically

unless you specify a value that includes local environment (one of All, LocalEnvironment, LocalEnvironment and Message, or Exception and LocalEnvironment).

If you specify one of these values, the integration node assumes that you are customizing the Compute node with ESQL that writes to local environment, and that you are copying any elements in that tree that are required in the output message.

To modify the local environment, add the following statement to copy the required aggregate information from input message to output message:

```
SET OutputLocalEnvironment.ComIbmAggregateControlNode =
            InputLocalEnvironment.ComIbmAggregateControlNode;
```

c. Optional: set values for any other properties that you want to configure for this node.

d. Connect the Out terminal of each Compute node to the In terminal of the output node that represents the destination of the output request message that you have created from the input message in this node.

Output node

Include an output node for each output message that you generate in your fan-out flow. Configure each node, as described later in this section, with the appropriate modifications for each destination.

The output node must be an output node that supports the request/reply model, such as an MQOutput node, or a mixture of these nodes (depending on the requirements of the target applications).

a. Select the output node to open the Properties view. The node properties are displayed.

b. Specify the destination for the output messages for this node. For example, specify the name of an IBM MQ queue in the `Queue name` property to which the MQOutput node sends messages. The target application must process its request, and send the response to the reply destination indicated in its input message (for example the IBM MQ ReplyToQueue).

c. Click **Request** in the left view and set values for these properties to specify that replies are sent to the input queue of the fan-in flow.

d. Optional: set values for any other properties that you want to configure for this node.

e. Connect the Out terminal of the output node to the In terminal of an AggregateRequest node. When the message is propagated through the output node's Out terminal, the built-in output node updates the WrittenDestination folder in the associated local environment with additional information required by the AggregateRequest node.

The information written by the built-in nodes is queue name, queue manager name, message ID, and correlation ID (from the MQMD), and message reply identifier (set to the same value as message ID).

AggregateRequest node

Include an AggregateRequest node for each output message that you generate in your fan-out flow.

a. Select the AggregateRequest node to open the Properties view. The node properties are displayed.

b. Set the Basic property `Folder name` to a value that identifies the type of request that has been sent out. This value is used by the AggregateReply node to match up with the reply message when it is received in the fan-in flow. The folder name that you specify for each request that the fan-out flow generates must be unique.

The AggregateRequest node writes a record in IBM MQ for each message that it processes. This record enables the AggregateReply node to identify which request each response is associated with. If your output nodes are non-transactional, the response message might arrive at the fan-in

flow before this IBM MQ update is committed. For details on how you can use timeouts to avoid this situation, see "Setting timeout values for aggregation" on page 1831.

CAUTION: Although the use of timeouts can help to avoid this situation described previously, configure your fan-out flow to be transactional. Therefore, response messages cannot get to the fan-in flow before the corresponding AggregateRequest nodes have committed their IBM MQ updates.

3. To save the message flow and validate its configuration, press **Ctrl-S** or click **File** > **Save**.

What to do next

To collect the aggregation responses initiated by your fan-out flow, create a fan-in flow, as described in "Creating the aggregation fan-in flow" on page 1826.

Creating the aggregation fan-in flow

The aggregation fan-in flow receives the responses to the request messages that are sent out by the fan-out flow, and constructs a combined response message containing all the responses received.

Before you begin

- Read an overview of aggregation in "Message flow aggregation" on page 1821.

About this task

You can include the fan-out and fan-in flow within the same message flow. However, you might prefer to create two separate flows. For more information about the benefits of configuring separate message flows, see "Associating fan-out and fan-in aggregation flows" on page 1829. Do not deploy multiple copies of the same fan-in flow either to the same or to different integration servers.

If you do not configure the fan-out flow to be transactional, the timeout values that you have specified might result in the combined response message being generated before the fan-in flow has received all the replies. For more information, see "Creating the aggregation fan-out flow" on page 1823.

To create the fan-in flow:

Procedure

1. Create a message flow to provide the fan-in processing.
2. Add the following nodes in the editor view and configure and connect them as described:

Input node

The input node receives the responses to the multiple request messages that are generated from the fan-out flow.

This node must be an input node that supports the request/reply model, such as an MQInput node, or a mixture of these nodes (depending on the requirements of the applications that send these responses). The response that is received by each input node must be sent across the same protocol as the request to which it corresponds. For example, if you include an MQOutput node in

the fan-out flow, the response to that request must be received by an MQInput node in this fan-in flow.

a. Select the input node to open the Properties view. The node properties are displayed.

b. Specify the source of input messages for this node; for example, specify the name of an IBM MQ queue in the Basic property Queue name from which the MQInput node retrieves messages.

c. Optional: specify values for any other properties that you want to configure for this node.

d. Connect the Out terminal of the input node to the In terminal of an AggregateReply node.

   Connect the terminals in this way to create the simplest configuration; if appropriate, you can include other nodes between the input node and the AggregateReply node; for example, you might want to store the replies for audit purposes (in a Database node).

Include just one input node that receives all the aggregation response messages at the beginnings of the fan-in flow as described previously. If you include multiple input nodes, threads that are started by a specific reply input node might complete the aggregation and execution of the message flow while other threads are sending their response messages to the AggregateReply node and becoming eligible to timeout. Use a single input node to enable sequential processing of replies for each aggregation. Specify additional instances to provide greater processing throughput in this single node, see Configurable properties in a file.

AggregateReply node

The AggregateReply node receives the inbound responses from the input node through its In terminal. The AggregateReply node stores each reply message for subsequent processing.

When all the replies for a particular group of aggregation requests have been collected, the AggregateReply node creates an aggregated reply message, and propagates it through the Out terminal.

a. Select the AggregateReply node to open the Properties view. The node properties are displayed.

b. Set the Aggregate name property of the AggregateReply node to identify this aggregation. Set this value to be the same value that you set for the Aggregate name property in the corresponding AggregateControl node in the fan-out flow.

c. Optional: to retain an unrecognized message before propagating it to the Unknown terminal, set a value for the Unknown message timeout property. If you are using separate fan-out and fan-in flows, set this value to a non-zero number if the control message might be delayed.

d. Optional: to explicitly handle unrecognized messages, connect the Unknown terminal to another node, or sequence of nodes. If you do not connect this terminal to another node in the message flow, messages propagated through this terminal are discarded.

e. Optional: if you have specified a timeout value for this aggregation in the AggregateControl node, and you want to explicitly handle timeouts that expire before all replies are received, connect the Timeout terminal to another node, or sequence of nodes. Partially complete aggregated replies are sent to the Timeout terminal if the timer expires. If you do not connect this terminal to another node in the message flow, messages propagated through this terminal are discarded.

f. Optional: specify values for any other properties that you want to configure for this node.

g. Connect the Out terminal of the AggregateReply node to the In terminal of a Compute node.

Attention: The Control terminal of the AggregateReply node was deprecated at Version 6.0, and by default any connections to this terminal (either direct or indirect) are ignored. This change maximizes the efficiency of aggregation flows and does not damage the reliability of aggregations. This configuration provides the optimum content.

However, if you want the AggregateReply node to receive, on its Control terminal, the control message that was sent by the corresponding AggregateControl node on the fan-out flow, you must make the necessary connections as described in “Creating the aggregation fan-out flow” on page 1823. Keep the path from the AggregateReply node to the output

node as direct as possible to maximize the performance of aggregations. Do not modify the content of this control message.

In addition, for the Control terminal and connections to it to be recognized, you must enable the environment variable MQSI_AGGR_COMPAT_MODE. If you choose this option, the performance and behavior of message aggregations might be affected; for a full description of these implications and the environment variable, see "Using control messages in aggregation flows" on page 1835.

Aggregated messages which are sent from the AggregateReply node output terminals (Out and Timeout) are not validated. Validation of data must be done before messages are sent to the AggregateReply node, because it ignores validation options when reconstructing the stored messages.

Compute node

The Compute node receives the message that contains the combined responses. Typically, the format of this combined message is not valid for output, because the aggregated reply message has an unusual structure and cannot be parsed into the bit stream required by some nodes, for example the MQOutput node. The Out and Timeout terminals always propagate an aggregated reply message, which always requires further processing before it can be propagated to an MQOutput node. Therefore you must include a Compute node and configure this node to create a valid output message.

a. Select the Compute node to open the Properties view. The node properties are displayed.
b. Specify in the Basic property ESQL module the name of the ESQL module that customizes the function of this node.
c. Right-click the node and click **Open ESQL** to open the ESQL file that contains the module for this node. The module is highlighted in the ESQL editor view.
d. Code the ESQL to create a single output message from the aggregated replies in the input message.

   The aggregated reply message is propagated through the Out terminal. Information about how you can access its contents is provided in "Accessing the combined message contents" on page 1828.
e. Optional: specify values for any other properties that you want to configure for this node.
f. Connect the Out terminal of the Compute node to the In terminal of the output node that represents the destination of the single response message.

Output node

Include an output node for your fan-in flow. This node can be any of the built-in nodes, or a user-defined output node.

a. Select the output node to open the Properties view. The node properties are displayed.
b. Specify the destination for the output message for this node; for example, specify in the Basic property Queue name the name of an IBM MQ queue to which the MQOutput node sends messages.
c. Optional: specify values for any other properties that you want to configure for this node.

3. To save the message flow and validate its configuration, press Ctrl-S or click **File** > **Save**.

Accessing the combined message contents

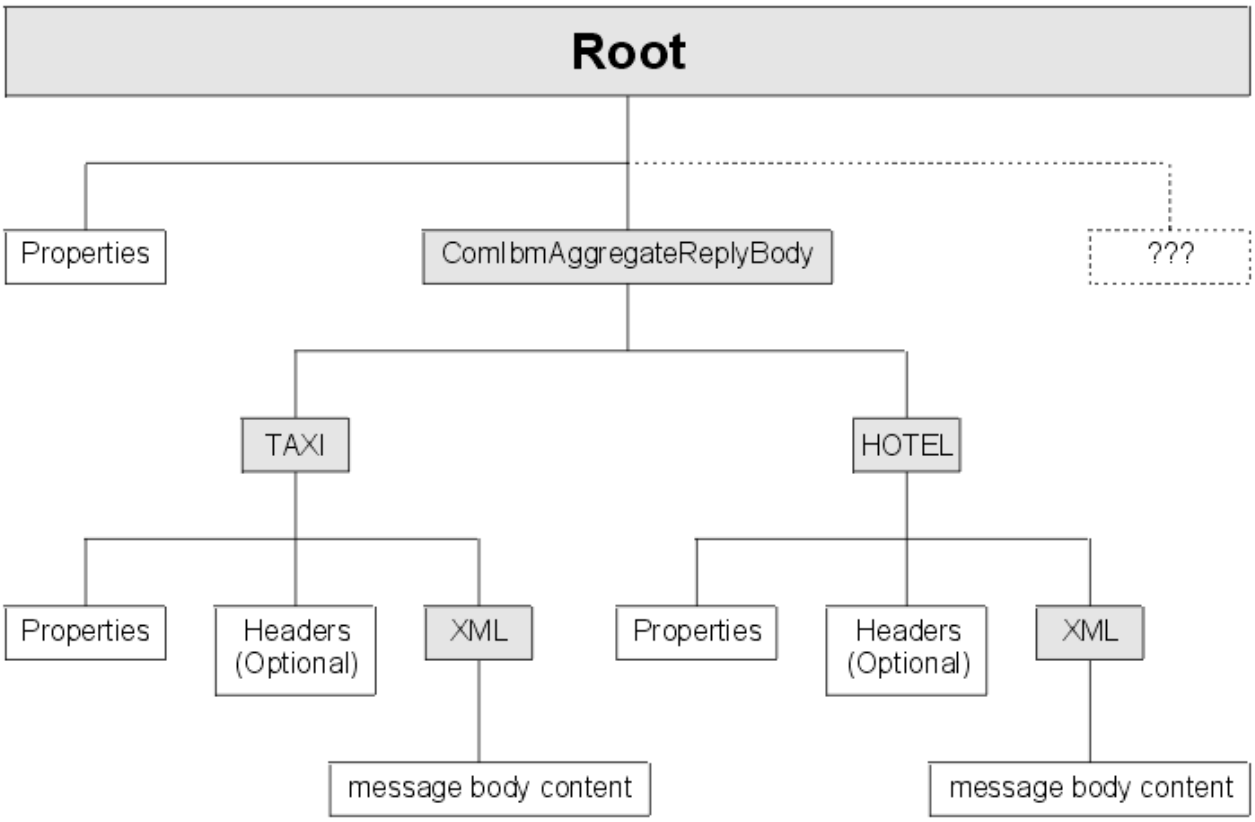
About this task

The AggregateReply node creates a folder in the combined message tree below Root, called ComIbmAggregateReplyBody. Below this folder, the node creates a number of subfolders using the names that you set in the AggregateRequest nodes. These subfolders are populated with the associated reply messages.

For example, the request messages might have folder names:

- TAXI
- HOTEL

The resulting aggregated reply message created by the AggregateReply node might have a structure like the following example:



Use ESQL within a Compute node to access the reply from the taxi company using the following correlation name:

```
InputRoot.ComIbmAggregateReplyBody.TAXI.xyz
```

The folder name does not have to be unique. If you have multiple requests with the folder name TAXI, you can access the separate replies using the array subscript notation, for example:

```
InputRoot.ComIbmAggregateReplyBody.TAXI[1].xyz
InputRoot.ComIbmAggregateReplyBody.TAXI[2].xyz
```

Associating fan-out and fan-in aggregation flows
Associate the fan-out message flow processing with its corresponding fan-in message flow processing by setting the `Aggregate Name` property of the AggregateControl and AggregateReply nodes in your aggregation flow to the same value.

Before you begin

If you did not configure this property when you created your fan-in and fan-out flows, you must complete this task.

You must have completed the following tasks:

- “Creating the aggregation fan-out flow” on page 1823
- “Creating the aggregation fan-in flow” on page 1826

About this task

The `Aggregate Name` must be contextually unique within an integration node. You can have only one AggregateControl node and one AggregateReply node with a particular `Aggregate Name`, although you can have more than one AggregateControl node with the same `Aggregate Name`, see "Using multiple AggregateControl nodes" on page 1833. Do not deploy a fan-in flow to multiple integration servers on the same integration node; results are unpredictable.

You can either create the fan-out and fan-in flows in the same message flow, or in two different message flows. In either case, the two parts of the aggregation are associated when you set the `Aggregate Name` property.

How you configure your aggregation flow depends on a number of factors:

- The design of your message flow.
- The hardware on which the integration node is running.
- The timeout values that you choose, see "Setting timeout values for aggregation" on page 1831.
- How you expect to maintain the message flows.

You can include the fan-out and fan-in flow within the same message flow. However, you might prefer to create two separate flows. The advantages of creating separate fan-out and fan-in flows are:

- You can modify the two flows independently.
- You can start and stop the two flows independently.
- You can deploy the two flows to separate integration servers to take advantage of multiprocessor systems, or to provide data segregation for security or integrity purposes.
- You can allocate different numbers of additional threads to the two flows, as appropriate, to maintain a suitable processing ratio.

To associate the fan-out flow with the fan-in flow:

Procedure

1. Switch to the Integration Development perspective.
2. Open the message flow that contains your fan-out flow.
3. Select the AggregateControl node to open the Properties view.

   The node properties are displayed.
4. Set the `Aggregate Name` property of the AggregateControl node to identify this aggregation. The `Aggregate Name` that you specify must be contextually unique within an integration node.
5. `If you have separate fan-out and fan-in flows:`
   a) Press Ctrl-S or click **File** > **Save *name*** on the taskbar menu (where *name* is the name of this message flow) to save the message flow and validate its configuration.
   b) Open the message flow that contains your fan-in flow.
6. Select the AggregateControl node to open the Properties view.

   The node properties are displayed.
7. Set the `Aggregate Name` property of the AggregateReply node to the same value that you set for the `Aggregate Name` property in the corresponding AggregateControl node in the fan-out flow.
8. Press Ctrl-S or click **File** > **Save *name*** to save the message flow and validate its configuration.

What to do next

In IBM App Connect Enterprise, fan-out and fan-in flows were also associated by sending control messages from the AggregateControl node to the AggregateReply node. This facility is no longer available. For optimum performance, do not connect the AggregateControl and AggregateReply node. However, if you do want to use control messages in your aggregations, and you want to connect these two nodes, see "Using control messages in aggregation flows" on page 1835.

Setting timeout values for aggregation
You can use two properties of the aggregation nodes to set timeout values for aggregated message processing.

Before you begin

To complete this task, you must have completed the following tasks:

- "Creating the aggregation fan-out flow" on page 1823
- "Creating the aggregation fan-in flow" on page 1826

About this task

Two situations might require the use of timeouts:

- The need to receive an aggregated reply message within a specified time. For this situation, you set the `Timeout` property of the AggregateControl node.
- The need to wait before propagating an unrecognized message to the Unknown terminal. For this situation, you set the `Unknown Message Timeout` property on the AggregateReply node.

The following sections describe each situation in more detail.

To receive an aggregated reply message within a specified time

About this task

In some situations, you might need to receive an aggregated reply message within a specified time. Some reply messages might be slow to return, or might never arrive. For these situations, open the fan-out message flow and set the timeout interval by using one of the following steps:

Directly on the AggregateControl node

Set the `Timeout` property of the AggregateControl node to specify how long (in seconds) the integration node must wait for replies. By default, this property is set to 0 (zero), which means that there is no timeout and the integration node waits indefinitely. For more information, see node.

Using an Aggregation policy

You can also use an Aggregation policy to specify the timeout interval. To use an Aggregation policy, set the `Aggregate name` property of the AggregateControl node to match the policy project and policy name (in the format *"{PolicyProjectName}:PolicyName"*), and specify the timeout value in the `Aggregation timeout` property of the policy.

To specify a default Aggregation policy for all message flows that are deployed to an integration server, set the **Aggregation** property in the `server.conf.yaml` file to the name of an Aggregation policy. For information about setting properties in the `server.conf.yaml` file, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172. If the default policy is in the default policy project, you do not need to specify the name of the policy project. If the default policy is in a non-default policy project, qualify the name of the policy with the name of the policy project in the format *{policyProjectName}:PolicyName*

The value of the `Aggregation timeout` property of the policy overrides the `Timeout` property of the AggregateControl node.

Unlike the `Timeout` property of the AggregateControl node, you can set the `timeoutSeconds` property value to one decimal place, allowing timeout intervals of less than one second if required. Values of 0.5, 1.7, and 100.1 are all valid, but a value of 0.22 is invalid.

When setting timeout intervals of less than one second, it is recommended that the `queuePrefix` property is set up and the `timeoutThreads` property is set to a minimum of 2. This is to make sure that the timeout processing has sufficient resources to meet the timeout requirements. Despite this, users may well encounter other unexpected operational factors that could impact on the ability to run timeout intervals below the one-second requirement.

For more information about the Aggregation policy, see Aggregation policy.

Dynamically from an incoming message

You can use the `Timeout location` property of the AggregateControl node to specify the location of a timeout value in the incoming message. Any timeout value that is specified in this way overrides the values that are specified by the AggregateControl node and the Aggregation policy.

In the same way, as for the Aggregation policy, the timeout value is specified down to one decimal place.

For more information, see node.

The timeout precedence is determined by values being set in the message, the policy, or the node, in the following order:

1. If a timeout value is specified in the incoming message (in the location that is specified by the `Timeout location` property of the AggregateControl node) this value is used.
2. If no location is specified by the `Timeout location` property, or if the location in the message is empty or does not exist, the value that is specified by the `timeoutSeconds` property of the Aggregation policy is used (if one exists).
3. If no Aggregation policy has been defined, or if the `Aggregation timeout` property of the policy is not set, the value that is set in the `Timeout` property of the AggregateControl node is used.

By default, timeout polling occurs every 5 seconds. Therefore, if you set the `Timeout` property to a value that is not a multiple of 5, an extra delay occurs. For example, if you set the `Timeout` property to 7 seconds, you see a delay of 3 seconds until timeout polling next occurs. You can change the default timeout polling interval by using the environment variable MQSI_AGGR_WAIT_TIMEOUT. Valid values are 1000 - 5000 milliseconds. To change the default polling interval, stop the integration node, then restart the integration node in an environment where you have set the MQSI_AGGR_WAIT_TIMEOUT environment variable.

If a `Timeout` property value has been set to less than one second the timeout polling interval rules are ignored. In this instance the timeout polling interval is automatically calculated as part of timeout processing. Therefore, no manual intervention is required in order to update the environment variable MQSI_AGGR_WAIT_TIMEOUT.

If the timeout interval passes without all the replies arriving, the replies that have arrived are turned into an aggregated reply message by the corresponding AggregateReply node, and propagated to its Timeout terminal. You can process this partial response message in the same way as a complete aggregated reply message. If you prefer, you can provide special processing for incomplete aggregated replies.

To wait before propagating an unrecognized message to the Unknown terminal

About this task

When a message arrives at the In terminal of an AggregateReply node, it is examined to see if it is an expected reply message. If it is not recognized, the message is propagated to the Unknown terminal. You might want the integration node to wait for a specified time period before propagating the message for the following reasons:

- The reply message might arrive before the work completed by the AggregateRequest node has been transactionally committed. This situation can be avoided by configuring the `Transaction mode` property of the input node, as described in “Creating the aggregation fan-out flow” on page 1823.
- The reply message might arrive before the control message. This situation can be avoided by leaving the Control terminal of the AggregateControl node unconnected. For more information about the implications of connecting the Control terminal, see “Using control messages in aggregation flows” on page 1835.

These situations are most likely to happen if you send the request messages out of syncpoint, and might result in valid replies being sent to the Unknown terminal. To reduce the likelihood of this event, complete the following steps.

1. Open the fan-in message flow.
2. Set the `Unknown Message Timeout` property of the AggregateReply node.

   When you set this property, a message that cannot be recognized immediately as a valid reply is held persistently in the integration node for the number of seconds that you specify for this property.

If the unknown timeout interval expires, and the message is recognized, it is processed. The node also checks to see if this previously unknown message is the last reply that is needed to make an aggregation complete. If it is, the aggregated reply message is constructed and propagated.

If the unknown timeout interval expires and the message is still not recognized, the message is propagated to the Unknown terminal.

Processing timed out aggregation messages
Assign additional processing threads to enable processing of timed out aggregation messages in the AggregateReply node.

Before you begin

To complete this task, the following conditions must be met:

- The AggregateReply node must be using an Aggregation policy.
- The associated Aggregation policy must have a queue prefix set that is unique across all Aggregation policies.
- The set of aggregation queues referred to by the associated Aggregation policy must only be used by a single integration server.

About this task

By default the AggregateReply node uses a single thread to process timed out aggregation messages. In scenarios where a high volume of messages are expected to timeout, a backlog of messages can accumulate on the SYSTEM.BROKER.AGGR.*QueuePrefix*.TIMEOUT queue. Follow this task to assign additional processing threads for timeout processing in the AggregateReply node.

You can configure the number of threads that are used to process timeout messages by setting the `Number of timeout threads` property of the associated Aggregation policy.

Using multiple AggregateControl nodes
You might find it useful to design a fan-out flow with multiple AggregateControl nodes, all with the same value set for the property `Aggregate Name`, but with different values for the `Timeout` property. You can reuse an aggregate name in only this situation.

Before you begin

For background information, see “Message flow aggregation” on page 1821.

About this task

You might want to use multiple AggregateControl nodes if, for example, you have created an aggregation flow that books a business trip, and you might have some requests that need a reply within two days. However, other, more urgent requests, need a reply within two hours.

To configure an aggregation flow that uses multiple AggregateControl nodes, complete the following steps.

Procedure

1. Create or open the fan-out message flow.

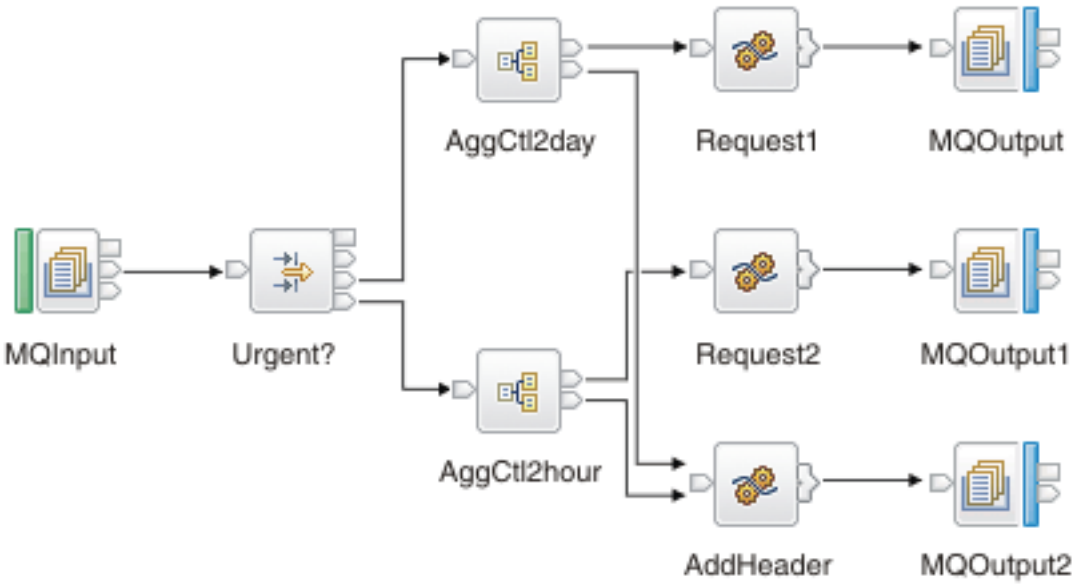
2. Configure the required number of AggregateControl nodes. Set the Basic property `Aggregate Name` of each node to the same value. For example, include two nodes and enter the name `JOURNEY` as the `Aggregate Name` for both.
3. Set the value for the `Timeout` property in each node to a different value. For example, set the `Timeout` in one node to two hours; set the `Timeout` in the second node to two days.
4. Configure a Filter node to receive incoming requests, check their content, and route them to the correct AggregateControl node.
5. Connect the nodes together to achieve the required result.

   For example, if you have configured the Filter node to test for requests with a priority field set to urgent, connect the true terminal to the AggregateControl node with the short timeout. Connect the false terminal to the AggregateControl node with the longer timeout. Connect the out terminals of the AggregateControl nodes to the following nodes in the fan-out flow.

   You must connect the two AggregateControl nodes in parallel, not in sequence. This means that you must connect both to the Filter node (one to the true terminal, one to the false), and both to the downstream nodes that handle the requests for the fan-out. Each input message must pass through only one of the AggregateControl nodes. If you connect the nodes such that a single message is processed by more than one AggregateControl node, duplicate records are created in the database by the AggregateRequest node and subsequent processing results are unpredictable.

Results

The following diagram shows an example fan-out message flow that uses this technique.



Correlating input request and output response aggregation messages
If you want to correlate initial request messages with their combined response messages, you can do so using the ReplyIdentifier in the Properties folder of the response message.

Before you begin

To complete this task, you must have completed the following tasks:

- “Creating the aggregation fan-out flow” on page 1823
- “Creating the aggregation fan-in flow” on page 1826

About this task

In some cases you might want to correlate aggregation request messages with the combined response message produced by your fan-in flow, there are two ways of doing this:

- Store some correlation information in one of the requests sent out as part of the aggregation.
- Send the original request message directly back to the AggregateReply node as one of the aggregation requests. To do this, the CorrelId must be set to the MsgId, and the MQOutput node must have its MessageContext set to 'Pass all'.

Using control messages in aggregation flows
The default behavior is that connections between AggregateControl and AggregateReply nodes for sending control messages are ignored. This configuration optimizes performance and removes the possibility that response messages will be received by the AggregateReply node before the control message.

Before you begin

To complete this task, you must have completed the following tasks:

- "Creating the aggregation fan-out flow" on page 1823
- "Creating the aggregation fan-in flow" on page 1826

About this task

Control messages are not required to make aggregations work correctly. However, you can send control messages in your aggregation flows if you want. To send control messages in a message flow, see "Configuring message flows to send control messages" on page 1835 and "Configuring an integration node environment to send control messages" on page 1836.

Configuring message flows to send control messages

About this task

To configure message flows to send control messages from an AggregateControl node to an AggregateReply node:

Procedure

1. If you have created the fan-out and fan-in flows in a single message flow:
   a) Open the aggregation message flow.
   b) Connect the Control terminal of the AggregateControl node to the Control terminal of the AggregateReply node to make the association.

   This connection is referred to as a direct connection between the two aggregation nodes.
2. If you have created separate fan-out and fan-in message flows:
   a) Open the fan-out message flow.
   b) Configure the AggregateControl node, see "Creating the aggregation fan-out flow" on page 1823.
   c) At this stage, you can configure a Compute node that creates a valid output message that contains the control message. For example, to pass the control message to an MQOutput node, configure the Compute node to add an MQMD to the message and complete the required fields in that header. For example, you can code the following ESQL:

   ```
   SET OutputRoot.MQMD.Version = MQMD_CURRENT_VERSION;
   SET OutputRoot.MQMD.Format = MQFMT_STRING;
   ```

   d) Configure an output node that represents the intermediate destination for the control message. For example, to send the control message to an intermediate IBM MQ queue, include an MQOutput

node and identify the target queue in the Basic properties `Queue Manager Name` and `Queue Name`.

e) Connect the Control terminal of the AggregateControl node to the In terminal of the Compute node, and connect the Out terminal of the Compute node to the In terminal of the output node that represents the intermediate destination for the control message.

f) Open the fan-in message flow.

g) Configure one input node to receive the reply messages, see "Creating the aggregation fan-in flow" on page 1826. This input node also receives the control information from the AggregateControl node. For example, set the Basic property `Queue Name` of the MQInput node to receive the response and control message from an intermediate IBM MQ queue.

h) Add a Filter node to your fan-in flow after the input node and before the AggregateReply node, see "Avoiding thread starvation on fan-in flows" on page 1837.

i) Connect the Out terminal of the input node to the In terminal of the Filter node.

j) Connect the Out terminals of the Filter node to the Control terminal and in terminal of the AggregateReply node.

This connection is referred to as an indirect connection between the two aggregation nodes.

Configuring an integration node environment to send control messages

About this task

By default, in WebSphere Message Broker Version 8.0, all connections from the Control terminal of the AggregateRequest node to the AggregateReply node are ignored. For these connections to be active, create the MQSI_AGGR_COMPAT_MODE environment variable in the integration node environment. By default, the environment variable does not exist. The existence of the environment variable means that connections from the AggregateControl node are active, regardless of the value to which the environment variable is set.

When the MQSI_AGGR_COMPAT_MODE environment variable has not been created, the default behavior for aggregation fan-out flows is used. If the Control terminal of the AggregateControl node is connected, either directly or indirectly, to the In terminal of the AggregateReply node, this connection is ignored and no control message is sent.

If the MQSI_AGGR_COMPAT_MODE environment variable is created, the default behavior for aggregation fan-out flows is not used, allowing you to send control messages from the AggregateControl node to the AggregateReply node. If the Control terminal of the AggregateControl node is connected, either directly or indirectly, to the In terminal of the AggregateReply node, see "Creating the aggregation fan-out flow" on page 1823, this connection is recognized and a control message is sent. Be aware that this configuration is not the optimal configuration and might affect performance.

To create the MQSI_AGGR_COMPAT_MODE variable to support connections between AggregateControl and AggregateReply nodes to be recognized:

- Windows On Windows:
  1. Open System Properties by clicking **Start** > **Control Panel** > **System**.
  2. Click the **Advanced** tab.
  3. Click **Environment Variables**.
  4. In the **System variables** pane, click **New**.
  5. Under **`Variable name`** type `MQSI_AGGR_COMPAT_MODE`.
  6. (Optional) You can type in the **`Variable value`** or leave it blank.
  7. For the environment variable to take effect, restart the computer.

- Linux UNIX z/OS On Linux, UNIX and z/OS:
  1. Edit the profile of the integration node userid and include the following code:

     ```
     export MQSI_AGGR_COMPAT_MODE=
     ```

  2. Reload the profile.
  3. Restart the integration node.

Avoiding thread starvation on fan-in flows
Follow this guidance to avoid thread starvation on fan-in flows if the Control terminal of the AggregateControl node in your fan-out flow is connected to output control messages to a queue.

About this task

By not connecting the Control terminal, you can overcome the issues that are discussed here. For further information about connecting the Control terminal of the AggregateControl node, see “Using control messages in aggregation flows” on page 1835.

The Aggregate Reply node has two input terminals: In and Control. The use of the Control terminal is optional. If you use both of these terminals, the MQInput nodes that supply the two terminals must not use threads from the message flow additional instance pool. If the nodes do use these threads, they compete for resources, and the Control terminal's MQInput node typically takes all available threads because it is activated before the In terminal.

Configure each MQInput node to use additional instances that are defined on the node, not at the message flow level.

Handling exceptions in aggregation flows
When you use aggregation flows, exceptions might occur.

Before you begin

Complete the following tasks:

- “Creating the aggregation fan-out flow” on page 1823
- “Creating the aggregation fan-in flow” on page 1826

Dealing with exceptions

About this task

If an error is detected downstream of an AggregateReply node, the integration node issues an exception. Another node in the message flow might also issue an exception using the ESQL THROW statement. In either case, when an exception occurs, it is caught in one of two places:

- The input node on which the replies arrive
- The AggregateReply node

The following table lists events and describes what happens to an exception that occurs downstream of the AggregateReply node.

Event	Message propagated	Output terminal	Exception caught at
An expected reply arrives at the input node and is passed to the In terminal of the AggregateReply node. The reply is the last one that is needed to make an aggregation complete.	An aggregated reply message that contains all the replies	Out	Input node

Event	Message propagated	Output terminal	Exception caught at
An unexpected reply arrives at the input node and is passed to the AggregateReply node. The reply is not recognized as a valid reply, and the `Unknown Message Timeout` property is set to `0`.	Message received	Unknown	Input node
A timeout occurs because all the replies for an aggregation have not yet arrived.	An aggregated reply message that contains all the replies that have been received	Timeout	AggregateReply node
An unknown timeout occurs because a retained message is not identified as a valid reply.	Retained message	Unknown	AggregateReply node
An aggregation is discovered to be complete at some time other than when the last reply arrived.	An aggregated reply message that contains all the replies	Out	AggregateReply node

To handle errors that occur in aggregation flows, you must catch these exceptions at all instances of each of these nodes in the message flow.

Procedure

1. Switch to the Integration Development perspective.
2. Open the message flow with which you want to work.
3. To handle these exceptions yourself, connect the Catch terminal of each input and AggregateReply node to a sequence of nodes that handles the error that has occurred.

   For a unified approach to error handling, connect the Catch terminals of all these nodes to a single sequence of nodes, or create a subflow that handles errors in a single consistent manner, and connect that subflow to each Catch terminal.
4. If you want the integration node to handle these exceptions using default error handling, do not connect the Catch terminals of these nodes.

Results

If you connect the Catch terminal of the AggregateReply node, and want to send the message that is propagated through this terminal to a destination from which it can be retrieved for later processing, include a Compute node in the catch flow to provide any transport-specific processing. For example, you must add an MQMD header if you want to put the message to an IBM MQ queue from an MQOutput node.

The following ESQL example shows you how to add an MQMD header and pass on the replies that are received by the AggregateReply node:

```
-- Add MQMD
SET OutputRoot.MQMD.Version = 2;
.
-- Include consolidated replies in the output message
SET OutputRoot.XMLNS.Data.Parsed = InputRoot.ComIbmAggregateReplyBody;
.
```

To propagate the information about the exception in the output message, set the `Compute mode` property of the Compute node to a value that includes `Exception`.

Exceptions when dealing with unknown and timeout messages
When timeout messages or unknown messages from unknown timeout processing are produced from an AggregateReply node, they originate from an internal queue and not from an MQInput node. This behavior affects how the error handling should be performed.

If a message that is sent down the timeout thread causes an exception, the message rolls back to the AggregateReply node and is sent to the Catch terminal. If this terminal is unattached or an exception occurs while processing the message, the timeout is rolled back onto the internal queue and is reprocessed. Potentially, this behavior can lead to an infinite loop, which can be stopped by deploying a version of the message flow that fixes the problem.

To avoid this infinite loop, take the following actions.

- Connect the Catch terminal to a set of nodes that handle errors.
- Ensure that the error-handling nodes cannot throw an exception by ensuring that they perform very simple operations; for example, converting the message to a BLOB, then writing it to a queue, or adding extra TryCatch nodes.

The failure terminal of the AggregateReply node is not used currently and messages are not passed to this terminal.

Configuring the storage of events for aggregation nodes
You can use an Aggregation policy to control the storage of events for AggregateControl and AggregateReply nodes.

About this task

Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ. The storage queues that hold the state information are owned by the queue manager that is associated with the integration server.

If you are using aggregation on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node in order to use the capabilities that are provided by the aggregation nodes. If you are using aggregation on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For more information about using a remote default queue manager, see “Using a remote default queue manager” on page 750 and “Configuring an integration server to use a remote default queue manager” on page 751.

If the integration server has the necessary permissions to create the default system queues, they are created automatically when a flow containing aggregation nodes is deployed. If the default queues are not created automatically, you can create them manually by running the **iib_createqueues** command, as described in “Creating the default system queues on an IBM MQ queue manager” on page 99.

By default, the storage queues used by all aggregation nodes are:

- SYSTEM.BROKER.AGGR.CONTROL
- SYSTEM.BROKER.AGGR.REPLY
- SYSTEM.BROKER.AGGR.REQUEST
- SYSTEM.BROKER.AGGR.UNKNOWN
- SYSTEM.BROKER.AGGR.TIMEOUT

However, you can control the queues that are used by different aggregation nodes by creating alternative queues containing a *QueuePrefix*, and using an Aggregation policy to specify the names of those queues for storing events.

Follow these steps to specify the queues that are used to store event states, and to set the expiry time of an aggregation:

Procedure

1. Create the storage queues to be used by the aggregation nodes.

   The following queues are required:

   - SYSTEM.BROKER.AGGR.*QueuePrefix*.CONTROL
   - SYSTEM.BROKER.AGGR.*QueuePrefix*.REPLY
   - SYSTEM.BROKER.AGGR.*QueuePrefix*.REQUEST
   - SYSTEM.BROKER.AGGR.*QueuePrefix*.UNKNOWN
   - SYSTEM.BROKER.AGGR.*QueuePrefix*.TIMEOUT

   The *QueuePrefix* variable can contain any characters that are valid in an IBM MQ queue name, but must be no longer than eight characters and must not begin or end with a period (.). For example, SET1 and SET`.`1 are valid queue prefixes, but `.`SET1 and SET1`.` are invalid.

   If you do not create the storage queues, IBM App Connect Enterprise creates the set of queues when the node is deployed; these queues are based on the default queues. If the queues cannot be created, the message flow is not deployed.
2. Create an Aggregation policy (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
   a) You can create a policy to be used with either a specific aggregation or with all aggregations in an integration server. If the policy is to be used with a specific aggregation, create the policy with the same name as the name that you specify in the `Aggregate name` property on the AggregateControl and AggregateReply nodes.

      To specify a default Aggregation policy for all message flows that are deployed to an integration server, set the **`Aggregation`** property in the `server.conf.yaml` file to the name of an Aggregation policy. For information about setting properties in the `server.conf.yaml` file, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172. If the default policy is in the default policy project, you do not need to specify the name of the policy project. If the default policy is in a non-default policy project, qualify the name of the policy with the name of the policy project in the format *{policyProjectName}:PolicyName*
   b) Set the **`Queue prefix`** property of the Aggregation policy to the required value (see Aggregation policy).
   c) Optional: Set the **`Timeout`** property of the Aggregation policy to control the expiry time of an aggregation.

   If you delete the Aggregation policy, the storage queues are not deleted automatically when the policy is deleted, so you must delete them separately.
3. In the AggregateControl and AggregateReply nodes, ensure that the name of the Aggregation policy is the same as the name that is specified in the `Aggregate name` property on the **Basic** tab; for example, `myAggregation`.

   If there is no Aggregation policy with the same name as the `Aggregate name` node property value, and if there is a default Aggregation policy specified in the `server.conf.yaml` file, that Aggregation policy is used instead.

What to do next

The properties for the policy are not used by the integration server until you restart or redeploy the message flow, or restart the integration server.

Using message collections

A message collection is a single message that contains multiple messages derived from one or more sources. You can use a Collector node to group together messages from one or more sources into a message collection, so that they can be processed together by downstream nodes. Information about the state of in-flight messages is held on system queues that are controlled by IBM MQ.

About this task

If you want to use message collections on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node. The system queues that hold the state information are owned by the queue manager that is specified on the integration server. You associate a queue manager with the integration server by specifying the queue manager name on the **defaultQueueManager** property in the `server.conf.yaml` configuration file; for more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

You must create the system queues by running the **iib_createqueues** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

If you want to use message collections with an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

The topics in this section describe how message collection works, and explain how you can configure your message flow to process message collections.

Message collections

A message collection is a single message that contains multiple messages derived from one or more sources.

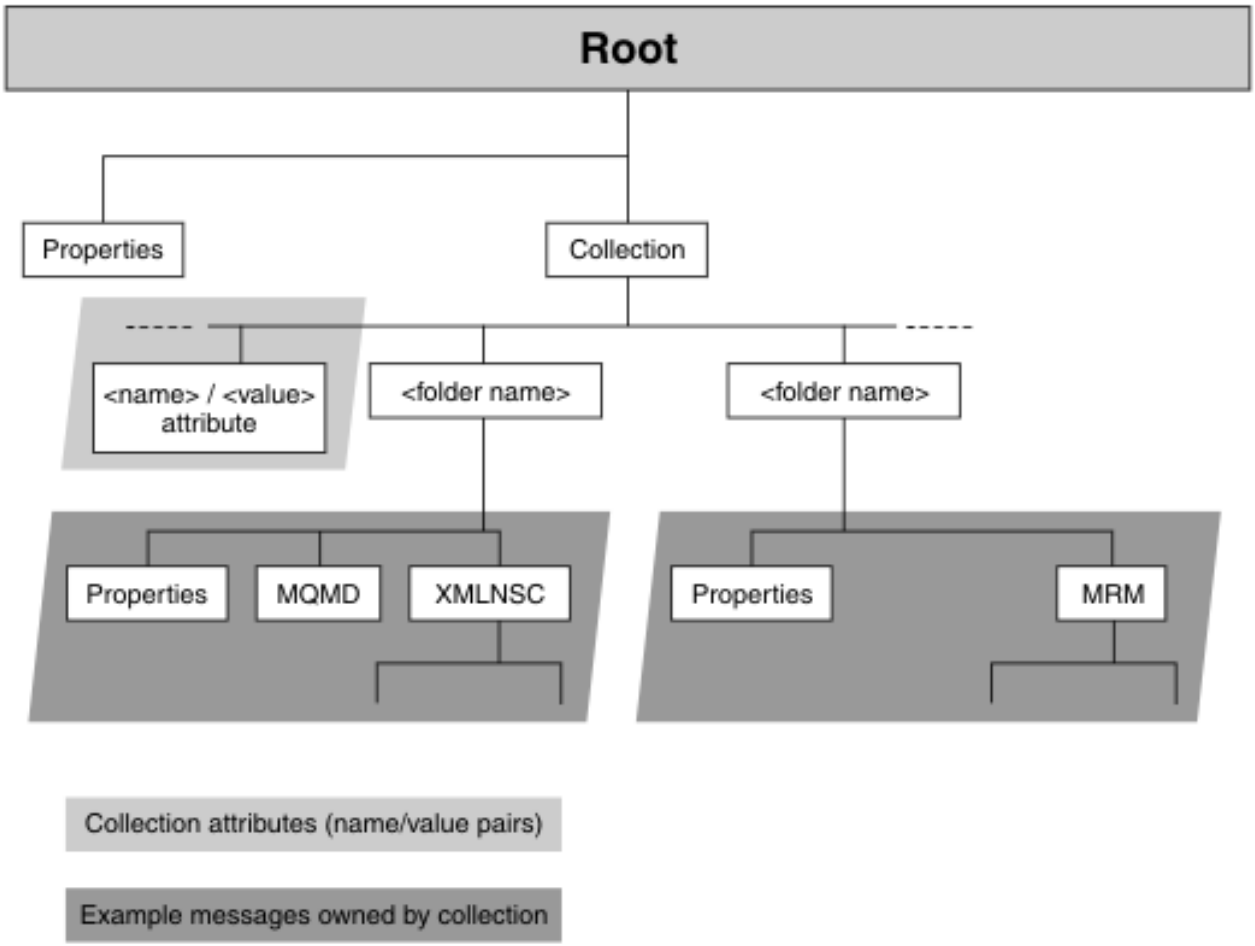
You can use a Collector node to group together messages from one or more sources into a message collection, so that they can be processed together by downstream nodes. You can also manually build a message collection using a Compute node.

Structure of a message collection

A message collection tree contains sub-trees that hold the content of the individual messages received by the Collector node. The message assembly that is propagated from the Collector node to other nodes in your message flow contains the following four components:

- Message (including transport headers)
- Local environment
- Global environment
- Exception list

The following figure shows an example of the message tree structure of a message collection.



The message collection in this example contains two messages, one received from IBM MQ, and one from a file input source.

A message collection has a Properties header and a single folder element named Collection. A message collection can also have zero or more attributes that are name/value pairs; the name of an attribute must be unique within a message collection. These are shown as `<name> / <value>` in the figure. A standard attribute for the message collection is an attribute called *`CollectionName`*. If you use a Collector node to generate a message collection, the value for the collection name is generated based on the values you configure in the node. The collection name attribute is not compulsory.

Within the Collection folder in the message collection tree structure are folders, shown as `<folder name>` in the diagram. These folders contain the message tree of each message added to the message collection. Each of these folders has a name, but this name does not have to be unique within the message collection. The value for the `<folder name>` is derived from the source of the input message.

Nested message collections are not permitted. You cannot therefore use a message collection as a source message for another message collection. For example, If you attempt to pass a message collection to a input terminal on a Collector node, an error is generated.

The LocalEnvironment, Environment and ExceptionList trees are not included in the structure, but are instead carried separately as a part of the message assembly. There is no concept of a LocalEnvironment associated with each message in a message collection.

Generating a message collection using a Collector node

You can use the Collector node to make multiple synchronous or asynchronous requests in parallel. The results of these requests can be joined together downstream if required. This is different from the behavior of the aggregation nodes where there is a fixed pattern of request/response and where reply

messages are grouped by request id. In contrast, the collector node does not need an initial fan-out stage and can group together unrelated input messages by correlating their content. You can configure dynamic input terminals on a Collector node to receive messages from different sources. You can also configure properties on the Collector node, known as event handlers, to determine how messages are added to a message collection, and when a message collection is complete.

Processing a message collection

A message collection is supported by the following nodes only:

- Compute
- JavaCompute
- CICSRequest

Errors are generated by other nodes if they receive a message collection.

You can use ESQL or XPath expressions to access the content of messages in a message collection by referencing the folder names preceded by `InputRoot.Collection`. To access the contents of a message in a message collection using ESQL you can use code similar to the following ESQL:

```
InputRoot.Collection.folder1.XMLNSC
```

In XPath, the root element is the body of the message. The root element for a message collection is the Collection element. Therefore, to access the contents of a message in a message collection using XPath, you must use an expression similar to the following XPath:

```
/folder1/XMLNSC
```

Examples of XPath expressions that you can use to access the message collection are:

- `/*`: returns a list of all the messages in the message collection.
- `/@*`: returns a list of all the attributes of the message collection.
- `/@Name`: returns the value of the attribute `Name`.

You might not be able to determine the order of the messages within a message collection. If you generate a message collection using the Collector node, the messages are arranged in the same order as the messages arrived at the node.

Creating a message collection by using ESQL

A message collection can be constructed by using ESQL. Using a message collection is useful if messages must be grouped together for parsing, or if the message collection must be constructed to represent a particular data structure, such as a CICS Transaction Server for z/OS channel data structure.

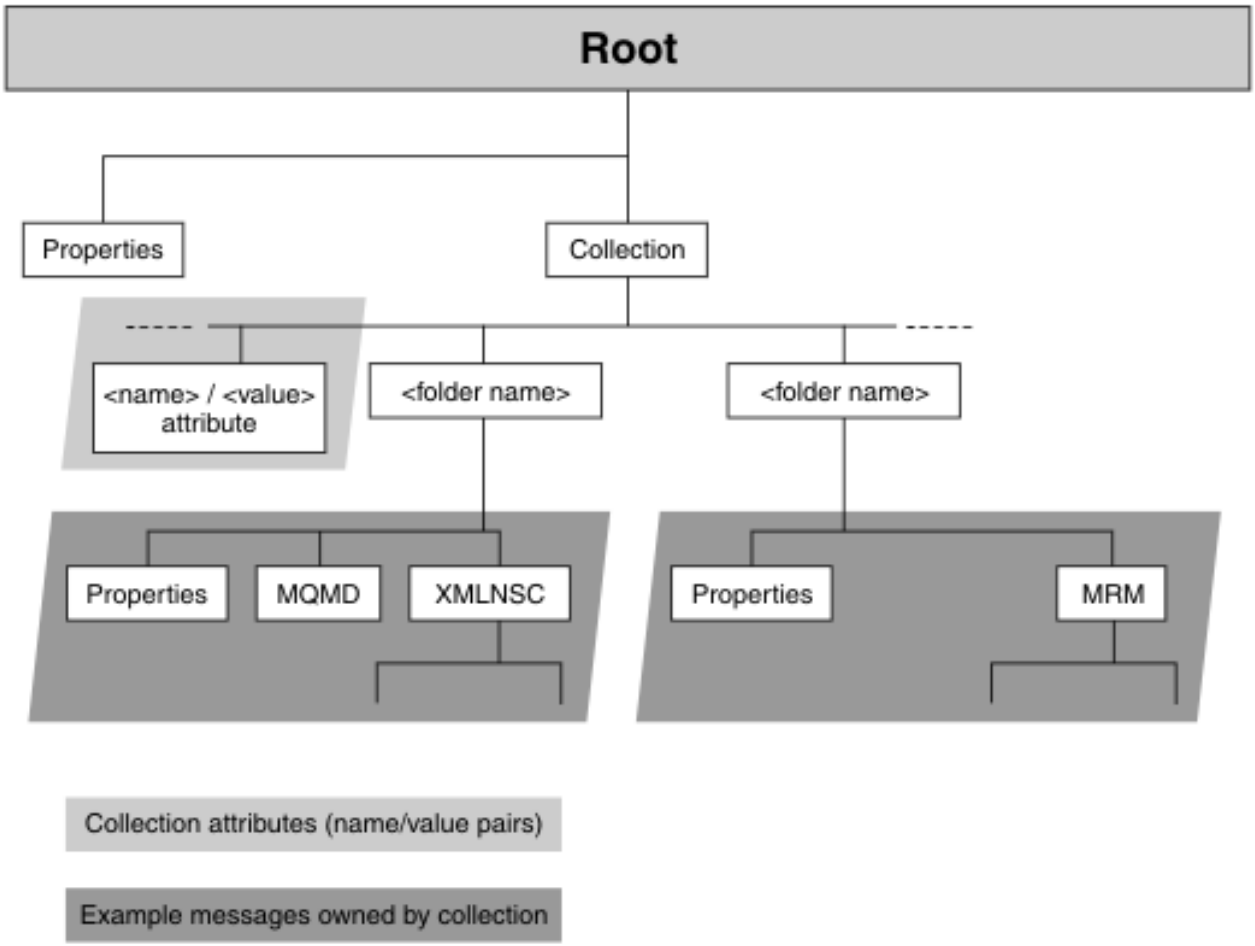
Before you begin

- Create an application, library, or integration project.
- For background information, read “Message collections” on page 1841.

About this task

A message collection is a message that consists of a `Properties` header and a single domain element named `Collection`. The `Collection` folder contains a number of child messages, each of which can contain a `Properties` folder, a number of headers (such as MQMD), and a body. A message collection can also have zero or more attributes that are name/value pairs. The name of an attribute must be unique within a message collection. A standard attribute for the message collection is an attribute called `CollectionName`.

The following figure shows an example of a message collection structure.



You can create a message collection by using ESQL to group messages together for parsing, or create a message collection that must be constructed to represent a particular data structure, such as a CICS channel data structure.

To configure a message collection by using ESQL, complete the following steps:

Procedure

1. Create a `Properties` folder for the collection by using the following ESQL statement:

```
CREATE FIRSTCHILD of OutputRoot domain 'Properties' NAME 'Properties';
```

2. Create the `Collection` domain element by using the following statement:

```
CREATE LASTCHILD OF OutputRoot DOMAIN 'Collection';
```

   As with message folders, the domain element is always the last child of the message.

3. Use the following statement to set an attribute in the collection called `CollectionName`:

```
SET OutputRoot.Collection.CollectionName = 'myCollectionName';
```

4. The following ESQL shows an example procedure to create a message within the collection:

```
SET OutputRoot.Collection.foldername.Properties.MessageSet     = set;
SET OutputRoot.Collection.foldername.Properties.MessageType    = type;
SET OutputRoot.Collection.foldername.Properties.MessageFormat  = format;
SET OutputRoot.Collection.foldername.Properties.Encoding       = encoding;
SET OutputRoot.Collection.foldername.Properties.CodedCharSetId = ccsid;
```

```
SET OutputRoot.Collection.foldername.domain.content=some data;
```

Creating a message collection by using Java

A message collection can be constructed by using Java and the MbMessageCollection class. Using a message collection is useful if messages must be grouped together for parsing, or if the message collection must be constructed to represent a particular data structure, such as a CICS Transaction Server for z/OS channel data structure.

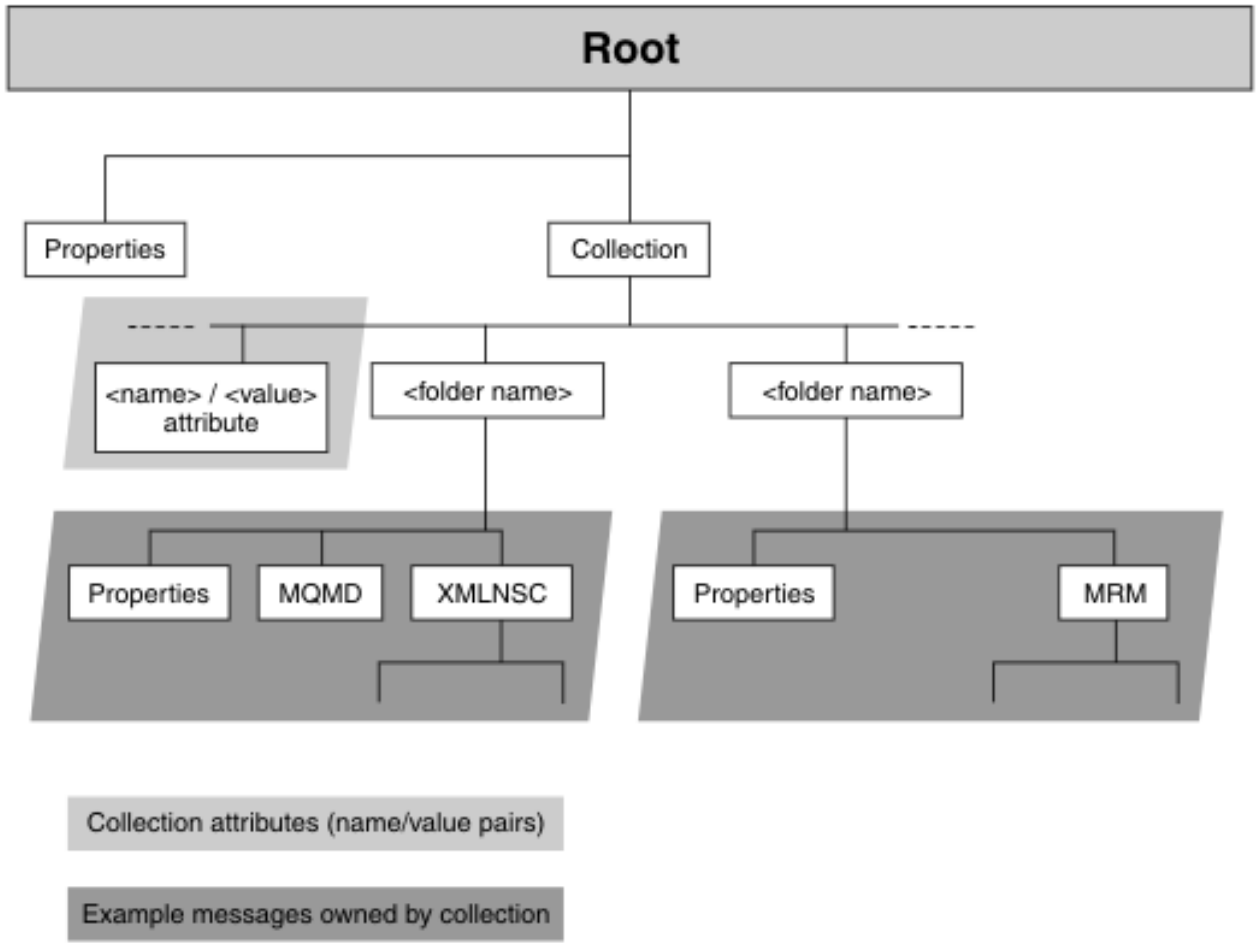
Before you begin

- For background information, read "Message collections" on page 1841.

About this task

A message collection is a message that consists of a `Properties` header and a single domain element named `Collection`. The `Collection` folder contains a number of child messages, each of which can contain a `Properties` folder, a number of headers (such as MQMD), and a body. A message collection can also have zero or more attributes that are name/value pairs. The name of an attribute must be unique within a message collection. A standard attribute for the message collection is an attribute called *`CollectionName`*.

The following figure shows an example of a message collection structure.



You can create a message collection by using Java, and the MbMessageCollection class, to group messages together for parsing, or create a message collection that must be constructed to represent a particular data structure, such as a CICS channel data structure.

To configure a message collection by using Java, complete the following steps:

Procedure

1. Create a new message by using the following example:

```
// create new message
MbMessageCollection outMessage = new MbMessageCollection();
MbMessageAssembly outAssembly = new MbMessageAssembly(inAssembly,
 outMessage);
```

2. Create a `Properties` folder for the collection by using the following example:

```
// create top level Properties folder and data
MbElement omroot = outMessage.getRootElement();
MbElement properties = omroot.createElementAsFirstChild("Properties");
MbElement property1 = properties.createElementAsLastChild(
 MbElement.TYPE_NAME_VALUE, "myProperty1", "propertyData1");
MbElement property2 = properties.createElementAsLastChild(
 MbElement.TYPE_NAME_VALUE, "myProperty2", "propertyData2");
```

3. Create the name value pairs by using the following example:

```
// create collection attributes (name/value pairs)
MbElement cn  = outMessage.createNameValue("CollectionName", "myCollectionName");
MbElement nv1 = outMessage.createNameValue("NAME1", "Value1");
MbElement nv2 = outMessage.createNameValue("NAME2", 12345);
```

   As with message folders, the domain element is always the last child of the message property.

4. The following example shows the procedure to create a message within the collection. Steps one, two, and three are repeated.

```
public void evaluate(MbMessageAssembly inAssembly) throws MbException {
 MbOutputTerminal out = getOutputTerminal("out");

 // create new message
 MbMessageCollection outMessage = new MbMessageCollection();
 MbMessageAssembly outAssembly = new MbMessageAssembly(inAssembly,
  outMessage);

 // create top level Properties folder and data
 MbElement omroot = outMessage.getRootElement();
 MbElement properties = omroot.createElementAsFirstChild("Properties");
 MbElement property1 = properties.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myProperty1", "propertyData1");
 MbElement property2 = properties.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myProperty2", "propertyData2");

 // create collection attributes (name/value pairs)
 MbElement cn  = outMessage.createNameValue("CollectionName", "myCollectionName");
 MbElement nv1 = outMessage.createNameValue("NAME1", "Value1");
 MbElement nv2 = outMessage.createNameValue("NAME2", 12345);

 // create folder 1
 MbElement folder1 = outMessage.createFolder("folder1");

 // create properties for folder 1
 MbElement folder1properties = folder1.createElementAsFirstChild("Properties");
 MbElement folder1property1 = folder1properties.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myFolder1Property1", "folder1propertyData1");
 MbElement folder1property2 = folder1properties.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myFolder1Property2", "folder1propertyData2");

 // create body of folder 1
 MbElement mrm = folder1.createElementAsLastChild("MRM");

 // create message domain element of folder 1
 MbElement msg = mrm.createElementAsLastChild(MbElement.TYPE_NAME,
  "msg", null);

 // create data within the message body for folder 1
 MbElement data = msg.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "data", "myData");

 // create folder 2
 MbElement folder2 = outMessage.createFolder("Folder2");
```

```
 // create properties for folder 2
 MbElement folder2properties = folder2.createElementAsFirstChild("Properties");
 MbElement folder2property1 = folder2properties.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myFolder2Property1", "folder2propertyData1");
 MbElement folder2property2 = folder2properties.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myFolder2Property2", "folder2propertyData2");

 // create body of folder 2
 MbElement xmlnsc = folder2.createElementAsLastChild("XMLNSC");

 // create message domain element of folder 2
 MbElement msg2 = xmlnsc.createElementAsLastChild(
  MbElement.TYPE_NAME, "msg2", null);

 // create data within the message body for folder 2
 MbElement data2 = msg2.createElementAsLastChild(
  MbElement.TYPE_NAME_VALUE, "myData2", "myXMLData");

 try {
  out.propagate(outAssembly);
 } finally {
  // clear the outMessage even if there's an exception
  outMessage.clearMessage();
 }
}
```

Results

The following example output from a Trace node shows the message structure built by this Java code:

```
TraceOutput:  Root ( ['MQROOT' : 0xee3a90]
 (0x01000000:Name):Properties = ( ['MQPROPERTYPARSER' : 0xae4370]
  (0x03000000:NameValue):myProperty1 = 'propertyData1' (CHARACTER)
  (0x03000000:NameValue):myProperty2 = 'propertyData2' (CHARACTER)
 )
 (0x01000000:Name):Collection = ( ['COLLECTION' : 0x58d0b08]
  (0x03000000:NameValue):CollectionName = 'myCollectionName' (CHARACTER)
  (0x03000000:NameValue):NAME1          = 'Value1' (CHARACTER)
  (0x03000000:NameValue):NAME2          = 12345 (INTEGER)
  (0x01000000:Name     ):Folder1     = ( ['COLLECTIONFOLDER' : 0xee42e8]
   (0x01000000:Name ):Properties = ( ['MQPROPERTYPARSER' : 0xae39e8]
    (0x03000000:NameValue):myFolder1Property1 = 'folder1propertyData1' (CHARACTER)
    (0x03000000:NameValue):myFolder1Property2 = 'folder1propertyData2' (CHARACTER)
   )
   (0x01000021:Name+):MRM        = ( ['mrm' : 0xdce588]
    (0x01000000:Name):msg = (
     (0x03000000:NameValue):data = 'myData' (CHARACTER)
    )
   )
  )
  (0x01000000:Name     ):Folder2     = ( ['COLLECTIONFOLDER' : 0xee3d58]
   (0x01000000:Name  ):Properties = ( ['MQPROPERTYPARSER' : 0xae4cf8]
    (0x03000000:NameValue):myFolder2Property1 = 'folder2propertyData1' (CHARACTER)
    (0x03000000:NameValue):myFolder2Property2 = 'folder2propertyData2' (CHARACTER)
   )
   (0x01000000:Folder):XMLNSC     = ( ['xmlnsc' : 0xee2188]
    (0x01000000:Folder):msg2 = (
     (0x03000000:PCDataField):myData2 = 'myXMLData' (CHARACTER)
    )
   )
  )
 )
)
```

Creating a flow that uses message collections

Use a Collector node in your message flow to group messages from one or more sources into a message collection. You can add dynamic input terminals to your Collector node for each message source that you want to configure for your message flow.

Before you begin

- For background information, read “Message collections” on page 1841.

- If you are using message collections on an integration server that is managed by an integration node, ensure that you have installed IBM MQ. Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ, and you must install IBM MQ on the same computer as your integration node if you want to use the capabilities provided by the aggregation nodes. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

  If you are using message collections on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

About this task

You can also use a Compute node to create a message collection by using ESQL, which is useful if messages must be grouped together for parsing, or if the message collection must be constructed to represent a particular data structure, such as a CICS Transaction Server for z/OS channel data structure. For more information about using ESQL to create a message collection, see "Creating a message collection by using ESQL" on page 1843.

To create a message flow to generate and process message collections, complete the following steps:

Procedure

1. Create a message flow.
2. Add the input nodes in the editor view.

   The input nodes receive the messages from which message collections are generated. You can use any of the built-in nodes, or user-defined input nodes. Configure and connect them as described.

   a) Add an input node for each source of input messages for your message flow, for example an MQInput node and a JMSInput node.

   b) Select each input node in turn to display its properties in the Properties view.

   c) Specify the source of input messages for each node. For example, specify the name of an IBM MQ queue in the Basic property `Queue Name` from which the MQInput node retrieves messages.

   d) Optional: Specify values for any other properties that you want to configure for each node.
3. Add the Collector node in the editor view.

   The Collector node receives messages from input nodes or other nodes in the message flow. You must add a dynamic input terminal to the Collector node for each input message source before you can connect the input nodes or any upstream nodes to the Collector node. Configure and connect them as described.

   a) Add a Collector node to your message flow.

   b) Right-click the Collector node and click **Add Input Terminal** to add a new dynamic input terminal to the Collector node. Add a new input terminal for each input source that you plan to add to your message flow; for more information about adding dynamic input see "Adding an input terminal to a Collector node for each input source" on page 1850.

   c) Connect the out terminal of each input node to a different dynamic input terminal of the Collector node. This represents the simplest configuration; if appropriate, you can include other nodes between the input node and the Collector node. For example, you might want to store the request for audit purposes (in a Database node), or add a unique identifier to the message (in a Compute node).

4. Add processing nodes to your message flow.

   You can process message collections from a Collector node by using the following nodes only:

   - Compute
   - JavaCompute
   - .NETCompute

   You must connect a Compute, JavaCompute, or .NETCompute node to the Collector node in your message flow. Use these nodes to process the message collection and propagate other messages. You can use ESQL or XPATH to access the contents of the individual messages in the message collection for processing. To process a message collection:

   a) Add a Compute, JavaCompute, or .NETCompute node to your message flow.

   b) Add code to your message flow node to create single output messages from the message collection.

   c) Optional: Specify values for any other properties that you want to configure for this processing node.

   d) Connect the out terminal of the processing node to the in terminal of an output node or other processing node.

   e) Optional: Add other message flow nodes to your message flow for further processing.

5. Include one or more output nodes for your message flow. These can be any of the built-in nodes, or a user-defined output node. An output node cannot process a message collection, therefore ensure that you connect the output node to a processing node that propagates single output messages. To configure an output node:

   a) Select each output node in turn to display its properties in the Properties view.

   b) Specify the destination properties for each node. For example, specify the name of an IBM MQ queue in the Basic property `Queue Name` to which the MQOutput node sends messages.

   c) Optional: Specify values for any other properties that you want to configure for each node.

6. Include processing for handling errors and expired message collections:

   a) Optional: Add processing nodes to your message flow to handle expired message collections. Connect these nodes to the Expire terminal of the Collector node.

   b) Optional: Add processing or error handling nodes to handle any exceptions in your message flow. Connect these nodes to the Catch terminal of the Collector node

   If an error is detected downstream of the Collector node, the integration node throws an exception. The message collection is propagated to the Catch terminal of the Collector node. Connect the Catch terminal to a sequence of nodes that handles the errors, to avoid losing any data, and ensure that no further exceptions can be generated during error processing. The message flow node that is connected to the Catch terminal must be a Compute, JavaCompute, or .NETCompute node to handle the message collection.

7. Press Ctrl-S or click **File** > **Save *name*** (where *name* is the name of this message flow) to save the message flow and validate its configuration.

Results

To control when complete message collections are propagated, you must add additional message flow nodes to your message flow. For more information, see “Using control messages with the Collector node” on page 1856.

What to do next

Next: Configure the Collector node.

Configuring the Collector node

You can configure the Collector node to determine how messages are added to message collections. You can also use properties on the Collector node to control when message collections are propagated.

Before you begin

This topic assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

Use the following topics to configure the Collector node:

Adding an input terminal to a Collector node for each input source

Add new dynamic input terminals to the Collector node for all of the sources of messages for your message collections.

Before you begin

This task assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

To add a dynamic input terminal to the Collector node for each message source, complete the following steps.

Procedure

1. Right-click the Collector node and select **Add Input Terminal**.
2. In the dialog box that is displayed, enter a name of your choice for the terminal, and click **OK**.
   The name that you give to the input terminal is used as the folder name in the message collection.
3. Repeat steps "1" on page 1850 and "2" on page 1850 to add further input terminals.

What to do next

When you have created all the required input terminals on the Collector node, you can set the event handler properties. For more information see, "Setting event handler properties" on page 1850.

Setting event handler properties

You can configure event handler properties for each dynamic input terminal on a Collector node. These event handler properties determine how the messages received by each terminal are added to message collections.

Before you begin

To complete this task, you must have completed the following tasks:

- "Creating a flow that uses message collections" on page 1847

- "Adding an input terminal to a Collector node for each input source" on page 1850

About this task

You can use one or more of the event handler properties to control the way that messages are added to message collections for each input terminal that you added to the Collector node. Incomplete message collections are stored on an IBM MQ queue. The message collections are stored in the order that they are generated by the Collector node (first in, first out). Each message collection has an event handler instance for each of the input terminals. The event handler determines whether an incoming message on that terminal is added to a message collection. The event handler instance maintains information about the state of the collection, the number of messages received, the timer, and the correlation string. When a new message is received on an input terminal, it is offered to the event handler for each message collection waiting on the queue in turn. When the message is accepted by one of the event handlers, it is added to the message collection. The accepted message is not offered to any other message collections. If all the event handlers reject the message, it is added to a new message collection, which is added to the end of the queue.

The first message accepted into a collection determines the correlation string for that message collection, if it is configured. Subsequent messages offered to that message collection are only accepted if their correlation string matches that of the collection. The first message accepted by each event handler starts the timeout timer, if it is configured. Each message accepted by each event handler increments the quantity count. An event handler becomes satisfied when the number of messages accepted equals the configured quantity, or when the timeout value is reached. When an event handler is satisfied, the event handler does not accept any more messages. A message collection is complete only when all of the message collection's event handlers are satisfied. The message collection is then ready for propagation.

You can configure the event handler properties by using the **Collection Definition** table, on the **Basic** tab of the Properties view.

To configure the event handler properties on the Collector node:

Procedure

1. Open the message flow with the Collector node.
2. Right-click the Collector node and select **Properties**.
3. Click the **Basic** tab.
4. Use the following instructions to configure the event handler properties that you want to set for each input terminal:
   - If you want to add a set number of messages to each message collection from one or more of the terminals, you must enter a value for `Quantity` in the Collection Definition table. This value is used to specify the number of messages that each configured input terminal accepts to complete a collection. For example, if you have set `Quantity` to wait for 2 messages on three of the input terminals, the message collection is not complete until 2 messages have been received on each of the three input terminals. The complete message collection contains 6 messages, 2 from each of the three terminals. As soon as more than 2 messages are received on one of the input terminals, the next message is added to a new message collection.
     a. In the Collection Definition table, click the row for the selected input terminal within the `Quantity` column.
     b. Enter a value for the number of input messages that you want to add to a message collection. If you select `Zero` or choose not to set this property, there is no limit to the number of messages accepted. In this case the value set on the `Timeout` property must be greater than zero. If you accept the default value of 1; only one message from the selected terminal is added to a collection.

     You must enter a value for `Quantity` if `Timeout` is not set.
   - If you want to collect messages for a set amount of time before the message collection is propagated you must enter a value for `Timeout`. This value is used to specify the maximum

time in seconds for which the selected input terminal accepts messages before completing a message collection. The timeout interval starts when the first message has arrived at the selected terminal. Any subsequent messages are added to the same message collection. When the timeout interval ends, no more messages are added to the message collection from this terminal. When the conditions on all the terminals are satisfied, the message collection is ready for propagation. When the next message reaches the selected input terminal, a new message collection is created and the timeout interval starts again. If a timeout is set on multiple input terminals, each terminal collects messages for the configured amount of time. During the timeout messages from all of the terminals are added to the same message collection.

a. In the Collection Definition table, click the row for the selected input terminal within the `Timeout` column.

b. Enter a value for the length of time in seconds that you want to wait to add messages to a message collection. For example, to wait for messages to add to a message collection for an hour, enter a value of `3600`. If you accept the default value `Zero`, timeout is not enabled and there is no limit on the time to wait for messages. In this case the value set on the `Quantity` property must be greater than zero.

You must enter a value for `Timeout` if `Quantity` is not set.

- If you want to add messages to different message collections based on the content of the message you must enter an XPath value for the `Correlation path`. This value is used to specify the path in the incoming message from which to extract the correlation string. The correlation string is the value that is extracted by the correlation path. If a correlation pattern is specified, the correlation string is matched against the correlation pattern. Messages are only accepted into a message collection with the same correlation string. If you specify an asterisk (`*`) in the name of the message collection, it is replaced by the correlation string.

  a. In the Collection Definition table, click the row for the selected input terminal within the `Correlation path` column.

  b. Either select a predefined correlation path from the list, or enter your own correlation path using XPath. The correlation path must begin with a correlation name, which can be followed by zero or more path fields. For example, in the following message the correlation string is `xxx` in the name field:

```
<library>
 <name>xxx</name>
 <more>
  ...
 </more>
</library>
```

  In this example, the correlation path using XPath is `$Body/library/name`.

  The variables `$Root`, `$LocalEnvironment`, and `$Environment` are available to allow the path to start at the roots of the message, local environment, environment trees, and message body.

  If the correlation path evaluates to an empty string the unmatched message is added to a default unnamed message collection.

  If you define a value for `Correlation path`, you can optionally configure a `Correlation pattern`.

- If you want to match a substring of the message content from the `Correlation path`, you can define a pattern to match in the message by using `Correlation pattern`. The `Correlation pattern` contains a single wildcard character and optional text. The correlation string, used for the name of the message collection, is the part of the substring that matches the wildcard. For example, if the correlation path contains the filename `part1.dat` in a file header, and the correlation pattern is specified as `*.dat`, the correlation string is `part1`. If this property is set, only messages that have the same correlation string are added to the same message collection. The first

message added to a message collection determines the correlation string that must be matched by all other messages in that message collection.

a. In the Collection Definition table, click the row for the selected input terminal within the `Correlation pattern` column.

b. Enter a value for the correlation pattern. The `Correlation pattern` must contain a single wildcard character: *. This wildcard character can optionally be surrounded by other text.

If the correlation pattern fails to match the wildcard to a substring, the unmatched message is added to a default unnamed message collection.

5. Repeat step "4" on page 1851 for each of the input terminals that you added to your Collector node.

You can configure different event handlers for different input sources.

What to do next

Note: Ensure that you set the event handler properties across different terminals carefully to match the expected delivery of messages to the terminals on the Collector node.

You can now configure the collection expiry, see "Setting the collection expiry" on page 1853.

Setting the collection expiry

The collection expiry is a property on the Collector node to set a maximum timeout for adding messages to a message collection.

Before you begin

This topic assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

When messages are added to a message collection, the incomplete message collection is stored on a queue. If the message collection's event handlers are not satisfied, the incomplete message collection is stored on the queue indefinitely, and not propagated for further processing. If a Collector node has 2 input terminals, and one of the terminals stops receiving messages, for example if the source application is not running, there is the potential for the queue of incomplete message collections to grow indefinitely. To ensure that these incomplete message collections are released after an appropriate amount of time, configure the *`Collection Expiry`* property. You can configure this timeout, as a value in seconds, in the *`Collection Expiry`* property on the Collector node. The collection expiry timeout starts when the first message is accepted into a message collection. The collection expiry overrides any individual event handler timers. When the collection expiry timeout has passed for a message collection, the incomplete message collection is propagated to the **Expire** terminal. Connect appropriate processing nodes to the **Expire** terminal, to handle any expired message collections in your message flow.

To configure a collection expiry:

Procedure

1. Open the message flow with the Collector node.
2. Right-click the Collector node and select **Properties**.
3. Click the **Basic** tab.
4. In `Collection Expiry`, enter a time in seconds for the collection expiry timeout.

What to do next

Next: Configure the collection name.

Setting the collection name
You can set a default name, or use a correlation string, for the name of your message collections, by using the `Collection name` property on the Collector node.

Before you begin

This task assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

Each message collection that is produced by the Collector node has a name. The collection name is the value that is associated with the CollectionName attribute in the message collection tree structure. Each message collection has only one name.

You can either use `Collection name` to set a default name to be used for each message collection, or you can use the event handler properties to create a correlation string to use for the message collection name. You can use the correlation string to generate a unique name for the message collection, based on the content of the input messages. To use the correlation string for the collection name, you must enter the wildcard symbol `*`. If you leave `Collection name` blank, or if it is set to `*` and the value of the correlation string is empty, the CollectionName attribute of the message collection is set to an empty value.

Any `*` characters in the collection name are replaced with the correlation string. The correlation string for each message collection is also copied into the local environment message that is associated with the propagated message collection. The location of the correlation string in the local environment is `Wildcard/WildcardMatch`.

To configure the message collection name:

Procedure

1. Open the message flow that contains the Collector node.
2. Right-click the Collector node and select **Properties**.
3. Click the **Basic** tab.
4. For the `Collection name` property, enter a name for the message collections that are generated by the Collector node.

   If you have set a value for `Correlation path` on your input terminals, you can use the `*` for the `Collection name` property to substitute the correlation string into the collection name value. Leave the collection name blank if you want to set your message collection name to an empty value.

What to do next

Next: "Setting the event coordination property" on page 1854.

Setting the event coordination property
Use the `Event coordination` property for controlling how message collections are propagated from the Collector node.

Before you begin

This topic assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

In addition to the dynamic input terminals that you can add to the Collector node, there is a static input terminal called **Control**. The purpose of this terminal is to allow an external resource to trigger the output from the collector node. Details are controlled through the Event coordination property settings.

Incomplete message collections that have exceeded the value for the *Collection expiry* timeout are immediately propagated to the Expire terminal, regardless of how you configure the *Event coordination* property.

To configure *Event coordination*:

Procedure

1. Open the message flow that contains the Collector node.
2. Right-click the Collector node and select **Properties**.
3. Click the **Advanced** tab.
4. Set the *Event coordination* property on the Collector node.
   Select from the following options:
   - If you select Disabled, messages to the **Control** terminal are ignored and message collections are propagated when they are complete.
   - If you select All complete collections, complete message collections are held on a queue. When a message is received on the **Control** terminal, all message collections on the queue are propagated to the **Out** terminal.
   - If you select First complete collection, complete message collections are held on a queue. When a message is received on the **Control** terminal, the first message collection on the queue is propagated to the **Out** terminal. If the queue is empty when a message arrives on the **Control** terminal, the next message collection that is completed is propagated to the **Out** terminal.

Results

You have completed configuration of the Collector node.

What to do next

Next: if you have configured your Collector node to use control messages, see "Using control messages with the Collector node" on page 1856.

Setting the persistence mode property

Use the Persistence Mode property to control whether incomplete message collections are stored persistently on the queues of a Collector node.

Before you begin

This topic assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

The storage of incoming messages and the Collector node state is handled internally by using IBM MQ queues. By default, incomplete message collections are stored non-persistently, which means that incomplete message collections persist if you restart your integration node, but not if you restart your queue manager.

You can use the Persistence Mode property on the Collector node to store incomplete message collections on a queue persistently. If you set the Persistence Mode property to Persistent, incomplete message collections are not lost if you restart your queue manager. However, if you do set the property to Persistent, the overall performance of the Collector node might be affected.

To configure the Persistence Mode:

Procedure

1. Open the message flow that contains the Collector node.

2. Right-click the Collector node and select **Properties**.
3. Click the **Advanced** tab.
4. Set the `Persistence Mode` property on the Collector node to one of the following values.
   - If you select `Non Persistent`, messages and collection state are stored by the integration node queue manager as non-persistent messages.
   - If you select `Persistent`, messages and collection state are stored by the integration node queue manager as persistent messages.

Results

You have completed configuration of the Collector node.

Setting the Policy property on the Collector node

Use the `Policy` property on the Collector node to specify a Collector policy that sets the values of properties at run time.

Before you begin

This task assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

You can use the `Policy` property on the Collector node to specify the name of a Collector policy to be used by the node. The Collector policy has the following properties:

Queue prefix
The identifier used to specify the names of queues in which events and collections are stored.

Collection expiry (seconds)
The expiry time (in seconds) of a collection. This property overrides the value specified by the `Collection expiry` property on the Collector node.

To configure the `Policy` property, complete the following steps.

Procedure

1. Open the message flow that contains the Collector node.
2. Right-click the Collector node and select **Properties**.
3. Click the **Advanced** tab.
4. Specify the name of the Collector policy in the `Policy` field.

What to do next

Deploy the Collector policy to an integration server before you deploy the message flow that contains the Collector node.

Using control messages with the Collector node

You can send control messages to the Collector node in order to control how complete message collections are propagated to other nodes in your message flow.

Before you begin

This task assumes that you have already created a message flow that contains a Collector node. For more information, see "Creating a flow that uses message collections" on page 1847.

About this task

You can control when complete message collections are propagated to other nodes for processing, using messages sent to the **Control** terminal. The exact behavior depends on the settings that you have chosen for the *Event coordination* property on the Collector node. If you want to use control messages to propagate completed messages collections you must set the *Event coordination* property to one of the following values:

- `All complete collections`
- `First complete collection`

In these cases, the complete message collections are held on a queue until a control message is received. If you set *Event coordination* to `All complete collections`, all the message collections held on the queue are propagated to the **Out** terminal. If you set *Event coordination* to `First complete collection`, only the first message collection on the queue is propagated to the **Out** terminal. If there are no complete message collections on the queue, the next message collection to complete is immediately propagated to the **Out** terminal.

Incomplete message collections that have exceeded the value for *Collection expiry* are immediately propagated to the **Expire** terminal regardless of the setting of *Event coordination*.

If you want to propagate any complete message collections after a set amount of time for further processing, connect a TimeoutNotification node to the **Control** terminal of the Collector node. You can use the TimeoutNotification node to send a control message to propagate the message collections to ensure that messages are processing within a reasonable time, or to schedule processing tasks.

For more information about driving a message flow using the TimeoutNotification node, see "Automatically generating messages to drive a flow" on page 1880.

Alternatively, you can propagate complete message collections using a message from another application or message flow by connecting an input node to the **Control** terminal of the Collector node.

You can send any message to the **Control** terminal of the Collector node. The message received on the **Control** terminal is not examined by the integration node and is discarded on receipt.

Configuring the storage of events for Collector nodes

You can use a Collector policy to control the storage of events for Collector nodes.

About this task

Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ. The storage queues that hold the state information are owned by the queue manager that is associated with the integration server.

If you are using message collections on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node in order to use the capabilities that are provided by the Collector node. If you are using message collections on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For more information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

If the integration server has the necessary permissions to create the default system queues, they are created automatically when a flow that contains Collector nodes is deployed. If the default queues are not created automatically, you can create them manually by running the **iib_createqueues** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

By default, the storage queues used by all Collector nodes are:

- SYSTEM.BROKER.EDA.EVENTS
- SYSTEM.BROKER.EDA.COLLECTIONS

These queues are also used by the Resequence node.

However, you can control the queues that are used by different Collector nodes by creating alternative queues that contain a *QueuePrefix* variable, and by using a Collector policy to specify the names of those queues for storing events.

Follow these steps to specify the queues that are used to store event states, and to set the expiry for the collection:

Procedure

1. Create the storage queues to be used by the Collector node.

   The following queues are required:

   - SYSTEM.BROKER.EDA.*QueuePrefix*.EVENTS
   - SYSTEM.BROKER.EDA.*QueuePrefix*.COLLECTIONS

   The *QueuePrefix* variable can contain any characters that are valid in an IBM MQ queue name, but must be no longer than eight characters and must not begin or end with a period (.). For example, SET1 and SET.1 are valid queue prefixes, but .SET1 and SET1. are invalid.

   If you do not create the storage queues, IBM App Connect Enterprise creates the queues when the node is deployed; these queues are based on the default queues. If the queues cannot be created, the message flow is not deployed.
2. Create a Collector policy (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
   a) You can create a policy to be used with either a specific collection or with all collections in an integration server. If you are creating a policy to be used with a specific collection, ensure that the name of the policy is the same as the name that you specify in the `Policy` property on the Collector node.

      To specify a default Collector policy for all message flows that are deployed to an integration server, set the **`Collector`** property in the `server.conf.yaml` file to the name of a Collector policy. For information about setting properties in the `server.conf.yaml` file, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172. If the default policy is in the default policy project, you do not need to specify the name of the policy project. If the default policy is in a non-default policy project, qualify the name of the policy with the name of the policy project in the format *{policyProjectName}:PolicyName*
   b) Set the **`Queue prefix`** property of the Collector policy to the required value.
   c) Optional: Set the **`Collection expiry`** property of the Collector policy to an appropriate value (for example, 60).

   If you delete a Collector policy, the storage queues are not deleted automatically when the policy is deleted, so you must delete them separately.
3. In the Collector node, if the policy is to be used for a specific collection, specify the name of the policy in the `Policy` property on the **Advanced** tab; for example, `myCollectorService`.

   If you do not set the `Policy` property, and if there is a default Collector policy specified in the `server.conf.yaml` file, that policy is used instead.

What to do next

The properties for the policy are not used by the integration server until you restart or redeploy the message flow, or restart the integration server.

Using message sequences

You can maintain or change the sequence of messages in a message flow based on the sequence number and group ID contained in each message.

Before you begin

- Read the following concept topics, which contain information that you need to understand before you can use message sequences:
  - "Message sequencing" on page 1860
  - "Sequence groups" on page 1861
  - "Starting a message sequence" on page 1862
  - "Ending a message sequence" on page 1864
  - "Duplicate message processing" on page 1865
- If you are using message sequencing on an integration server that is managed by an integration node, ensure that you have installed IBM MQ. Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ, and you must install IBM MQ on the same computer as your integration node if you want to use the capabilities provided by the Sequence and Resequence nodes. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

  If you are using message sequencing on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

About this task

Information about the state of in-flight messages is held on system queues that are controlled by IBM MQ, and these queues are owned by the queue manager that is specified on the integration server. You create these system queues by running the **`iib_createqueues`** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

You associate a queue manager with the integration server by specifying the queue manager name on the **`defaultQueueManager`** property in the `server.conf.yaml` configuration file; for more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

IBM App Connect Enterprise enables you to configure the sequence of messages in a message flow by using the following nodes:

- node
- node

The following topics describe the tasks involved in configuring message sequences:

- "Adding sequence numbers to messages" on page 1866
- "Reordering messages in a message flow" on page 1868
- "Maintaining the sequential order of messages" on page 1869
- "Handling missing messages" on page 1873
- "Configuring the storage of events for Resequence nodes" on page 232

The following topics provide examples of how to use a Resequence node, and show how the node processes messages in a message flow:

- "Message sequencing scenario 1" on page 1870
- "Message sequencing scenario 2" on page 1871

Message sequencing

Use message sequencing to ensure that messages are delivered to the receiving application in a particular order.

IBM App Connect Enterprise provides support for adding sequence numbers to messages, and for reordering messages in the message flow based on their sequence number. Messages can arrive in any order and you can use the Sequence and Resequence nodes to reorder the messages into the required sequence.

In some applications, the ability to process messages in a specific order is important for maintaining the integrity of the workflow. For example, a series of debits and credits against a bank account must be processed in the order in which they took place, and patient records that are received, processed, and forwarded must be sent on in the order in which they arrived.

Messages arriving in the message flow might or might not contain sequence numbers. If messages without sequence numbers are received from an input source, you can preserve the order in which the messages are received by using a Sequence node to generate a monotonically increasing sequence number for each message in the sequence group. When each message arrives at the Sequence node, the sequence number is incremented and stored with the message in a location specified on the node.

Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ. If you are using message sequencing on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node in order to use the capabilities that are provided by the Sequence and Resequence nodes. If you are using these nodes on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For more information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

The current sequence numbers for each active sequence group are stored on the following IBM MQ queues:

- SYSTEM.BROKER.SEQ.GROUP
- SYSTEM.BROKER.SEQ.NUMBER

For more information, see node.

When the input messages contain sequence numbers, whether they were added by the Sequence node or already defined in an integer field in the message, you can use a Resequence node to change the order of the messages in the message flow.

When messages arrive at the Resequence node, they are held in a storage queue until all previous messages in the sequence have been propagated and committed. When each message becomes the next one in the sequence, it is taken off the queue and propagated down the Out terminal. This sequence of events ensures that messages are kept in the correct order even when message processing fails.

By default, the storage queues used by the Resequence node are:

- SYSTEM.BROKER.EDA.COLLECTIONS
- SYSTEM.BROKER.EDA.EVENTS

However, you can use a Resequence policy to specify alternative queues to be used by the Resequence node (see "Configuring the storage of events for Resequence nodes" on page 232).

You can configure the Resequence node to time out if a message in the sequence fails to arrive in a specified period of time, and you can specify how subsequent messages are processed if a message is missing. For example, you can configure the node so that:

- The message sequence must always be maintained
- Gaps are allowed in the message sequence but all other messages must remain in sequence
- Occasional out-of-sequence messages are allowed

For information about how to configure the Resequence node for these scenarios, see "Handling missing messages" on page 1873.

You can divide messages into sequence groups, which can be processed independently, allowing multiple sequences to be processed at the same time. For more information about sequence groups and duplicate message processing, see "Sequence groups" on page 1861.

For more information about the way in which the beginning and end of sequences are controlled, see "Starting a message sequence" on page 1862.

Sequence groups

Use sequence groups to control the way in which messages are grouped together for processing by Sequence and Resequence nodes.

By default, all messages arriving at the Sequence and Resequence nodes are ordered as part of a single sequence group. However, you can divide messages into multiple sequence groups, based on a sequence group identifier in the message, and order each sequence group independently. For example, you might have a message flow that receives, processes, and forwards patient records. It is important that the order of records is maintained for each individual patient, but ordering between patients is not necessary. In this case, the sequence group identifier would be the name or ID of the patient.

The group to which a message belongs is determined by the group identifier that is specified in the message. You can use the **Path to sequence group identifier** property on the Sequence and Resequence nodes to specify the location of the sequence group identifier in the message.

Messages that have the same group identifier are considered part of the same sequence group. If no sequence group is specified, a single default sequence group is used for all messages. However, if the **Path to sequence group identifier** property specifies a location in the message that does not exist, an error occurs.

Each sequence group can be associated with only one Sequence node. Multiple nodes can have a sequence group with the same name, but each of those sequence groups is associated with only one node and is separate from other groups with the same name on different nodes. For example, SequenceNode1 might have a sequence group called GroupA, and SequenceNode2 might also have a sequence group called GroupA, but they are separate groups.

Although you can reuse sequence groups when they have been closed, there is a risk that two occurrences of the same sequence group could overlap, with unpredictable results.

For example, if you have a sequence group including the numbers 1-10 and the group is used twice in close succession, it is possible for the second occurrence of sequence number *1* to arrive before sequence number *10* of the first occurrence. If this happens, a duplicate message exception occurs. For this reason, it is advisable to use a group name for only one set of sequence numbers, rather than reusing it in a Resequence node. If you do decide to reuse a sequence group, ensure that you reuse it only when you can be certain that the preceding use has been finished for a significant amount of time.

Even if all the numbers have been received by the first occurrence of the group, it can be difficult to know for certain exactly when the group is closed because it closes only when the final message has completely finished processing; this includes any processing that is required downstream of the node. Any message from the second occurrence fails as a duplicate unless all processing is complete. When a sequence group has started overlapping, it is very difficult to recover all the messages (in both uses of the group) in the correct order, although no messages are lost).

Starting a message sequence

The start of a message sequence is determined by the `Start of sequence definition` property on the Resequence and Sequence nodes.

Using a Resequence node

When you use the Resequence node to reorder messages in a message flow, you use the `Start of sequence definition` property on the Resequence node to define how the reordered message sequence will start. You can specify the starting sequence number in one of the following ways:

As a literal number

Select `Literal` to specify a literal sequence number, which can be any positive or negative numeric value in the range -9223372036854775807 to 9223372036854775807. When a message with the specified sequence number arrives, it is identified as the first message in the sequence and the messages are propagated.

Using the smallest number received

Select `Automatic` and specify the length of time (in seconds) during which the node collects messages, before it identifies the message that contains the smallest sequence number. When the smallest number has been determined, that sequence number becomes the first in the message sequence.

For example, assume that you have a Resequence node with the following properties:

- `Path to sequence number` property with a value of `/doc/seq`
- `Path to sequence group identifier` property with a value of `/doc/grp`
- `Start of sequence definition` property set to `Automatic` with a value of 5. This value means that, for any new group, the Resequence node collects messages for 5 seconds before determining the starting sequence number.
- `End of sequence definition` property set to `Automatic` with a value of 60. This value means that, for any new group, the Resequence node waits for 60 seconds before determining the ending sequence number.

The following messages are received by the Resequence node:

```
<doc><grp>a<grp><seq>5</seq></doc>
<doc><grp>a<grp><seq>4</seq></doc>
<doc><grp>a<grp><seq>3</seq></doc>
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>b<grp><seq>0</seq></doc>
<doc><grp>b<grp><seq>2</seq></doc>
```

At this point, the automatic period for the start of sequence expires (5 seconds), then the following messages are received:

```
<doc><grp>a<grp><seq>6</seq></doc>
<doc><grp>b<grp><seq>3</seq></doc>
```

For group *a*, the following messages are propagated to the Out terminal after 5 seconds:

```
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>a<grp><seq>3</seq></doc>
<doc><grp>a<grp><seq>4</seq></doc>
<doc><grp>a<grp><seq>5</seq></doc>
<doc><grp>a<grp><seq>6</seq></doc>
```

For group *b*, the following message is propagated to the Out terminal after 5 seconds:

```
<doc><grp>b<grp><seq>0</seq></doc>
```

No more messages are received before a missing message timeout occurs, at which point the following messages are propagated to the Expire terminal:

```
<doc><grp>b<grp><seq>2</seq></doc>
```

```
<doc><grp>b<grp><seq>3</seq></doc>
```

Using predicate set on the Resequence node

Select `Predicate` and specify an XPath expression to calculate whether the message is the first in the sequence. The predicate evaluates to either True or False, and messages continue to be collected while the expression evaluates to False. When the expression of a message is evaluated to True, it indicates that the message is the first in the sequence.

For example, you might specify the following XPath expression:

```
/Employee/EmpStartSeq="10"
```

When the input message field *EmpStartSeq* contains the value *10*, the start of sequence predicate is evaluated to True, and the message is identified as the first in the sequence:

```
<Employee>
 <EmpStartSeq>10</EmpStartSeq>
</Employee>
```

Typically, the XPath expression evaluates to a Boolean; however, if other data types are returned, the predicate is determined in the following way:

Table 73.

Returned data type	**True**	**False**
Boolean	True	False
Numeric	Any non-zero value	0 or 0.0
String	Any string matching `true` (case-insensitive)	Any string not matching `true` (case insensitive)
NodeSet	Never	Always

When a message evaluates the expression to True (and is therefore identified as the start of the sequence), the node checks that the message has the smallest sequence number collected up to that point. If messages are found with lower sequence numbers, an exception is thrown.

When the first message that evaluates to true has been processed successfully, the XPath expressions of subsequent messages are not checked. If a message arrives with a lower sequence number than the message that was identified as the start of the sequence, an exception is thrown.

Using a Sequence node

When you use the Sequence node to add sequence numbers to messages in the message flow, you use the `Start of sequence definition` property to specify a literal number that is to be used as the starting sequence number. The value can be any positive or negative integer in the range -9223372036854775807 to 9223372036854775807.

The Sequence node allocates a monotonically increasing sequence number for each input message that arrives at the node, starting with the sequence number that you define in the `Start of sequence definition` property. However, this value can be overridden by the value of the *StartOfSequenceNumber* field in the *LocalEnvironment* of the incoming message. For example: `InputLocalEnvironment.Sequence.StartOfSequenceNumber = 10`.

Ending a message sequence

The end of a message sequence is determined by the `End of sequence definition` property on the Resequence and Sequence nodes.

Using a Resequence node

When you use the Resequence node to reorder messages in a message flow, you use the `End of sequence definition` property on the Resequence node to define how the reordered message sequence will end. You can specify the end sequence number in the Resequence node in one of the following ways:

As a literal number

Select `Literal` to specify a literal sequence number as the end of the sequence. This value can be any positive or negative numeric value in the range -9223372036854775807 to 9223372036854775807. When a message with the specified sequence number arrives, the sequence group is closed. If there are any messages missing from the sequence, the sequence group remains open for the period of time specified by the `Missing message timeout` property.

For example, assume that you have a Resequence node with the following properties:

- `Path to sequence number` property with a value of `/doc/seq`
- `Path to sequence group identifier` property with a value of `/doc/grp`
- `Start of sequence definition` property set to `Literal` with a value of `0`.
- `End of sequence definition` property set to `Literal` with a value of 6. This value means that the group will be closed when a message with the sequence number 6 is received and when all earlier messages in the sequence have been received (or the missing message timeout expires).

The following messages are received by the Resequence node:

```
<doc><grp>a<grp><seq>6</seq></doc>
<doc><grp>a<grp><seq>5</seq></doc>
<doc><grp>a<grp><seq>4</seq></doc>
<doc><grp>a<grp><seq>3</seq></doc>
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>a<grp><seq>1</seq></doc>
<doc><grp>a<grp><seq>0</seq></doc>
```

The following messages are propagated to the Out terminal:

```
<doc><grp>a<grp><seq>0</seq></doc>
<doc><grp>a<grp><seq>1</seq></doc>
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>a<grp><seq>3</seq></doc>
<doc><grp>a<grp><seq>4</seq></doc>
<doc><grp>a<grp><seq>5</seq></doc>
<doc><grp>a<grp><seq>6</seq></doc>
```

When the sequence group has closed, any further messages arriving at the node for that sequence group are processed as part of a new instance of the group.

By an automatic timeout

Select `Automatic` and specify the length of time (in seconds) during which the node waits for new messages to arrive onto an empty queue. Each time the queue of messages waiting to be propagated is empty, the Resequence node starts a timer, which expires after the specified number of seconds. If no new messages arrive within the specified time, the sequence group is closed, and any new messages that arrive subsequently are treated as part of a new group. If new messages arrive at the node within the specified time limit, the timer is reset.

Using predicate set on the Resequence node

Select `Predicate` and specify an XPath expression to calculate whether the message is the last in the sequence. The predicate evaluates to either True or False, and messages continue to be collected while the expression evaluates to False. When the expression of a message is evaluated to True, it indicates that the message is the last in the sequence and the sequence group is closed. However,

if earlier messages are missing from the sequence group, the sequence group remains open for the period of time specified by the `Missing message timeout` property.

When the sequence group has closed, any further messages arriving at the node for that sequence group are processed as part of a new instance of the group.

Typically, the XPath expression evaluates to a Boolean; however, if other data types are returned, the predicate is determined in the following way:

Table 74.

Returned data type	**True**	**False**
Boolean	True	False
Numeric	Any non-zero value	0 or 0.0
String	Any string matching `true` (case-insensitive)	Any string not matching `true` (case insensitive)
NodeSet	Never	Always

When a message evaluates the expression to True (and is therefore identified as the last message in the sequence), the node checks that the message has the highest sequence number collected up to that point. If messages are found with higher sequence numbers, an exception is thrown.

Using a Sequence node

When you use the Sequence node to add sequence numbers to messages, you use the `End of sequence definition` property to define how the message sequence will end. The Sequence node allocates a monotonically increasing sequence number for each input message that arrives at the node, ending with the sequence number that you define in the `End of sequence definition` property.

You can specify the end sequence number in the Sequence node in one of the following ways:

As a literal number
Select `Literal` and specify a positive or negative numeric value as the end of sequence number (for example, 15). The value must be in the range -9223372036854775807 to 9223372036854775807. The monotonically increasing sequence ends when it reaches the end of sequence number specified by this property.

Using predicate set on the Sequence node
Select `Predicate` to specify that the sequence ends when the XPath expression evaluates to True. For more information, see the table above.

By an automatic timeout
Select `Automatic` and specify the length of time (in seconds) during which the node waits for new messages after a message for the sequence group has been propagated. If a new message arrives, the timer is canceled and reset when the message is propagated. If no new messages arrive within the specified time, the sequence group is closed, and any new messages that arrive subsequently are treated as part of a new group.

Duplicate message processing

Each sequence number within a sequence group must be unique.

If a Resequence node receives a message containing a sequence number that has already been processed in the current sequence group, an exception is thrown (BIP4821) and the duplicate message is propagated to the Failure terminal. An exception occurs only if the duplicate message arrives after the first message with that sequence number has arrived and before the sequence group closes.

For example, assume that you have a Resequence node with the following properties:

- `Path to sequence number` property with a value of `/doc/seq`
- `Path to sequence group identifier` property with a value of `/doc/grp`

- `Start of sequence definition` property set to `Literal` with a value of `1`
- `End of sequence definition` property set to `Literal` with a value of `3`

The following messages arrive at the Resequence node:

```
<doc><grp>a<grp><seq>1</seq></doc>
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>a<grp><seq>2</seq>/doc>
<doc><grp>a<grp><seq>3</seq></doc>
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>a<grp><seq>1</seq></doc>
<doc><grp>a<grp><seq>3</seq></doc>
```

The following messages are propagated to the Out terminal:

```
<doc><grp>a<grp><seq>1</seq></doc>
<doc><grp>a<grp><seq>2</seq></doc>
<doc><grp>a<grp><seq>3</seq></doc>
<doc><grp>a<grp><seq>1</seq></doc>
<doc><grp>a<grp><seq>2</seq>/doc>
<doc><grp>a<grp><seq>3</seq></doc>
```

The second occurrence of the input message with sequence number 2 causes an exception to be thrown and is propagated to the Failure terminal:

```
<doc><grp>a<grp><seq>2</seq>/doc>
```

Adding sequence numbers to messages

You can add sequence numbers to messages entering a message flow by using the Sequence node.

Before you begin

Read the concept topic about "Message sequencing" on page 1860.

About this task

The Sequence node allocates a monotonically increasing sequence number for each input message that arrives at the node. As each message arrives at the Sequence node, the sequence number is incremented and stored with the message in the location specified by the `Path to store sequence number` property. The allocation of sequence numbers continues until the sequence ends, as specified by the `End of sequence definition` property.

You can divide input messages into independent sequence groups, based on an identifier defined in the message. Each group has a separate group identifier, and the sequence of messages within each group is managed independently.

The Sequence node allocates a sequence number to each message in the sequence group, and the next sequence number in the group is not allocated until the current message in the group has finished processing (either by being committed or rolled back). This ensures that sequencing is maintained for the group when there are multiple threads in the message flow.

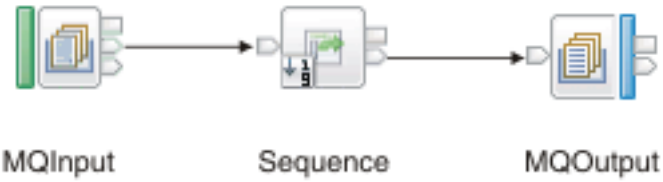
If you need to save the message with the newly assigned sequence number (for example, if you need to save the message to IBM MQ for processing by another flow), and if there is no convenient place in the message to save the sequence number, you can add an MQRFH2 header to the message before the Sequence node, and set the sequence number in a field in the `usr` folder.

Multiple sequence groups can be managed independently, in parallel, and sequence group state is preserved when the integration node is restarted.

The following steps show how to create a message flow that adds a sequence number to each message in a sequence group.

Procedure

1. Create a message flow containing an MQInput node, a Sequence node, and an MQOutput node.
2. Connect the Out terminal of the MQInput node to the In terminal of the Sequence node.
3. Connect the Out terminal of the Sequence node to the In terminal of the MQOutput node.



4. On the MQInput node, specify the source of input messages for the node by setting the `Queue name` property (on the **Basic** tab) to the name of an IBM MQ queue, from which the MQInput node retrieves messages. For example: `SEQ.TASK1.IN1`.
5. Set the following properties of the Sequence node:
   a) On the **Basic** tab, set the following properties:
   - Set the `Path to store sequence number` property to the location in the message where the sequence number is to be set. For example, `$OutputBody/doc/seq`. The sequence number is also set in the local environment, with the *LocalEnvironment.Sequence.Number* variable.
   - Set the `Path to sequence group identifier` property to the location of the sequence group identifier in the message. For example, `$InputBody/doc/grp`. The sequence group identifier is also copied to the local environment, with the *LocalEnvironment.Sequence.Group* variable.
   - Set the `Start of sequence definition` property to `Literal` with the required starting value; for example, `0`.

     Although the starting sequence number must be specified by a literal number, the value can be overridden in the local environment by the *LocalEnvironment.Sequence.StartOfSequenceNumber* variable.

     The start of sequence message is indicated in the local environment by the *LocalEnvironment.Sequence.Start* variable, which takes a Boolean value.
   - Set the `End of sequence definition` property to one of the following values:
     - `Automatic` with the required timeout value; for example, `60`. This value specifies that the sequence group is closed automatically when the message queue in the node has been empty for 60 seconds.
     - `Literal` with the required end value; for example, `100`. This value specifies that the sequence group is closed when the message with the sequence number `100` is processed.
     - `Predicate` with the required XPATH expression; for example, `$InputBody/doc/endFlag`. This value specifies that the sequence group is closed when the `$InputBody/doc/endFlag` predicate evaluates to True (`$InputBody/doc/endFlag=True`).

     The end of sequence message is indicated in the local environment by the *LocalEnvironment.Sequence.End* variable, which takes a Boolean value.

   b) On the **Advanced** tab, set the `Persistence mode` property to `Non-persistent`.

   Select `Persistent` if you want the sequence to be preserved if the queue manager is restarted.
6. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to the name of a WebSphere MQ queue to which the MQOutput node sends messages. For example: `SEQ.TASK1.OUT1`.
7. Save your message flow.

Reordering messages in a message flow

When messages entering a message flow contain sequence numbers and a group ID, you can use the Resequence node to re-establish the sequential order of the messages before propagating them through the message flow.

Before you begin

Read the concept topic about "Message sequencing" on page 1860.

Ensure that each message contains a monotonically increasing sequence number.

About this task

The sequence number might have been added to the message by the Sequence node or it might be another integer field in the message.

When the Resequence node receives an input message, it propagates the message only if it is the next one in the sequence. If the message is not next in the sequence, the Resequence node stores it until further messages arrive that allow the node to correct the sequence, at which point the node propagates the stored message. If a message fails to arrive, preventing the Resequence node from completing the sequence, the remaining messages are processed according to the way in which the Resequence node has been configured. For more information about this configuration, see "Handling missing messages" on page 1873.

A transaction break occurs at the Resequence node. When a message is delivered to the Resequence node, control is returned to the previous node in the message flow. All messages that are propagated from the Resequence node are propagated in a new transaction, even if the sequence is complete. For more information, see node.

The message sequence is preserved when the integration node is restarted. If the `Persistent` option is selected on the **Advanced** tab of the Resequence node, the sequence is also preserved when the queue manager is restarted.

The following steps show how to create a message flow that enables you to re-establish the sequential order of the messages in a sequence group:

Procedure

1. Switch to the Integration Development perspective.
2. Create a message flow containing an MQInput node, a Resequence node, and an MQOutput node.
3. Connect the Out terminal of the MQInput node to the In terminal of the Resequence node.
4. Connect the Out terminal of the Resequence node to the In terminal of the MQOutput node.

5. On the MQInput node, specify the source of input messages for the node by setting the `Queue name` property (on the **Basic** tab) to the name of an IBM MQ queue, from which the MQInput node retrieves messages. For example: `RESEQ.TASK1.IN1`.

6. Set the following properties of the Resequence node:
   a) On the **Basic** tab, set the following properties:
      - Set the `Path to sequence number` property to the location of the sequence number in the message. For example, `$InputBody/doc/seq`. The sequence number is also set in the local environment, with the *LocalEnvironment.Sequence.Number* variable.
      - Set the `Path to sequence group identifier` property to the location of the sequence group identifier in the message. For example, `$InputBody/doc/grp`. The sequence group identifier is also copied to the local environment, with the *LocalEnvironment.Sequence.Group* variable.
      - Set the `Start of sequence definition` property to the first sequence number in the group. For example, select `Literal` with a value of `0`.
      - Set the `End of sequence definition` property to `Automatic` with the required timeout value; for example, `60`. This value specifies that the sequence group is closed automatically when the message queue in the node has been empty for 60 seconds. The end of sequence message is indicated in the local environment by the *LocalEnvironment.Sequence.End* variable, which takes a Boolean value.
      - Set the `Missing message timeout` property to `10`. This value specifies that the Resequence node will wait for a missing message for 10 seconds before propagating subsequent messages in the sequence group to the Expire terminal. When the subsequent message is propagated, the sequence numbers of any missing (timed-out) messages are copied to the local environment, as *LocalEnvironment.Sequence.Missing* variables.
7. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to the name of a WebSphere MQ queue to which the MQOutput node sends messages. For example: `SEQ.TASK1.OUT1`.
8. Save your message flow.

Maintaining the sequential order of messages

You can maintain the order in which messages enter a message flow by using the Sequence and Resequence nodes.

Before you begin

Read the concept topic about "Message sequencing" on page 1860.

About this task

When messages have been processed in a message flow, they might be propagated in a different order to the order in which they arrived at the input node, so the original message sequence can be altered. You can use the Sequence and Resequence nodes to rearrange the messages into sequential order based on a sequence number in the message, restoring the original sequence in which they entered the input node.

If the messages contain sequence numbers, you can use the Resequence node to re-establish the order in which they arrived at the input node. If the messages do not contain sequence numbers, you can use a Sequence node to apply sequence numbers to the messages, before reordering them into sequential order using the Resequence node.

Procedure

- If the messages contain sequence numbers, rearrange the messages into sequential order by creating a message flow containing a Resequence node. See "Reordering messages in a message flow" on page 1868.

- If the messages do not contain sequence numbers, establish the sequential order of the messages by completing the following steps:
  a) Create a message flow containing a Sequence node, which you can use to apply sequence numbers to the messages. See “Adding sequence numbers to messages” on page 1866.
  b) Create a message flow containing a Resequence node, which you can use to re-establish the sequential order of the messages. See “Reordering messages in a message flow” on page 1868.

Message sequencing scenario 1

Change the sequence of messages received from WebSphere MQ, so that they are propagated in the correct order using a sequence number defined in an XML message.

Before you begin

Read the concept topic about “Message sequencing” on page 1860.

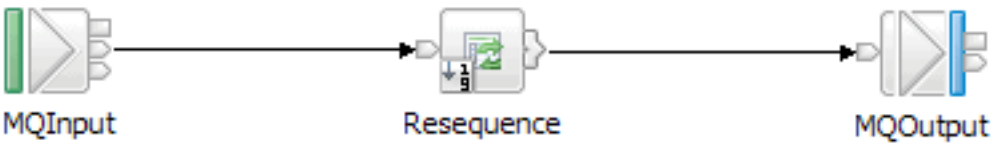
About this task

In this example task, the sequence is defined as starting at sequence number 0 (which is the default) and finishing at sequence number 8. The message flow is configured so that messages can arrive out of order but cannot be propagated out of order, even if one of the sequence numbers never arrives.

The following steps show how to write a message flow that can receive the XML document from WebSphere MQ, reorder the messages based on a sequence number in an XML message (in this example the path `$Root/XMLNSC/Doc/SeqNo` is used) and write it to a IBM MQ queue:

Procedure

1. Create a message flow called Resequence_Task1, containing an MQInput node, a Resequence node, and an MQOutput node.
   For more information about how to do this, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the Resequence node.
3. Connect the Out terminal of the Resequence node to the In terminal of the MQOutput node.



4. Set the following properties of the MQInput node:
   a) On the **Basic** tab, set the `Queue name` property to `RESEQUENCE_TASK1_IN1`
   b) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
5. On the Resequence node, set the following properties on the **Basic** tab:
   a) Set the `Path to sequence number` property to `$Root/XMLNSC/Doc/SeqNo`
   b) Set the `End of sequence definition` property to `Literal` with a value of 8.
6. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `RESEQUENCE_TASK1_OUT1`.
7. Save the message flow.

Results

Message processing in the message flow:

This section describes the way in which the Resequence node processes the messages that enter the message flow.

1. The following messages arrive on the WebSphere MQ queue RESEQUENCE_TASK1_IN1:

```
<Doc><SeqNo>0</SeqNo></Doc>,<Doc><SeqNo>1</SeqNo></Doc>,<Doc><SeqNo>2</SeqNo></Doc>,
<Doc><SeqNo>3</SeqNo></Doc>,<Doc><SeqNo>4</SeqNo></Doc>,<Doc><SeqNo>5</SeqNo></Doc>,
<Doc><SeqNo>6</SeqNo></Doc>,<Doc><SeqNo>7</SeqNo></Doc>,<Doc><SeqNo>8</SeqNo></Doc>,
```

2. The Resequence node first receives the message with sequence number 0. The Resequence node creates a new sequence group to manage the reordering process; the new sequence group is a default group because no sequence group has been defined in the message. The message (with sequence number 0) is the first one in the sequence, so it is propagated to the Out terminal.
3. The Resequence node then receives the rest of the messages up to and including sequence number 8, and propagates them in the order in which they arrived. Each message is stored before it is propagated, and a different transaction is used for propagating the messages downstream from the Resequence node.
4. When the message containing sequence number 8 is processed, the sequence group is closed. Any new message in the same group that arrives later causes a new group to be created.
5. The next messages arrive on the RESEQUENCE_TASK1_IN1 queue:

```
<Doc><SeqNo>8</SeqNo></Doc>,<Doc><SeqNo>7</SeqNo></Doc>,<Doc><SeqNo>6</SeqNo></Doc>,
<Doc><SeqNo>5</SeqNo></Doc>,<Doc><SeqNo>4</SeqNo></Doc>,<Doc><SeqNo>3</SeqNo></Doc>,
<Doc><SeqNo>2</SeqNo></Doc>,<Doc><SeqNo>1</SeqNo></Doc>,<Doc><SeqNo>0</SeqNo></Doc>,
```

6. The Resequence node first receives the message containing sequence number 8. At this point, the Resequence node creates a new (default) sequence group. The message is the last one in the sequence so it is not propagated but is stored internally.
7. The Resequence node then receives the rest of the messages up to and including sequence number 0. All the messages are stored and none are propagated until the first number in the sequence is received (in this case, sequence number 0).
8. When the message with sequence number 0 is received, it is propagated down the message flow, followed by each of the other messages, in order, until the final message (sequence number 8) is propagated. At this point, the sequence group is closed again.

Message sequencing scenario 2

Change the sequence of messages received from WebSphere MQ, so that they are propagated in the correct order using a sequence number defined in an XML message.

Before you begin

Read the concept topic about “Message sequencing” on page 1860.

About this task

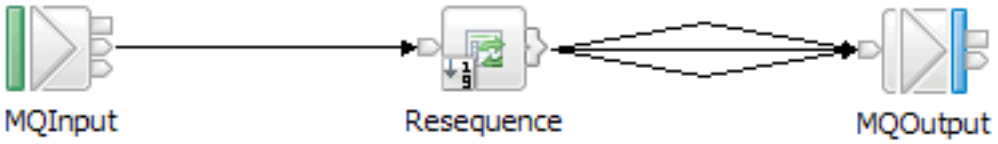
In this example task, the sequence is defined as starting at sequence number 0 (which is the default) and finishing when it has received no new messages in the group for 60 seconds. The message flow is configured so that messages can arrive out of order but the Resequence node attempts to propagate them in the correct order. If a required message in the sequence fails to arrive for 10 seconds, the Resequence node skips the missing message and propagates the next message in the sequence, even though it is now out of order.

The following steps show how to write a message flow that can receive the XML document from WebSphere MQ, reorder the messages based on a sequence number in an XML message (in this example the path `$Root/XMLNSC/Doc/SeqNo` is used) and write it to a IBM MQ queue:

Procedure

1. Create a message flow called Resequence_Task2, containing an MQInput node, a Resequence node, and an MQOutput node.

   For more information about how to do this, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the Resequence node.
3. Connect the Out, Missing, and Expire terminals of the Resequence node to the In terminal of the MQOutput node.



4. Set the following properties of the MQInput node:
   a) On the **Basic** tab, set the `Queue name` property to `RESEQUENCE_TASK2_IN1`
   b) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
5. On the Resequence node, set the following properties on the **Basic** tab:
   a) Set the `Path to sequence number` property to `$Root/XMLNSC/Doc/SeqNo`
   b) Set the `Missing message timeout` property to `10`
   c) Set the `End of sequence definition` property to `Automatic` with a value of `60`.
6. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `RESEQUENCE_TASK2_OUT1`.
7. Save the message flow.

Results

Message processing in the message flow:

This section describes the way in which the Resequence node processes the messages that enter the message flow:

1. The following messages arrive on the WebSphere MQ queue RESEQUENCE_TASK2_IN1:

```
<Doc><SeqNo>0</SeqNo></Doc>,<Doc><SeqNo>1</SeqNo></Doc>,<Doc><SeqNo>2</SeqNo></Doc>,
<Doc><SeqNo>3</SeqNo></Doc>,<Doc><SeqNo>4</SeqNo></Doc>,<Doc><SeqNo>5</SeqNo></Doc>,
<Doc><SeqNo>6</SeqNo></Doc>,<Doc><SeqNo>7</SeqNo></Doc>,<Doc><SeqNo>8</SeqNo></Doc>,
```

2. The Resequence node first receives the message with sequence number 0. The Resequence node creates a new sequence group to manage the reordering process; the new sequence group is a default group because no sequence group has been defined in the message. The message (with sequence number 0) is the first one in the sequence, so it is propagated to the Out terminal.
3. The Resequence node then receives the rest of the messages up to and including sequence number 8, and propagates them in the order in which they arrived. Each message is stored before it is propagated, and a different transaction is used for propagating the messages downstream from the Resequence node.
4. Sixty seconds elapse and the sequence group is closed.
5. The next messages arrive on the WebSphere MQ queue RESEQUENCE_TASK2_IN1:

```
<Doc><SeqNo>0</SeqNo></Doc>,<Doc><SeqNo>3</SeqNo></Doc>,<Doc><SeqNo>2</SeqNo></Doc>,
<Doc><SeqNo>4</SeqNo></Doc>,<Doc><SeqNo>6</SeqNo></Doc>,<Doc><SeqNo>7</SeqNo></Doc>,
```

6. The Resequence node first receives the message containing sequence number 0. At this point, the Resequence node creates a new (default) sequence group and propagates the message with sequence number 0 to the Out terminal.
7. The next message contains sequence number 3, which is out of sequence. The `Missing message timeout` property is set on the Resequence node with a value of 10 seconds, and the timer starts.
8. Sequence number 2 arrives, which is still not the next required message but it is lower than the lowest message currently stored, so the missing message timer is reset.
9. The Resequence node then receives the rest of the messages, all of which have a higher sequence number than 2, so they are stored but not propagated. The missing message timer is not reset this time because each number is later in the sequence than number 2.
10. Sequence number 1 fails to arrive during the specified period, and after 10 seconds the timeout period expires.
11. The Resequence node propagates all the messages that are stored, starting with the lowest sequence number (in this case, 2) followed by all other messages up to the next missing number in the sequence (in this case, messages with sequence numbers 3 and 4). Messages 2, 3, and 4 are propagated to the Expire terminal.
12. The Resequence node is moved to an unordered state for this sequence group, and will not propagate any messages in this group to the Out terminal. The Resequence node remains in the unordered state for this sequence group until the group expires and is closed.
13. When another 10 seconds has passed, the missing message timer expires again and messages 6 and 7 are propagated to the Expire terminal. At this point there are no more missing messages so the missing message timer is not restarted.
14. The group expiry timer is started and the group is closed after 60 seconds have passed. The group expiry timer is never started when a missing message timer is running.

Handling missing messages

You can configure the Resequence node to control how missing messages in a sequence are processed.

About this task

You can configure the Resequence node to time out if a message in the sequence fails to arrive in a specified period of time, and you can specify how subsequent messages are processed if a message is missing.

You can use the `Missing message timeout` property of the Resequence node to specify how long (in seconds) the node waits for the next message in the sequence before it moves on to the next message. Messages that arrive within the specified time limit are propagated in sequential order to the Out terminal. When the specified time limit has been exceeded, the messages are propagated in sequential order to the Expire terminal. Subsequent messages in the sequence group are also routed to the Expire terminal. If the missing message eventually arrives, it is propagated to the Missing terminal.

You can configure the Resequence node for any of the following scenarios:

- **The message sequence must always be maintained**

  If a message goes missing, you can route all subsequent messages to a holding queue after a specified timeout period. To configure the Resequence node in this way, wire the Out terminal to the main-line flow and wire the Expire and Missing terminals to separate branches for re-queueing.

- **Missing messages are allowed in the message sequence but all other messages must remain in sequence**

  If a message goes missing, you can pass over it and continue processing the rest of the sequence. If the missing message eventually arrives, you can either discard it or process it separately from the main-line processing. To configure the Resequence node in this way, wire the Out and Expire terminals to the main-line flow and leave the Missing terminal unwired (to discard the message) or wire it to a separate branch of the message flow.

- **Occasional out-of-sequence messages are allowed**

  You want the message flow to process the messages in sequential order, but you are prepared to tolerate occasional messages out of order. To configure the Resequence node in this way, wire the Out, Expire, and Missing terminals to the main-line message flow.

Configuring the storage of events for Resequence nodes

You can use a Resequence policy to control the storage of events for Resequence nodes.

About this task

Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ. The storage queues that hold the state information are owned by the queue manager that is associated with the integration server.

If you are using Resequence nodes on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node in order to use the capabilities that are provided by the Resequence node. If you are using Resequence nodes on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For more information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

If the integration server has the necessary permissions to create the default system queues, they are created automatically when a flow containing Resequence nodes is deployed. If the default queues are not created automatically, you can create them manually by running the **iib_createqueues** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

By default, the storage queues used by all Resequence nodes are:

- SYSTEM.BROKER.EDA.EVENTS
- SYSTEM.BROKER.EDA.COLLECTIONS

These queues are also used by the Collector node.

However, you can control the queues that are used by different Resequence nodes by creating alternative queues that contain a *QueuePrefix* variable, and by using a Resequence policy to specify the names of those queues for storing events.

Follow these steps to specify the queues that are used to store event states, and to set the timeout and the start and end of the sequence:

Procedure

1. Create the storage queues to be used by the Resequence node.

   The following queues are required:

   - SYSTEM.BROKER.EDA.*QueuePrefix*.EVENTS
   - SYSTEM.BROKER.EDA.*QueuePrefix*.COLLECTIONS

   The *QueuePrefix* variable can contain any characters that are valid in a IBM MQ queue name, but must be no longer than eight characters and must not begin or end with a period (.). For example, SET1 and SET.1 are valid queue prefixes, but .SET1 and SET1. are invalid.

   If you do not create the storage queues, IBM App Connect Enterprise creates the set of queues when the node is deployed; these queues are based on the default queues. If the queues cannot be created, the message flow is not deployed.

2. Create a Resequence policy (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
   a) You can create a policy to be used with either a specific sequence or with all sequences in an integration server. If you are creating a policy to be used with a specific sequence, ensure that the name of the policy is the same as the name that you specify in the `Policy` property on the Resequence node.

      To specify a default Resequence policy for all message flows that are deployed to an integration server, set the **Resequence** property in the `server.conf.yaml` file to the name of a Resequence policy. For information about setting properties in the `server.conf.yaml` file, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172. If the default policy is in the default policy project, you do not need to specify the name of the policy project. If the default policy is in a non-default policy project, qualify the name of the policy with the name of the policy project in the format *{policyProjectName}:PolicyName*
   b) Set the **Queue prefix** property of the Resequence policy to the required value (see Resequence policy).
   c) Optional: Set the **Missing message timeout**, **Start of sequence**, and **End of sequence** properties of the Resequence policy.

   If you delete the Resequence policy, the storage queues are not deleted automatically when the policy is deleted, so you must delete them separately.
3. In the Resequence node, if the policy is to be used for a specific sequence, specify the name of the policy on the **Advanced** tab; for example, `myResequenceService`.

   If you do not set the `Policy` property, and if there is a default Resequence policy specified in the `server.conf.yaml` file, that policy is used instead.

What to do next

The properties for the policy are not used by the integration server until you restart or redeploy the message flow, or restart the integration server.

Configuring timeout flows

Use the TimeoutControl and TimeoutNotification nodes in message flows to process timeout requests or to generate timeout notifications at specified intervals.

Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ. If you are using timeout flows on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node in order to use the capabilities that are provided by the TimeoutControl and TimeoutNotification nodes. If you are using these nodes on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For more information about using a remote default queue manager, see "Using a remote default queue manager" on page 750 and "Configuring an integration server to use a remote default queue manager" on page 751.

The system queues that hold the state information are owned by the queue manager that is specified on the integration server. You associate a queue manager with the integration server by specifying the queue manager name on the **defaultQueueManager** property in the `server.conf.yaml` configuration file; for more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

You must create the system queues by running a script command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99.

For more information about using IBM MQ with IBM App Connect Enterprise, see "Enhanced flexibility in interactions with IBM MQ " on page 26 and "Installing IBM MQ" on page 96.

The following topics show how the timeout nodes can be used in a message flow:

- “Sending timeout request messages” on page 1876
- “Sending a message after a timed interval” on page 1878
- “Sending a message multiple times after a specified start time” on page 1879
- “Automatically generating messages to drive a flow” on page 1880
- “Configuring the storage of events for timeout nodes” on page 234

Sending timeout request messages

To set a controlled timeout, send a message with a set of elements with well known names to a TimeoutControl node. These elements control the properties of the timeout to be created or deleted.

Elements and format

The following example shows the elements and format of a timeout request message, showing the well known names and permissible values.

```
<TimeoutRequest>
  <Action>SET | CANCEL</Action>
  <Identifier>String (any alphanumeric string)</Identifier>
  <StartDate>String (TODAY | yyyy-mm-dd)</StartDate>
  <StartTime>String (NOW | hh:mm:ss)</StartTime>
  <Interval>Integer (seconds)</Interval>
  <Count>Integer (greater than 0 or -1)</Count>
  <IgnoreMissed>TRUE | FALSE</IgnoreMissed>
  <AllowOverwrite>TRUE | FALSE</AllowOverwrite>
</TimeoutRequest>
```

Message fields

The following table describes the fields in the message. The column headed M indicates whether the property is mandatory, and the column headed C indicates whether the property is configurable.

Property	M	C	Default	Description
Action	Yes	No	None	Set this element to either SET or CANCEL. An error is generated if you omit this element or set it to a different value. If you set it to CANCEL, the only other element that is required is the Identifier, which must match the Identifier of the TimeoutRequest that is to be canceled.
Identifier	Yes	No	None	Enter an alphanumeric string. An error is generated if you omit this element.
StartDate	No	No	TODAY	Set this element to TODAY or to a date specified in yyyy-mm-dd format. The default value is TODAY.
StartTime	No	No	NOW	Set this element to NOW or to a time in the future specified in hh:mm:ss format. The default value is NOW. StartTime is assumed to be the integration node's local time. The start time can be calculated by adding an interval to the current time. If a delay occurs between the node that calculates the start time and the TimeoutControl node, the start time in the message will have passed by the time it reaches the TimeoutControl node. If the start time is more than approximately five minutes in the past, a warning is issued and the TimeoutControl node rejects the timeout request. If the start time is less than five minutes in the past, the node processes the request as if it were immediate. Therefore, ensure that the start time in the timeout request message is now or a time in the future.
Interval	No	Yes	0	Set this element to an integer that specifies the number of seconds between propagations of the message. The default value is 0.

Property	M	C	Default	Description
Count	No	Yes	1	Set this element to an integer value that is either greater than 0 or is -1 (which specifies a timeout request that never expires). The default value is 1.
IgnoreMissed	Yes	No	TRUE	Set this element to TRUE or FALSE to control whether timeouts that occur while either the integration node or the timeout notification flow is stopped, are processed the next time that the integration node or timeout notification flow is started. The default value is TRUE, which means that missed timeouts are ignored by the TimeoutNotification node when the integration node or message flow is started. If this value is set to FALSE, the missed timeouts are all processed immediately by the TimeoutNotification node when the flow is started. You must set the `Request Persistence` property of the TimeoutControl node to Yes or Automatic (with the originating request message being persistent) for the stored timeouts to persist beyond the restart of the integration node or the timeout notification flow.
AllowOverwrite	N	N	TRUE	Set this element to TRUE or FALSE, to specify whether subsequent timeout requests with a matching `Identifier` can overwrite this timeout request. The default value is TRUE.

How the TimeoutControl node uses these values

Set the `Request Location` on the TimeoutControl node to `InputRoot.XML.TimeoutRequest` to read these properties. If you want to obtain properties from a different part of your message, specify the appropriate correlation name for the parent element for the properties. The correlation name for the parent element can be in the local environment.

For details of how the TimeoutControl uses these values, see node

Working with the predefined schema definition of an XML timeout request message
A predefined schema definition of an XML timeout request message is provided in the IBM App Connect Enterprise Toolkit.

About this task

Take the following steps to review the definition or to define it in a message set.

1. Create or select a message set project that contains the message set.
2. Create a new message definition file (**File** > **New** > **Message Definition File From...**).
3. Select **IBM supplied message** and click **Next**.
4. Expand the tree for **Message Brokers IBM supplied Message Definitions**.
5. Select **Message Broker Timeout Request** and click **Finish**.

Example XML timeout request message
The format used here is XML, but you can use any format that is supported by an installed parser.

```
<TimeoutRequest>
  <Action>SET</Action>
  <Identifier>TenTimes</Identifier>
  <StartDate>TODAY</StartDate>
  <StartTime>NOW</StartTime>
  <Interval>10</Interval>
  <Count>10</Count>
  <IgnoreMissed>TRUE</IgnoreMissed>
  <AllowOverwrite>TRUE</AllowOverwrite>
</TimeoutRequest>
```

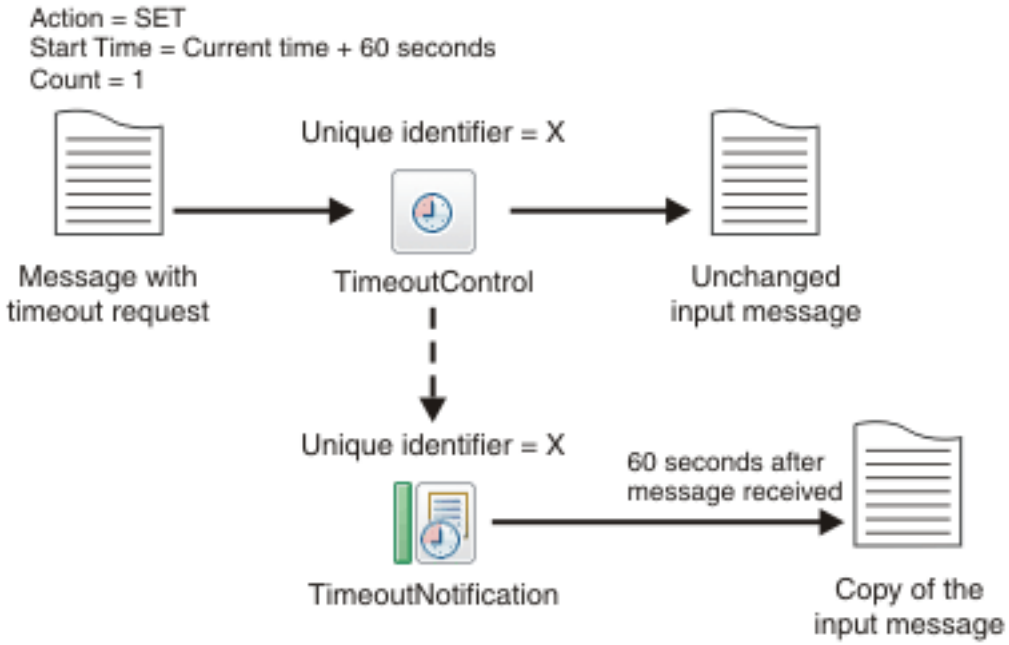
Sending a message after a timed interval

Use TimeoutControl and TimeoutNotification nodes to send a message into a message flow after a timed interval.

Aim

Use TimeoutControl and TimeoutNotification nodes to send a message into a message flow 60 seconds after the message is received.

Description of the flow



The diagram shows the path of a message that contains a timeout request through a TimeoutControl node. A TimeoutNotification node with an identifier matching the TimeoutControl node then processes the timeout request. The diagram also shows the message that the TimeoutNotification node produces after processing the timeout request.

The message comes into the TimeoutControl node with the following values set in the timeout request section of the message:

Action set to *SET*
Start Time set to *current time + 60*
Count set to *1*

The TimeoutControl node validates the timeout request; default values are assumed for properties that are not explicitly defined. The original message is then sent on to the next node in the message flow. If the request is valid, the TimeoutNotification node with the same `Unique identifier` as the TimeoutControl node propagates a copy of the message to the message flow 60 seconds after the message was received.

Timeout request messages are stored for processing on a queue used by the TimeoutNotification node. By default this queue is the `SYSTEM.BROKER.TIMEOUT.QUEUE`. However, you can use a Timer policy to specify an alternative timeout queue, which provides greater control over the storage of messages. For information about using an alternative timeout queue, see “Configuring the storage of events for timeout nodes” on page 234.

If a delay occurs between the node that calculates the start time and the TimeoutControl node, the start time in the message will have passed by the time it reaches the TimeoutControl node. If the start time is more than approximately five minutes in the past, a warning is issued and the TimeoutControl node

rejects the timeout request. If the start time is less than five minutes in the past, the node processes the request as if it were immediate. Therefore, ensure that the start time in the timeout request message is a time in the future.

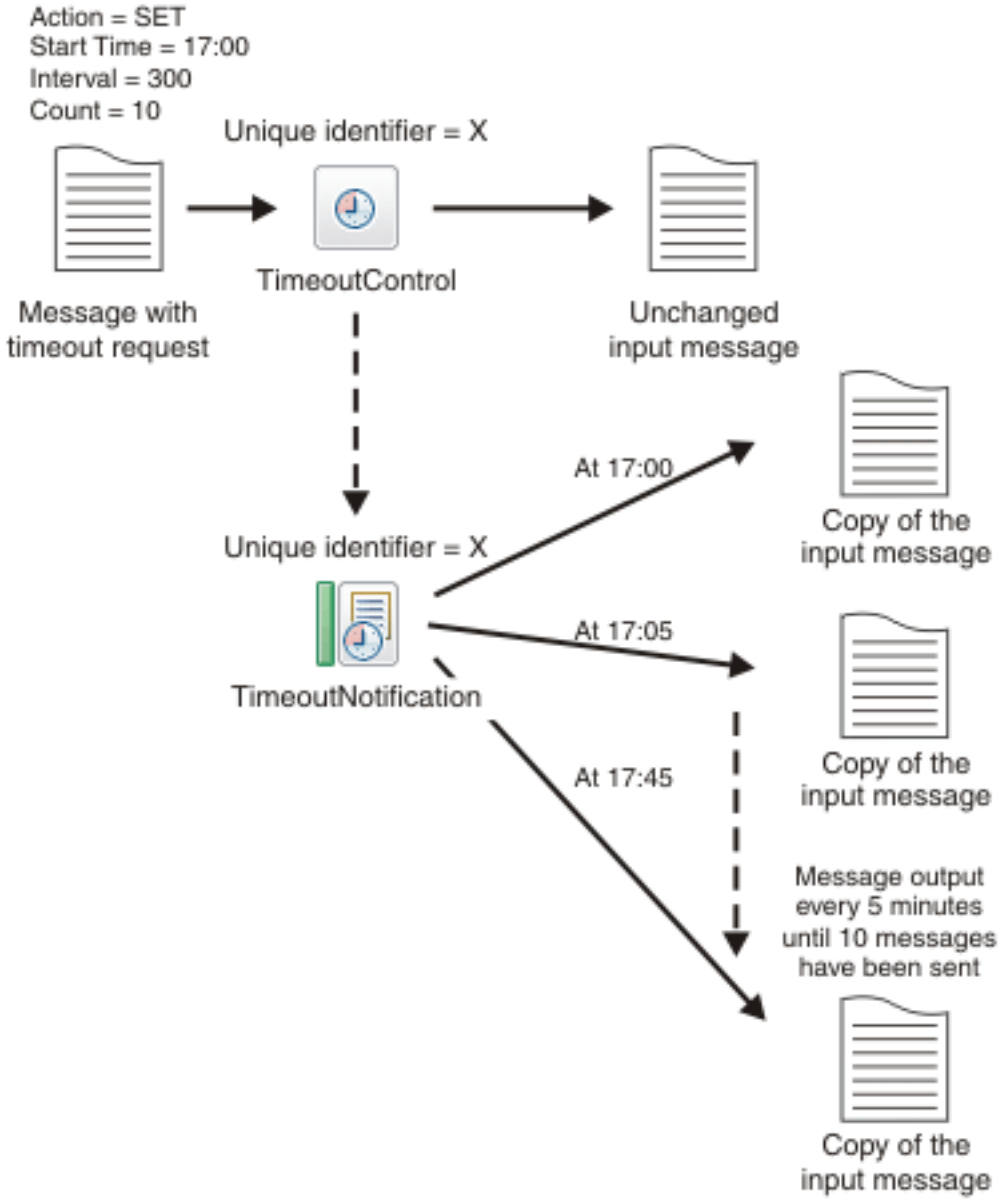
Sending a message multiple times after a specified start time

Use TimeoutControl and TimeoutNotification nodes to send a message into a message flow multiple times after a specified start time.

Aim

Use TimeoutControl and TimeoutNotification nodes to send a message into a message flow at 17:00 hours, then send the message again every 5 minutes until the message has been sent 10 times.

Description of the flow



The diagram shows the path of a message that contains a timeout request through a TimeoutControl node. A TimeoutNotification node with an identifier matching the TimeoutControl node then processes the timeout request. The diagram also shows the message that he TimeoutNotification node produces after processing the timeout request.

The message comes into the TimeoutControl node with the following values set in the timeout request section of the message:

Action set to *SET*
Start Time set to *17:00*
Interval set to *300*
Count set to *10*

The TimeoutControl node validates the timeout request; default values are assumed for properties that are not explicitly defined. The original message is then sent on to the next node in the message flow. If the request is valid, the TimeoutNotification node with the same `Unique identifier` as the TimeoutControl node propagates a copy of the message to the message flow at 17:00. The message is sent again after an interval of 300 seconds, at 17:05. and every 300 seconds until the message has been sent 10 times, as the *Count* value in the timeout request specifies.

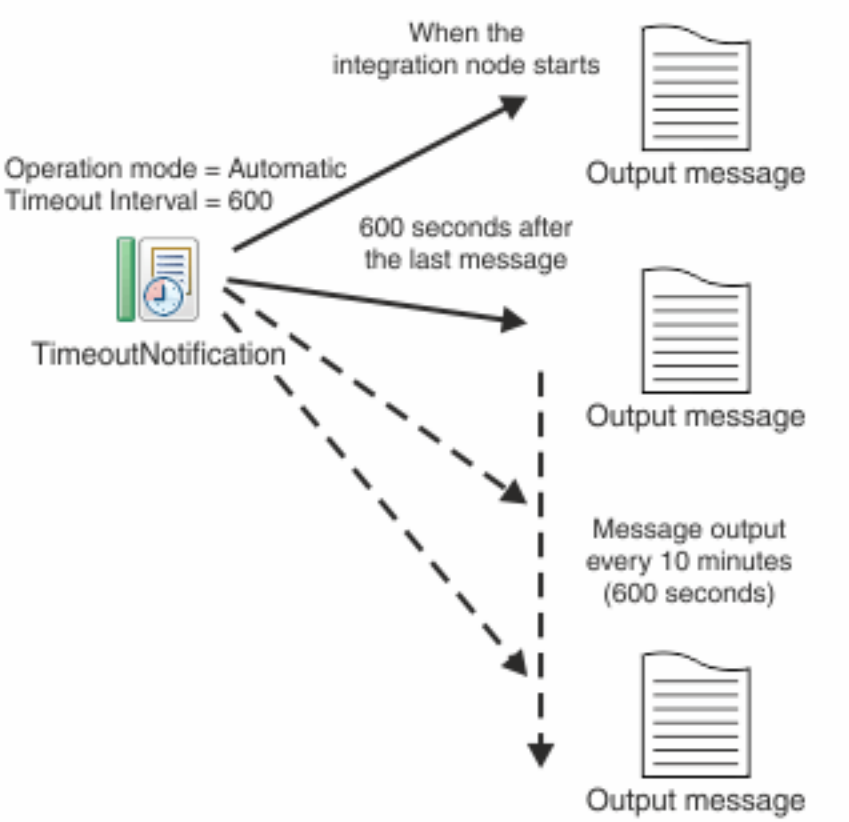
Automatically generating messages to drive a flow

Using the TimeoutNotification node to automatically send a message into a message flow.

Aim

Use the TimeoutNotification node to automatically send a message into a message flow every 10 minutes.

Description of the flow



The diagram shows a TimeoutNotification node automatically generating messages and propagating them every 10 minutes. To get the TimeoutNotification node to automatically generate messages, set the `Operation Mode` property of the node to automatic and specify a value for the `Timeout Interval` property. In this example the TimeoutNotification node has the following properties:

`Operation Mode` set to automatic
`Timeout Interval` set to 600

You can also use a Timer policy to control the timeout interval. A value that is set by the **Timeout interval** property of the Timer policy overrides the value that is specified on the TimeoutNotification node (see Timer policy).

When the integration node has started, the TimeoutNotification node sends a message every 10 minutes (600 seconds). This message contains only a properties folder and a LocalEnvironment folder. A Compute node can then process this message to create a more meaningful message.

If the downstream processing is intensive, and the flow is still busy when the next timeout occurs, the TimeoutNotification node does not send a message immediately. When the flow completes current processing, all timeouts that were missed while the flow was busy are processed individually.

Configuring the storage of events for timeout nodes

You can use a Timer policy to control the storage of events for TimeoutNotification and TimeoutControl nodes.

About this task

Information about the state of in-flight messages is held on storage queues that are controlled by IBM MQ. The storage queues that hold the state information are owned by the queue manager that is associated with the integration server.

If you are using TimeoutControl and TimeoutNotification nodes on an integration server that is managed by an integration node, you must install IBM MQ on the same computer as your integration node in order to use the capabilities that are provided by these nodes. If you are using TimeoutControl and TimeoutNotification nodes on an independent integration server, you can use a remote default queue manager to control the system queues, without the need to install IBM MQ on the same machine as the integration server. Interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting. For more information about using a remote default queue manager, see “Using a remote default queue manager” on page 750 and “Configuring an integration server to use a remote default queue manager” on page 751.

If the integration server has the necessary permissions to create the default system queues, they are created automatically when a flow containing TimeoutControl or TimeoutNotification nodes is deployed. If the default queues are not created automatically, you can create them manually by running the **iib_createqueues** command, as described in “Creating the default system queues on an IBM MQ queue manager” on page 99.

By default, the storage queue used by all timeout nodes is the SYSTEM.BROKER.TIMEOUT.QUEUE. However, you can control the queues that are used by different timeout nodes by creating alternative queues that contain a *QueuePrefix* variable, and by using a Timer policy to specify the names of those queues for storing events.

Follow these steps to specify the queue that is used to store event states:

Procedure

1. Create the storage queue to be used by the timeout nodes.

   The following queue is required:

   - SYSTEM.BROKER.TIMEOUT.*QueuePrefix*.QUEUE

   The *QueuePrefix* variable can contain any characters that are valid in an IBM MQ queue name, but must be no longer than eight characters and must not begin or end with a period (.). For example, SET1 and SET`.`1 are valid queue prefixes, but `.`SET1 and SET1`.` are invalid.

   If you do not create the storage queue, IBM App Connect Enterprise creates the queue when the node is deployed; this queue is based on the default queue. If the queue cannot be created, the message flow is not deployed.

2. Create a Timer policy (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
   a) You can create a policy to be used with either specific timeout requests or with all timeout requests in an integration server. If the policy is to be used with specific timeout requests, create the policy with the same name as the `Unique identifier` property on the TimeoutNotification and TimeoutControl nodes.

      To specify a default Timer policy for all message flows that are deployed to an integration server, set the **`Timer`** property in the `server.conf.yaml` file to the name of a Timer policy. For information about setting properties in the `server.conf.yaml` file, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172. If the default policy is in the default policy project, you do not need to specify the name of the policy project. If the default policy is in a non-default policy project, qualify the name of the policy with the name of the policy project in the format *{policyProjectName}:PolicyName*.
   b) Set the **`Queue prefix`** property of the Timer policy to the required value (see Timer policy).

   If you delete the Timer policy, the storage queue is not deleted automatically when the policy is deleted, so you must delete it separately.
3. In the TimeoutNotification and TimeoutControl nodes, ensure that the name of the Timer policy is the same as the name specified in the `Unique Identifier` property on the **Basic** tab; for example, `myTimer`. Specify the name of the policy project and the policy on the message flow node in the format *{policyProjectName}:PolicyName*. If there is no Timer policy with the same name as the `Unique Identifier`, and if there is a default Timer policy specified in the `server.conf.yaml` file, that Timer policy is used instead.

What to do next

The properties for the policy are not used by the integration server until you restart or redeploy the message flow, or restart the integration server.

Considering performance for timeout flows

When you design timeout flows, the decisions that you make can affect the performance of your integration nodes and applications.

You can use the timeout nodes TimeoutControl and TimeoutNotification in your message flows to control the way in which your message flows operate:

- Set the Operation Mode property of the TimeoutNotification node to Automatic. This setting causes a flow to be invoked at the interval that you specify in the Timeout Value property. If the downstream processing is intensive, and the flow is still busy when the next timeout occurs, the TimeoutNotification node does not send a message immediately. When the flow completes current processing, all timeouts that were missed while the flow was busy are processed individually.

  The value of the Additional Instances property of the message flow is ignored downstream of a TimeoutNotification node, and you cannot use this property to change the behavior of the flow.
- Use two associated flows to perform user-defined timeout processing. Set a timeout with a TimeoutControl node, and notify the flow using a TimeoutNotification node (which behaves like an input node to start a new message flow thread). If the downstream processing from the TimeoutNotification node is significant, requests that are set up in the TimeoutControl node can build up. These requests are subsequently processed individually by the TimeoutNotification node in a single thread.

  You cannot increase the Additional Instances property of the message flow if it starts with a TimeoutNotification node, therefore you cannot apply more threads to increase the capacity of the flow.

Although you can use a TimeoutNotification node to cause nodes in a message flow to poll for the next item of work, this approach forces a delay between each transaction, and typically does not provide an efficient solution. If you want to periodically check a resource for the next piece of work, and process it immediately, consider one or more of the following alternative solutions:

- Use a built-in input node.
- Write your own input node by using the user-defined node API (in Java or C).

- Consider purchasing an IBM or vendor-provided adapter which polls the subsystem you want, and triggers the flow.

A message flow that uses these options can process more work overall than it can if you implement a timeout solution, and incurs lower CPU cost, although your initial development costs might be slightly higher.

Handling errors in message flows

The integration node provides basic error handling for all your message flows. If basic processing is not sufficient, and you want to take specific action in response to certain error conditions and situations, you can enhance your message flows by using message flow node terminals to provide your own error handling.

About this task

For example, you might design a message flow that expects certain errors that you want to process in a particular way. Another example is that your message flow updates a database, and must roll back those updates if other message processing does not complete successfully.

The options that you can use to do this are quite complex in some cases. The options that are provided for MQInput and TimeoutNotification nodes are extensive because these nodes deal with persistent messages and transactions. The MQInput node is also affected by configuration options for IBM MQ.

Because you can decide to handle different errors in different ways, there are no fixed procedures to describe. This section provides information about the principles of error handling, and the options that are available, and you must decide what combination of choices that you require in each situation based on the details that are provided in this section.

There are two general approaches to handling errors in a message flow:

- Failure checking

  Wire the Failure terminal of a node to explicitly check for any errors that occur within that node. If errors occur, an exception list is propagated to the Failure terminal. The inflight message remains the same as it was before the node was invoked.

  You can introduce more specialized error checking in nodes that can be customized by using ESQL. For example, you can create exit handlers within these nodes. For more information about using ESQL to create exit handlers, see DECLARE HANDLER statement.

- Catching exceptions

  If you do not wire a Failure terminal, a failure in the node is converted into an exception which is thrown from the node. Any changes that were made to the inflight message before the exception was thrown are reversed. The exception might cause the current transaction to be rolled back, which means that any updates to transactional resources are reversed. Root and Local Environment trees are rolled back in parallel. The Environment tree is not rolled back unless the entire transaction for the flow rolls back.

  You can prevent the transaction from being rolled back, and control the extent to which message changes are reversed, by including a TryCatch node in your message flow. If an exception is thrown beyond the Try terminal of the TryCatch node, then an exception list is propagated to the node's Catch terminal. The inflight message reverts to the state it was in before it reached the TryCatch node.

  Most message flow nodes have a Catch terminal. These nodes are typically at the start of a transaction, where an uncaught exception would cause a rollback. In these nodes, the Catch terminal behaves as though a TryCatch node was wired directly to the Out terminal. Use the Catch terminal to handle any exceptions that are thrown beyond the message flow node. Wire the Failure terminal to handle errors within the node itself.

You can choose one or more of these options in your message flows:

- Connect the Failure terminal of the node to a sequence of nodes that processes the node's internal exception (the fail flow).

- Connect the Catch terminal of the node to a sequence of nodes that processes exceptions that are generated beyond it (the catch flow).
- Insert one or more TryCatch nodes at specific points in the message flow to catch and process exceptions that are generated by the flow connected to the Try terminal.
- Include a Throw node, or code an ESQL THROW statement, to generate an exception.
- Ensure that all the messages received by an MQInput node are processed in a transaction, or are not processed in a transaction.
- Ensure that all the messages received by an MQInput node are persistent, or are not persistent.

If you include user-defined nodes in your message flow, you must see the information provided with the node to understand how you might handle errors with these nodes. The descriptions in this section cover only the built-in nodes.

When you design your error handling approach, consider the following factors:

- Most of the built-in nodes have Failure terminals. The exceptions are the AggregateControl, AggregateRequest, Input, Label, Output, Passthrough, Publication, Trace, and TryCatch nodes.

  When an exception is detected in a node, the message and the exception information are propagated to the node's Failure terminal. If the node does not have a Failure terminal, or it is not connected, the integration node throws an exception and returns control to the closest upstream node that can process it. This node might be a TryCatch node, an AggregateReply node, or the input node.

  If an MQInput node detects an internal error, its behavior is slightly different. If the Failure terminal is not connected, the MQInput node attempts to put the message to the input queue's backout queue, or if that is not defined, to the dead letter queue of the queue manager that is associated with the integration node.

  For more information, see "Handling MQInput node errors" on page 1886.
- Many built-in nodes have Catch terminals. These nodes are typically at the start of a transaction. For example:
  - Input nodes: FileInput, HTTPInput, JMSInput, MQInput, PeopleSoftInput, SAPInput, SiebelInput, SOAPInput, TCPIPClientInput, TCPIPServerInput
  - Output and response nodes: SOAPAsyncResponse
  - Routing nodes: AggregateReply, Collector, Resequence
  - Construction nodes: TryCatch
  - Timer nodes: TimeoutNotification

  A message is propagated to a Catch terminal only if it has first been propagated beyond the node (for example, to the nodes connected to the Out terminal).
- When a message is propagated to the Failure or Catch terminal, the node creates and populates a new exception list tree with an exception that represents the error that has occurred. The exception list is propagated as part of the message tree. When a message is propagated to the Failure terminal because of a problem that occurred in the Out or Catch flows (for example, repeated parsing errors that caused the backout threshold to be met), the original parsing errors are not in the exception list; the exception list contains the exception that indicates that the backout threshold has been met.
- The MQInput and TimeoutNotification nodes have additional processing for transactional messages (other input nodes do not handle transactional messages).

  For more information, see "Handling MQInput node errors" on page 1886 and "Handling timeout notification errors" on page 1889.
- If you include a Trace node that specifies `$Root` or `$Body`, the complete message is parsed. This might generate parser errors that are not otherwise detected.

The general principles of error handling are:

- If you connect the Catch terminal of the input node, you are indicating that the flow handles all the exceptions that are generated anywhere in the out flow. The integration node does not rollback a

transaction unless there is an exception on the catch flow. If the catch flow completes successfully, the message is committed. If you want any rollback action after an exception has been raised and caught, you must provide this in the catch flow.

- If you do not connect the Catch terminal of the input node, you can connect the Failure terminal and provide a fail flow to handle exceptions generated by the node. The fail flow is started immediately when an exception occurs in the node.

  The HTTPInput node does not propagate the message to the Failure terminal if an exception is generated beyond the node and you have not connected the Catch terminal.
- If a node propagates a message to a catch flow, and another exception occurs that returns control to the same message flow node again, the node handles the message as though the Catch terminal is not connected.
- If you do not connect either the Failure or Catch terminals of the input node, the integration node provides default processing (which varies with the type of input node).
- If you need a more comprehensive error and recovery approach, include one or more TryCatch nodes to provide more localized areas of error handling.
- If you have a common procedure for handling particular errors, you might find it appropriate to create a subflow that includes the sequence of nodes required. Include this subflow wherever you need that action to be taken.
- If you have set security processing in an input node, and a security exception is thrown, then the message is not propagated on the message flow. The message is either backed out, or an error is returned. For more information, see “Security exception processing” on page 2582.
- Parsing exceptions are passed straight to the Failure terminal. If the Failure terminal is not connected, or an exception occurs in the fail flow, then the message is backed out. The backouts in the fail flow continue until the backout threshold has been exceeded once, and not twice as before.

For more information, see “Connecting Failure terminals” on page 1885, and “Catching exceptions in a TryCatch node” on page 1890.

If your message flows include database updates, the way in which you configure the nodes that interact with those databases can also affect the way that errors are handled:

- You can specify whether updates are committed or rolled back. You can set the node property `Transaction` to specify whether database updates are committed or rolled back with the message flow (option Automatic), or are committed or rolled back when the node itself terminates (option Commit). You must ensure that the combination of these property settings and the message flow error processing give the correct result.
- You can specify how database errors are handled. You can set the properties `Treat warnings as errors` and `Throw exception on database error` to change the default behavior of database error handling.

Message flows for aggregation involve additional factors that are not discussed in this topic. For information about message flows for aggregation, see “Handling exceptions in aggregation flows” on page 1837.

Connecting Failure terminals

When a message flow node that has a Failure terminal detects an internal error, it propagates the message to that terminal. If it does not have a Failure terminal, or the Failure terminal is not connected, the integration node generates an exception.

About this task

Message flow nodes can generate errors that you can predict. In these cases, you might want to consider connecting the Failure terminal to a sequence of nodes that can respond to the expected errors.

Some examples of expected errors:

- Temporary errors when the input node retrieves the message.

- Validation errors that are detected by an MQInput, Compute, or Mapping node.
- Messages with an internal or format error that cannot be recognized or processed by the input node.
- Acceptable errors when a node accesses a database, and you choose not to configure the node to handle those errors.
- ESQL errors during message flow development. Some ESQL errors cannot be detected by the editor, but are recognized only by the integration node; these errors cause an exception if the Failure terminal is not connected. You can then remove the fail flow when you finish testing the runtime ESQL code.

You can also connect the Failure terminal if you do not want IBM MQ to try a message again, or put it to a backout or dead letter queue. For more information, see "Handling MQInput node errors" on page 1886.

Handling MQInput node errors

The MQInput node has its own error handling for message flows. Consider how you want your solution to handle errors when your message flow contains an MQInput node.

Warning: When you set up your IBM MQ queue manager, configure a backout queue, or a dead letter queue (DLQ), or both, to ensure that failure errors are handled correctly. If you do not configure a backout queue or DLQ, you might risk message loss, as described in "Handling rollbacks and then attempting to process the message again" on page 1887. If your solution requires that you do not use either of these queues, consider how you will handle failure errors in your message flow design.

Internal MQInput node error conditions

The MQInput node handles errors as described in "Handling errors in message flows" on page 1883. In addition, the MQInput node detects an internal error in the following situations:

- The queue manager that is specified on the MQInput node cannot be reached. For example, it might be stopped, or not yet created. The message flow that contains the MQInput node deploys, but an error shows in the syslog that messages cannot be read from the specified queue. When the queue manager becomes available, the MQInput node automatically starts reading messages from the queue. This error also occurs if the queue manager is available, but the specified queue is unavailable.
- If a connection to a queue manager is lost, and that connection is enlisted in a transaction, automatic reconnection is delayed until the inflight transaction is complete. Other queue managers that are required, but are not part of the transaction, reconnect automatically without delay. A completed transaction can include the following cases:
  - The unavailable MQ resource was not required and was not used, because exception handling was defined in the message flow, so the inflight transaction was successful and committed.
  - The unavailable MQ resource was required, and the message flow cannot succeed without it, so the inflight transaction was rolled back.
- An exception occurs when the associated message parser is initialized. If the `Parse timing` property is set to `Immediate` or `Complete`, the parser parses the input message after initialization. This parsing can cause a parsing or validation error, which is treated as an internal error.
- A warning is received on an `MQGET` call. This condition is handled in the same way as a parsing error.
- If an error occurs in a transactional message flow, and a Failure terminal is not connected:
  1. The message is rolled back to the input queue.
  2. The MQInput node writes the error and MQPUT error to the local error log, and starts its retry logic, as described in "Handling rollbacks and then attempting to process the message again" on page 1887.
- When a message is rolled back to the input queue, and the IBM MQ backout threshold is reached. This case is described in "Handling rollbacks and then attempting to process the message again" on page 1887.

MQ connection errors

The MQInput node attempts to connect to the queue manager when the flow is deployed and started. The MQOutput, MQGet, and MQReply nodes attempt to connect when the first message is sent or received. If any connection problems occur, see the IBM MQ product documentation for information about any `mqrc` return code values that are reported in the IBM App Connect Enterprise BIP messages.

Handling rollbacks and then attempting to process the message again

When a message is rolled back to the input queue, the MQInput node attempts to process the message again. The MQInput node checks whether the backout threshold value has been reached. The `BackoutCount` for each message is maintained by IBM MQ in the MQMD.

When you create the queue, you can specify the value of the backout threshold attribute BOTHRESH, or use the default, 0. If you accept the default value of 0, the MQInput node increases this value to 1. The MQInput node also sets the value to 1 if it cannot detect the current value. If the backout threshold is set to 1, the message is processed once, and does not try again through the Out terminal of the MQInput node. For the message to try again at least once, set the backout threshold to 2.

The retry behavior for the MQInput node is as follows:

1. The MQInput node reads the message, and checks the `BackoutCount` against the backout threshold.
2. If the backout threshold is not reached, the MQInput node attempts to get the message from the queue again. If the attempt fails, it is handled as an internal error. If the message processing succeeds on the Out terminal, the MQInput node propagates the message to the output flow.

   Typically, the backed out message is read again by the same MQInput node. However, depending on your IBM MQ queue manager configuration, it is possible for an MQInput node in a different message flow, or another IBM MQ application, to read the same input queue and get the backed-out message.

   If you want to control or prevent roll back, you can use the Catch terminal, as described in "Handling errors in message flows" on page 1883.
3. If the backout threshold is reached:
   - If a Failure terminal is connected, the MQInput node propagates the message to the fail flow. You must handle the error on the fail flow that is connected to the Failure terminal.

     When a message is propagated through the Failure terminal, the exception list does not contain the exceptions that occurred in the flows that are connected to the Out or Catch terminals. The exception list contains new exceptions only, which describe the reason that the message went through the Failure terminal (for example, that the backout threshold was reached).

     The MQInput node re-reads the message from the input queue before it is propagated through the Failure terminal. Therefore, the exception list does not contain the exceptions that occurred in the flows that are connected to the Out or Catch terminals. The exception list contains new exceptions only, which describe the reason that the message went through the Failure terminal (for example, that the backout threshold was reached).
   - If a Failure terminal is not connected, the MQInput node attempts to put the message on an available queue, in order of preference:
     a. If a backout queue name is defined for the input queue (queue attribute BOQNAME), the message is put on the backout queue.
     b. If the backout queue is not defined, or it cannot be identified by the MQInput node, the message is put on the dead letter queue (DLQ), if a DLQ is defined. The MQDLH **`PutApplName`** property

is set to `WebSphereMQIntegrator` and appended with the broker major version number, for example: `WebSphereMQIntegrator9`

c. If the message cannot be put on either of these queues because there is an MQPUT error (because the queue does not exist, or the queues cannot be identified by the MQInput node), the message cannot be handled safely without risk of loss.

The message cannot be discarded, therefore the message flow continues to attempt to backout the message. It records the error situation by writing errors to the local error log. A second indication of this error is the continual increase of the `BackoutCount` value of the message in the input queue.

If this situation occurs because neither queue exists, you can define one of the queues to resolve the problem. If the condition that prevented the message from being processed is resolved, you can temporarily increase the value of the B0THRESH attribute, which forces the message through normal processing.

4. If the backout threshold value is reached twice in the Failure terminal, the MQInput node attempts to put the message on an available queue, in the order of preference that is defined in step 2.

When a backed out message is read, the MQInput node can put the message to the backout queue or the DLQ. The `BackoutCount` value is checked when the message is received from the input queue. If the backout threshold is exceeded, the message is backed out immediately with no further processing performed on the message. The backout operation occurs in a separate transaction from previous processing failures, and the message is not parsed or validated during the backout transaction. The backout transaction generates its own set of monitoring events. Therefore, information that is obtained through message parsing, such as the *exceptionList*, might not be available.

Handling message group errors

IBM MQ supports message groups. You can specify that a message belongs to a group and its processing is then completed with the other messages in the group (that is, either all messages are committed or all messages are rolled back). When you send grouped messages to an integration node, this condition is upheld if the message flow is configured correctly, and errors do not occur during group message processing.

To configure the message flow to handle grouped messages correctly, review "Receiving messages in an IBM MQ message group" on page 783. However, if an error occurs while one of the messages is being processed, the message group might not be processed correctly.

If the MQInput node is configured as described, all messages in the group are processed in a single unit of work, which is committed when the last message in the group is successfully processed. However, if an error occurs before the last message in the group is processed, the unit of work that includes the messages, up to and including the message that generates the error, is subject to the error handling defined by the rules that are documented here, which might result in the unit of work being backed out.

Any of the remaining messages in the group might be successfully read and processed by the message flow, and therefore are handled and committed in a new unit of work. The unit of work is committed when the last message is processed. Therefore, if an error occurs in a group, but not on the first or last message, it is possible that part of the group is backed out and another part is committed.

Depending on the type of message processing that you require, you might need to provide extra error handling for message groups. For example, you might record the failure of the message group in a database, and include a check on the database when you retrieve each message. This check would force a rollback if the current group already encountered an error. This error handling configuration would ensure that the whole group of messages is backed out and not processed unless all are successful.

Handling timeout notification errors

The TimeoutNotification node takes various actions when it handles errors with transactional messages, depending on whether the Failure and Catch terminals are connected.

- If the TimeoutNotification node detects an internal error, one of the following actions occur:
  - If you have not connected the Failure terminal:
    1. The TimeoutNotification node writes the error to the local error log.
    2. The TimeoutNotification node repeatedly tries to process the request until the problem has been resolved.
  - If you have connected the Failure terminal, you are responsible for handling the error in the flow connected to the Failure terminal. The integration node creates an exception list to represent the error, which is propagated to the Failure terminal as part of the message tree. The TimeoutNotification node and the integration node do not provide further failure processing. The message is written to the Failure terminal as part of the same transaction, and if the failure flow handles the error successfully the transaction is committed.
- If the TimeoutNotification node has successfully propagated the message to the Out terminal and an exception is thrown in the flow connected to the Out terminal, the message is returned to the TimeoutNotification node. The TimeoutNotification node writes the error to the local error log and takes one of the steps:
  - If you have not connected the Catch terminal, the TimeoutNotification node tries to process the message again until the problem is resolved.
  - If you have connected the Catch terminal, you are responsible for handling the error in the flow connected to the Catch terminal. The integration node creates an exception list to represent the error, which is propagated to the Catch terminal as part of the message tree. The TimeoutNotification node and the integration node do not provide further failure processing. The message is written to the Catch terminal as part of the same transaction, and if the flow connected to the Catch terminal handles the error successfully the transaction is committed.
- If the TimeoutNotification node has already propagated the message to the Catch terminal and an exception is thrown in the flow connected to the Catch terminal, the message is returned to the TimeoutNotification node. The TimeoutNotification node writes the error to the local error log and tries to process the message again.
- If the TimeoutNotification node has already propagated the message to the Failure terminal and an exception is thrown in the flow connected to the Failure terminal, the message is returned to the TimeoutNotification node. The TimeoutNotification node writes the error to the local error log, and tries to process the message again. The message is not propagated to the Catch terminal, even if that is connected.

This action is summarized in the following table.

Error event	Failure terminal connected	Failure terminal not connected	Catch terminal connected	Catch terminal not connected
The node detects an internal error.	The flow that is connected to the Failure terminal handles the error.	The error is logged and the node retries the operation.	Not applicable	Not applicable
The node propagates a message to the Out terminal and an exception occurs in the output flow.	Not applicable	Not applicable	The flow that is connected to the Catch terminal handles the error.	The error is logged and the node retries the operation.

Error event	Failure terminal connected	Failure terminal not connected	Catch terminal connected	Catch terminal not connected
The node propagates a message to the Catch terminal and an exception occurs in the flow that is connected to the Catch terminal.	The error is logged and the node retries the operation.	The error is logged and the node retries the operation.	Not applicable	Not applicable
The node propagates a message to the Failure terminal and an exception occurs in the flow that is connected to the Failure terminal.	Not applicable	Not applicable	The error is logged and the node retries the operation.	The error is logged and the node retries the operation.

Catching exceptions in a TryCatch node

You can design a message flow to catch exceptions before they are returned to the input node. You can include one or more TryCatch nodes in a flow to provide a single point of failure for a sequence of nodes. With this technique, you can provide specific error processing and recovery.

About this task

A TryCatch node does not process a message in any way, it represents only a decision point in a message flow. When the TryCatch node receives a message, it propagates it to the Try terminal. Control is passed to the sequence of nodes that are connected to that terminal (the try flow).

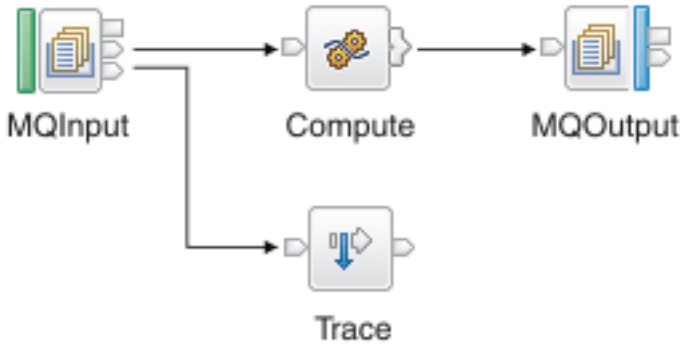
If an exception is thrown in the try flow,control is returned to the TryCatch node. The TryCatch node writes the current contents of the exception list tree to the local error log, then writes the information for the current exception to the exception list tree, overwriting the information that is stored there.

The TryCatch node propagates the message to the sequence of nodes that are connected to the Catch terminal (the catch flow). The content of the message tree that is propagated is identical to the content that was propagated to the Try terminal, which is the content of the tree when the TryCatch node first received it. The node enhances the message tree with the new exception information that it has written to the exception list tree. Any modifications or additions that the nodes in the try flow made to the message tree are not present in the message tree that is propagated to the catch flow.

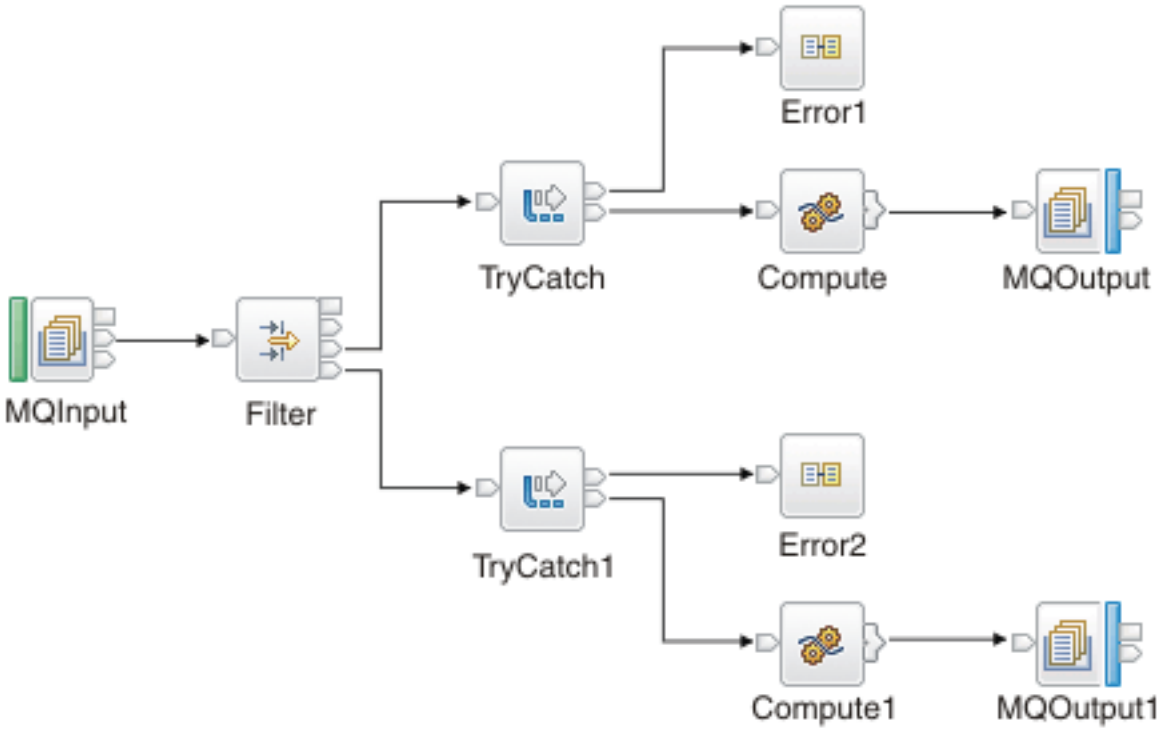
However, if the try flow completes processing that involves updates to external databases, these updates are not lost; they persist while the message is processed by the catch flow, and the decision about whether the updates are committed or rolled back is made on the configuration of your message flow and the individual message flow nodes that interact with the databases. If the updates are committed because of the configuration that you set, you must include logic in your catch flow that rolls back the changes that were made.

If an exception is thrown in the catch flow of the TryCatch node (for example, if you include a Throw node, or code an ESQL THROW statement), then control is returned to the next catch point in the message flow, such as another TryCatch node.

The following example shows how you can configure the flow to catch exceptions in the input node. The MQInput node's Catch terminal is connected to a Trace node to record the error.



In the following example, the message flow has two separate processing flows connected to the Filter node's True and False terminals. Here a TryCatch node is included on each of the two routes that the message can take. The Catch terminal of both TryCatch nodes is connected to a common error processing subflow.



If the input node in your message flow does not have a Catch terminal, and you want to process errors in the flow, you must include a TryCatch node.

Developing integration tests

You can create and run unit tests to validate the operation of your IBM App Connect Enterprise flows and message flow nodes.

Before you begin

Read the following topics:

- "Integration testing overview" on page 1893

About this task

You can create and run unit tests while you are developing your message flows and nodes, or you can create and run tests for flows that have already been deployed, by generating tests in bulk from messages that were recorded as they passed through a message flow.

The tests that you use to validate the message flows and nodes are written in Java and are stored in App Connect Enterprise test projects. You can write the tests by using a text editor, a source code editor, or a Java IDE such as the IBM App Connect Enterprise Toolkit. The simplest way to create a unit test for a message flow node is to use the **Create Test Case** wizard in the Toolkit, as described in "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894. For information about generating tests from recorded messages, see "Generating tests from recorded messages in a message flow" on page 1908.

To test a message flow node, an input message assembly is required to invoke the node, and the contents of the output message assembly are examined to determine whether the operation of the message flow node was successful. A message assembly is an object that is used to represent an instance of a message at a given point in time as it is being processed by a message flow. The message assembly contains the message headers and payload (which can be XML, JSON, DFDL or BLOB data), together with the environment tree, the local environment tree, and the exception list tree. The contents of the message assembly are accessed and modified by each message flow node as the message is processed.

A set of Java classes in the supplied `IntegrationTest.jar` file provides a mechanism for creating, building, testing and comparing message assemblies and their contents.

You can record messages as they pass through a message flow, and each recorded message is stored as an `.mxml` file, which is a serialized form of a message assembly. These `.mxml` files can then be used by unit tests, to validate the operation of the message flow nodes and flows. You can record the messages and create the serialized message assembly files either by setting the **`RecordAllMessages`** property in the integration server's `server.conf.yaml` file, or by opening the flow in the IBM App Connect Enterprise Toolkit and invoking the **Create Test Case** wizard on the message flow node in the Flow Exerciser.

You can control the level of granularity in your testing by creating integration tests for a single message flow node, a sequence of message flow nodes (such as a subflow or callable flow), or a whole message flow:

- **Testing a message flow node:**

  You can test the operation of an individual node in a message flow, in isolation from the rest of the nodes in the flow. An input message is passed into the message flow node, and the operation of the node is validated by comparing the output message against the expected output, together with any secondary actions such as updates to a database or any exceptions thrown. The tests pass messages directly to the message flow node that is being tested, rather than through the input node of the flow; this means that the owning message flow must be deployed to the integration server and initialized, but it does not need to be running.

- **Testing a partial message flow:**

  You can test a subflow or sequence of nodes in a message flow without testing the whole flow. An input message is passed into the first message flow node in the sequence and it is propagated through the flow until it reaches a defined stop point or the end of the flow. The tests pass messages directly to the first message flow node in the sequence, rather than through the input node of the flow; this means that the message flow being tested must be deployed to the integration server, but it does not need to be running.

  The success of the test can be established by validating the route of the message as it propagates through the flow, and the contents of the message at any point throughout the flow, as well as any secondary actions such as updates to a database or exceptions thrown.

  When testing a sequence of node nodes, you might need to alter the behavior of some nodes in the sequence to avoid accessing unavailable resources or to force the execution to follow a particular path.

- **Testing a whole message flow:**

  You can test a whole message flow by invoking the message flow using its published interfaces, such as HTTP, MQ, File, and so on. The input nodes are typically invoked using their native transport interfaces supported by the input node called from the code in the test project. The message flow is invoked through the input node, which means that the message flow must be deployed and running in order for the tests to run.

  Like partial message flow testing, the test can validate the route of the message as it propagates through the flow, in addition to the contents of the message at any point throughout the flow. The test can also alter the behavior of nodes in the flow by substituting responses or by modifying behavior.

For information that you need to know before you start developing integration tests, see "Integration testing overview" on page 1893.

Procedure

Read the following sections to learn more about developing and running integration tests:

- "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894
- "Generating tests from recorded messages in a message flow" on page 1908
- "Testing a sequence of message flow nodes in a single test case" on page 1912
- "Editing a message assembly" on page 1921
- "Running integration tests" on page 1932
- "Example message flow node tests " on page 1938

For demonstrations of some of the App Connect Enterprise integration testing capabilities, see the following videos:

- Creating and running a JUnit test for a message flow node
- An in-depth look at how to create a test case for a message flow node
- Understanding a message assembly
- Generating a test case using recorded messages in the Flow Exerciser
- Generating a test case for a REST API operation
- Creating a test case for a message flow that uses external resources
- Generating and running tests from the command line

Integration testing overview

You can create and run unit tests to validate the operation of your IBM App Connect Enterprise flows and message flow nodes.

IBM App Connect Enterprise facilitates test-driven development through its test framework, which makes it easier to adopt new product versions and make architectural changes, such as modernizing and moving to a container-based environment. You can use integration tests to check whether your integration flows operate as expected after development changes, upgrades, or changes to services that your flow interacts with. You might also want to check whether changes to external services have impacted the operation of your flows. By using this integration test capability as part of your test-driven development, you can develop and run unit tests more rapidly as part of a pipeline, without the need for third-party tools.

In addition to the test framework for running unit tests in the integration server process, the IBM App Connect Enterprise Toolkit provides powerful tools to help you write the tests, including a template that you can use as a starting point for developing a variety of tests. You can develop spies that spy on the behavior of an individual message flow node, or stubs that describe how you can interact using trained messages to define the behavior of a particular part of the flow. If your flow invokes an external service or a database, you might not have access to that system when you are executing the tests; in this situation it can be useful to record messages and then use them as part of your unit tests, without requiring the external services to be online.

Figure 5. Unit test using trained messages in place of an offline system

App Connect Enterprise also enables interaction with third-party matcher libraries. Support is provided for JUnit assertions and third-party matcher libraries such as Hamcrest, JSONAssert, and XMLUnit, as well as matchers for the App Connect Enterprise message assembly.

In addition to creating and running tests during development, you can test existing flows that have already been deployed, by recording messages in bulk and then using them to generate tests for each of the message flow nodes. To automatically create tests for deployed flows, you switch on recording for the flows, store the messages that flow through them, and then generate tests from those stored message assemblies (`.mxml files`) by using the **`ibmint generate tests`** command. You can extend these generated tests with additional functionality, or you can use the stored message assemblies to write your own tests.

For information about how to develop unit tests for your message flows and nodes, see "Developing integration tests" on page 1891.

Developing integration tests by using the IBM App Connect Enterprise Toolkit

You can create a test case for a message flow node by using a wizard in the IBM App Connect Enterprise Toolkit.

Before you begin

Read the following topics:

- "Integration testing overview" on page 1893
- "Developing integration tests" on page 1891

About this task

You can use the IBM App Connect Enterprise Toolkit to create a test case for a message flow node, either from a recorded message flow or by using XML or JSON files to generate input or output message assembly files. You can also create a test case for a REST API operation subflow or for an individual message flow node in a REST API operation subflow.

For information about how to record messages and then use them to generate tests, see "Generating tests from recorded messages in a message flow" on page 1908.

Procedure

Use the Toolkit to create a test case for an individual message flow node or REST API subflow, by completing the steps in one of the following topics:

- "Creating a test case for a message flow node using recorded messages" on page 1895
- "Creating a test case using XML or JSON data files" on page 1900
- "Creating a test case for a REST API operation subflow" on page 1902
- "Creating a test case for a message flow node in a REST API operation subflow" on page 1904

Creating a test case for a message flow node using recorded messages

You can use the IBM App Connect Enterprise Toolkit to create a test case for a message flow node by using messages that are recorded as they pass through a message flow.

Before you begin

Read the following topics:

- "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894
- "Integration testing overview" on page 1893

About this task

The steps in this task include importing and running a tutorial to create a message flow and record messages as they pass through the flow, and then using the recorded messages to generate unit tests. In this example, the tests are generated for a Compute node in a simple message flow.

Video: Creating and running a JUnit test for a message flow node

This video demonstrates the capability to create a JUnit Test for a message flow node using recorded messages in the Flow Exerciser.

For more videos about generating and running tests, see the IBM App Connect Enterprise playlist on YouTube.

Procedure

Complete the following steps to create a test case for a message flow node by using messages in a recorded message flow:

1. In the IBM App Connect Enterprise Toolkit, open the Tutorials Gallery and select **Using an HTTP input to drive a message flow**.
2. Follow the instructions in the tutorial.

   The tutorial provides a simple message flow consisting of HTTP input and reply nodes, and a Compute node to convert two field names. The tutorial then guides you through using the Flow Exerciser to record the flow of messages through the message flow.

When messages have been sent through the flow, you can create a test case using the messages that were recorded by the Flow Exerciser.

In this example, an input message assembly is used for input to the Compute node and an output message assembly is propagated from the Compute node, as shown in the following diagram:

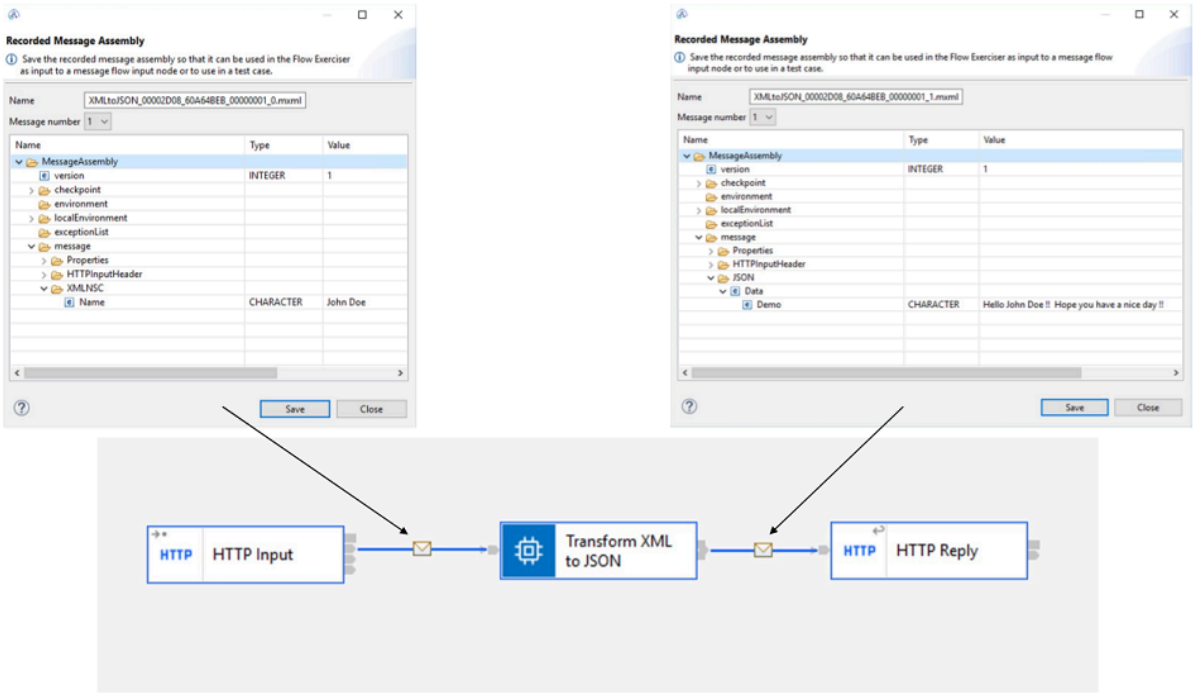


Figure 6. Message assemblies used as input and output for a Compute node test.

You can then use these message assemblies to create a test case for testing the Compute node.

3. In the Flow Exerciser, right-click the Compute node in the message flow and click **Create Test Case...**.

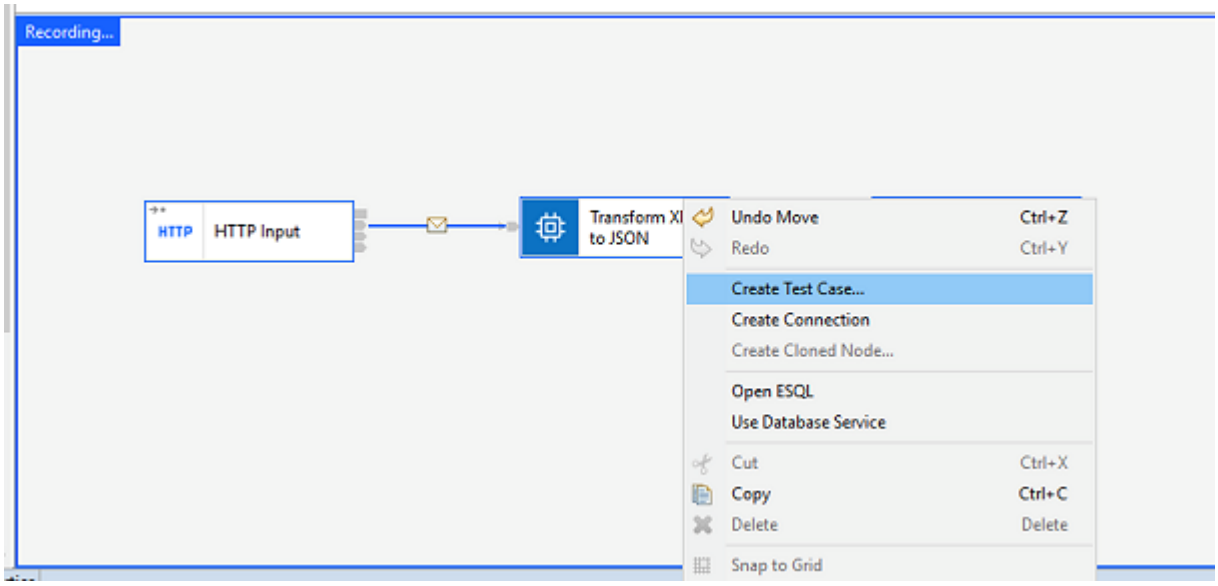

Figure 7. Selecting the Create Test Case option for a Compute node test

4. The **Create Test Case** dialog is displayed, containing information about the selected message flow node, the names of the files to be used for the input and output message assemblies, the assertions

and matchers to be included in the generated test, and a read-only preview of the test case that will be generated for the message flow node.

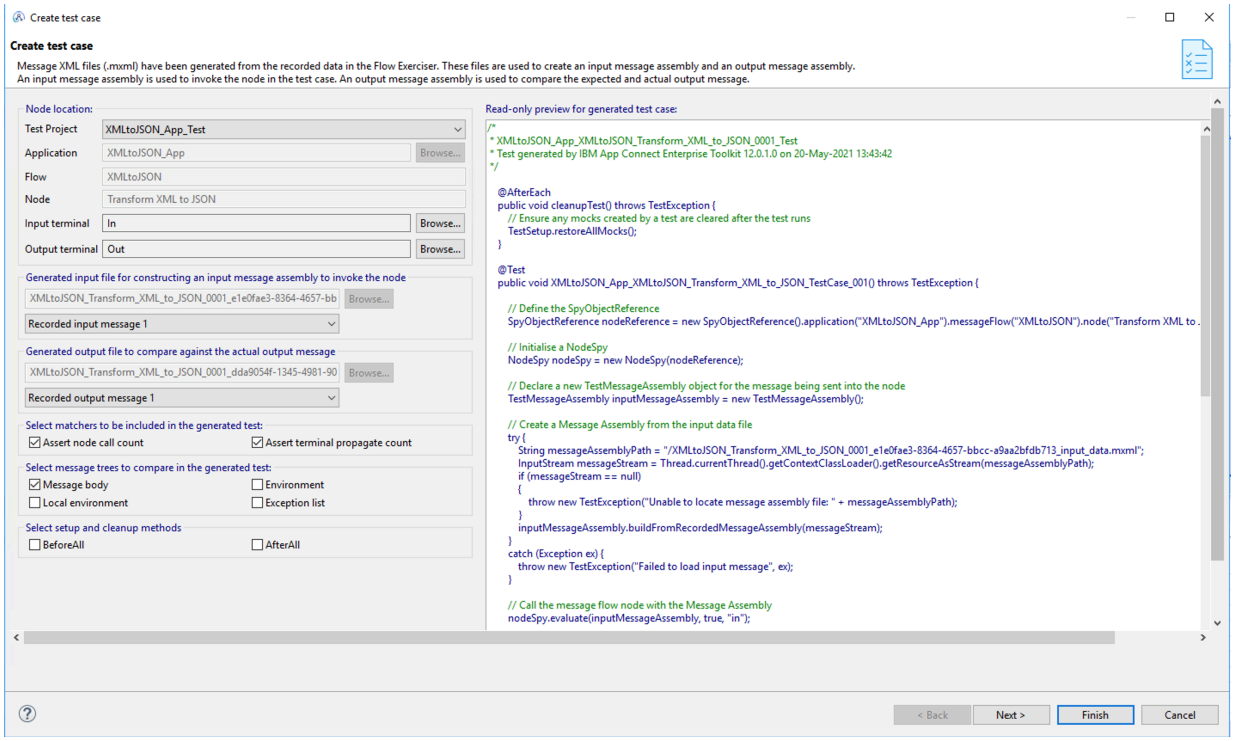

Figure 8. Create Test Case dialog for a message flow node test

5. You can choose which message trees in the message assembly are to be compared in the generated test, by selecting one or more of the following options:
   - Message body
   - Local environment
   - Environment
   - Exception list

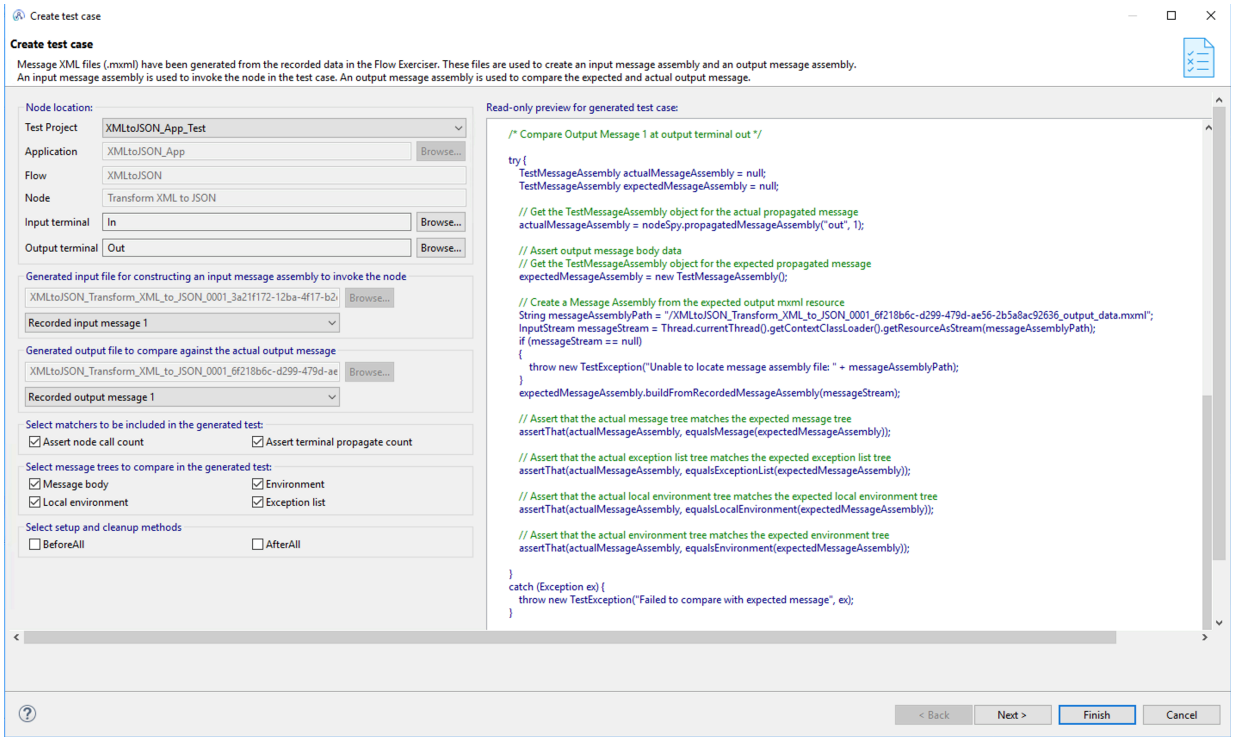

Figure 9. Select message trees to be compared

6. Click **Finish**.

   The generated test case is displayed in the Java Editor, showing the following objects:

   - The test project name: `XMLtoJSON_App_Test` (which is the *ApplicationName* followed by `_Test`)
   - The class name: `XMLtoJSON_App_XMLtoJSON_Transform_XML_to_JSON_0001_Test` (which is the *ApplicationName_FlowName_NodeName* followed by `0001_Test`)
   - The test case method name: `XMLtoJSON_App_XMLtoJSON_Transform_XML_to_JSON_TestCase_001()` (which is the *ApplicationName_FlowName_NodeName* followed by `TestCase_001()`)
   - The generated message assembly files (`*.mxml`) are located in the `resources` folder in the test project.

   Any character that is not valid for Java is changed to an underscore character (_). In this example, the spaces in the integration node name (`Transform XML to JSON`) are replaced with underscores in the generated class and method name (`Transform_XML_to_JSON`).

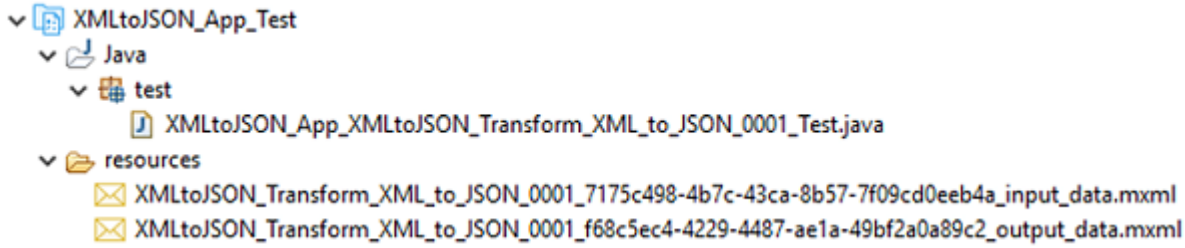

Figure 10. Objects generated by the Create Test Case wizard

7. The required objects are added to the Java test class automatically, and you can then edit the `.java` file to make additional modifications, if required. For example:

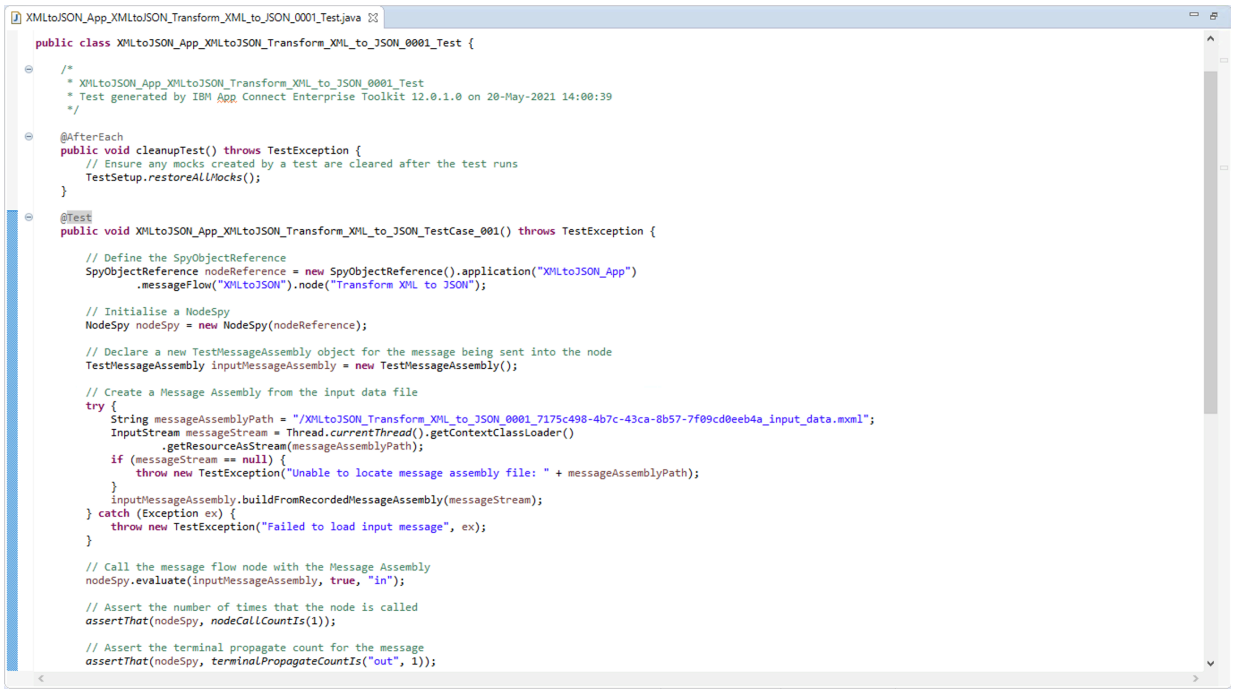

Figure 11. Java test class for Mapping node unit test

8. Optional: You can run the test by right-clicking the test project `XMLtoJSON_App_Test` and then clicking **Run Test Project**.

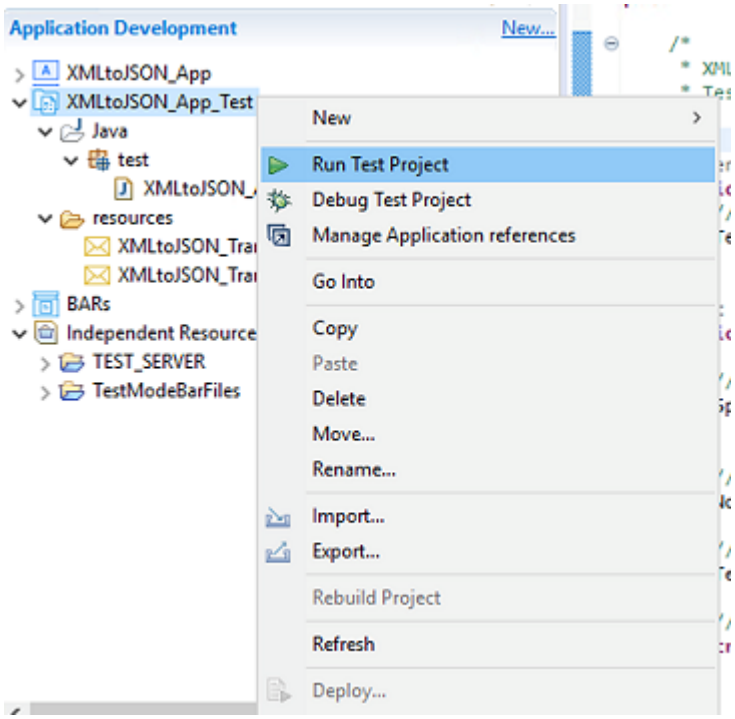

Figure 12. Run the test project

9. Optional: View the test result by opening the JUnit view in the Toolkit:

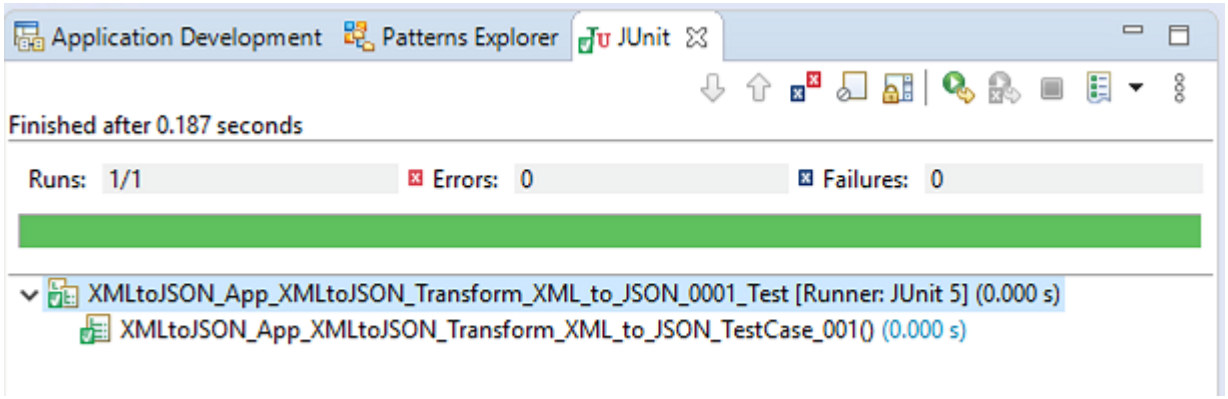

Figure 13. Test result in the JUnit view of the Toolkit

Creating a test case using XML or JSON data files

You can use the IBM App Connect Enterprise Toolkit to create a test case using XML or JSON files to generate input or output message assembly files.

Before you begin

Read the following topics:

- "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894
- "Integration testing overview" on page 1893

About this task

You can use the **Create Test Case** wizard in the IBM App Connect Enterprise Toolkit to select an input file and an output file to create input and output message assemblies. The example used in the following steps shows a Compute node being used to transform an XML message to a JSON message:

Procedure

1. In the Flow Exerciser, right-click the Compute node in your message flow and then select **Create Test Case**.

   The **Create test case** dialog is displayed, containing information about the selected message flow node, and a read-only preview of the test case that will be generated for the message flow node.

2. Select an XML file to be used as an input message assembly, and a JSON file to be used as an output message assembly. The files that you select must be in the toolkit workspace or filesystem. In the following example, the selected files are `demo_input.xml` and `demo_output.xml`:

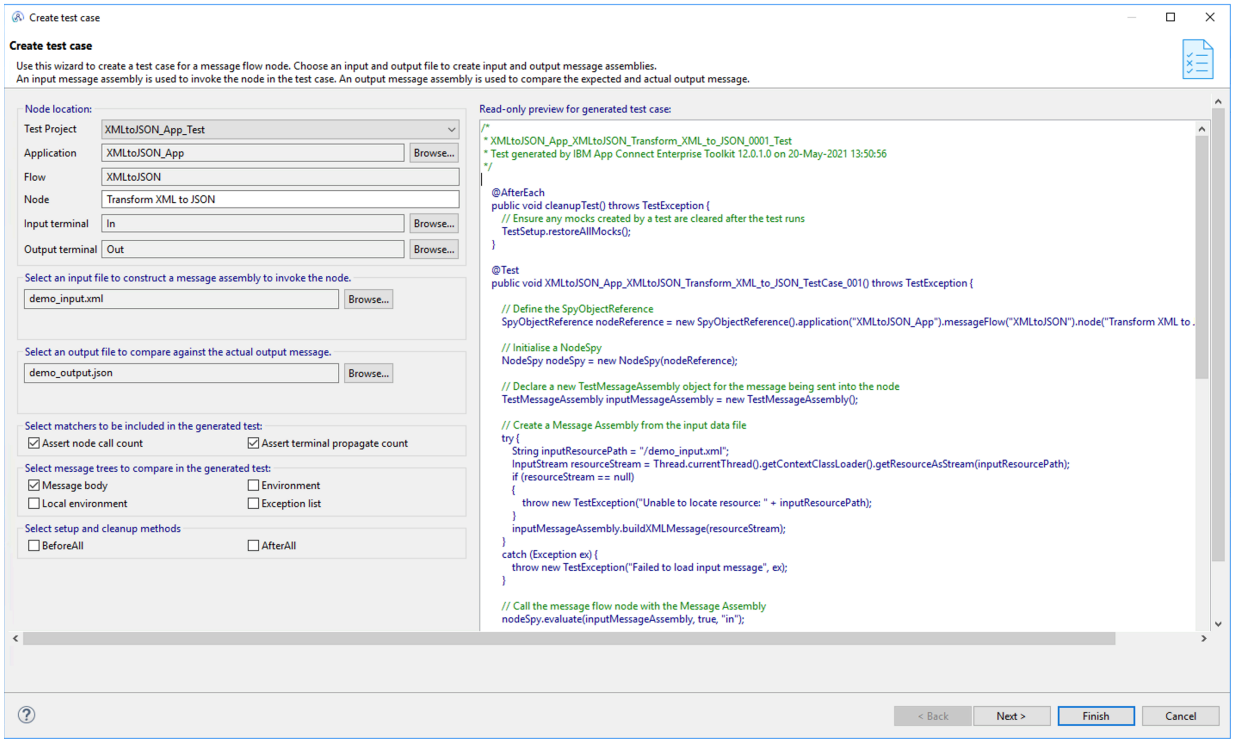

Figure 14. Create test case wizard

When an XML data file is used, the `TestMessageAssembly` object is created using the `buildMessageBodyFromXML` method in the generated code. When a JSON data file is used, the `TestMessageAssembly` object is created using the `buildMessageBodyFromJSON` method in the generated code.

3. You can control the content of the test case code that is generated, by selecting options in the **Create test case** dialog.

   For example:

   - Select **Assert node call count** to add an assert that uses the `nodeCallCountIs` matcher
   - Select **Assert terminal propagate** to add an assert that uses the `terminalPropagateCountIs` matcher

4. Click **Finish**.

Creating a test case for a REST API operation subflow

You can create and run a test case for a REST API operation subflow.

Before you begin

Read the following topics:

- “Developing integration tests by using the IBM App Connect Enterprise Toolkit” on page 1894
- “Integration testing overview” on page 1893

About this task

REST API operations are implemented by subflows, and the OpenAPI document for the REST API describes the input and output messages that are used by each operation.

For information about how to use the IBM App Connect Enterprise Toolkit to generate a test case for an individual message flow node in a REST API subflow, see “Creating a test case for a message flow node in a REST API operation subflow” on page 1904.

Video: Generating a test case for a REST API operation

This video demonstrates the capability to create a JUnit test for an operation in a REST API. The capability can be used on both REST APIs that are using Open API v2.0 or v3.0 documents which define the APIs.

For more videos about generating and running tests, see the IBM App Connect Enterprise playlist on YouTube.

To create a test case for a whole REST API operation subflow, complete the following steps:

Procedure

1. In the Application Development view, right-click the operation subflow and then click **Create Operation Test Case**.

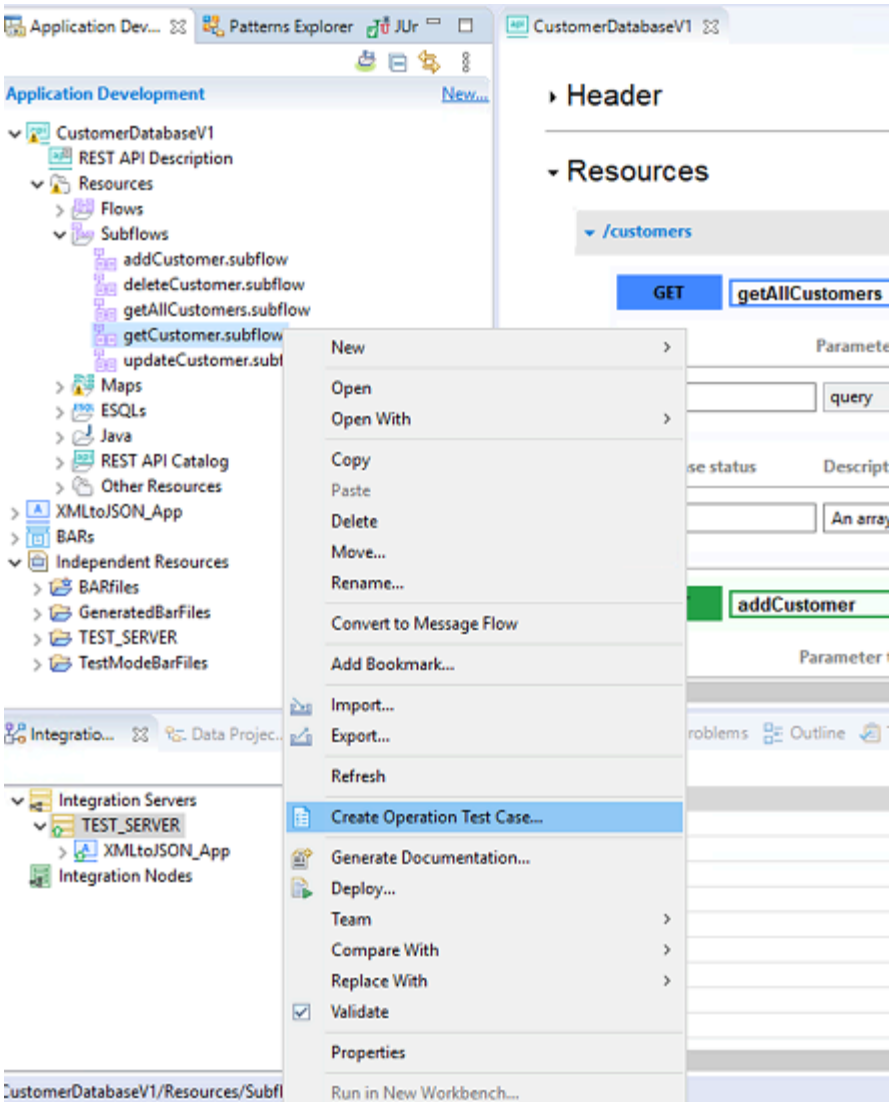

Figure 15. Create Operation Test Case option in the Application Development view

2. The **Create test case** wizard is displayed, containing a read-only preview of the generated test case.

   The OpenAPI document defines the message format used by each operation, and an instance of the message is generated and used to create the message assembly in the test case.

   Local environment entries for HTTP and REST are defined in the generated test case, using the path or query parameters for the operation. The input message assembly can be generated using the local environment entries.

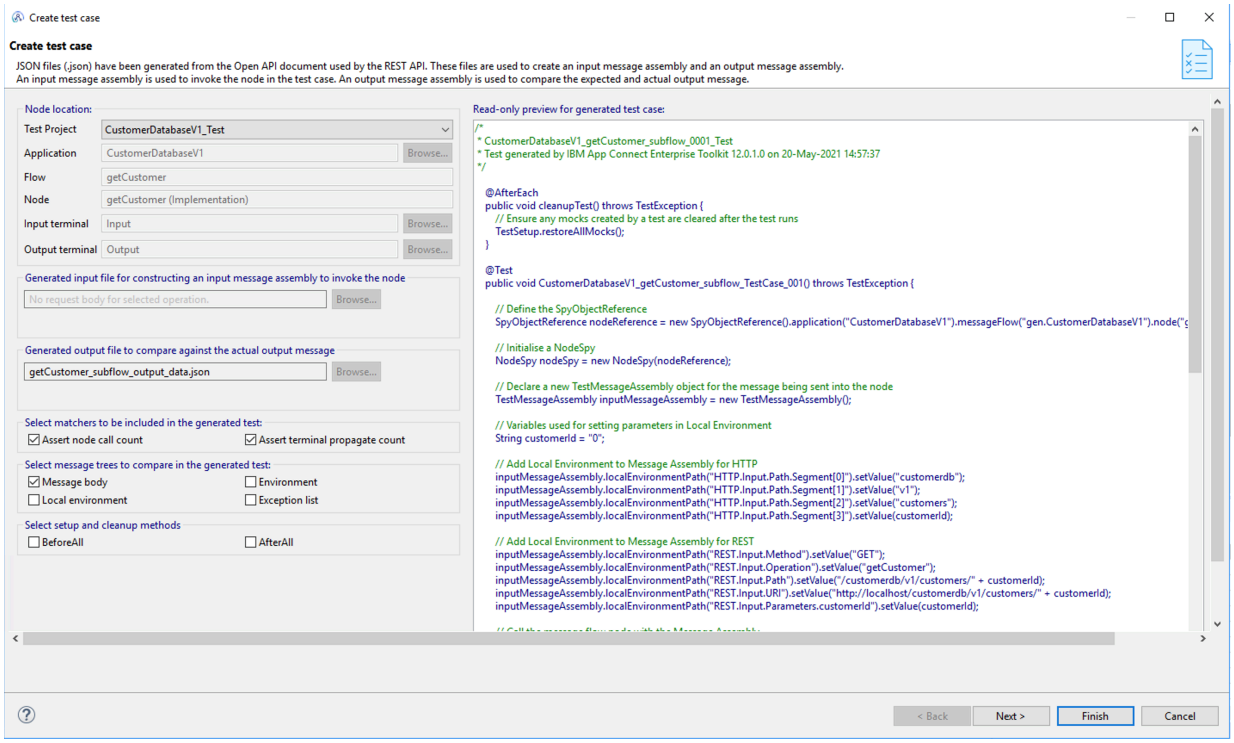

Figure 16. Create test case dialog for a REST API operation subflow

   For an example of a test case generated for a GET operation, see "Example test case for a REST API GET operation" on page 1906.

3. Click **Finish**.

Creating a test case for a message flow node in a REST API operation subflow

You can create and run a test case for an individual message flow node in a REST API operation subflow.

Before you begin

Read the following topics:

- "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894
- "Integration testing overview" on page 1893

About this task

REST API operations are implemented by subflows, and the OpenAPI document for the REST API describes the input and output messages that are used by each operation.

You can generate a test case for an individual message flow node in a REST API operation subflow, by following these steps:

Procedure

1. In the Application Development view of the Toolkit, open the REST API operation subflow that contains the node that you want to test, right-click the node, and then click **Create Test Case**.

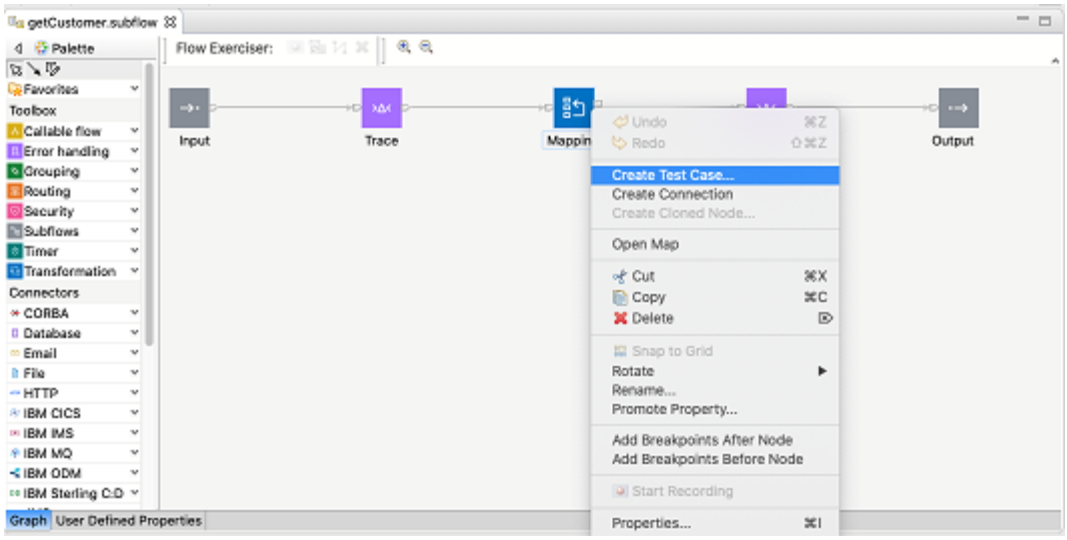

Figure 17. Create Test Case option in the Application Development view

2. The **Create test case** dialog is displayed, containing a read-only preview of the generated test case.

   The OpenAPI document defines the message format used by each operation, and an instance of the message is generated and used to create the message assembly in the test case.

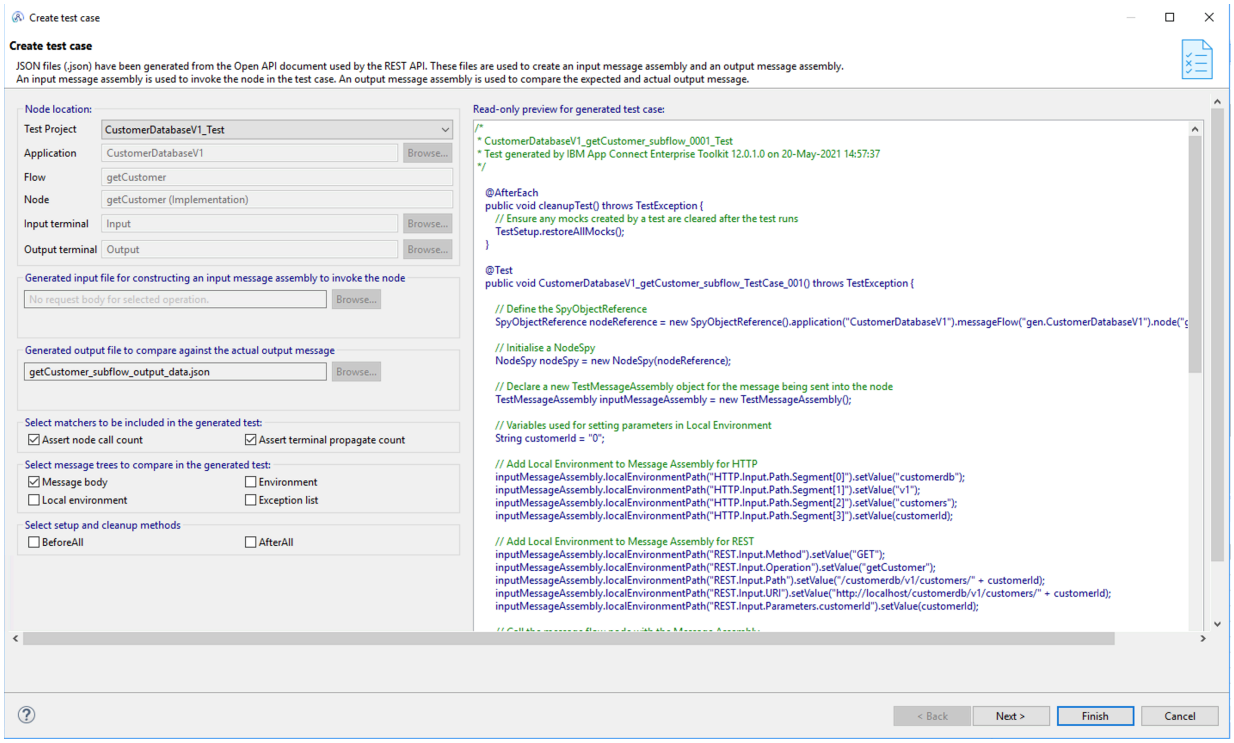

Figure 18. Create test case dialog for a REST API operation subflow

The node to be tested (in this case a Mapping node) is specified in the `SpyObjectReference` object in the generated test case, as shown in the following example:

```
// Define the SpyObjectReference
```

```
 SpyObjectReference nodeReference = new
 SpyObjectReference().application("CustomerDatabaseV1").messageFlow("gen.CustomerDatabaseV1").subflowNode(
 (Implementation)").node("Mapping");
```

If you generate a test case for a whole subflow, no node is specified in the SpyObjectReference object definition:

```
// Define the SpyObjectReference
 SpyObjectReference nodeReference = new
 SpyObjectReference().application("CustomerDatabaseV1").messageFlow("gen.CustomerDatabaseV1").node("getCus
 (Implementation)");
```

For an example of a test case generated for a GET operation, see "Example test case for a REST API GET operation" on page 1906.

3. Click **Finish**.

Example test case for a REST API GET operation

You can generate a test case for a REST API GET operation, as shown in this example.

Before you begin

Read the following topics:

- "Creating a test case for a REST API operation subflow" on page 1902

About this task

The following example code shows a test case generated for a GET operation, in which an ID is specified using a path parameter:

```
package test;

import java.io.InputStream;
import java.nio.charset.StandardCharsets;

import org.junit.jupiter.api.Test;

import com.ibm.integration.test.v1.NodeSpy;
import com.ibm.integration.test.v1.SpyObjectReference;
import com.ibm.integration.test.v1.TestMessageAssembly;
import com.ibm.integration.test.v1.exception.TestException;

import static com.ibm.integration.test.v1.Matchers.*;
import static net.javacrumbs.jsonunit.JsonMatchers.jsonEquals;
import static org.hamcrest.MatcherAssert.assertThat;

public class CustomerDatabaseV1_getCustomer_subflow_0001_IntegrationTest {

 /*
  * CustomerDatabaseV1_getCustomer_subflow_0001_IntegrationTest
  * Integration test generated by IBM App Connect Enterprise Toolkit 12.0.0.0 on 26-Apr-2021
 14:28:46
  */

 @Test
 public void CustomerDatabaseV1_getCustomer_subflow_TestCase_001() throws TestException {

  // Define the SpyObjectReference
  SpyObjectReference nodeReference = new SpyObjectReference().application("CustomerDatabaseV1")
    .messageFlow("gen.CustomerDatabaseV1").node("getCustomer (Implementation)");

  // Initialise a NodeSpy
  NodeSpy nodeSpy = new NodeSpy(nodeReference);

  // Declare a new TestMessageAssembly object for the message being sent into the node
  TestMessageAssembly inputMessageAssembly = new TestMessageAssembly();

  // Variables used for setting parameters in Local Environment
  String customerId = "0";

  // Add Local Environment to Message Assembly for HTTP
```

```
 inputMessageAssembly.localEnvironmentPath("HTTP.Input.Path.Segment[0]").setValue("customerdb");
  inputMessageAssembly.localEnvironmentPath("HTTP.Input.Path.Segment[1]").setValue("v1");
  inputMessageAssembly.localEnvironmentPath("HTTP.Input.Path.Segment[2]").setValue("customers");
  inputMessageAssembly.localEnvironmentPath("HTTP.Input.Path.Segment[3]").setValue(customerId);

  // Add Local Environment to Message Assembly for REST
  inputMessageAssembly.localEnvironmentPath("REST.Input.Method").setValue("GET");
  inputMessageAssembly.localEnvironmentPath("REST.Input.Operation").setValue("getCustomer");
  inputMessageAssembly.localEnvironmentPath("REST.Input.Path").setValue("/customerdb/v1/
customers/" + customerId);
  inputMessageAssembly.localEnvironmentPath("REST.Input.URI")
    .setValue("http://localhost/customerdb/v1/customers/" + customerId);

 inputMessageAssembly.localEnvironmentPath("REST.Input.Parameters.customerId").setValue(customerId);

  // Call the message flow node with the Message Assembly
  nodeSpy.evaluate(inputMessageAssembly, true, "Input");

  // Assert the number of times that the node is called
  assertThat(nodeSpy, nodeCallCountIs(1));

  // Assert the terminal propagate count for the message
  assertThat(nodeSpy, terminalPropagateCountIs("Output", 1));

  /* Compare Output Message 1 at output terminal Output */

  try {

   TestMessageAssembly actualMessageAssembly = null;
   String actualOutputData = null;
   String expectedOutputData = null;

   // Get the TestMessageAssembly object for the actual propagated message
   actualMessageAssembly = nodeSpy.propagatedMessageAssembly("Output", 1);

   // Assert output message body data
   // Get the string containing the actual data that was propagated from the node
   actualOutputData = actualMessageAssembly.getMessageBodyAsString();

   // Create an InputStream from the expected resource
   String expectedResourcePath = "/getCustomer_subflow_output_data.json";
   InputStream resourceStream = Thread.currentThread().getContextClassLoader()
     .getResourceAsStream(expectedResourcePath);
   if (resourceStream == null) {
    throw new TestException("Unable to locate resource: " + expectedResourcePath);
   }
   byte[] buffer = new byte[resourceStream.available()];
   resourceStream.read(buffer);

   // Get the expected output data using output data file
   expectedOutputData = new String(buffer, StandardCharsets.UTF_8);

   // Assert that the actual data matches the expected data
   assertThat(actualOutputData, jsonEquals(expectedOutputData));

  } catch (Exception ex) {
   throw new TestException("Failed to compare with expected message", ex);
  }

 }

}
```

The output file `/getCustomer_subflow_output_data.json` is generated from the Open API definition for the REST API. It contains the following string:

```
{"id":0,"firstname":"string","lastname":"string","address":"string"}
```

The output message assembly is generated from `/getCustomer_subflow_output_data.json`. It is generated using the following code:

```
// Assert output message body data
// Get the string containing the actual data that was propagated from the node
 actualOutputData = actualMessageAssembly.getMessageBodyAsJSON();
```

Generating tests from recorded messages in a message flow

You can create and run unit tests of your message flows by recording messages that pass through a flow and then using the recorded message assemblies to generate the tests.

Before you begin

Read the following topics:

- "Developing integration tests" on page 1891
- "Integration testing overview" on page 1893

About this task

As an alternative to using the Toolkit to create and run tests during development, you can create tests using command line tools. You can configure an integration server to store message assembly files in a specified directory for every message that is processed by a message flow.

You can generate a test project by using the command line. The test project contains a test case for every node in a message flow, apart from an input node. Each test case uses a message assembly file for input to the node and another message assembly to do a comparison check.

Procedure

Complete the following steps to generate unit tests from recorded messages:

1. Configure an integration server to record messages
2. Generate a test project by using the ibmint generate tests command
3. Compile the test project and create a BAR file by using the command line
4. Optional: Import the test project into the toolkit for editing
5. Optional: Run the tests in the test project by using either the command line or the toolkit:
   - Run the tests in the test project by using the command line
   - Run the tests in the test project by using the toolkit

Configuring an integration server to record messages

You can configure an integration server to record message assembly files for all messages that are propagated through the message flow.

Before you begin

Read the following topics:

- "Generating tests from recorded messages in a message flow" on page 1908
- "Integration testing overview" on page 1893

About this task

The recorded message assembly files are XML files that have a `.mxml` file suffix. A recorded message assembly file is written each time a message flow node propagates a message from an output terminal to the input terminal of the next node in the message flow. You can import these files into a test project and use them in your tests as:

- Input data when invoking a message flow node
- Expected data for comparisons of the test results
- Substitute data to be returned by a Node Stub instead of invoking the actual node

You can configure an integration server to record all messages that pass through a message flow by setting properties in the **RecordedMessageManager** section of your integration server's `server.conf.yaml` file:

```
ResourceManagers:
   RecordedMessageManager:
      recordedMessagePath: 'C:\temp\IntegrationServer\recorded_messages'   # Set the directory
 to store recorded messages
      recordAllMessages: true  # Set to 'true' to enabling recording of messages from all
 message flows
```

Procedure

Complete the following steps to configure the recording of messages as they pass through a message flow:

1. Open the `server.conf.yaml` configuration file for your integration server by using a YAML editor.

   If you are not able to access a YAML editor, you can edit the file by using a plain text editor. However, you must ensure that you do not include any tab characters, which are not valid in YAML and will cause your integration server configuration to fail. If you are using a plain text editor, ensure that you use a YAML validation tool to validate the content of your file.
2. Enable recording of all messages that pass through all message flows, by setting the **recordAllMessages** property to `true`.
3. Set the **recordedMessagePath** property to specify the location where the recorded message assembly files will be saved when recording is enabled.
4. Stop and restart the integration server for the changes to take effect.

   The recorded message assemblies are saved in `.mxml` files, in a subdirectory of the directory specified by the **recordedMessagePath** property.

Generating tests by using the `ibmint generate tests` command

You can use the **`ibmint generate tests`** command to generate a test project and unit tests by using recorded messages.

Before you begin

Read the following topics:

- "Generating tests from recorded messages in a message flow" on page 1908
- "Integration testing overview" on page 1893

About this task

The command recursively searches for recorded message assemblies in the specified directory name, and analyzes the files that are found, identifying pairs of messages that represent the corresponding input and output messages from the invocation of the message flow node. A Java test case is then created for each pair of messages, and is written to the test project directory together with the recorded message assembly files.

Procedure

1. Open a command console and run the **`ibmint generate tests`** command to generate tests based on the recorded message assembly (`.mxml`) files:

   ```
   ibmint generate tests
    --recorded-messages C:\tmp\IntegrationServer\recorded_messages
    --output-test-project C:\tmp\MyIntegrationTestProject
   ```

```
  --java-class com.ibm.mytests.MyIntegrationTestClass
```

where:

- **--recorded-messages** specifies the file name and path of the recorded messages that are to be used in the tests.
- **--output-test-project** specifies the name and location of the generated test project.
- **--java-class** specifies the fully-qualified classpath of the Java class that will contain the generated tests.

2. You can import the generated tests into the IBM App Connect Enterprise Toolkit for editing, as described in "Importing a test project into the IBM App Connect Enterprise Toolkit for editing" on page 1911, or you can build the tests by using Gradle before running them on an integration server, as described in "Compiling a test project and creating a BAR file by using the command line" on page 1910.

Compiling a test project and creating a BAR file by using the command line

You can compile a test project and create a BAR file by using the App Connect Enterprise command line.

Before you begin

Read the following topics:

- "Generating tests from recorded messages in a message flow" on page 1908
- "Integration testing overview" on page 1893

About this task

The **ibmint generate tests** command creates the `build.gradle` and `settings.gradle` files required to compile the test project, so that it can be packaged into a BAR file or copied directly into the `run` directory of an integration server, ready for the tests to be run.

The Gradle application is not supplied with App Connect Enterprise, but you can install it from https://gradle.org/install/.

Procedure

1. At the command prompt, change to the directory that contains your test project and then start Gradle, as shown in the following example:

```
# cd /tmp/MyIntegrationTestProject
# gradle
Starting a Gradle Daemon (subsequent builds will be faster)
BUILD SUCCESSFUL in 15s
2 actionable tasks: 2 executed
```

When the command finishes, the tests in the integration test project (in this example, `MyIntegrationTestProject`) are ready to be run.

2. Optional: Build a BAR file containing the test project by using the `ibmint package` command, as shown in the following example:

```
ibmint package --input-path /tmp/MyIntegrationTestProject --output-bar-file /tmp/
MyIntegrationTestProject.bar --do-not-compile-java
```

3. Optional: Run the tests by copying the output directory (which has the same name as the test project) to the `run` directory of your integration server. The application that contains the message

flows required by the test project must also be deployed; if it has not yet been deployed, copy the application BAR file into the integration server's `run` directory.

a) Create an integration server work directory if you have not done so already.
For example:

```
# mqsicreateworkdir /tmp/work-dir
mqsicreateworkdir: Copying sample server.config.yaml to work directory
1 file(s) copied.
Successful command completion.
```

b) Copy the compiled test project to the run directory:

```
# cp -r /tmp/MyIntegrationTestProject /tmp/work-dir/run
```

c) Copy the application BAR file to the integration server run directory, if it is not already deployed:

```
# cp ../MyApplication.bar /tmp/work-dir/run
```

d) Run the **IntegrationServer** command to start the integration server, specifying the name of the test project by using the **--test-project** parameter, as shown in the following example:

```
# IntegrationServer –work-dir /tmp/work-dir --test-project MyIntegrationTestProject
--start-msgflows false
.......2021-01-25 12:16:16.457748: [Thread 44425] (Msg 1/1) BIP9901I: Messages are
now being recorded and stored at '/tmp/recorded_messages'.
.............2021-01-25 12:16:20.274600: [Thread 44425] (Msg 1/1) BIP2155I: About to
'Initialize' the deployed resource 'App1' of type 'Application'.
..2021-01-25 12:16:21.016478: [Thread 44501] (Msg 1/1) BIP2866I: IBM App Connect
Enterprise administration security is inactive.
2021-01-25 12:16:21.040458: [Thread 44501] (Msg 1/1) BIP3132I: The HTTP Listener
has started listening on port '7600' for 'RestAdmin http' connections.
2021-01-25 12:16:21.459 1 STARTING
TEST:App1_Flow1_Pass_through_TestCase_001()
2021-01-25 12:16:21.528 1 FINISHED
TEST:App1_Flow1_Pass_through_TestCase_001() SUCCESSFUL
2021-01-25 12:16:21.542 1
TEST RESULTS:
 com.ibm.mytests.MyIntegrationTestClass:
 App1_Flow1_Pass_through_TestCase_001():SUCCESSFUL
TOTALS:
 PASSED :1
 FAILED :0
 ABORTED :0
 TIME(secs):0.157
```

In this example, the `--start-msgflows false` parameter prevents the deployed message flows from starting and accepting requests through their input nodes, but still allows the tests to run.

Importing a test project into the IBM App Connect Enterprise Toolkit for editing

When you have generated tests for your message flow nodes, you can import them into a test project in the IBM App Connect Enterprise Toolkit, where you can extend them with additional checks. You can also add further tests to the test project.

Before you begin

Read the following topics:

- “Generating tests from recorded messages in a message flow” on page 1908
- “Integration testing overview” on page 1893

About this task

The test project is associated with the specific application that you want to test. The following instructions assume that your test project is imported into the workspace that contains the application to be tested.

Procedure

Import the test project into the IBM App Connect Enterprise Toolkit and then create a BAR file, by completing the following steps:

1. Create an empty test project by right-clicking in the Application Development view and then selecting **New** > **Test Project**.
2. Right-click the new test project, and then select **Import** > **Import generated test files into a test project**.
3. Click **Browse** and navigate to the test project folder (for example, `/tmp/TestProject1`).

   To import the entire test project, select the test project directory to import all the Java source and resource files; when you are prompted to overwrite existing files, select **No to all**. To import only selected test and resource files, use the navigator to select the required files.

   The project references from the imported test files are combined with any existing application references on the test project.
4. Click **Finish** to import the messages into the test project.

Testing a sequence of message flow nodes in a single test case

You can test a sequence of message flow nodes by using the `evaluate()` method or the `propagate()`method.

Before you begin

Read the following topics:

- "Developing integration tests" on page 1891
- "Integration testing overview" on page 1893

About this task

You can test a sequence of message flow nodes, by using either the `evaluate()` method or the `propagate()` method, as described in the following topics:

- "Testing a sequence of nodes by using the evaluate() method " on page 1913
- "Testing a sequence of nodes by using the propagate() method" on page 1914

.

When you use the `propagate()` or `evaluate()` method to test a section of a message flow, you can configure an additional NodeSpy or NodeStub on the message flow, to perform the following actions:

- Observe and validate the message content at any node in the message flow
- Prevent message propagation past a specific message flow node terminal, by using the `setStopAtTerminal()` method
- Substitute the operation of a message flow node

For information about using node stubs on the message flow, see "Replacing a message flow node with a NodeStub in a unit test" on page 1917.

When you are testing a part of a message flow, you can stop the message flow before it completes, by using the `setStopAtInputTerminal()` and `setStopAtOutputTerminal()` methods on a node spy. For information about how to do this, see "Stopping a flow before it completes" on page 1915.

For information about verifying exceptions that were caught while propagating, see "Verifying exceptions" on page 1916.

You can also test an individual message flow node (without propagating the message to any subsequent message flow nodes), by using the `evaluate()` method on a node spy and setting the **`singleNodeTest`** parameter to `true`:

```
 /**
  * Calls the specified input terminal of the message flow node with the supplied message
assembly.
  *
  * @param testAssembly   The message assembly to call the node that contains
  *                       the test time message trees
  * @param singleNodeTest when true, prevents message propagation from any of the
  *                       output terminals on the message flow node
  * @param inputTerminalName The name of the input terminal to call
  * @throws TestException Why the invocation failed
  */
 public void evaluate(final TestMessageAssembly testAssembly, boolean singleNodeTest, String
inputTerminalName) throws TestException
```

Testing a sequence of nodes by using the evaluate() method

You can test a sequence of message flow nodes by using the `evaluate()` method.

Before you begin

Read the following topics:

- "Developing integration tests" on page 1891
- "Testing a sequence of message flow nodes in a single test case" on page 1912

About this task

You can test a sequence of message flow nodes by using the `evaluate()` method and setting the **`singleNodeTest`** parameter to `false`. When the **`singleNodeTest`** parameter is set to `false`, messages can be propagated from any of the output terminals on the node spy. The `evaluate()` method injects the message to the input terminal of a message flow node, and the flow continues either until the injected message reaches the end of the flow, or until an uncaught message-flow exception occurs.

When the `evaluate()` method is called with the **`singleNodeTest`** parameter set to `false`, the sequence of message flow nodes is executed synchronously on the unit test thread. The `evaluate()` method completes when evaluation of the sequence of nodes completes. If any of the evaluated nodes makes a request to other flows (such as a Callable Invoke node), invokes external APIs, or accesses external resources, these must be running and available in order for the `evaluate()` to complete successfully.

In addition to the **`singleNodeTest`** parameter, you can set two other properties on the `evaluate()` method:

- The payload to be propagated.
- Optionally, the name of the terminal to send the payload to. The terminal name (if specified) must be the name of an input terminal. If it is not specified, the 'in' terminal is used.

Figure 19. Example message flow

This example calls a message flow node by sending a message to the 'in' terminal of the Compute1 node. The HTTPReply node detects that there was no initial HTTP Input node in scope, so it does nothing. Other transport types might need extra code to prevent errors from being generated.

```
// Define the Spy on the Compute1 that is used to inject the message
SpyObjectReference compute1Reference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("Compute1");
NodeSpy compute1NodeSpy = new NodeSpy(compute1Reference);

// Define the Spy on the Compute2 that is used to verify the required nodes were executed
SpyObjectReference compute2Reference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("Compute2");
NodeSpy compute2NodeSpy = new NodeSpy(compute2Reference);

// Define the Spy on the HTTP Reply that is used to verify the operation
SpyObjectReference httpReplyReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("HTTP Reply");
NodeSpy httpReplyNodeSpy = new NodeSpy(httpReplyReference);

// Declare a new TestMessageAssembly object for the message being sent into the node
TestMessageAssembly inputMessageAssembly = new TestMessageAssembly();

/*
 * Loading of message assembly would be done here
 */

// Send the message assembly to the 'in' terminal of the Compute1 node
compute1NodeSpy.evaluate(inputMessageAssembly, false, "in"); // Note: singleNodeTest = false

// Assert the Compute1 node and Compute2 nodes are both called
assertThat(compute1NodeSpy, nodeCallCountIs(1));
assertThat(compute2NodeSpy, nodeCallCountIs(1));

// Assert the HTTP Reply node is also called
assertThat(httpReplyNodeSpy, nodeCallCountIs(1));
```

When you use the `evaluate()` method to test a section of a message flow, you can configure additional node spies and node stubs on the message flow to perform any of the following actions:

- Observe and validate the message content at any node in the message flow
- Prevent message propagation past a specific message flow node terminal, by using the `setStopAtTerminal()` method
- Substitute the operation of a message flow node

Testing a sequence of nodes by using the propagate() method

You can test a sequence of message flow nodes by using the `propagate()` method.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Testing a sequence of message flow nodes in a single test case” on page 1912

About this task

You can test a sequence of message flow nodes by using the `propagate()` method, which allows the message to be injected to an output terminal of a message flow node. When you use the `propagate()` method, the message flow node itself is not called, but the message is propagated down the flow from the node's output terminal.

When the `propagate()` method is called, the sequence of nodes is executed synchronously on the unit test thread. The `propagate()` method completes when evaluation of the sequence of nodes completes. If any of the evaluated nodes make requests to other flows (such as using a Callable Invoke node), invokes external APIs, or accesses external resources, these must be running and available in order for the propagate to complete successfully.

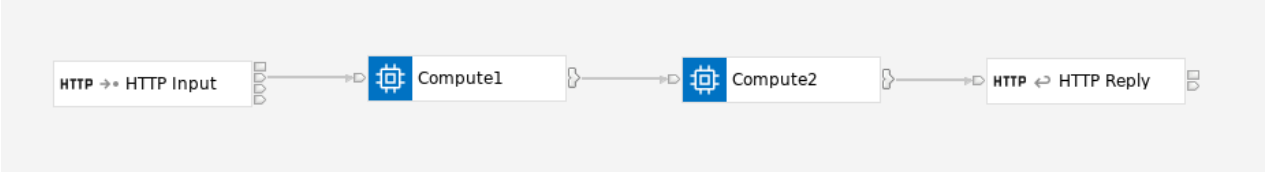

Figure 20. Example message flow

This example propagates a message to the 'out' terminal of the HTTPInput node. The HTTPReply node detects that there was no initial HTTPInput node, so it does nothing. Other transports might need extra code to prevent errors from being generated.

```
// Define the Spy on the HTTP Input which is used to inject the message
SpyObjectReference httpInputReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("HTTP Input");
NodeSpy httpInputNodeSpy = new NodeSpy(httpInputReference);

// Define the Spy on the Compute2 which is used to verify the required nodes were executed
SpyObjectReference compute2Reference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("Compute2");
NodeSpy compute2NodeSpy = new NodeSpy(compute2Reference);

// Define the Spy on the HTTP Reply which is used to verify the operation
SpyObjectReference httpReplyReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("HTTP Reply");
NodeSpy httpReplyNodeSpy = new NodeSpy(httpReplyReference);

// Declare a new TestMessageAssembly object for the message being sent into the node
TestMessageAssembly inputMessageAssembly = new TestMessageAssembly();

/*
 * Loading of message assembly would be done here
 */

// Send the message assembly to the 'out' terminal of the HTTP Input node
httpInputNodeSpy.propagate(inputMessageAssembly, "out");

// Assert the HttpInput node was not called, because we injected the message at the
// output terminal using propagate
assertThat(httpInputNodeSpy, nodeCallCountIs(0));

// Assert the Compute2 node is called
assertThat(compute2NodeSpy, nodeCallCountIs(1));

// Assert the HTTP Reply node is called
assertThat(httpReplyNodeSpy, nodeCallCountIs(1));
```

When you use the `propagate()` method to test a section of a message flow, you can configure additional node spies and node stubs on the message flow to perform any of the following actions:

- Observe and validate the message content at any node in the message flow
- Prevent message propagation past a specific message flow node terminal, by using the `setStopAtTerminal()` method
- Substitute the operation of a message flow node

Stopping a flow before it completes

When you are testing part of a message flow, you can stop the flow before it completes, by using the `setStopAtInputTerminal()` and `setStopAtOutputTerminal()` methods on a node spy.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Testing a sequence of message flow nodes in a single test case” on page 1912

About this task

You can use the `setStopAtInputTerminal()` method on a node spy to stop the execution of a message flow at an input terminal, as if the input terminal was not connected. As a result, the node and any subsequent nodes that it is connected to are not evaluated.

Alternatively, you can use the `setStopAtOutputTerminal()` method to stop the execution of the message flow at an output terminal, as if the output terminal was not connected. As a result, the node is evaluated but subsequent nodes are not.

The following example tests a partial message flow containing MQInput, Compute, and MQOutput nodes. In this example, the `setStopAtInputTerminal()` method stops propagation at the input terminal on the MQOutput node:

```
// Define the Spy on the MQ Input which is used to inject the message
SpyObjectReference mqInputReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example4").node("MQ Input");
NodeSpy mqInputNodeSpy = new NodeSpy(mqInputReference);

// Define the Spy on the Compute node which is used to validate the operation
SpyObjectReference computeReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example4").node("Compute");
NodeSpy computeNodeSpy = new NodeSpy(computeReference);

// Define the Spy on the MQ Output node as we do not want this node to execute
SpyObjectReference mqOutputReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example4").node("MQ Output");
NodeSpy mqOutputNodeSpy = new NodeSpy(mqOutputReference);
mqOutputNodeSpy.setStopAtInputTerminal("in");

// Declare a new TestMessageAssembly object for the message being sent into the node
TestMessageAssembly inputMessageAssembly = new TestMessageAssembly();
/* Loading of message assembly would be done here */

// Declare a new TestMessageAssembly object for the expected message propagated from Compute2
 node
TestMessageAssembly afterComputeExpectedMessageAssembly = new TestMessageAssembly();
/* Loading of message assembly would be done here */

// Send the message assembly to the 'out' terminal of the HTTP Input node
mqInputNodeSpy.propagate(inputMessageAssembly, "out");

// Assert the Compute node is called and that the expected message is returned
assertThat(computeNodeSpy, nodeCallCountIs(1));
assertThat(computeNodeSpy, terminalPropagateCountIs("out", 1));

// Proof that the MQ Output node is not called
assertThat(mqOutputNodeSpy, nodeCallCountIs(0));

// Assert that the actual message assembly matches the expected message assembly
assertThat(actualMessageAssembly, equalsMessage(afterComputeExpectedMessageAssembly));
```

You could achieve a similar result by using the `setStopAtOutputTerminal()` method to stop propagation at the 'out' terminal of the Compute node.

Verifying exceptions

You can verify the details of an exception that was caught during propagation, by inspecting the generated test exception.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Testing a sequence of message flow nodes in a single test case” on page 1912

About this task

If a node in the sequence throws an exception that is not caught, it is returned to the caller of the `propagate()` or `evaluate()` method. Details of a root cause exception can be extracted from the exceptions nested in the **`TestException`**. If the flow catches an exception by using either a TryCatch node or a Catch terminal on a node in the sequence, the exception is processed as usual by the flow and is not returned as a test exception to the `propagate()` method.

The following example shows how the details of an exception generated by an MQGet node (when a queue does not exist) can be verified by inspecting the generated test exception:

```
// Define the Spy on the HTTP Input which is used to inject the message
SpyObjectReference httpInputReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("HTTP Input");
NodeSpy httpInputNodeSpy = new NodeSpy(httpInputReference);

// Define the Spy on the HTTP Reply which is used to verify the operation
SpyObjectReference httpReplyReference = new SpyObjectReference().application("ExamplesApp").
    messageFlow("Example1").node("HTTP Reply");
NodeSpy httpReplyNodeSpy = new NodeSpy(httpReplyReference);

// Declare a new TestMessageAssembly object for the message being sent into the node
TestMessageAssembly inputMessageAssembly = new TestMessageAssembly();

/*
 * Loading of message assembly would be done here
 */

// We expect that the failure thrown by the MQGet node is returned
TestException propagateEx = assertThrows(TestException.class, () -> {
    // Now call propagate on the "out" terminal of the HTTP Input node
    // Note: this approach works equally well with the evaluate method on an input terminal
    httpInputNodeSpy.propagate(inputMessageAssembly, "out");
});

// Verify that one exception in the exception chain has message number BIP266 and contains
// the queue name 'QUEUE1' and the reason 'Unable to open queue'
assertThat(propagateEx, causedBy(hasMessageNumber(2666),
                                 containsMessageText("Unable to open queue"),
                                 containsMessageText("QUEUE1")));
```

Replacing a message flow node with a NodeStub in a unit test

When you are testing a message flow that accesses external resources, you can use a NodeStub in place of calling the external resource.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Testing a sequence of message flow nodes in a single test case” on page 1912

About this task

You can test a message flow without accessing external resources by using a NodeStub trained to return a substitute message assembly instead of accessing the external resources. For example, your message flow might contain a subflow that carries out a database query before returning data back to the main flow. You can create a test case that propagates a message through the main flow, but stubs the behavior of the subflow node by using a NodeStub, so that the test case can be run on a system that does not have access to the database.

For example, a message flow accepts an HTTP input request message and then uses it to look up the price of an item by issuing a database query, before sending back the price details in the reply message:

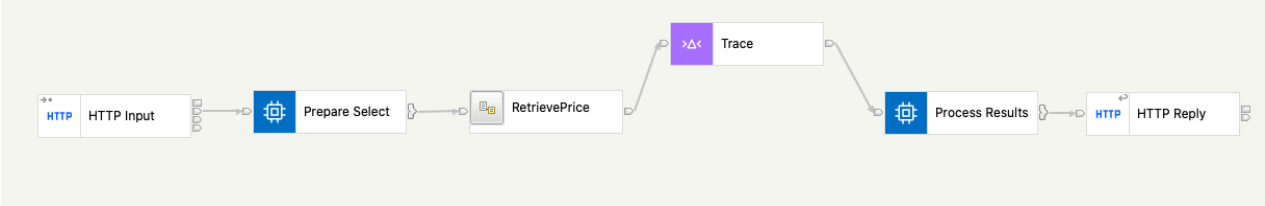

Figure 21. Message flow containing RetrievePrice Subflow

Procedure

Complete the following steps to develop a test case that propagates a message through the main message flow, but uses a NodeStub in place of the RetrievePrice subflow:

1. Define the message assembly that you would expect to be returned by the subflow after it successfully retrieves data from the database.

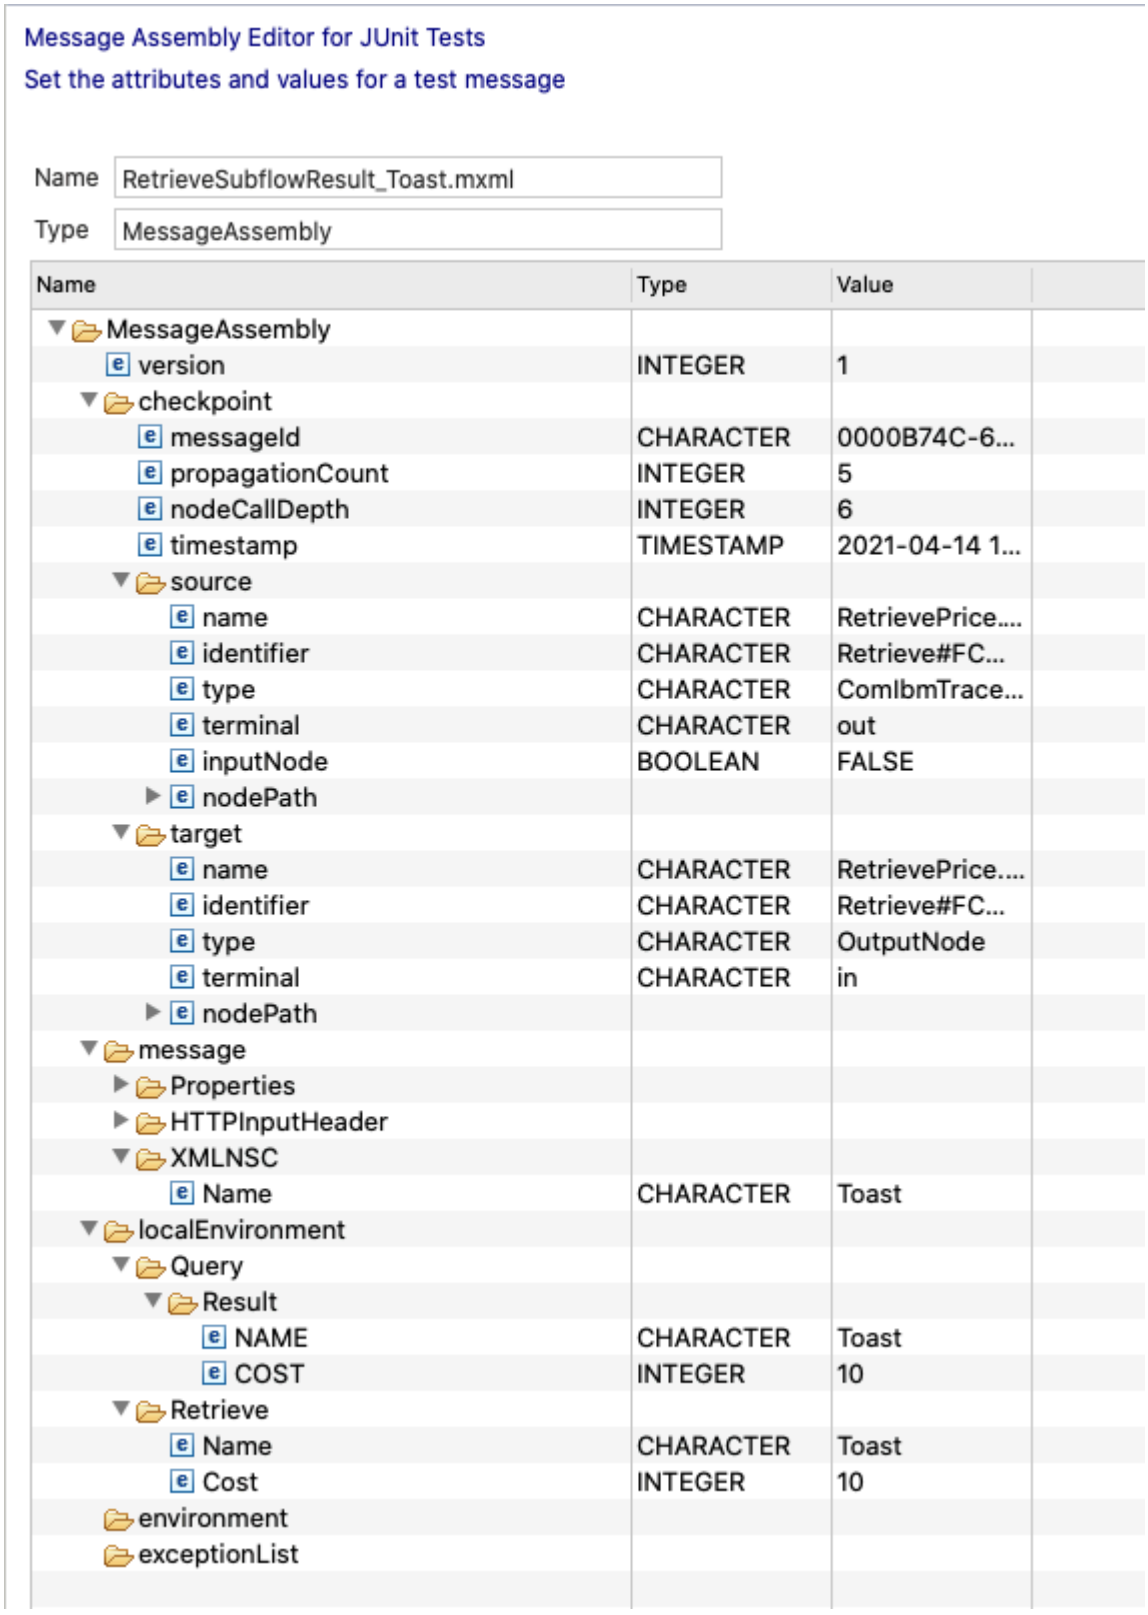

Figure 22. Retrieve subflow result message assembly

You can create the message assembly by recording the message, as described in "Configuring an integration server to record messages" on page 1908.

2. Use the `com.ibm.integration.test.v1.NodeStub` to replace the subflow node, specifying the **SpyObjectReference** object:

```
// Define the Stub on the Subflow, and configure it to return its recorded message
 SpyObjectReference subflowReference = new
 SpyObjectReference().application("AppTwo").messageFlow("Retrieve").node("RetrievePrice");
 NodeStub subflowStub = new NodeStub(subflowReference);
```

3. Use the recorded message assembly to construct a **TestMessageAssembly** object:

```
// Create a Message Assembly and load it with the recorded result for 'Toast'
 TestMessageAssembly subflowResultMessageAssembly = new TestMessageAssembly();
 try {
  String messageAssemblyPath = "/RetrieveSubflowResult_Toast.mxml";
  InputStream messageStream = Thread.currentThread().getContextClassLoader()
    .getResourceAsStream(messageAssemblyPath);
  if (messageStream == null) {
   throw new TestException("Unable to locate message assembly file: " + messageAssemblyPath);
  }
  subflowResultMessageAssembly.buildFromRecordedMessageAssembly(messageStream);
 } catch (Exception ex) {
  fail("Failed to load input message: " + ex.getMessage());
 }
```

4. Use the `com.ibm.integration.test.v1.TrainedBehaviour.propagatesMessage()` method to return the prerecorded message assembly instead of invoking the subflow:

```
// And program stub to return this dummy result instead of calling the subflow
subflowStub.onCall().propagatesMessage("Input", "Output", subflowResultMessageAssembly);
```

   The `propagatesMessage()` method is part of the `TrainedBehaviour` class. You can use this class to create an object that represents the action to be performed by a NodeStub when a message flow node is called.

5. Run the test case by propagating a message to the 'out' terminal of the HTTPInput node, using the propagate method for the NodeSpy on the HTTPInput node:

```
// Now call the flow by propagating the message from the HTTPInput out terminal
httpInputSpy.propagate(inputMessageAssembly, "out");
```

Results

The following complete method code propagates a message through a message flow and uses a NodeStub in place of the `RetrievePrice` subflow:

```
      @Test
public void AppTwo_Retrieve_RetrievePrice_TestCase_001() throws TestException {

 // Define the Spy on the HttpInput node we will use for calling tye flow
 SpyObjectReference httpInputReference = new
SpyObjectReference().application("AppTwo").messageFlow("Retrieve")
   .node("HTTP Input");
 NodeSpy httpInputSpy = new NodeSpy(httpInputReference);

 // Define the Spy on the Process Results compute node we will use for verifying the result
 SpyObjectReference resultsReference = new
SpyObjectReference().application("AppTwo").messageFlow("Retrieve")
   .node("Process Results");
 NodeSpy resultsSpy = new NodeSpy(resultsReference);

 // Declare a new TestMessageAssembly object for the message being sent into the node
 TestMessageAssembly inputMessageAssembly = new TestMessageAssembly();
 try {
  String messageAssemblyPath = "/HttpInput_Toast.mxml";
  InputStream messageStream = Thread.currentThread().getContextClassLoader()
    .getResourceAsStream(messageAssemblyPath);
  if (messageStream == null) {
   throw new TestException("Unable to locate message assembly file: " + messageAssemblyPath);
```

```
   }
   inputMessageAssembly.buildFromRecordedMessageAssembly(messageStream);
  } catch (Exception ex) {
   fail("Failed to load input message: " + ex.getMessage());
  }

  // Create a Message Assembly from the expected output mxml resource
  TestMessageAssembly expectedMessageAssembly = new TestMessageAssembly();
  try {
   String messageAssemblyPath = "/HttpReply_Toast.mxml";
   InputStream messageStream = Thread.currentThread().getContextClassLoader()
     .getResourceAsStream(messageAssemblyPath);
   if (messageStream == null) {
    throw new TestException("Unable to locate message assembly file: " + messageAssemblyPath);
   }
   expectedMessageAssembly.buildFromRecordedMessageAssembly(messageStream);
  } catch (Exception ex) {
   fail("Failed to load input message: " + ex.getMessage());
  }

  // Define the Stub on the Subflow, and configure it to return it's recorded message
  SpyObjectReference subflowReference = new
 SpyObjectReference().application("AppTwo").messageFlow("Retrieve").node("RetrievePrice");
  NodeStub subflowStub = new NodeStub(subflowReference);

  // Create a Message Assembly and load it with the recorded result for 'Toast'
  TestMessageAssembly subflowResultMessageAssembly = new TestMessageAssembly();
  try {
   String messageAssemblyPath = "/RetrieveSubflowResult_Toast.mxml";
   InputStream messageStream = Thread.currentThread().getContextClassLoader()
     .getResourceAsStream(messageAssemblyPath);
   if (messageStream == null) {
    throw new TestException("Unable to locate message assembly file: " + messageAssemblyPath);
   }
   subflowResultMessageAssembly.buildFromRecordedMessageAssembly(messageStream);
  } catch (Exception ex) {
   fail("Failed to load input message: " + ex.getMessage());
  }

  // And program stub to return this fake result instead of calling the subflow
  subflowStub.onCall().propagatesMessage("Input", "Output", subflowResultMessageAssembly);

  // Now call the flow by propagating the message from the HTTPInput out terminal
  httpInputSpy.propagate(inputMessageAssembly, "out");

  // Declare a new TestMessageAssembly object for the actual propagated message
  TestMessageAssembly actualMessageAssembly = resultsSpy.propagatedMessageAssembly("out", 1);

  // Assert that the actual message tree matches the expected message tree
  assertThat(actualMessageAssembly, equalsMessage(expectedMessageAssembly));

 }
```

Editing a message assembly

You can view, edit, and create message assemblies by using the IBM App Connect Enterprise Toolkit.

Before you begin

Read the following topics:

- “Integration testing overview” on page 1893
- “Developing integration tests” on page 1891

About this task

A message assembly is an object that is used to represent an instance of a message at a given point in time as it is being processed by a message flow, and the contents of the message assembly are accessed and modified by each message flow node as the message is processed. The message assembly contains four trees:

- Message tree
- Environment tree

- Local environment tree
- Exception list tree

The message headers and payload are under the message tree in the message assembly.

You can save a message assembly from the Flow Exerciser when you click on the wire connection in the 'blue-line' view. Alternatively, you can save all message assemblies by selecting the **Save All** button in the Flow Exerciser toolbar.

When you record messages that pass through a message flow, each recorded message is stored as a `.mxml` file, which is a serialized form of a message assembly. These `.mxml` files can then be used in your integration tests.

When you have created a test case from a recorded message, you can view or edit the generated `.mxml` files by using the Message Assembly Editor in the IBM App Connect Enterprise Toolkit. You can also create message assemblies through a test project in the Toolkit.

Procedure

You can view and edit a recorded message, or create a message assembly, by completing the steps in the following tasks:

- "Viewing recorded messages" on page 1922
- "Editing recorded messages" on page 1923
- "Creating a message assembly" on page 1926

For example message assemblies, see the following topics:

- "Example message assembly (XMLNSC)" on page 1929
- "Example message assembly (JSON)" on page 1931

Viewing recorded messages

You can view recorded messages by using the Flow Exerciser in the IBM App Connect Enterprise Toolkit.

Before you begin

Read the following topics:

- "Editing a message assembly" on page 1921
- "Developing integration tests" on page 1891

About this task

When the Flow Exerciser is in record mode, a blue line shows the path that a message has taken through a message flow. You can click on any wire connection to see a read-only view of the message assembly between two message flow nodes.

While you are viewing a message assembly, you can save it by clicking the **Save** button. The message assembly file name is generated automatically, but you can choose a different file name. The message assembly is saved in the application that contains the message flow that is being recorded in the Flow Exerciser. You can save message assemblies for all wire connections in the blue-line view, by clicking **Save All**. All message assemblies are then saved in the application.

Procedure

1. Select an input message to test your message flow with the Flow Exerciser, as described in "Testing your message flow by using the Flow Exerciser" on page 648.

   When a message has been sent through the message flow, a blue line indicates the path that was taken through the flow.

2. Click a highlighted connection to view the data that passed through it. A read-only view of the message assembly is displayed.

   If more than one message was sent through the message flow, or if a single message passed through a connection multiple times, you can see the message assembly for each message instance by selecting or clicking through the message numbers at the top of the view.
3. Click **Save** to save the message assembly in the application that contains the message flow.

   You can either accept the file name that is generated automatically, or specify a new file name.

   As an alternative to clicking each connection, you can save the message assembly for every wire connection that is highlighted by clicking **Save All**.

Editing recorded messages

You can edit recorded messages by using the Message Assembly Editor in the IBM App Connect Enterprise Toolkit.

Before you begin

Read the following topics:

- "Editing a message assembly" on page 1921
- "Developing integration tests" on page 1891

About this task

When you have saved a message assembly file, you can open it in the Message Assembly Editor and make changes to the elements in each of the four trees that it contains. You can edit entries in the **Name**, **Type**, and **Value** columns, and you can add new entries to each of the trees.

You can also add HTTP headers (`HTTPInputHeader`,`HTTPReplyHeader`, `HTTPRequestHeader`, and `HTTPResponseHeader`) and MQ headers (`MQMD`, `Dead Letter`, `MQRFH2`, and `MQRFH2C`). Each header has an initial set of values, which you can modify. You can use the Local Environment wizard to select parts of the local environment to add to your message assembly.

Procedure

1. To open a message assembly (`.mxml`) file in the Message Assembly Editor, either double-click the `.mxml` file or right-click the file and then click **Open with** > **Message Assembly Editor**.

   The message assembly is shown in the Message Assembly Editor.

2. In the Message Assembly Editor, you can open any of the trees in the message assembly and change the entries in the **Name**, **Type**, and **Value** columns.

   You can change an entry in the **Name** or **Value** column by clicking in the cell and modifying the entry that it contains. You can change an entry in the **Type** column by clicking a cell and selecting the required type from the drop-down list.

   Mixed content is not supported in a message assembly file; as a result, if an element has a type and value in the message body and you add a child element, the entries in the **Value** and **Type** columns are removed.

   You can select **Copy ESQL Path** or **Copy XPath** on an element. The path to the element is copied to the clipboard, and you can then paste it into the ESQL Compute Node Editor or the Java Compute Node Editor.

   You can remove whole sections from the message assembly by selecting the element and then clicking **Delete** in the context menu.

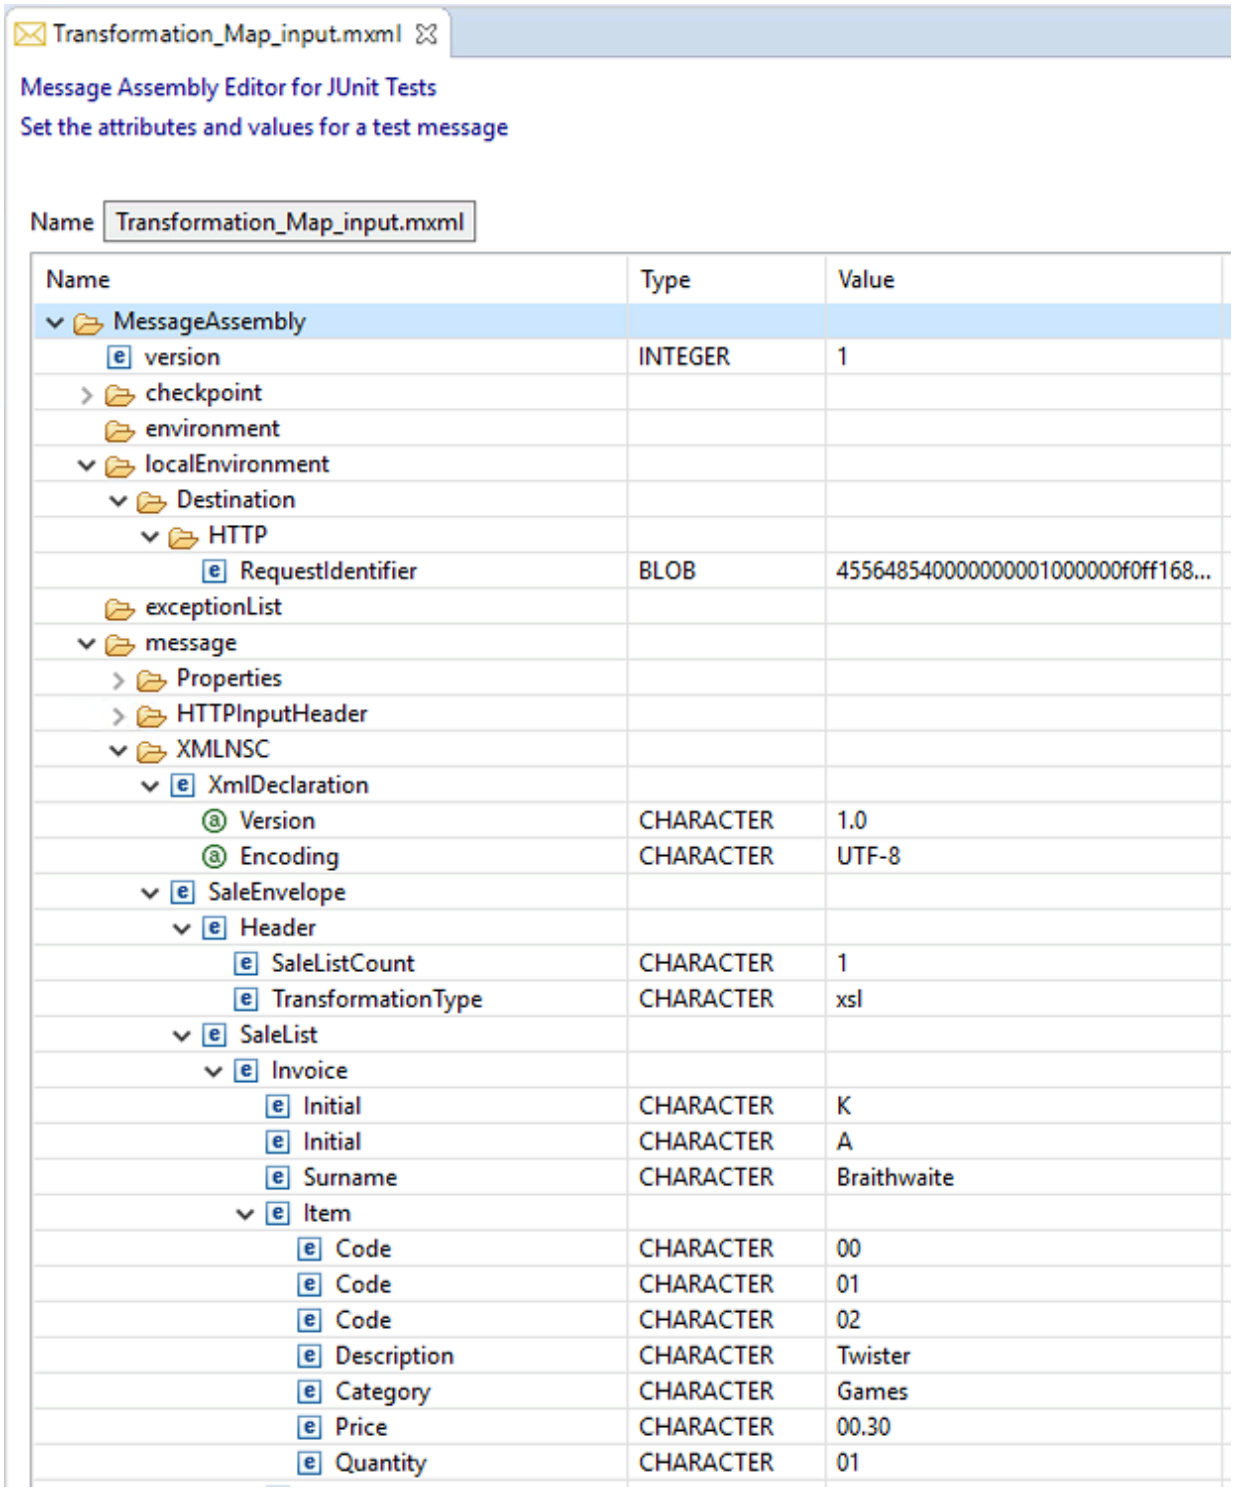

Figure 23. Message Assembly Editor for JUnit tests

3. When you have finished editing the message assembly, click **File** > **Save** to save the file.

   The Message Assembly is saved in the Application that contains the message flow, and the modified `.mxml` file is now available for use in your integration test case.

Creating a message assembly

You can create message assemblies by using the IBM App Connect Enterprise Toolkit.

Before you begin

Read the following topics:

- "Integration testing overview" on page 1893
- "Developing integration tests" on page 1891

About this task

A message assembly is an object that is used to represent an instance of a message at a given point in time as it is being processed by a message flow. The message assembly contains the message headers and payload (which can be XML, JSON, DFDL or BLOB data), together with the environment tree, the local environment tree, and the exception list tree. The contents of the message assembly are accessed and modified by each message flow node as the message is processed.

For examples of messages that were created by using the Message Assembly Editor, see the following topics:

- "Example message assembly (XMLNSC)" on page 1929
- "Example message assembly (JSON)" on page 1931

Video: Understanding a message assembly

This video demonstrates the capability to view and edit a message assembly.

Procedure

You can create a message assembly by completing the following steps:

1. In the Application Development view of the IBM App Connect Enterprise Toolkit, right-click the test project that will contain your message assembly, and then click **New** > **Message Assembly**.
2. In the **Create a message assembly** window, enter a name for your new message assembly and then click **Finish**.

   The Message Assembly Editor is displayed.

3. Right-click the `MessageAssembly` tag in the displayed table. A menu is displayed, which you can use to create each tree in the message assembly (Environment, Local Environment, Exception List, and Message):

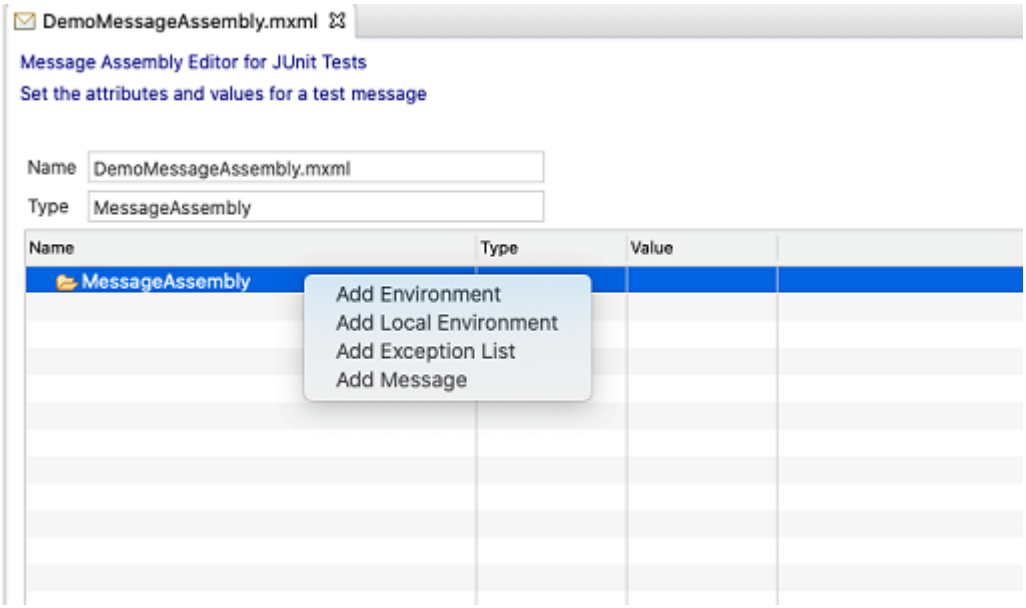

Figure 24. Message Assembly Editor context menu

4. Add an environment tree to the message assembly:
   a) Select **Add Environment** to add an environment tree. An `environment` tag is added to the message assembly.
   b) Add elements to the environment tree, by right-clicking the `environment` tag and then clicking **Add child** > **Element**.
   c) Add attributes to the element by right-clicking the element and then clicking **Add Attribute**.

5. Add the local environment tree to the message assembly:
   a) Right-click the `MessageAssembly` tag and click **Add Local Environment**.
      The **Create Local Environment Tree** window is displayed.
   b) Select the entries that you want to add to the local environment tree.
      You can expand the entries and select individual elements or folders.
   c) When you have finished adding entries to the local environment tree, click **Finish**.
      The local environment entries are shown in the Message Assembly Editor.

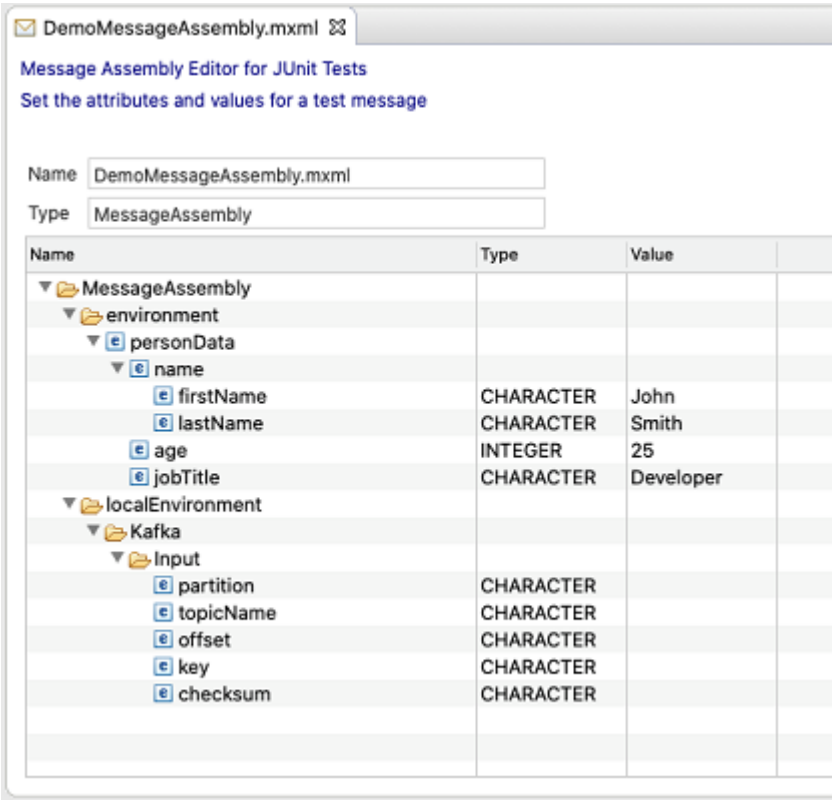

Figure 25. Environment and local environment trees in the Message Assembly Editor

      You can add further entries to the local environment tree by right-clicking the `localEnviroment` element and then clicking **Select and add elements**.
   d) Click **Finish**.
6. Add an exception list tree to the message assembly:
   a) Right-click the `MessageAssembly` tag and then click **Add Exception List**.
   b) To add entries to the exception list tree, right-click `exceptionList`, click **Add Exception List entry**, and then select the specific types of exception that you want to add to the tree.
      The entries are added to the exception list tree. You can also add nested exceptions and extra inserts.

7. Add the message tree to the message assembly:
   a) Right-click the `MessageAssembly` tag and then click **Add Message**.
      The **Create Message Tree** window is displayed.
   b) Select the transport protocol and message body parser for the message tree.
      - Choose one of the following transport protocols: `HTTP`, `SOAP`, `MQ`, `TCPIP`, `File`, or `Other`.

        If you select `HTTP`, an `HTTPInputHeader` is added automatically. If you select `MQ`, an `MQMD` is added automatically.

        The value for `ReplyProtocol` in the Properties tree is set based on the selected transport. For example, if you select `MQ`, the **`ReplyProtocol`** property is set to `MQ`.
      - Choose one of the following message body parsers: `XMLNSC`, `JSON (Object)`, `JSON (Array)`, `DFDL`, or `BLOB`.
      - Set values for the properties and headers that you require for your unit test.

        XMLNSC and DFDL message body parsers require a root element, which you can add by selecting them from the context menu. For XMLNSC, you can add elements and attributes. For DFDL, you can add elements but no attributes.

        For a JSON Object, you can add a child element that is a JSON Object or JSON Array. For a JSON Array, you can add a child element that is a JSON Array Item. For a JSON Array Item, you can add a child element that is a JSON Object or JSON Array.

        Elements that contain child elements do not have a type associated with them, but you can associate a type with each of the child elements. When you select a type, validation is performed and the type is set in the **`iib:valueType`** attribute.
   c) Click **Finish**.
      The properties tree and message domain element are added under the message.
   d) Add message headers by right-clicking the `message` element and then clicking either **Add HTTP Header** or **Add MQ Header**, and then selecting the type of header.
      - For `HTTP`, you can add one of the following headers: `Input`, `Reply`, `Request`, or `Response`.
      - For `MQ`, you can add one of the following headers: `MQMD`, `Dead Letter`, `MQRFH2`, or `MQRFH2C`.
8. Save your message assembly.

Example message assembly (XMLNSC)

You can create message assemblies by using the Message Assembly Editor in the IBM App Connect Enterprise Toolkit.

The following example shows an XMLNSC message that was constructed by using the Message Assembly Editor:

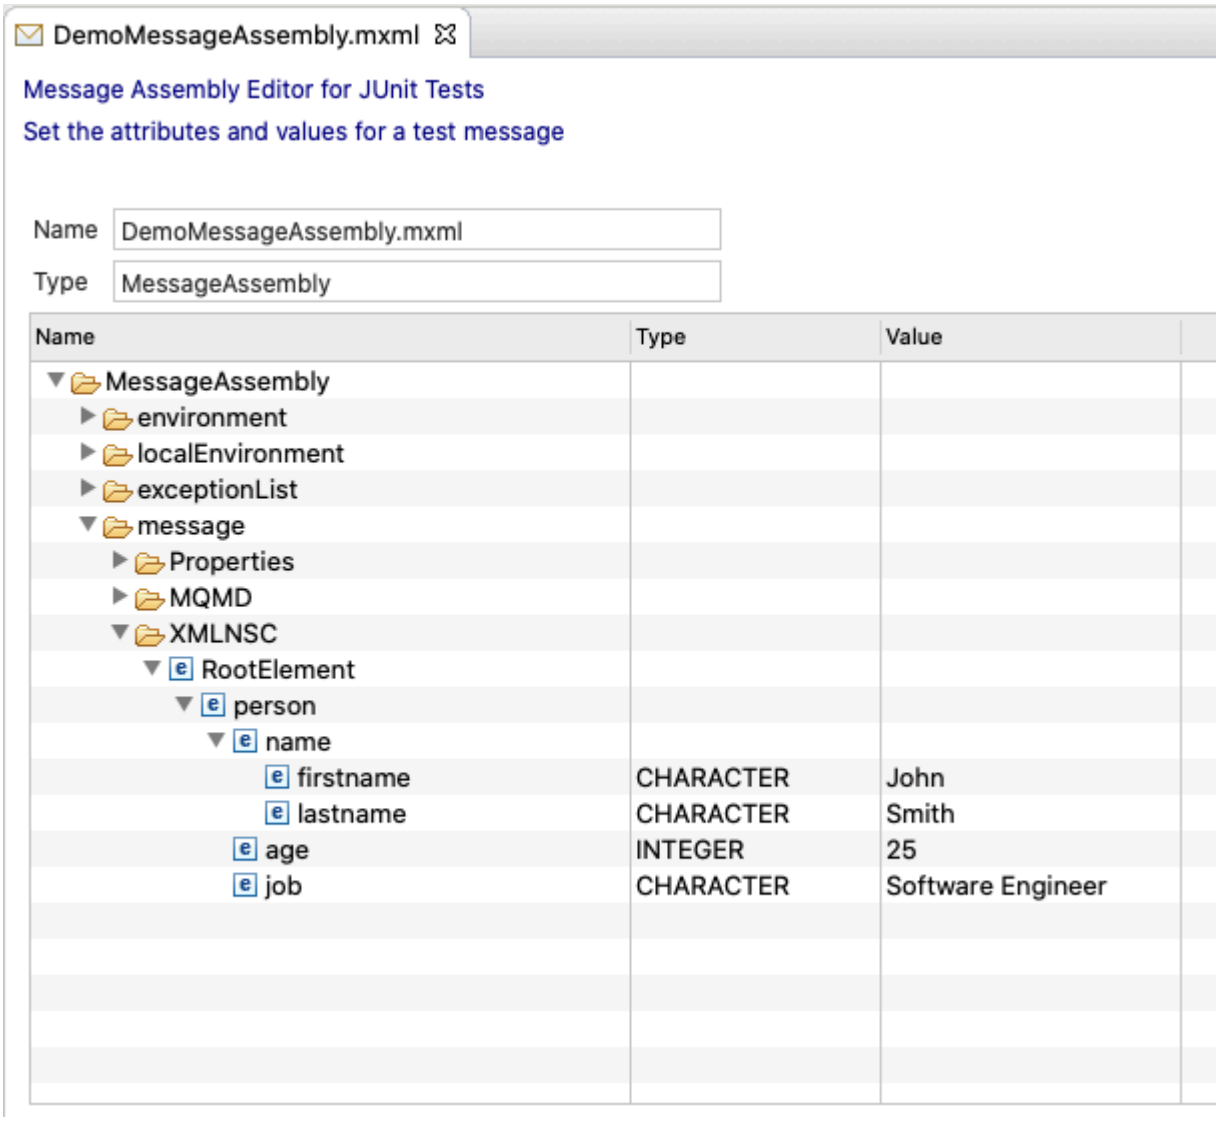

Figure 26. XMLNSC message constructed using the Message Assembly Editor

When this message was created in the Message Assembly Editor, the following entries were saved to the `.mxml` file under the XMLNSC element of the message tree:

```
<XMLNSC iib:parser="xmlnsc">
    <RootElement>
       <person>
          <name>
             <firstname iib:valueType="CHARACTER">John</firstname>
             <lastname iib:valueType="CHARACTER">Smith</lastname>
          </name>
          <age iib:valueType="INTEGER">25</age>
          <job iib:valueType="CHARACTER">Software Engineer</job>
       </person>
    </RootElement>
 </XMLNSC>
```

For information about how to create message assemblies by using the Message Assembly Editor, see "Creating a message assembly" on page 1926. For information about using message assemblies in unit tests, see "Developing integration tests" on page 1891.

Example message assembly (JSON)

You can create message assemblies by using the Message Assembly Editor in the IBM App Connect Enterprise Toolkit.

The following example shows a JSON message that was constructed by using the Message Assembly Editor:

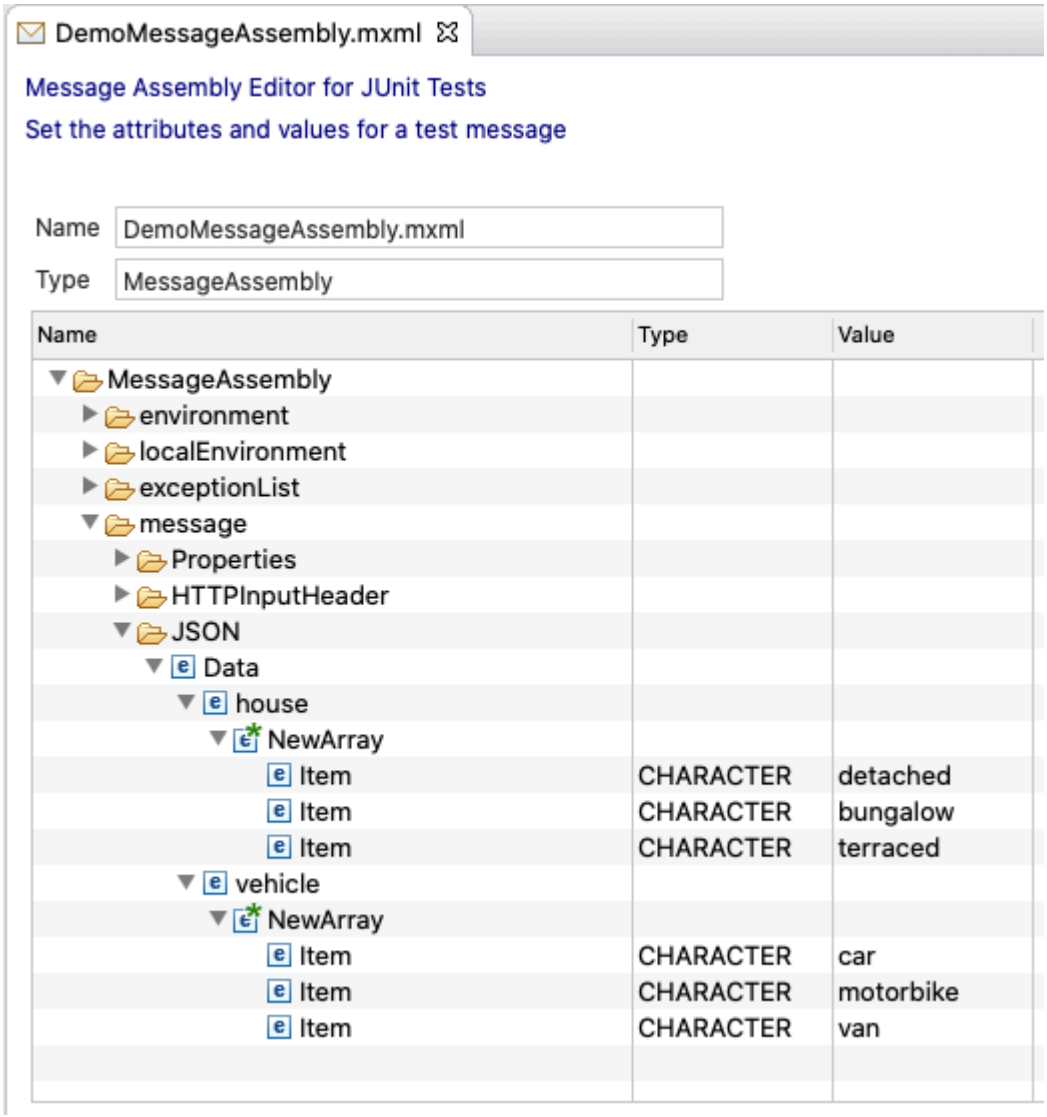

Figure 27. JSON message constructed using the Message Assembly Editor

When this message was created in the Message Assembly Editor, the following entries were saved to the `.mxml` file under the JSON element of the message tree:

```
<JSON iib:parser="json">
   <Data>
      <house>
         <NewArray iib:elementType="0x01001000">
            <Item iib:valueType="CHARACTER">detached</Item>
            <Item iib:valueType="CHARACTER">bungalow</Item>
            <Item iib:valueType="CHARACTER">terraced</Item>
         </NewArray>
      </house>
   <vehicle>
         <NewArray iib:elementType="0x01001000">
            <Item iib:valueType="CHARACTER">car</Item>
            <Item iib:valueType="CHARACTER">motorbike</Item>
            <Item iib:valueType="CHARACTER">van</Item>
         </NewArray>
```

```
            </vehicle>
         </Data>
      </JSON>
```

For information about how to create message assemblies by using the Message Assembly Editor, see “Creating a message assembly” on page 1926. For information about using message assemblies in unit tests, see “Developing integration tests” on page 1891.

Running integration tests

You can run integration tests by using the IBM App Connect Enterprise Toolkit or the command line.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Integration testing overview” on page 1893

About this task

Test projects are the top-level artifacts in App Connect Enterprise that contain your test cases. All the test cases for an application are stored in a test project, with the following structure:

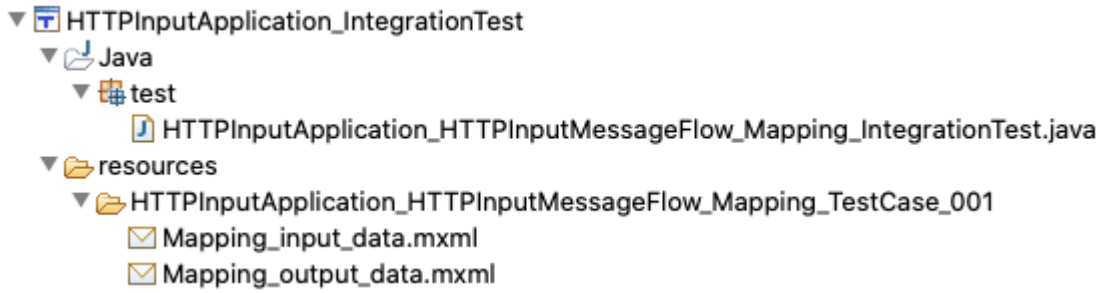

Figure 28. Test project structure

The test cases are methods in a Java Class that can use resources in the test project. The resources are in a folder called `resources`, under the test project. The test project contains a reference to the application that is under test, and you run the test project in order to run the tests that it contains.

Procedure

To run your integration tests, complete the steps in one of the following topics:

- “Running tests in the IBM App Connect Enterprise Toolkit” on page 1933
- “Running tests by using the command line” on page 1932

Optionally, you can configure a specific integration server to run the tests, and you can add an existing test project to a BAR file to deploy and run it, by following the steps in the following topics:

- “Configuring an integration server to run the test case” on page 1935
- “Adding a test project to a BAR file” on page 1936

Running tests by using the command line

You can run tests in a test project by using the command line.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Running integration tests” on page 1932

About this task

You can run tests in a test project by using the **IntegrationServer** command to start the integration server, specifying the name of the integration test project with the **--test-project** parameter. For example:

```
IntegrationServer –work-dir /tmp/work-dir --test-project MyIntegrationTestProject --start-
msgflows false
```

where the **--work-dir** parameter specifies the work directory of the integration server that will run the tests, and the **--test-project** specifies the name of the test project to be run. The *false* value on the **--start-msgflows** parameter prevents the deployed message flows from starting and accepting requests through their input nodes, but still allows the tests to run.

In addition to the parameters used in the example, the following optional flags can be used when running test projects in a pipeline, to speed up test operation:

- Use the **--admin-rest-api -1** parameter to disable the REST admin listener
- Use the **--no-nodejs** parameter to disable Node.js
- Use the **--stop-after-duration <seconds>** parameter to configure a maximum timeout in seconds, after which the integration server will terminate if the tests have not completed

Video: Generate and run tests from the command line

This video demonstrates how to generate and run tests from the command line.

Running tests in the IBM App Connect Enterprise Toolkit

You can run the unit tests from the IBM App Connect Enterprise Toolkit by running the test project.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Running integration tests” on page 1932

About this task

You can run unit tests by running their test project in the IBM App Connect Enterprise Toolkit.

Procedure

1. In the Application Development view of the IBM App Connect Enterprise Toolkit, right-click the test project and then click **Run test project**:

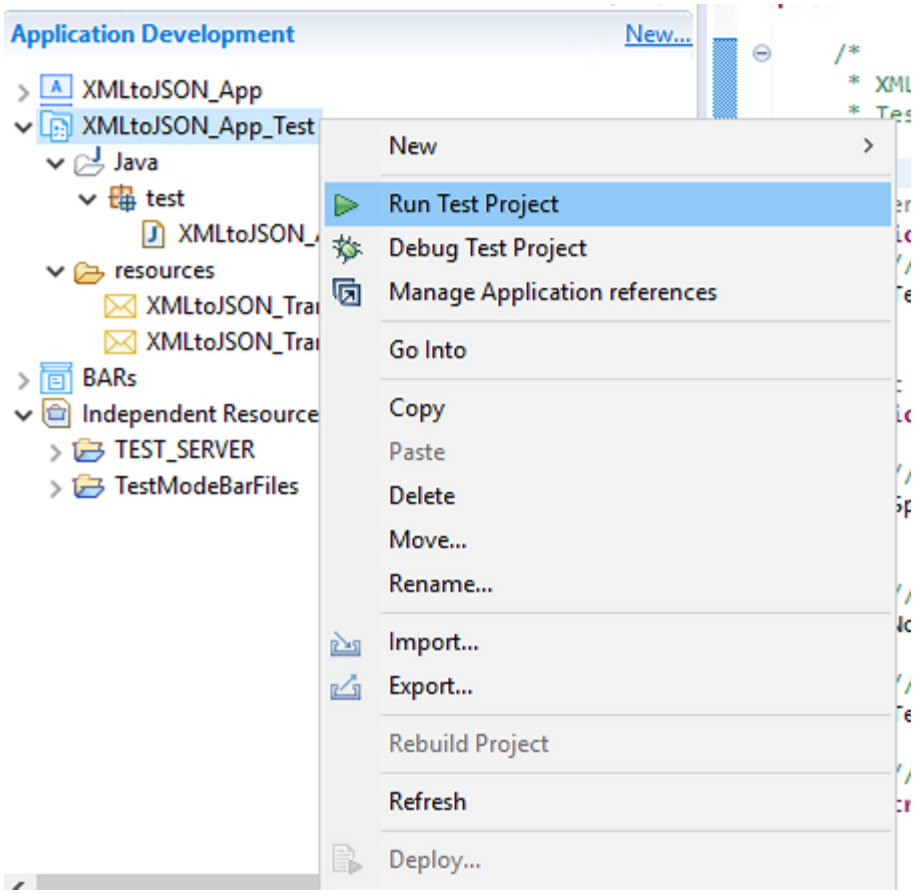

Figure 29. Running a test project in the Toolkit.

2. When the test project is run, a BAR file is generated. This BAR file is automatically deployed to an integration server, which starts with the **`--test-project`** argument. The BAR file automatically includes any applications that are referenced by the test project.

   By default, the tests are run on a temporary integration server, but you can configure an alternative integration server by following the steps in "Configuring an integration server to run the test case" on page 1935.

   The BAR file that is generated is stored in the `GeneratedBarFiles` folder. For example: `/GeneratedBarFiles/MyApplication_IntegrationTestproject.generated.bar`

3. You can view the test results by switching to the JUnit view in the Toolkit. The test results are displayed in the JUnit results panel.

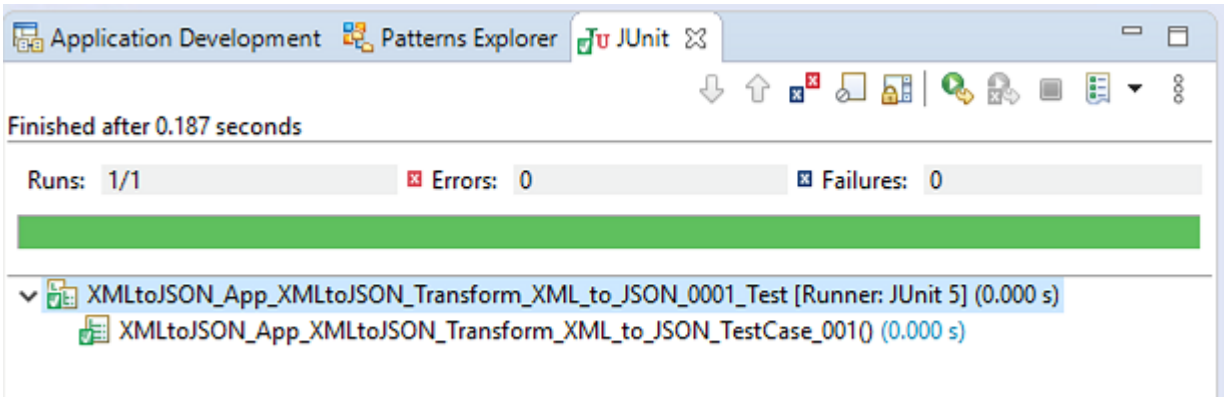

Figure 30. Unit test results in the JUnit view.

4. You can see the output from the integration server console by switching to the Console view.

Figure 31. Integration server output in the Console view.

Configuring an integration server to run the test case

By default, tests are run on a temporary integration server, but you can configure an alternative integration server to run them.

Before you begin

Read the following topics:

- "Developing integration tests" on page 1891
- "Running integration tests" on page 1932

About this task

When you run a test project, a launch configuration is created automatically. You can then change the configuration that is used to run the tests, including the integration server that runs them, by editing this launch configuration.

Procedure

1. To edit the launch configuration, select **Run configurations** from the **Run** menu in the Toolkit.
   The **Create, manage, and run configurations** window is displayed.

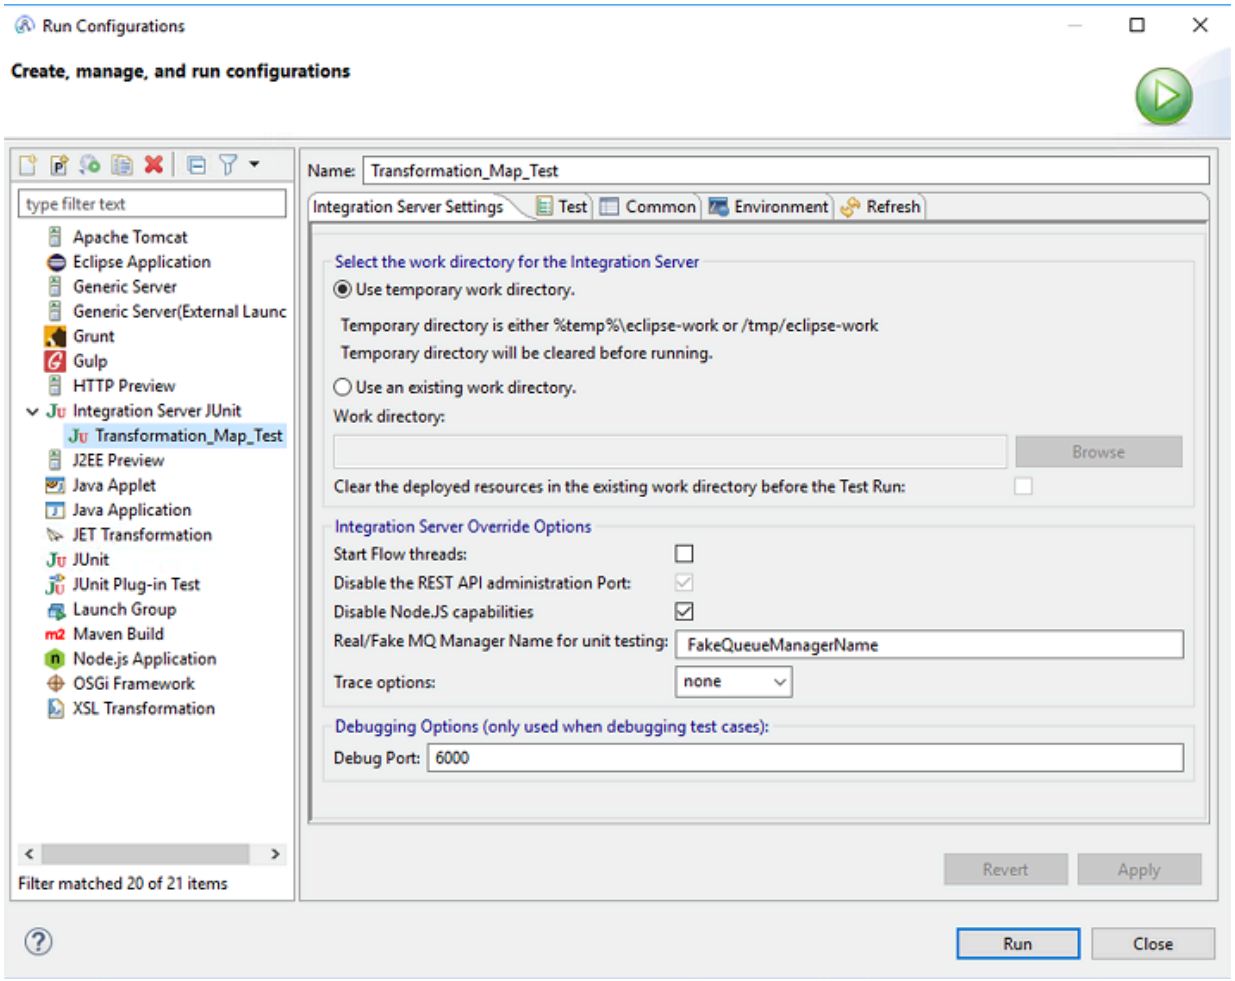

Figure 32. Create, manage, and run configurations window

2. Specify the name of the test project in the **Name** field.
3. Choose an integration server to run the test case, by specifying the location of its work directory in the **Integration Server Settings** tab.

   You can also choose to start flow threads, specify a debug port, and run a service trace or diagnostic trace while running the test case.
4. Click **Run** to launch the tests on the specified integration server.

Adding a test project to a BAR file

You can add a test project to an existing BAR file by using the BAR file editor.

Before you begin

Read the following topics:

- “Developing integration tests” on page 1891
- “Running integration tests” on page 1932

About this task

To add a test project to an existing BAR file, complete the following steps:

Procedure

1. Open the BAR file in the BAR file editor, and then select **Applications, shared libraries, services, REST APIs, and Test Projects**.
2. Select **Test Projects** from the list of deployable resources to include in the BAR file.

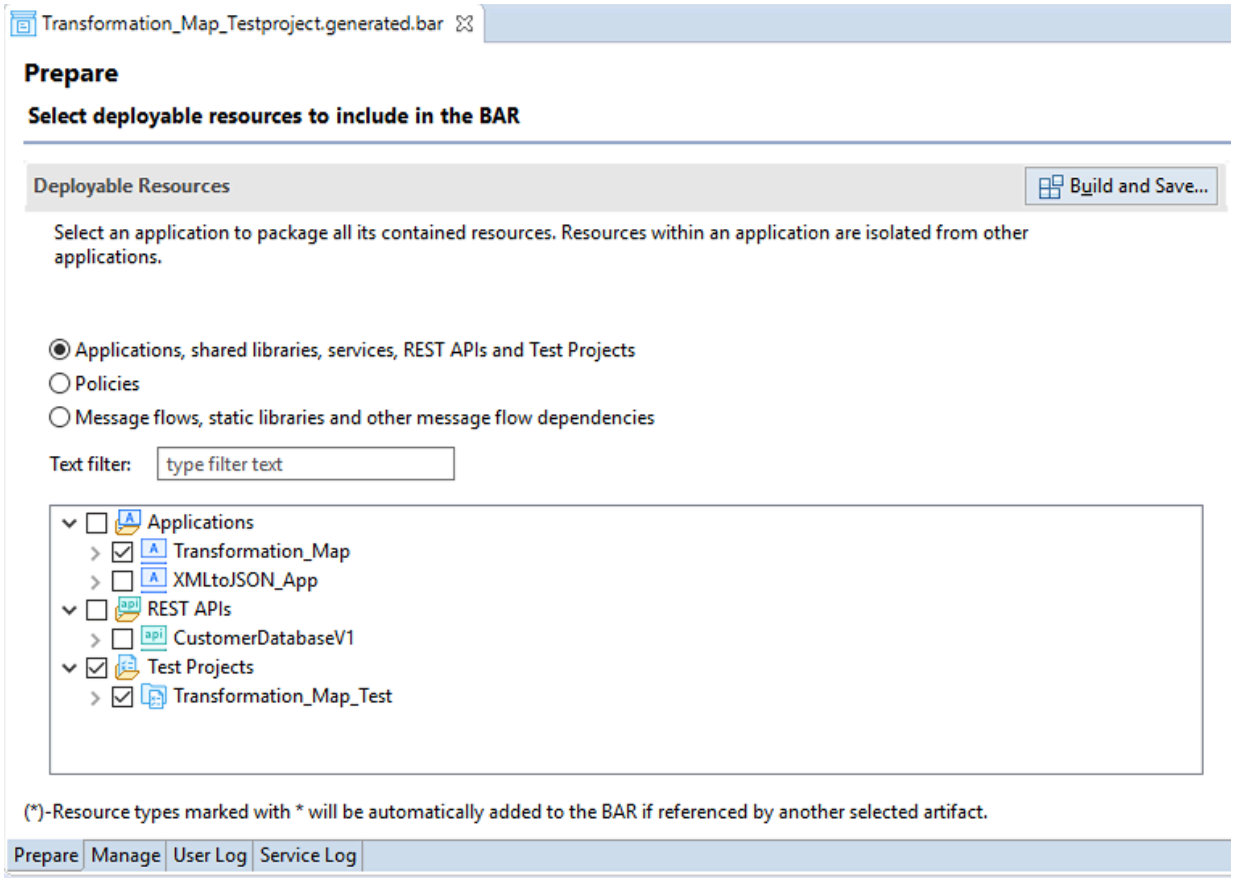

Figure 33. Add test project to BAR file

3. If you are creating a new BAR file that contains a test project, ensure that you also add the application that is being tested, so that the test project and the application can be extracted to the `run` directory of the integration server's work directory.

   The **Manage** tab shows the test project and the application under test:

   Figure 34. Manage tab showing the test project and application to be tested

4. When the test project is run, the Java class containing the test case is compiled. The `.jar` file that contains the built classes is added in the BAR file under the test project. The resources that are used by the test cases are also added to the test project.

Example message flow node tests

You can create unit tests for message flow nodes by using the IBM App Connect Enterprise Toolkit.

Before you begin

Read the following topics:

- "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894
- "Integration testing overview" on page 1893

About this task

To test a message flow node, you must create a message assembly with which to invoke the node, and then examine the contents of the message assembly to check whether the operation of the message flow node was successful. For more information about message assemblies, see "Editing a message assembly" on page 1921.

You can create a unit test for a message flow node by following the instructions in "Developing integration tests by using the IBM App Connect Enterprise Toolkit" on page 1894.

Procedure

The following examples show segments of code generated by the Create Test Case wizard:

- **Creating a message assembly from a recorded message**

  The following code segment loads a `.mxml` file from the resource directory associated with the test project. The `.mxml` file contains the message body as well as property headers, the environment tree, the local environment tree, and the exception list tree.

```
// Declare a new TestMessageAssembly object
TestMessageAssembly messageAssembly = new TestMessageAssembly();
try {
 String msgPath = "/HTTP-Input_0000CE13-600ED4AE-00000001-0.mxml";
 InputStream messageStream =

Thread.currentThread().getContextClassLoader().getResourceAsStream(msgPath);
 if (messageStream == null) {
 throw new TestException("Unable to locate message assembly file:"+msgPath);
 }
 messageAssembly.buildFromRecordedMessageAssembly(messageStream);
}
catch (Exception ex) {
 fail("Failed to load input message: " + ex.getMessage());
}
```

- **Creating a message assembly from a JSON string**

  The following code segment generates a message assembly that contains a JSON message tree for the message body, together with a default Properties folder. The environment, local environment and exception list trees are empty.

```
// Declare a new TestMessageAssembly object
String sJSON = “{ \”name\”: { \”first\”: \”John\”, \”last\”: \”Doe\” } }”;
TestMessageAssembly messageAssembly = new TestMessageAssembly();
inputMessageAssembly.buildMessageBodyFromJSON(sJSON);
```

- **Creating a message assembly from an XML string**

  The following code segment generates a message assembly that contains a JSON message tree for the message body, together with a default Properties folder. The environment, local environment and exception list trees are empty.

```
// Declare a new TestMessageAssembly object
String sXML = “<name><first>John</first><last>Doe</last></name>”
TestMessageAssembly messageAssembly = new TestMessageAssembly();
inputMessageAssembly.buildMessageBodyFromXML(sXML);
```

- **Invoking a message flow node by using a message assembly**

  If you have already created a message assembly, either by loading a recorded message or by building it directly, you can invoke a message flow node with the message assembly. The **SpyObjectReference** object is used to build a path to the message flow node to be tested. The application and the message flow that contains the message flow node to be tested must be deployed to the integration server alongside the test project.

```
// Locate the message flow node to be tested
SpyObjectReference nodeReference = new SpyObjectReference()
 .application("ApplicationOne").
 .messageFlow("FlowOne")
 .node("My Compute Node");
// Create a spy on the message flow node to be tested
NodeSpy nodeSpy = new NodeSpy(nodeReference);
// Invoke the message flow node with the message assembly prepared earlier
nodeSpy.invoke(inputMessageAssembly);
```

- **Extracting the output message assembly from a message flow node**

  After a message flow node has been invoked, in order to verify that it operated correctly you must extract the output message assembly from the node spy.

```
// Assert the terminal propagate count for the message
assertThat(nodeSpy, terminalPropagateCountIs("out", 1));
assertThat(nodeSpy, terminalPropagateCountIs("failure", 1));
// Retrieve the outupt message from the Node spy
TestMessageAssembly actualMessage = nodeSpy.propagatedMessageAssembly("out",
```

```
1);
```

The first parameter is the terminal from which to retrieve the output message, and the second parameter is the message number. When a message flow node is invoked, more than one output message assembly can be generated, which means that your test must check all terminals for the expected number of messages as well as the message content. Note that the terminal names are the names that are defined internally and typically start with a lower-case letter, rather than the terminal names that are displayed in the Toolkit, which typically start with an upper-case letter.

- **Comparing the output message using the App Connect Enterprise Test Message Assembly matcher**

  The App Connect Enterprise Test Message Assembly matcher compares two message assemblies and reports details on the first difference it detects. The most common use of this matcher is to compare against an expected message assembly that has been loaded from a previously recorded message.

```
// Assert that the actual message assembly matches the expected message assembly
assertThat(actualMessageAssembly, equalsMessage(expectedMessageAssembly));
```

  Comparing the entire content of a message can reduce the stability of a test, in which an apparently insignificant change in message content can cause the test to fail. You can use the **`ignoreTimeStamps`** method in the matcher to make a test more robust against expected or insignificant parts of the message tree:

```
// Assert that the actual message assembly matches the expected message assembly
assertThat(actualMessageAssembly,
 equalsMessage(expectedMessageAssembly).ignoreTimeStamps());
```

- **Comparing the output message using alternative Hamcrest matchers**

  In addition to using the JSON Unit and XMLUnit Hamcrest matchers that are provided with App Connect Enterprise, you can use third-party matchers.

```
// Retrieve a JSON string representation of the Message body
String expectedJSON = “{ \”name\”: { \”first\”: \”John\”, \”last\”: \”Doe\” } }”;
String actualJSON = messageAssembly.getMessageBodyAsJSON();
assertThatJson(expectedJSON, jsonEquals(actualJSON));
```

- **Using Test Exception matchers**

  The **`TestException`** class is used to report exceptions in the integration test framework, including the following types of failure:

  – Operational test failures such as trying to locate a message flow node in an application that has not been deployed

  – Execution test failures in which a message flow node is invoked with a message and the message flow node has thrown an exception and neither the failure or catch terminals are attached

  Test exceptions can form a chain, so when a test exception is checked it might be necessary to navigate the chain of exceptions in order to locate the root cause. App Connect Enterprise provides a number of Hamcrest matchers to validate test exceptions.

```
try {
 // Invoke the message flow node with the message assembly prepared earlier
 nodeSpy.invoke(inputMessageAssembly);
}
catch (TestException te) {
 // Verify the top level exception is message number BIP3687
 asserThat(te, hasMessageNumber(3687));
 // Verify the root exception contains the message text “Parser failure”
 assertThat(te.getRootCause(), containsMessageText("Parser failure")));
 // Verify that an exception somewhere in the exception chain contains
 // message number BIP2112 and the message text contains the work ‘Broken’
 assertThat(te, causedBy(hasMessageNumber(2112),
containsMessageText("Broken")));
}
```

Developing integration solutions from scratch

To integrate client applications that use different protocols and message formats, create integration solutions by using applications, libraries, and integration projects.

Before you begin

If you are not familiar with message flow concepts, message model concepts, and common tasks to manage message flow resources, see “Developing message flows” on page 482 and “Constructing message models” on page 2133.

About this task

In IBM App Connect Enterprise, you have different ways in which you can create an application:

- Create an application from scratch. For more information, see “Creating an application” on page 1963.
- Create an application by using patterns. For more information, see “Developing integration solutions by using patterns” on page 2056.
- Create an application that is based on a REST API Swagger document. For more information, see “Developing integration solutions by using REST APIs” on page 2011.
- Create an application that is based on WSDL and XSD files. For more information, see “Creating a solution based on WSDL or XSD files” on page 1967.
- Create an application that is based on an existing message set. For more information, see “Creating a solution based on an existing message set” on page 1968.

If you are not ready to create an application or library yet, you can use an integration project to hold resources in the meantime. When you are ready, you can either create an application or library and move the resources from the integration project, or you can convert your integration project to an application or library. To convert an integration project to an application or library, see “Converting existing projects to applications and libraries” on page 1970.

Procedure

For example, to create an application from scratch:

1. Create an application. An application is the container for resources that are required to develop your solution.
2. Optional: Create a library to contain a logical grouping of related code, schemas, message models, and other resources that can be reused. For more information, see “Creating a library” on page 1964.
3. Optional: Define the required library references in the application, as described in “Referencing resources in other libraries” on page 1976. To include one or more libraries of resources in your application, you create references to those libraries.
4. Create one or more message flows in your application to process your business data. For more information, see “Defining message flow content” on page 614, “Designing a message flow” on page 583, and “Creating a message flow” on page 574.
5. Use the default broker schema that is created when you create the message flow. Alternatively, create another broker schema. For more information, see “Creating a broker schema” on page 1966.
6. Create other resources that you need in the application and library. For more information, see “Creating resources in an application” on page 1964 and “Creating resources in a library” on page 1965.

What to do next

After you create your application, deploy and test the application. For more information, see How do I deploy and test ?.

Resource management overview

IBM App Connect Enterprise provides several types of container project that you can use to organize your message flow development resources.

When you develop message flows in the IBM App Connect Enterprise Toolkit, you can choose the type of container project, depending on your development style.

- An *application* is a container for the resources that are required to create a solution, and that should be deployed and managed together. Applications provide encapsulation, and resources within an application are packaged and deployed as a single unit, and can be managed as a single unit. For more information, see “Applications” on page 1943.
- A *service* is a special type of application that has a defined interface and implementation. Services provide assisted development to provide web services in an integration node. Like applications, services provide encapsulation and are deployed and managed as a single unit. For more information, see “Integration services” on page 1944.
- In IBM App Connect Enterprise, a *REST API* is a specialized application that can be used to expose integrations as a RESTful web service that can be called by HTTP clients. For more information, see “REST APIs” on page 2013.
- A *library* is a logical grouping of related code, data, or both. A library typically contains reusable helper routines and resources such as subflows, ESQL modules, message definitions, maps, and Java utilities. A library is useful to group resources of the same type or function, for reuse or ease of management. A library is also packaged and deployed as a single unit. You can use shared libraries and static libraries. A shared library can be used by applications. A static library can be used by applications or by independent message flows.

  If you use a static library to contain resources, each application that references that static library is deployed with its own private copy of that library. If a static library is updated, each application that references it must be redeployed with the updated static library. A shared library is deployed directly to an integration server. Any application can reference the resources in that deployed shared library. If that shared library is updated, the changes are immediately visible to all referencing applications. For more information, see “Libraries” on page 1945.
- An integration project is an unstructured container in which you can develop message flows and related resources. When resources from an integration project are packaged for deployment, you can choose exactly which resources should be packaged together. Integration projects cannot contain message models. For more information, see “Integration projects” on page 1959.

Containers in the Application Development view

Applications, integration services, REST APIs, libraries, and integration projects are shown in the Application Development view. Resources that are contained in an application, integration service, REST API, or library are also shown, whether the container refers to them directly or indirectly.

Message flow projects were replaced by integration projects in WebSphere Message Broker Version 8.0 (previously called Message Broker projects).

Applications, integration services, REST APIs, libraries, integration projects, and other types of project are represented by the following icons.

Icon	Description
	Application
	Integration service
	REST API
	Shared library

Icon	Description
	Static library
	Integration project
	Java project
	Message set project

Applications and libraries that have been deployed to an integration server are displayed directly beneath the integration server in the IBM App Connect Enterprise Toolkit and the web user interface. You can also view deployed applications and libraries by using the IBM Integration API or the **mqsilist** command.

Libraries that are referenced by applications are displayed beneath the application. Shared libraries are contained in the Referenced Libraries folder, and static libraries are contained in the Included Libraries folder.

You can also specify how an application or message flow is started after it is deployed, or after the integration node, integration server, or containing application is restarted. You can choose to start an application or flow manually, or for it to be started automatically. You can also choose to maintain the existing state of an application or library.

If you focus on a library or application, the Application Development view shows only that library or application. When you are viewing projects, you can also filter resources by using working sets.

For more information about applications, libraries, and integration projects, see the following topics:

- "Benefits of using applications and libraries" on page 1959
- "Runtime isolation and resource sharing with applications and libraries" on page 1960
- "Naming conventions in applications and libraries" on page 1962

For detailed instructions about how to manage your resources by using applications and libraries, see "Managing message flow resources" on page 572.

Applications

An *application* is a container for all the resources that are required to create a solution. An application can contain IBM App Connect Enterprise resources, such as flows, message definitions, libraries, and JAR files.

At design time, you define references to the following items:

- Zero or more message flow dependencies (such as a Java project or message set).
- Zero or more libraries that contain reusable resources.

You use applications to group all the resources that are required to deliver an integration solution, enabling easier development and management. If you are developing resources for multiple integration solutions in the IBM App Connect Enterprise Toolkit, then consider grouping your resources into applications. The use of a shared or static library helps organization by grouping reusable resources together. A shared library can also be used by other applications, services, shared libraries, or integration projects.

Applications typically contain message flows. If the message flow requires only one or two additional resources, such as one schema file and one ESQL file, consider storing all resources at the application level. But when you require multiple resources for your solution, or resources that might be shared with other solutions, consider putting the resources that your message flow requires into a shared library. That shared library can then be referenced by the application.

Applications provide runtime isolation whereby resources inside the application are not visible to other resources, such as message flows, libraries, or other applications that are running outside the application. Consider using applications if you need to ensure that updates to one group of deployed resources do not

affect another group. For example, use an application when you want to control which flows pick up the latest version of an ESQL module. For examples of how to use applications to achieve runtime isolation, see “Runtime isolation and resource sharing with applications and libraries” on page 1960.

Viewing applications

Applications are shown in the Application Development view. Resources that are contained in an application are also shown, whether an application refers to them directly or indirectly.

Applications are represented by the application icon  .

Applications that have been deployed to an integration server are displayed directly beneath the integration server in the IBM App Connect Enterprise Toolkit and the web user interface. Libraries that are referenced by applications are displayed directly beneath the application. Shared libraries are contained in a Referenced Libraries folder, and static libraries are contained in an Included Libraries folder. You can also view deployed applications by using theIBM Integration API or the **mqsilist** command; for example:

```
mqsilist integrationNodeName -e integrationServerName -k applicationName
```

This command specifies whether the application is running, and on which integration server. You can also see the deployed objects that are contained in that application, and a list of shared libraries that are referenced by the application.

You can also specify how an application or message flow is started after it is deployed, or after the integration node, integration server, or containing application is restarted. You can choose to start an application or flow manually, or for it to be started automatically. You can also choose to maintain the existing state of an application or library. You can also use the **mqsiapplybaroverride** command, as described in “Setting the start mode of message flows and applications at run time” on page 316.

If you focus on an application, the Application Development view shows only that application. When viewing projects, you can also filter resources by using working sets.

For more information about applications, see the following topics:

- “Benefits of using applications and libraries” on page 1959
- “Runtime isolation and resource sharing with applications and libraries” on page 1960
- “Naming conventions in applications and libraries” on page 1962

For detailed instructions about how to manage your resources by using applications, see “Managing message flow resources” on page 572.

Integration services

An integration service is a specialized application with a defined interface and structure that acts as a container for a web services solution.

You can integrate applications by using a service-oriented architecture (SOA). In an SOA, a service is often defined as a logical representation of a repeatable activity that has a specified outcome. Typically, a service is self-contained and its implementation is hidden from its consumers. To facilitate their reuse, services define a prescribed interface, which specifies how data is exchanged with the service.

In IBM App Connect Enterprise, an integration service is a specialized application with a defined interface that acts as a container for a web services solution:

- It contains message flows to implement the specified web service operations.
- The interface is defined through a WSDL file.

Like an application, an integration service can reference resources in shared libraries. The shared library is deployed before or with the integration service. If you update the resources in the shared library and redploy it, those changes are immediately available to the deployed integration service.

When you implement an integration service, you can deploy it to an integration server. You can start and stop the deployed service as you would an application. A web service consumer can interrogate the deployed service to return its interface.

Interfaces

An *interface* consists of one or more operations and a binding style.

An *operation* is a description of an action that is implemented by the service. Each operation can have either of the following types:

- *Request-response* type operations mean that a request is sent and a response returned to the interface.
- *One-way* type operations mean that only a request is sent, and no response is needed.

Each operation in the interface defines the data that can be passed in the form of inputs to and outputs from the component when the operation is called. A one-way operation has only an input. A request-response operation has both an input and output. Each operation can have one or more faults defined to handle error conditions.

The *binding style* specifies the protocol and data format of the operation.

Integration service API

You can generate a JavaScript client API from an existing integration service. The JavaScript client API provides operation functions that you can call from a program that is running in a JavaScript environment.

Libraries

A *library* is a logical grouping of related code, data, or both. A library typically contains reusable helper routines and resources such as subflows, ESQL modules, message definitions, maps, and Java utilities. You can use a library to group resources of the same type or function, and to aid the management and reuse of such resources

Consider using libraries for the following functions:

- To group common types of resource (such as all your ESQL routines)
- To group resources by function (such as all your error-handling routines)
- To share routines and definitions across multiple teams or projects
- To use different versions of a coherent set of routines and definitions

Two types of library exist in IBM App Connect Enterprise: *shared libraries* and *static libraries*.

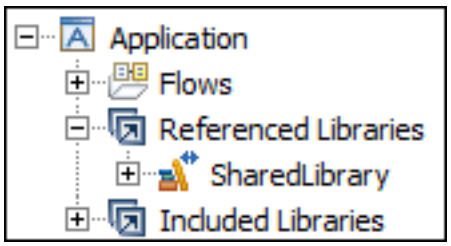
Consider a scenario when you want to develop a set of common resources and make them available to multiple applications.

Shared libraries
: If you want to deploy and manage just one copy of those common resources, use a shared library. A shared library can be deployed directly to an integration server. Any application can reference the resources in that deployed shared library. If that shared library is updated, the changes are immediately visible to all referencing applications.

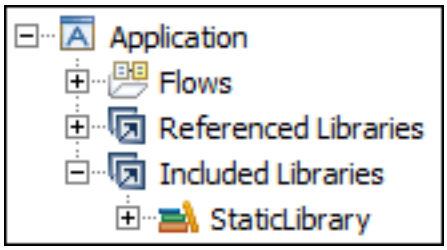
Static libraries
: If you want each application to use a different version of the contained resource, use a static library. Each application that references that static library is deployed with its own private copy of that library. If a static library is updated, each application that references it must be repackaged and redeployed with the updated static library.

Static libraries are represented by the static library icon  . Shared libraries are represented by the shared library icon  .

A shared library that is referenced by an application or another shared library is shown in the Referenced Libraries folder of the application or shared library.



A static library that is referenced by an application or another static library is shown in the Included Libraries folder of the application or static library.



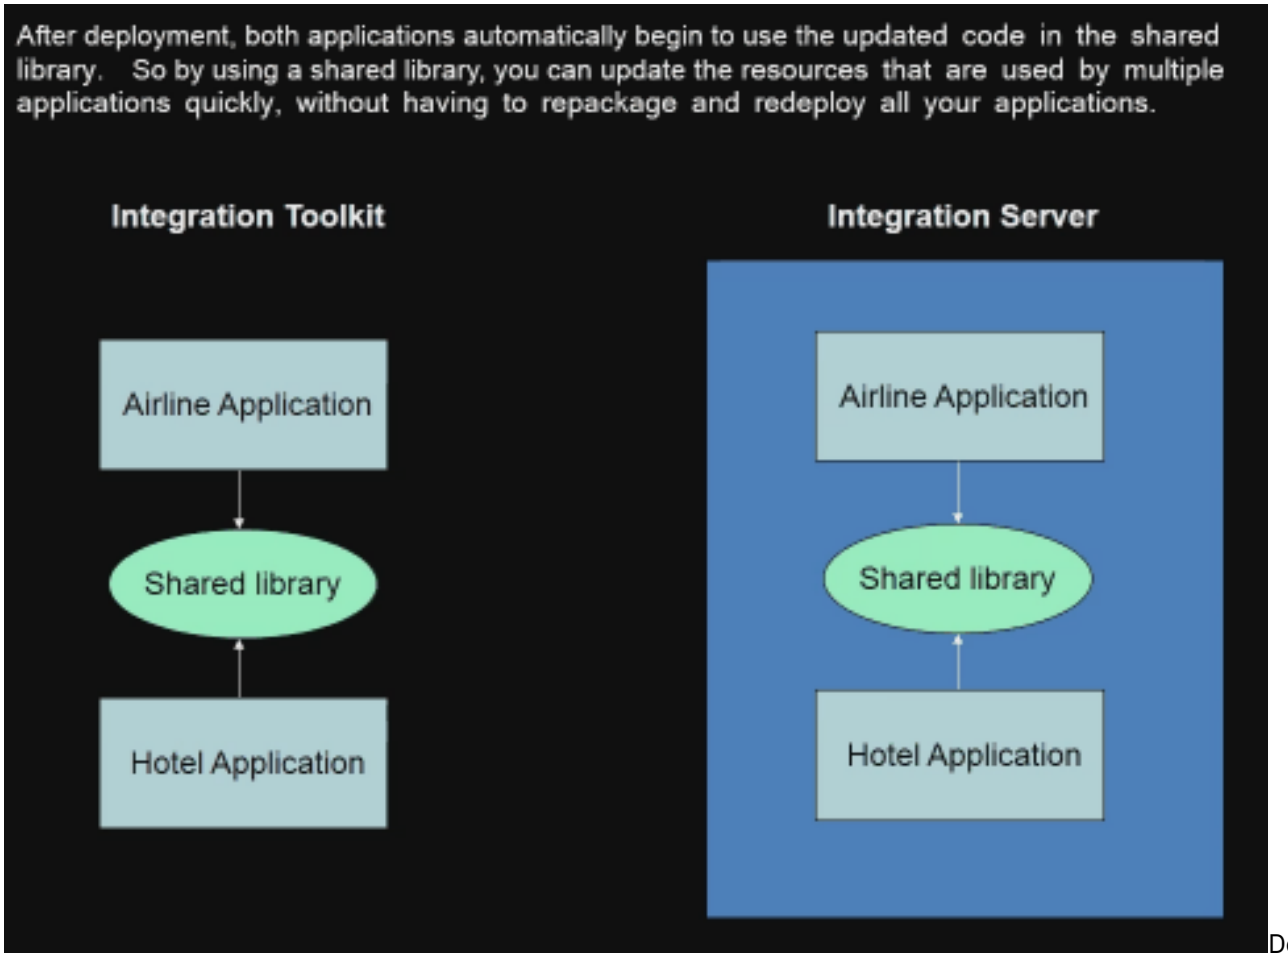
A shared library can refer to other shared libraries only. Similarly, a static library can refer to other static libraries only.

Libraries that are deployed to an integration server are displayed directly beneath the integration server in the IBM App Connect Enterprise Toolkit and the web user interface. Libraries that are referenced by applications are displayed directly beneath the application in the IBM App Connect Enterprise Toolkit. You can also view deployed libraries by using theIBM Integration API or the **mqsilist** command, for example:

```
mqsilist integrationNodeName -e integrationServerName -y sharedLibraryName
```

In this example, the command lists the resources that are deployed in a shared library, the integration server to which that shared library is deployed, and any applications that refer to the shared library.

The following animation illustrates the difference between a static and shared library.



Download mp4 file

The following table summarizes the differences between static and shared libraries.

	Shared library	**Static library**
Support for libraries	Shared libraries are introduced in IBM Integration Bus 10.0.	The libraries that were introduced in WebSphere Message Broker Version 8.0 are renamed as static libraries.
Referencing libraries	If multiple applications reference a shared library, when the applications are deployed, each application uses the artifacts directly from the deployed shared library.	If multiple applications reference a static library, when the applications are deployed, each application has its own private copy of the library and the resources that are contained in it.
Updating libraries	If you update and redeploy a shared library, all applications that reference that shared library see the updates automatically.	If you update a static library, you must repackage and redeploy each application that references that library, unless applications need to use different versions of that library.

	Shared library	Static library
Deploying libraries	Shared libraries can be deployed directly to the integration server, or they can be deployed in the same BAR file as the applications that reference them. If a shared library is deployed in a BAR file, it can still be used by applications or shared libraries in other deployed BAR files.	Static libraries are packaged and deployed in the same BAR file as the applications that reference them.

For more information, see the following topics:

- "Shared libraries" on page 1948
- "Static libraries" on page 1958

Shared libraries

You might want to develop a set of common resources and make them available to multiple applications. If you want to deploy and manage just one copy of those common resources, use a shared library.

A shared library can be deployed directly to an integration server. Any application can reference the resources in that deployed shared library. If that shared library is updated, the changes are immediately picked up by all referencing applications. (If you use a static library to contain resources, each application that references that static library is deployed with its own private copy of that library. If a static library is updated, each application that references it must be repackaged and redeployed with the updated static library.)

A shared library must be deployed with or before an application that references it. If you deploy resources by dragging them onto an integration server, deploy the shared library first. If you deploy resources by adding them to a BAR file, ensure that you include any shared libraries that your application references. Similarly, you cannot remove a deployed shared library while deployed applications are referencing it.

The following conditions apply to the referencing of shared libraries:

- Shared libraries can reference other shared libraries but cannot reference static libraries.
- Static libraries and integration projects cannot reference shared libraries.
- If an application references more than one shared library, the application has visibility of the resources in all of the shared libraries, but each shared library does not automatically have visibility of the resources in the other shared libraries.
- If a shared library (A) references another shared library (B), shared library A has visibility of the resources in shared library B, but shared library B does not have visibility of the resources in shared library A.
- If a shared library (A) references another shared library (B), shared library B cannot create a reference to shared library A.

The shared library hierarchy is preserved across development, deployment, and operational management processes. For example, you can see the shared library hierarchy in the IBM App Connect Enterprise Toolkit and the BAR File editor. You can also view deployed libraries by using the IBM Integration API, or the **mqsilist** command with the -y option; for example, using the command with an integration node:

```
mqsilist integrationNodeName -e integrationServerName -y sharedLibraryName
```

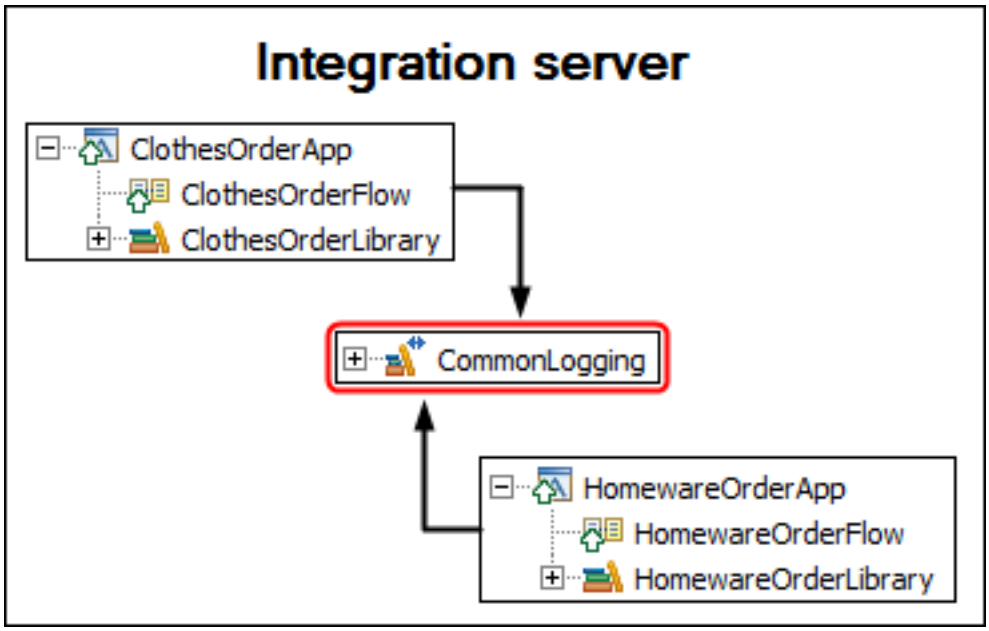
In this example, the command lists the resources that are deployed in a shared library, the integration server

The following examples demonstrate when you might use shared libraries.

Example 1: Sharing common logging code

You build a shared library that contains subflows and ESQL code that provides common logging functions. Multiple applications explicitly reference the shared library so that they can use the common logging functions. These applications are built and deployed.

You then update the shared library to ensure that additional information is recorded to the log. When you redeploy the shared library, all the deployed applications that explicitly reference this shared library pick up the changes automatically and start to log the additional information.



Example 2: Sharing a set of XML or DFDL schema files

You build a shared library that contains a logical set of complex DFDL or XML schema files, such as those for the Health Level Seven (HL7) standard. Multiple applications explicitly reference this shared library so that they can use the HL7 schema files for Mapping nodes or XMLNSC validation. These applications are built and deployed.

When the shared library is deployed, memory usage can be affected because the complex schema files must be compiled into a model. However, you reduce this memory usage when you update and redeploy the applications that reference the shared library because the schema files do not need to be recompiled.

Example 3: Mapping between clashing XML or DFDL schema files

You might want to map between different versions of an XML or DFDL schema. Both versions might declare the same elements and types, which cannot coexist in one application.

You can build one shared library that contains version 1 of a schema file, and another shared library that contains version 2. You can then build a map that references the schema files in the shared libraries and maps between the two versions.

At deployment time, separate models are built for each of the shared libraries. Therefore, no clash results from the duplicated elements and types.

Resources that are not supported in a shared library

The following resources are not supported in shared libraries:

- Message flows
- CORBARequest node and IDL files
- SCA nodes

- WebSphere Adapters nodes
- XSLTransform node
- MRM message sets
- XML files
- XSL files

The following sections describe how to use supported resources in shared libraries:

- "XML or DFDL schema files" on page 1950
- "WSDL files" on page 1950
- "ESQL files" on page 1950
- "Java files" on page 1951
- "Subflows" on page 1951

XML or DFDL schema files

When you validate against deployed XML or DFDL schema files in shared libraries, you must specify the name of the shared library that contains the appropriate compiled model. For example, when you create a message flow, you can configure the input node to validate against the message model for a shared library that is called HL7.

For more information, see "Shared libraries and XML or DFDL schema files" on page 1953.

WSDL files

When you validate against deployed WSDL files in shared libraries, you must specify the name of the shared library that contains the appropriate compiled model. You can use a WSDL file in a shared library to configure a SOAPInput, SOAPRequest, or SOAPAsyncRequest node. When you drag a WSDL file from a shared library onto one of these nodes, the `WSDL file name` property specifies the name of shared library; for example:

```
CurrentAccount.wsdl in Shared Library Shlib1
```

The `Message model` field is also set to the name of the top-level shared library that contains the WSDL file inside braces {}; for example: `{Shlib1}`. The WSDL might be contained in this specific shared library, but might be contained in one of the shared libraries that is referenced by this library. To drag a WSDL file from a shared library onto a SOAP node, the container of the message flow must reference the shared library that contains the WSDL file.

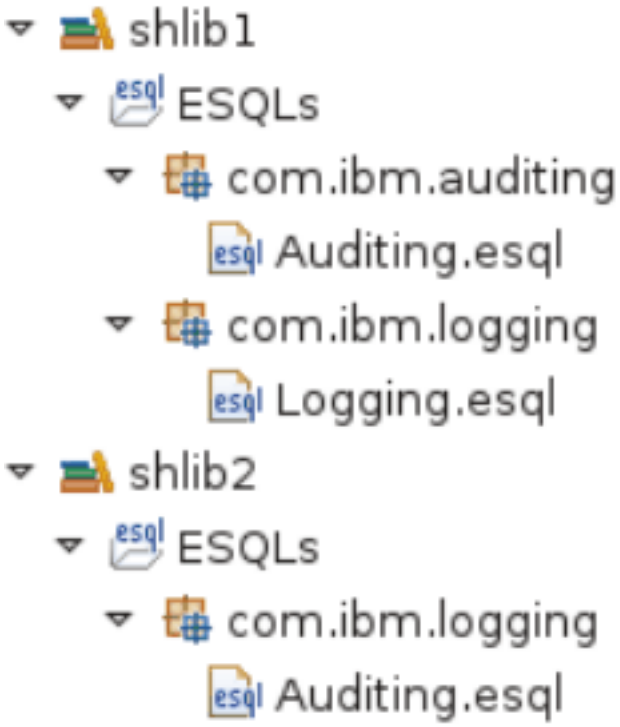
Multiple applications can access the same WSDL file in a single shared library. The shared library that contains the WSDL file must be deployed with or before the applications that refer to it. If you update the WSDL file and redeploy the shared library, those changes are immediately available to all referring applications.

A WSDL file of the same name can exist in multiple containers. For example, WSDL files with the same name can exist in an application and a shared library that is referenced by that application. You can also use multiple SOAPInput nodes in a message flow that reference different WSDL files with the same name in referenced shared libraries. A WSDL file in one shared library can use a schema file in another referenced shared library.

ESQL files

To avoid clashes between ESQL files in an application and its referenced shared libraries, the broker schema for the ESQL files is used. When you store ESQL files in a shared library, you must place the ESQL files inside a schema that is not the default empty schema.

Each shared library can have one or more ESQL files in one or more ESQL schemas. However, no two libraries in the same scope can have ESQL files in the same schema.



ESQL code in applications or shared libraries can also call static Java methods in referenced shared libraries by using the shared library qualifier in the CLASSLOADER clause. For more information, see Java routine example 4 in CREATE PROCEDURE statement.

Java files

You can store Java files in shared libraries. JAR files are packaged inside shared libraries. Java classes that are deployed in a shared library are not available to the integration server wide class loader. When you deploy a shared library that contains Java files, a new classloader is created for that shared library.

Java classes in the integration server wide classloader are isolated from the Java classes in any shared library classloaders. Similarly, Java classes in shared library classloaders are isolated from Java classes in the integration server wide classloader.

Java classes in applications, static libraries, or independent projects cannot access Java classes in shared libraries.

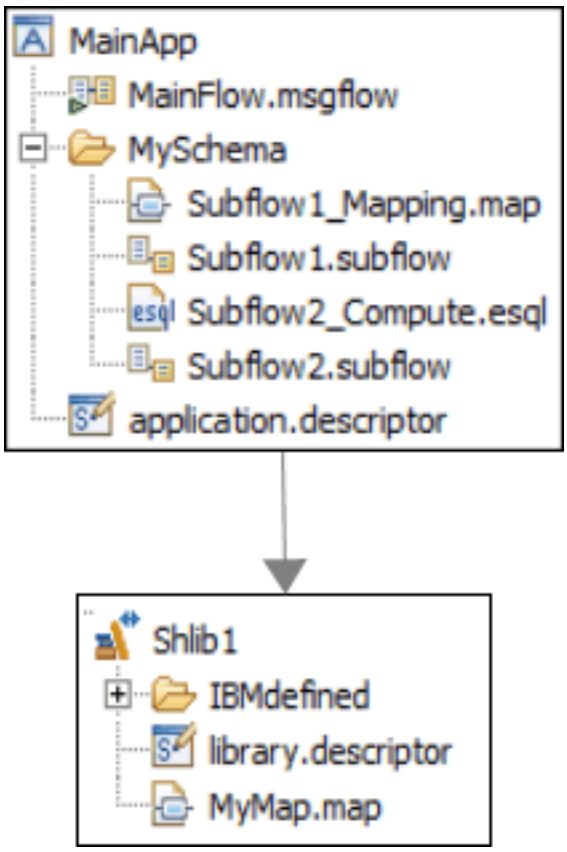
For more information about storing Java files in shared libraries, see “Shared libraries and Java files” on page 1954.

Subflows

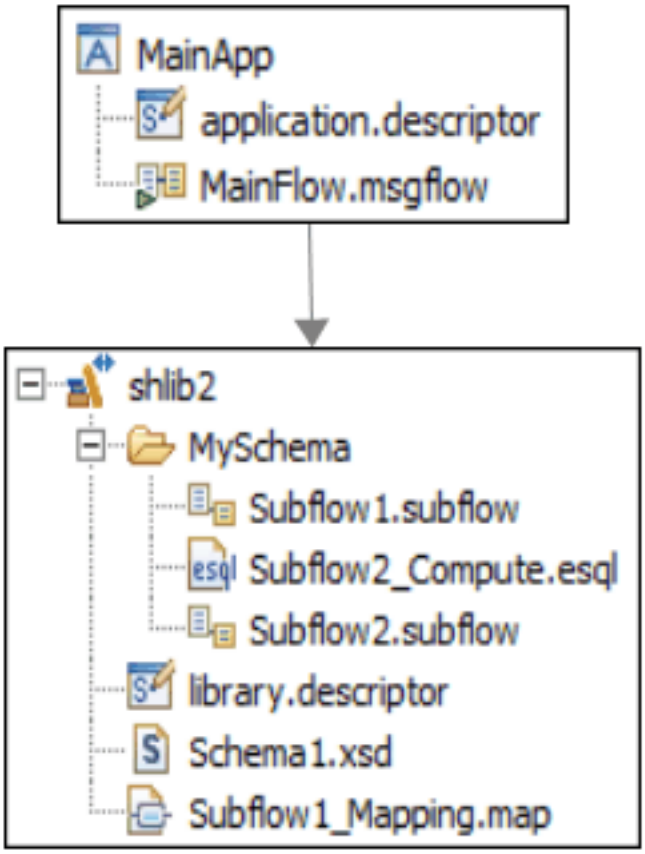
When you store subflows in a shared library, you must place the subflows inside a schema that is not the default empty schema.

When an application or shared library references other shared libraries, all the subflows for a broker schema must be in a single container. Subflows for a broker schema must not be in both an application (or shared library) and a shared library that is referenced by that application (or shared library). Subflows for a broker schema must not be in two or more shared libraries that are referenced by a single application or shared library. All the subflows in a broker schema must be either in the main application or shared library, or in a single referenced shared library.

Example 1: All subflows in the same broker schema are stored in the main application.



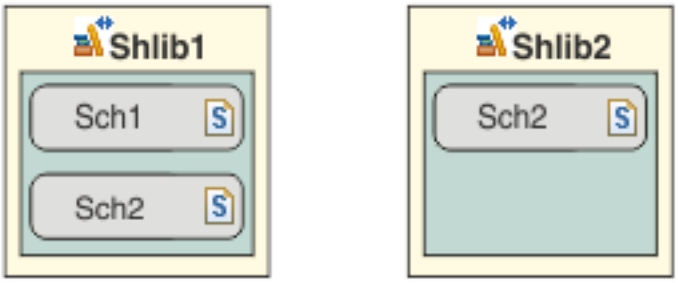
Example 2: All subflows in the same broker schema are stored in a referenced shared library.



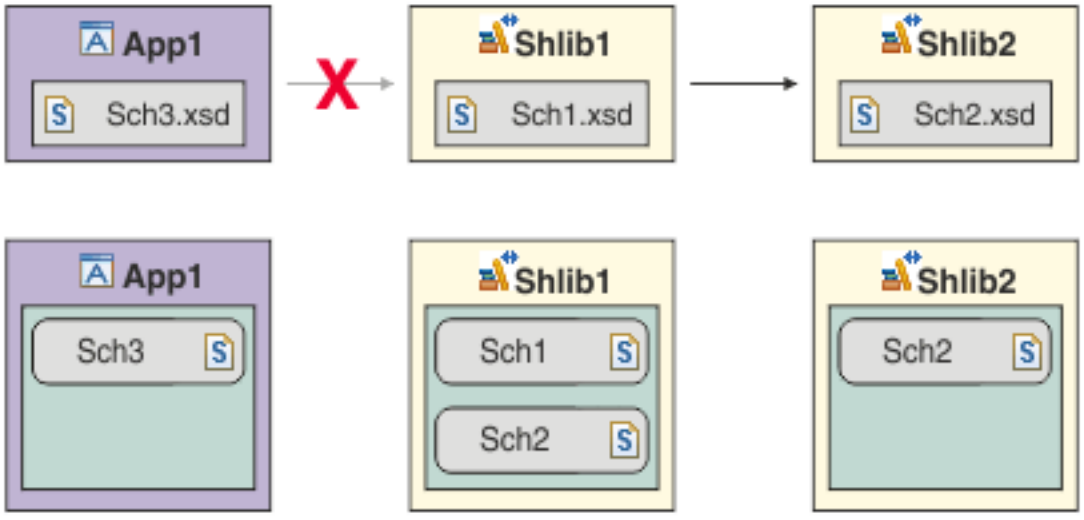
Shared libraries and XML or DFDL schema files
When you validate against deployed XML or DFDL schema files in shared libraries, you must specify the name of the shared library that contains the appropriate compiled model.

Shared libraries can contain XML or DFDL schema files. Shared libraries can also access schema files that are contained in referenced shared libraries, either by using the import or include options.

When the first shared library is deployed, a model is compiled that contains all the schema files in that shared library and any referenced shared libraries.



The application or applications that reference the shared libraries can also contain their own schema files. A separate model is compiled that contains only the schema files from the application. The schema files in the application cannot access schema files in a shared library.



To validate against the deployed schema files, the compiled representation of the XML schemas is passed to the parser. Therefore, you must specify the name of the shared library that contains the appropriate compiled model. For example, when you create a message flow, you can configure the input node to validate against the message model for a shared library that is called hl7 by specifying a value of {hl7} in the **Message model** property on the **Input Message Parsing** panel of the node. To access the **Message model** value in the Validate node, you can set the **MessageSet** field of the Properties tree by including the following ESQL statement in a Compute node:

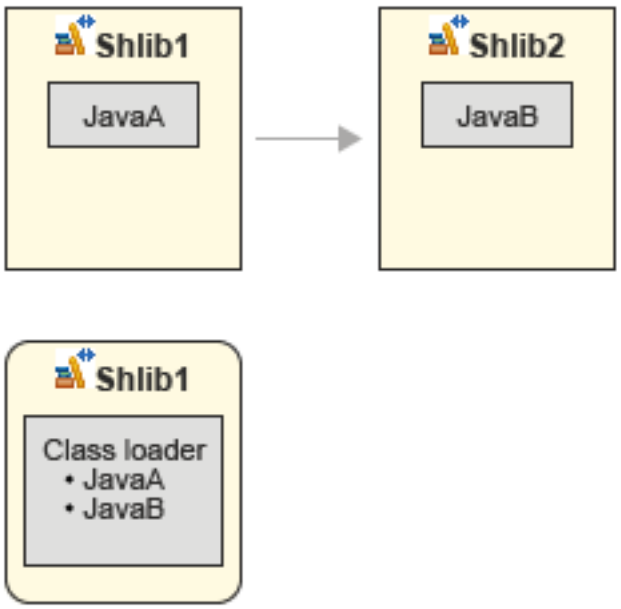
```
SET OutputRoot.Properties.MessageSet = '{Shared LibraryName};'
```

You can use the following methods to view the relationships between applications and shared libraries:

- The **mqsilist** command
- User trace and system trace
- The web user interface
- The Integration Explorer view of the IBM App Connect Enterprise Toolkit

Shared libraries and Java files
You can store Java files in shared libraries. JAR files are packaged inside shared libraries.

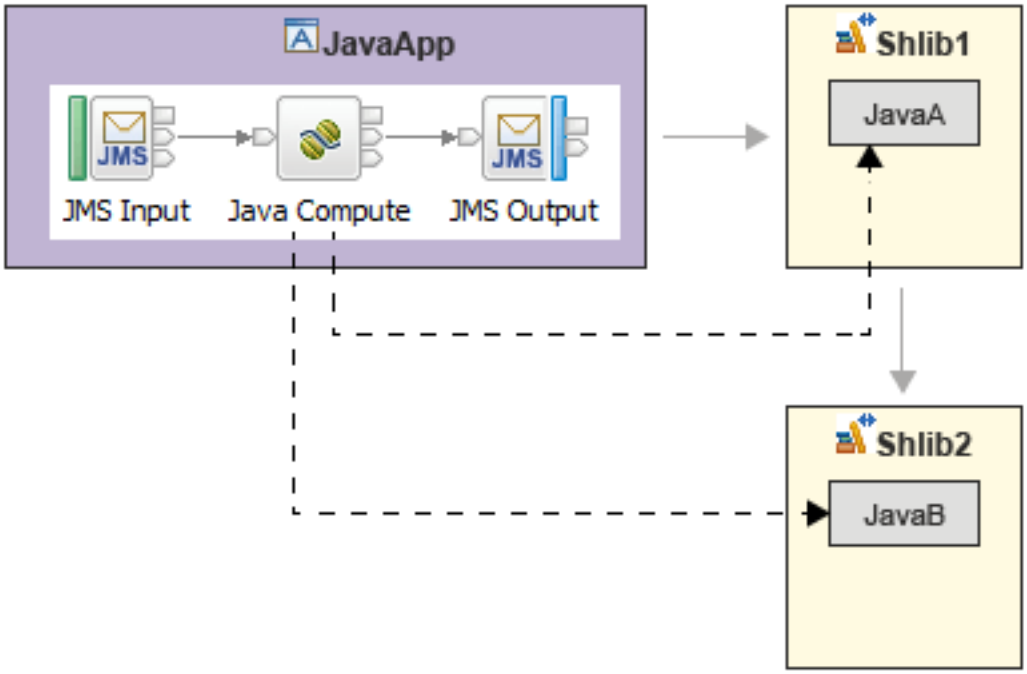
Java classes that are deployed in a shared library are not available to the integration server-wide class loader. When you deploy a shared library that contains Java files, a new class loader is created for that shared library. This class loader contains all Java classes in the shared library, as well as the Java classes from all referenced shared libraries. Delegation does not exist from one shared library class loader to another shared library class loader. The following diagram shows that a shared library, `shlib1`, contains a Java file called `JavaA`. Shared library `shlib1` refers to another shared library, `shlib2`, which contains a Java file called `JavaB`. When `shlib1` is deployed, a class loader is created for the Java files in that shared library as well as the referenced shared library.



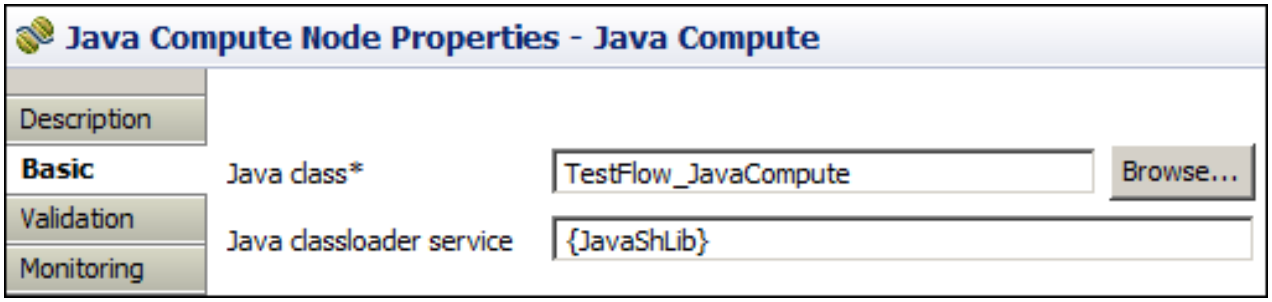
A Java class can exist in multiple class loaders if that Java class is contained in a shared library that is referenced by other shared libraries. When you update that Java class by redeploying the shared library that contains it, all class loaders for all shared libraries that contain that Java class are deleted and re-created.

Java classes in the integration server-wide class loader are isolated from the Java classes in any shared library class loaders. Similarly, Java classes in shared library class loaders are isolated from Java classes in the integration server-wide class loader.

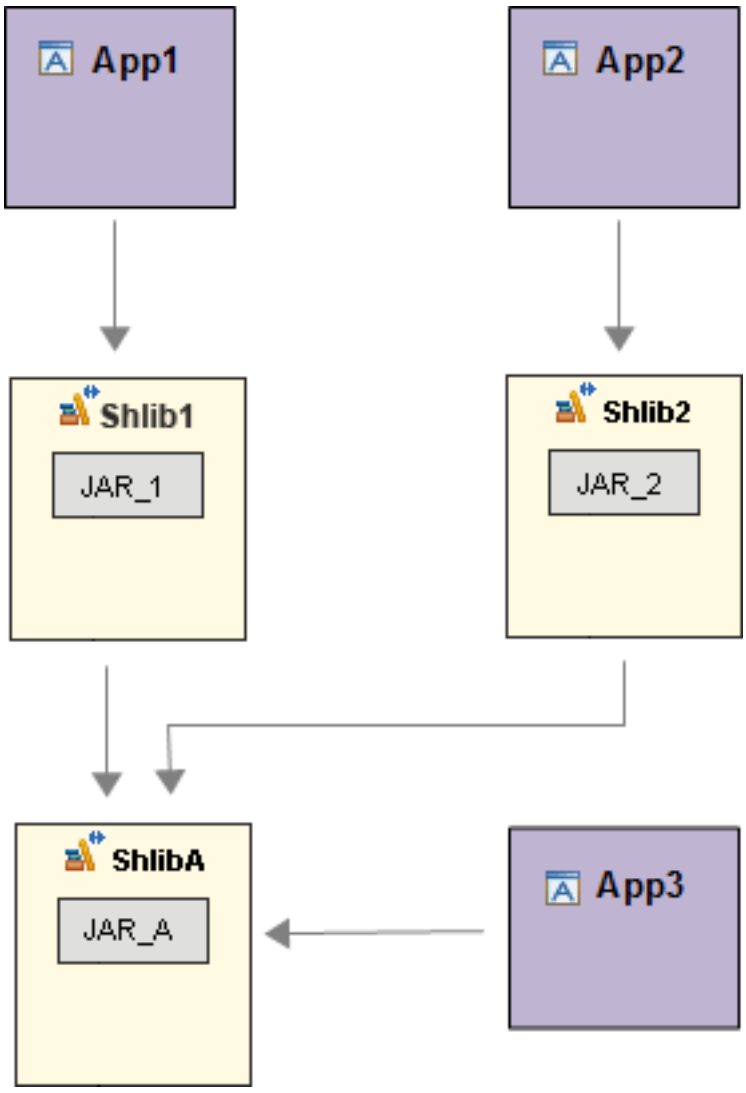
A JavaCompute node in a message flow or subflow can access the Java classes in a shared library and any referenced shared libraries. The following diagram shows a JavaCompute node in a message flow in an application, but the JavaCompute node could be in a subflow in a shared library.



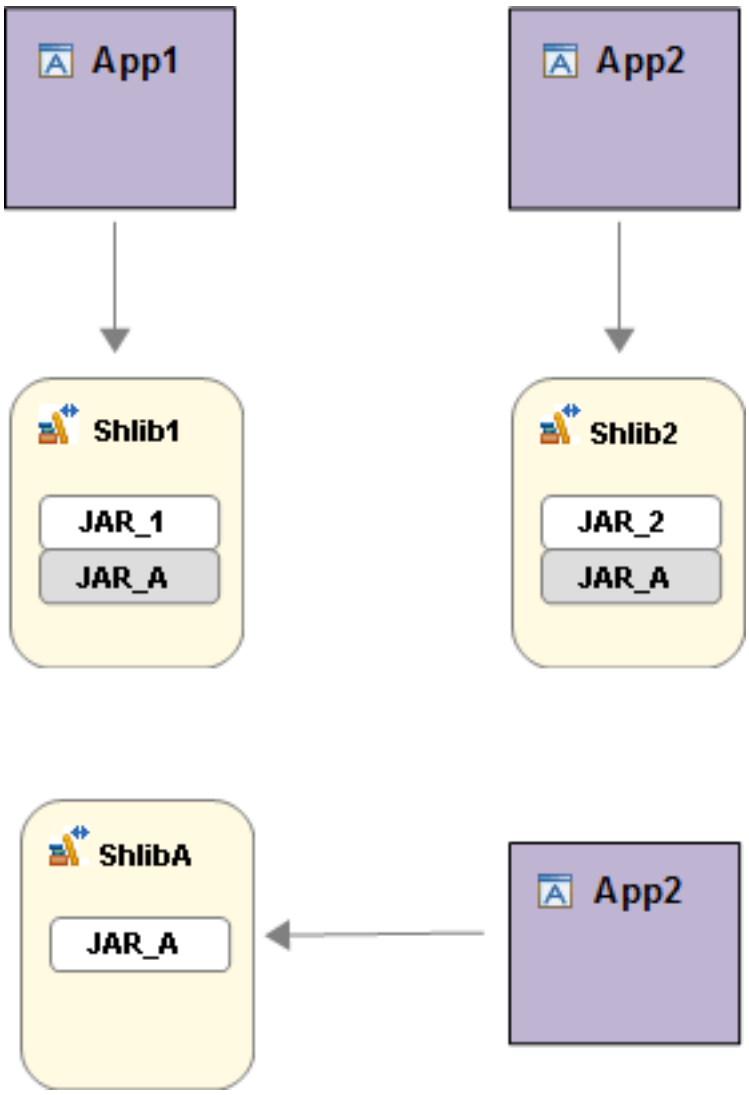
To access these Java classes, you specify a shared library qualifier for the Java Class Loader policy on the JavaCompute node. The shared library qualifier is inside braces {}, as shown in the following example:



When you refer to a shared library that contains Java classes, all of the Java classes might be loaded into multiple class loaders. The Java classes can be loaded into the class loader for that shared library, and the class loader for any other shared libraries that refer to that shared library. The following diagram shows how three different applications refer to three shared libraries. Application 1 refers to shared library 1, which also refers to shared library A. Application 2 refers to shared library 2, which also refers to shared library A. Application 3 refers to shared library A only.



The following diagram shows how the applications access the Java classes at run time. Shared libraries 1 and 2 have their own loaded copy of the classes from JAR_A in memory. Applications 1, 2, and 3 all see different copies of JAR_A.



For applications 1 and 3 to access the same loaded copy of the classes from JAR_A, application 1 would need to use the shared library qualifier for shared library A. Static variables in a shared library are duplicated for each shared library qualifier. JavaCompute nodes access the same static variables by using the same shared library qualifier. However, when you redeploy a shared library, the Java class loaders for that shared library, and any other shared libraries that reference that shared library, reload the Java classes.

ESQL code in applications or shared libraries can also call static Java methods in referenced shared libraries by using the shared library qualifier in the CLASSLOADER clause. For more information, see Java routine example 4 in CREATE PROCEDURE statement.

Here are some more examples of possible scenarios:

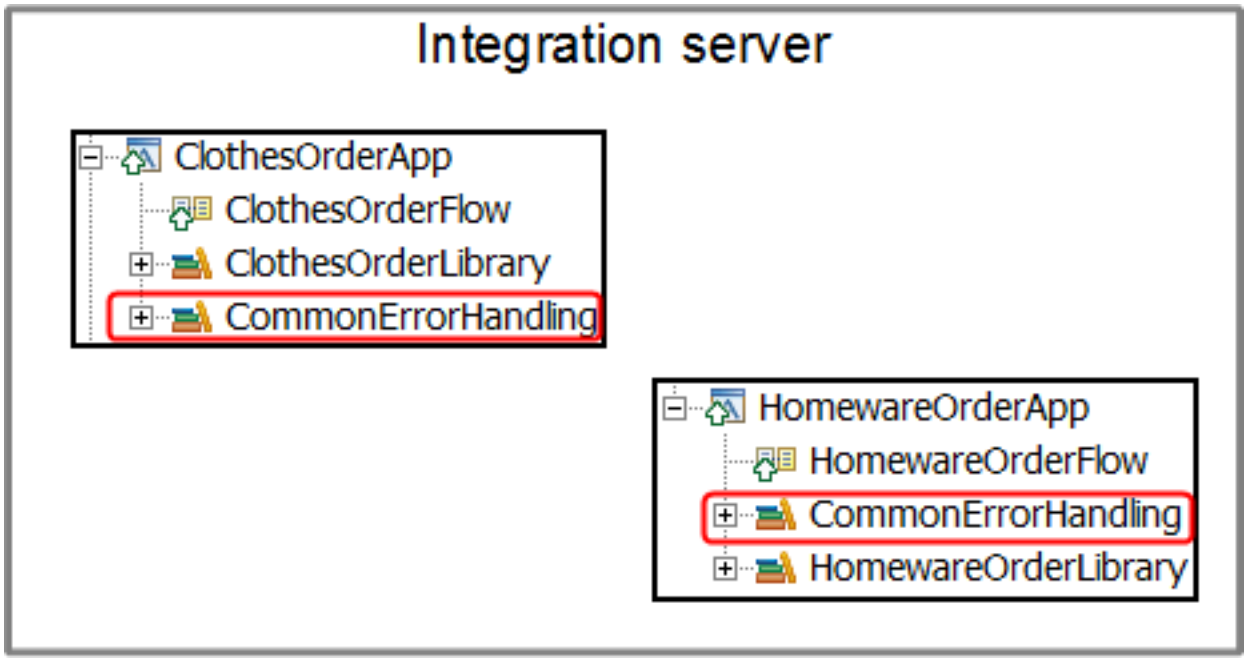
- A JavaCompute node in a subflow in a shared library can access the Java classes in the same shared library or in referenced shared libraries.
- If a message flow contains multiple JavaCompute nodes, each JavaCompute node can refer to a different shared library.
- Multiple applications can use the Java classes in a single shared library.

Java classes in applications, static libraries, or independent projects cannot access Java classes in shared libraries.

Static libraries

The libraries that were introduced in WebSphere Message Broker Version 8.0 are static libraries.

A static library can be referenced by one or more applications. Changes that are made to the library in the IBM App Connect Enterprise Toolkit are available to all applications that reference that library. However, when the applications are packaged into a BAR file and deployed, each application has its own private copy of the library and the resources that are contained in it. If you update a static library, you must repackage and redeploy each application that references that library.



Static libraries can be referenced by applications, services, integration projects, or other static libraries. You cannot refer to a static library from a shared library. Similarly, you cannot reference a shared library from a static library.

Static libraries behave in the following ways, depending on the resources that reference them.

- If a static library is referenced by an application, a copy of that referenced library is isolated at run time from resources outside the application. This copy of the library is not available to resources outside the application.
- If a static library is referenced by a service, a copy of that referenced library is isolated at run time from resources outside the service. This copy of the library is not available to resources outside the service.
- If a static library is referenced by an independent resource, that referenced library is available to all independent resources that are deployed in the same integration server as the library.

Some restrictions are associated with static libraries. You can overcome the following restrictions by using shared libraries.

- When an application is deployed, all the XML and DFDL schema files in that application and its referenced static libraries are compiled into a single model that represents the application. Duplicate element or type names cannot coexist in a single model. Therefore, an application cannot include conflicting XML or DFDL schema files. However, you might need to use multiple conflicting XML or DFDL schema files in a single application. For example, you might want to map elements between versions one and two of a particular XML schema file.
- The presence of complex XML schema files in static libraries can affect the compilation process and the time that is taken to deploy the application. Static libraries are redeployed with the application. Therefore, every time the application is deployed, all the XML schema files are recompiled, even if they have not changed.

Integration projects

An integration project is a specialized container in which you create and maintain all the resources associated with one or more message flows.

Message flow projects have been replaced by integration projects in IBM Integration Bus 10.0.

You can create an integration project to contain a single message flow and its resources, or you can group together related message flows and resources in a single integration project to provide an organizational structure to your message flow resources. An integration project can contain the following resources:

- Message flows
- Subflows
- Message maps
- ESQL files
- Database definitions
- BAR files
- Test Clients

You cannot create schema files in an integration project; you can create them in an application or library only.

An integration project can reference a static library but not a shared library.

Integration projects are shown in the Independent Resources folder in the Application Development view. Integration project resources are created as files, and are displayed under the project. These resources define the content of the message flow, and additional objects that contain detailed configuration information. For example, a project might contain ESQL modules or message mappings, used by one or more nodes in the message flow.

You can add resources to an integration project and deploy those resources directly from the integration project, without having to deploy them in an application or library.

You can share your Integration projects with others by exporting and importing an integration project as a compressed file known as a *project interchange file*. You can also copy project directories from your workspace directory to another location; for example, to backup the project directory or to use in another workspace directory.

Benefits of using applications and libraries

Use applications and libraries to help manage multiple solutions and to share resources across multiple teams or projects.

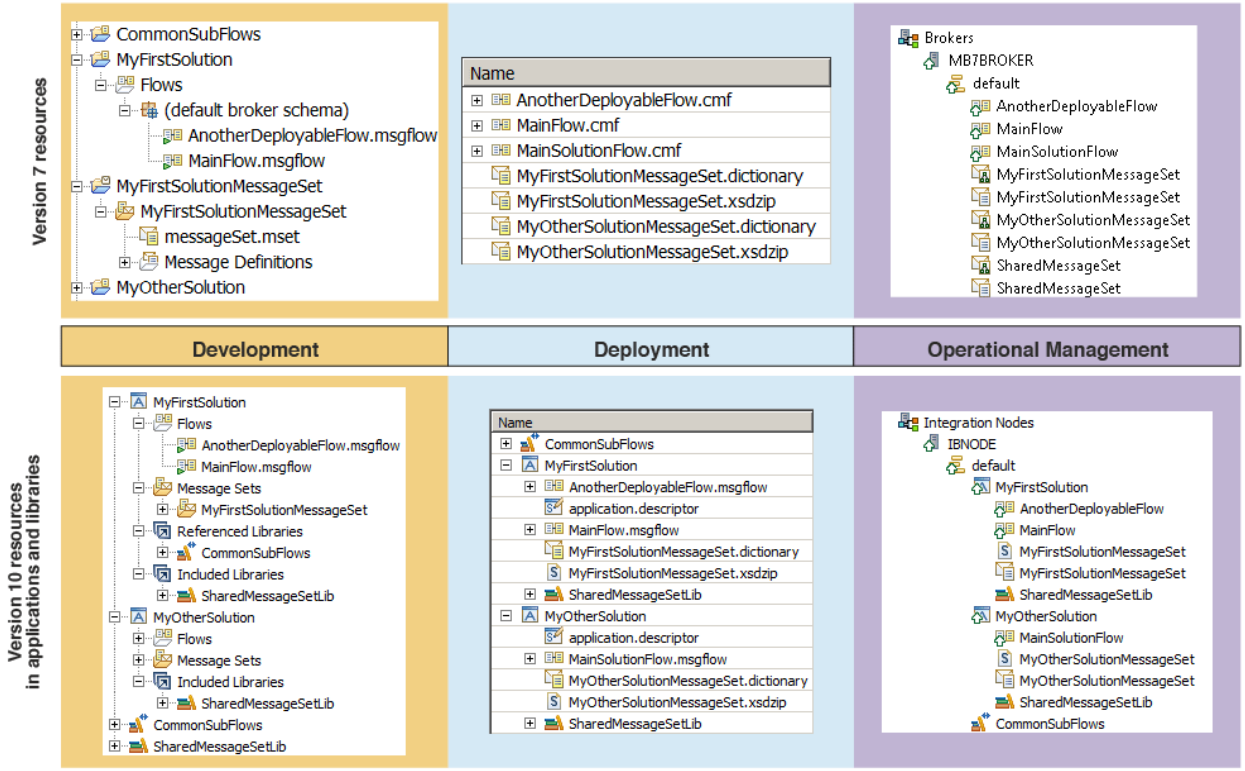
The use of applications and libraries has the following benefits:

- Flexible organization of resources.
  - You can organize resources that are required by message flows (such as XSD files, IDL files, WSDL, and `.inadapter` or `.outadapter` components) into libraries.
  - You control the structure of the library.
  - You can build a library by using resources from several projects (for example, a message set, and a Java project).
- Encapsulated packaging of flows and their dependencies.
  - Applications are packages of message flows and libraries.
  - You can use message flows from several projects to build an application.
  - You can deploy and redeploy a whole application.
- Modular and collaborative development.
  - Libraries can reference other libraries to reuse resources.

- Unified packaging and organization through application development, deployment, and operational environments.
  - You can develop, deploy, then administer applications.
  - You can administer individual libraries.
  - You can maintain dependency relationships during operation.

Consistency through the development, deployment, and operational management processes

Applications, libraries, and integration projects provide a consistent view of your resources through the development, deployment, and operational management processes. In WebSphere Message Broker Version 7.0 and earlier versions, file types and concepts were different at each stage of the development process. Multiple project types were used in the IBM App Connect Enterprise Toolkit to contain different types of resource. No consistent method existed to reuse common components across all processes. However, applications and libraries span the IBM App Connect Enterprise Toolkit for development, the BAR file for deployment, and tools like the web user interface for operational management.

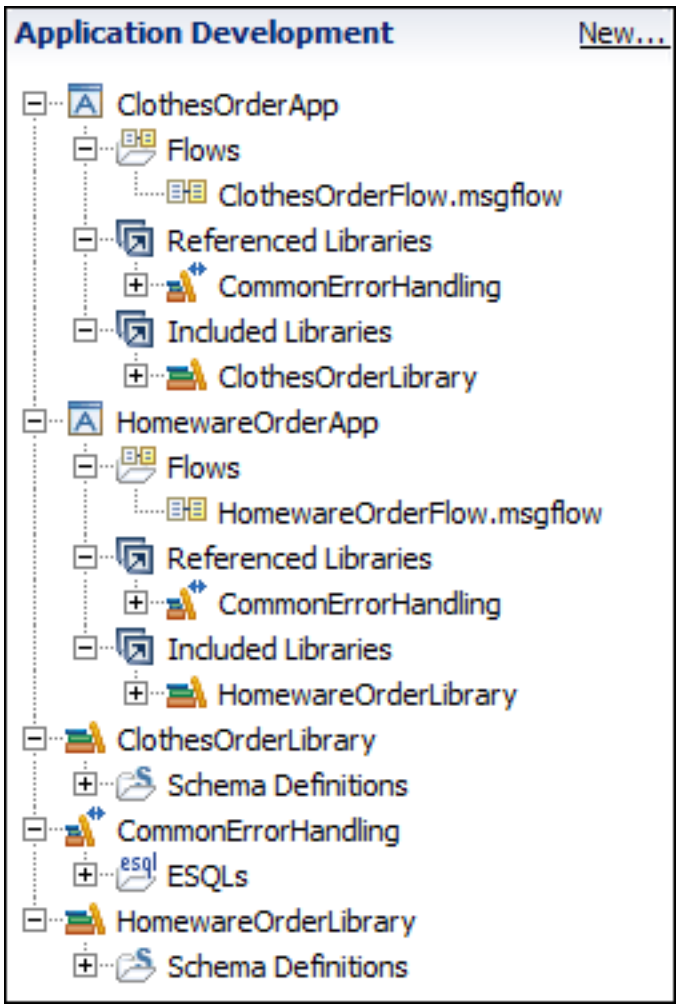


Runtime isolation and resource sharing with applications and libraries

You can use applications to encapsulate resources for a solution or to provide runtime isolation. You can use libraries to group common resources or share routines and definitions between teams, projects, or integration nodes.

Applications provide runtime isolation whereby resources inside the application are not visible to other resources, such as message flows, libraries, or other applications that are running outside the application. Consider using applications if you need to ensure that updates to one group of deployed resources do not affect another group. For example, use an application when you want to control which flows pick up the latest version of an ESQL module.

The following example illustrates how you can use applications to contain separate solutions, and libraries to contain shared error-handing code.



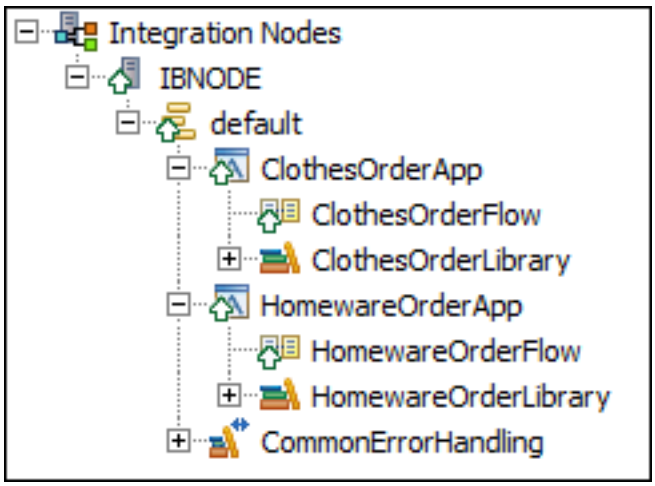
The ClothesOrderApp application contains the following resources:

- A message flow called ClothesOrderFlow
- A reference to a static library called ClothesOrderLibrary, which contains XSD schema files that are specific to the order type
- A reference to a shared library called CommonErrorHandling, which contains some common error-handling ESQL code

The HomewareOrderApp application contains the following resources:

- A message flow called HomewareOrderFlow
- A reference to a static library called HomewareOrderLibrary, which contains XSD schema files that are specific to the order type
- A reference to a shared library called CommonErrorHandling, which contains some common error-handling ESQL code

The following diagram shows the resources in the Integration Explorer view after they are deployed. The shared library is deployed with or before the applications that reference it.



The shared library appears at the same level as the applications that reference it. The static libraries are shown nested under the applications that reference them. Resources in the applications and their referenced static libraries are not visible to other resources outside those applications.

Applications provide this isolation at run time. This isolation also applies if a resource that is contained in an application is also deployed separately to the same integration server.

Assume that a static library is deployed to an integration server with a message flow that references that library. The same static library is also contained in an application that is deployed to the same integration server. If that static library is updated in the IBM App Connect Enterprise Toolkit and redeployed, the message flow that is deployed to the integration server can see the changes. However, the application cannot see the changes. For the application to pick up the updated static library, you would need to rebuild and redeploy the BAR file that contains the application.

Naming conventions in applications and libraries

When you add resources to applications and libraries, ensure that you use appropriate naming conventions to avoid conflicts. For example, you can qualify a file path with a library name, or differentiate a schema element by using a QName.

A *QName* refers to a namespace-qualified element from a message model, which can be an XML schema, DFDL schema file, or a message set. These QNames must be unique throughout an application or library and any of their referenced libraries. For example, "Application1" contains two schema files, `schemaOne.xsd` and `schemaTwo.xsd`. Both schema files contain the element "sameElement", which is qualified by the namespace `http://mynamespace.com`. This naming convention causes a conflict because both schema files have the same QName for the element named "sameElement", which is qualified by the same namespace.

Both schema files also contain the element "diffNSElement", but this element is qualified by a different namespace in each schema file. Therefore, no conflict occurs. If a conflict of QNames is detected, each XML or DFDL schema file, or message set, that contains a construct with that QName is marked with an error in the Application Development view and Problems view.

The broker schema defines the relative path from the application or library to the resource name. The following resource names must be unique in an application or library and all referenced libraries:

- An XSD resource name and path pair
- A WSDL resource name and path pair
- A message flow resource name and path pair
- An adapter resource name and path pair (`.inadapter` and `.outadapter`)
- A CORBA IDL resource name and path pair
- A message map resource name and path pair (`.map`)
- An XSLT resource name and path pair

If a conflict of a resource name and path is detected, each resource is marked in the Application Development view and Problems view. If a conflict of a file resource and path is detected, each resource is marked in the Application Development view and Problems view.

You cannot reference `.inadapter` and `.outadapter` files for the same SAP operations in separate libraries in the same application. Instead, you must use one of the following configurations:

- Two separate applications and adapter libraries for inbound and outbound operations
- A single adapter library with both inbound and outbound adapters that are generated in different namespaces and used in two separate applications. In this configuration, one application must have an inbound flow, and the other must have an outbound flow.
- A single adapter library with both inbound and outbound adapters. These adapters must be generated in different namespaces and used in one application with both inbound and outbound flows.
- Two separate applications that have their own business object schema, adapter, and flows.

Creating an application

Create an application to contain all the resources that are required to develop your solution.

Before you begin

Read concept information about applications in "Applications" on page 1943.

About this task

The order in which you create resources is flexible. You can begin by creating an application, then create resources to add to it, or you can begin by creating libraries of resources, then create an application that refers to them. You can also convert an existing project into an application.

The resources that an application can contain include message flows, ESQL files, and subflows. An application can also refer to one or more libraries. The resources that a library can contain include Adapter connections, CORBA IDL files, and schemas. To create a library of resources, see "Creating a library" on page 1964.

To create an application, complete the following steps.

Procedure

1. Open the New Application wizard by using one of the following methods:
   - Click **File** > **New** > **Application**.
   - In the Application Development view, click **New**, then click **Start by creating an application**.
   - Right-click the white space of the Application Development view, then click **New** > **Application**.
2. Enter a name for the application, then click **Next**.
3. Existing libraries are listed; select the libraries that you want to add to the application.

   If libraries are referenced by the libraries that you have selected, they are shown.
4. Click **Finish**.

   An application is created and is shown in the Application Development view. You can expand the application to view library references. Shared libraries are stored in a Reference Libraries folder, and static libraries are stored in an Included Libraries folder.

What to do next

- If you have not already done so, you can create a library by following the instructions in "Creating a library" on page 1964.
- To create resources in an application, see "Creating resources in an application" on page 1964.

- To add and remove project references to the application, see "Referencing resources in other libraries" on page 1976.
- To include an existing project in an application, see "Adding a project to an application, integration service, or library" on page 1979.

Creating resources in an application

You can create resources such as message flows, maps, and ESQL files in an application.

Before you begin

Learn more about applications by reading "Applications" on page 1943.

This topic assumes that you have created an application. For more details, see "Creating an application" on page 1963.

About this task

An application is a specialized container in which you create and maintain all the resources associated with a business solution. You can create resources such as message flows, maps, broker schemas, and database definitions. You can also generate message models and import resources such as CORBA IDL files, XSLT files, and database records.

To create resources in your application, complete the following steps.

Procedure

1. Click **File** > **New**.

   (Alternatively, in the Application Development view, right-click an application, then click **New**.)
2. Select the resource to create.

   The appropriate wizard opens; for example, the **New Message Flow** wizard.
3. If the application name is not already provided, select it from the list of available applications.
4. Follow the instructions in the wizard, then click **Finish**.

   The new resource is displayed under the application in the Application Development view.

Creating a library

Create a library to contain a logical grouping of related code, data, or both, that can be reused.

About this task

The order in which you create resources is flexible. You can begin by creating an application and adding resources to it, or you can begin by creating libraries of resources, then create an application that refers to them. Libraries are optional; create one if you want to reuse resources.

Two types of library exist in IBM App Connect Enterprise: *shared libraries* and *static libraries*. A shared library can be deployed directly to an integration server or in a BAR file with referencing applications. If that shared library is updated, the changes are immediately available to all applications or shared libraries that refer to it.

A static library is deployed with the application that references it. Each application that references that static library is deployed with its own private copy of that library. If a static library is updated, each application that references it must be repackaged and redeployed with the updated static library.

A static library is the original container that was introduced in WebSphere Message Broker Version 8.0. In IBM Integration Bus 10.0 and later, the preferred way to share resources is to store them in a shared library. If you want each application to use a different version of the contained resource, you can use a static library.

For more information about libraries, see “Libraries” on page 1945.

Procedure

To create a library, complete the following steps.

1. Open the **New Library** wizard by using one of the following methods in the IBM App Connect Enterprise Toolkit:
   - Click **File** > **New** > **Library**.
   - In the Application Development view, click **New**, then click **Start by creating a library**.
   - Right-click the white space in the Application Development view, then click **New** > **Library**.
2. Enter a name for the library.
3. Select either **Shared Library** or **Static Library**.
4. If this library is the first one to be created, click **Finish**. If another library exists, you can click **Next** to add a reference to an existing library.
5. Optional: If you click **Next**, existing libraries are listed. Select the existing libraries that you want to reference from the new library.

   A shared library can reference other shared libraries only; a shared library cannot reference a static library. Similarly, a static library can reference other static libraries only. If you add a reference to a static library that refers to other static libraries, all referenced static libraries are included.
6. Click **Finish**.

Results

A library is created and is shown in the Application Development view. You can expand the library to view library references. Shared libraries are represented by the shared library icon  . Static libraries are represented by the static library icon  . A shared library that is referenced by an application or another shared library is shown in the Referenced Libraries folder for that application or shared library. A static library that is referenced by an application or another static library is shown in the Included Libraries folder for that application or static library.

What to do next

- Create an application by following the instructions in “Creating an application” on page 1963.
- To create resources in a library, see “Creating resources in a library” on page 1965.
- To add and remove project references in the library, see “Referencing resources in other libraries” on page 1976.

Creating resources in a library

You can create resources in a library that you want to reuse in multiple solutions.

Before you begin

- Find out more about libraries in “Libraries” on page 1945.
- You can add resources to an existing library. (For more information, see “Creating a library” on page 1964.) Alternatively, you can create a library when you create a resource.

About this task

A library is a container for resources that you want to reuse for multiple solutions. You can create resources such as maps, broker schemas, and database definitions. You can also generate message models and import resources such as CORBA IDL files, SCA files, and XSLT files. You can create subflows in a shared library, but you cannot create message flows in a shared library.

You can create resources in an existing library, or you can create a library when you create a resource.

Creating resources in an existing library

Procedure

1. In the Application Development view, right-click a library, then click **New**.
2. Select the resource to create.

   When you select a resource to create, the appropriate wizard opens; for example, the **New Message Model** wizard.
3. If the library name is not already provided in the **Application or Library** field, select it from the list of available libraries.
4. Follow the instructions in the wizard, then click **Finish**.

   The new resource is displayed under the library in the Application Development view.

Creating a library when you create a resource

Procedure

1. In the Application Development view, click **New**, or right-click white space, then click **New**.
2. Select the resource to create.

   When you select a resource to create, the appropriate wizard opens; for example, the **New Message Model** wizard.
3. Create a library by clicking **New** next to the **Application or Library** field.
4. Select **Library**, then click **OK**.
5. Enter a name for the library, then click **Finish**.

   A new shared library is created and shown in the Application Development view.
6. Follow the instructions in the wizard, then click **Finish**.

   The new resource is displayed under the library in the Application Development view.

Creating a broker schema

To organize your resources, and to define the scope of resource names to ensure uniqueness, you can create broker schemas. A default schema is created when you create a message flow, but you can create additional schemas.

Before you begin

The order in which you create your resources is flexible. You can add a schema to an existing application, library, or integration project, or you can create a container when you create the schema. To create a container first, follow the instructions in the following topics:

- “Creating an application” on page 1963
- “Creating a library” on page 1964
- “Creating an integration project” on page 1969

If your schema file is intended for use by multiple solutions, consider creating it in a shared library.

To find out more about schemas, see “Broker schemas” on page 498.

About this task

When you create a message flow, a schema is created by default. The default schema is not displayed in the Application Development view. Only additional schemas that you create are displayed in the Application Development view, under the containing project. For more information about creating a message flow, see “Creating a message flow” on page 574.

To create additional schemas, complete the following steps.

Procedure

1. To open the **New Broker Schema** wizard, use one of the following methods.
   - Right-click the space in the Application Development view and click **New** > **Broker Schema**.
   - Click **File** > **New** > **Other** > **IBM App Connect Enterprise - Application Development** > **Broker Schema**, then click **Next**.
   - Right-click an application, static library, or integration project, then click **New** > **Broker Schema**.
2. Select the name of the application, library, or integration project in which to create the schema.

   Alternatively, create a new container by clicking **New**.
3. Enter a name for the schema.

   Choose a name that reflects the resources that the schema contains; for example, if you want to use this schema for message flows for retail applications, you might give it the name `Retail`.

   A schema name must be a character string that starts with a Unicode character followed by zero or more Unicode characters or digits, and the underscore symbol (_). You can use the period to provide a structure to the name, for example `Stock.Common`.
4. Click **Finish**.

   The schema is shown in the Application Development view under the relevant container.

   If category view is selected in the Application Development view when you create the schema, you see a message to say that the schema was created. However, it might not be visible in the Application Development view when it is empty. To show the new schema in the Application Development view, click **Hide Categories**  on the Application Development view toolbar.

Results

The schema directory is created in the project directory. If the schema name is structured by using periods, further subdirectories are defined. For example, the schema `Stock.Common` results in a directory `Common`, in directory `Stock`, in the application, library, or integration project directory.

Creating a solution based on WSDL or XSD files

You can use existing WSDL or XSD files as the basis for your solution.

Procedure

1. In the Application Development view of the IBM App Connect Enterprise Toolkit, click **New**, then click **Start from WSDL and/or XSD files**.
2. Decide how you want the resources to be organized by creating an application, library, or integration service to contain them, then click **Next**.

   An application typically contains all the resources required for your solution. A shared library typically contains resources that you might reuse for other solutions. You can choose to contain all of your resources in an application if you do not plan to reuse them elsewhere. Alternatively, you can choose to store all your resources (except for the main message flow) in a shared library for reuse.

   Depending on the option that you select, default names are provided for the containers that are created, but you can edit the names.

3. Select the WSDL or XSD files that you want to use, then click **Next**.
   - To choose WSDL or XSD files that exist in your workspace, select **Use resources from the workspace**.

     Your resources are shown in the same format as the Application Development view. Expand the folders and select the resources that you want to use. Resources might be filtered if you have selected a working set.
   - To choose WSDL or XSD files that exist outside your workspace, select **Use external resources**.

     To locate your resources, enter a directory name or click **Browse**.

   If the only use of the XSD file is from the WSDL bindings, you do not have to select an XSD file on which a selected WSDL files depends.
4. Select one or more bindings for each of the WSDL files that you selected, then click **Finish**.

Results

Your container and resources are created and are shown in the Application Development view.

What to do next

After you import a WSDL file into a container, drag the WSDL file onto the Message Flow editor to create a message flow. You need to open or create a message flow. If you are dragging a WSDL file from a shared library into a message flow in an application or other container, that container must reference the shared library. When you drag a WSDL file onto a message flow, the **Configure New Web Service Usage** wizard guides you through the creation of the message flow.

Creating a solution based on an existing message set

Import or copy an existing message set into your workspace, then create an integration project and message flow that refer to that message set.

About this task

To create a solution that is based on an existing message set, complete the following steps.

Procedure

1. Click **File** > **New** > **Other**, or right-click anywhere in the Application Development view and click **New** > **Other**.

   The New Project wizard opens.
2. Expand **Integration Bus - Message Set Development**.
3. Click **Start from existing message set**, then click **Next**.
4. Set up the basic resources that are required to develop an application from an existing message set, then click **Next**.
   - If the message set that you want to use is in a compressed (`.zip`) file, select **Import a message set from a .zip file**, and either type the location of the message set in the **.zip file** and **Compressed message set** fields, or click **Browse** and select, and open, the `.zip` file from the list that is displayed. Then select the required message set.

     If the `.zip` file that you specify does not contain a message set, you receive a message. You can then type a different location for the message set in the **.zip file** field. Otherwise, click **Cancel**.
   - If the message set that you want to use is not in a compressed file, click **Create a new message set by copying an existing message set** and type into the **Message set to copy** field the name of the message set file that you want to copy.

     A list is displayed of the message set names from which you can choose. Message sets are filtered to show resources in the active working set only.

5. If necessary, you can change the default name for the integration project that is created.

   By default, a message flow and working set are also created. You can choose different names for these resources. If the message set is copied from a `.zip` file that is a project interchange file, you cannot edit the names of the message set project and the message set. In this case, the names are imported from the `.zip` file.
6. Click **Finish**.

   The new message set project, message set, integration project, and message flow are created. The integration project contains a project reference to the message set project. A new working set is also created, if required. The new projects are displayed in the specified working set. The contents of the message set project and the integration project are displayed in the Application Development view. The message flow is opened in the message flow editor.

What to do next

The next step is to develop the message flow. For more information about how to start, see "Designing a message flow" on page 583.

Creating an integration project

Create an integration project to contain resources such as message flows, maps, and database definitions.

Before you begin

Read the concept information in "Integration projects" on page 1959.

About this task

Integration projects replaced message flow projects in IBM Integration Bus 10.0.

If you are not ready to create an application or library yet, you can use an integration project to hold resources in the meantime. When you are ready, you can either create an application or library and move the resources from the integration project, or you can convert your integration project to an application or library.

You can create an integration project when you create resources, such as message flows and maps.

To create and populate an integration project manually, complete the following steps.

Procedure

1. Open the **New Integration Project** wizard by clicking **File** > **New** > **Integration Project**.
2. Enter a name for the project and select any existing projects to which you want to refer. Click **Next**.
3. Select any existing static libraries to which you want to refer, then click **Finish.**

Results

The new integration project is created and shown in the Independent Resources folder of the Application Development view.

What to do next

When you have created an integration project, you might want to create resources to add to the project. For more information, see "Creating resources in an integration project" on page 1970.

To see the project references for your integration project, right-click the integration project and click **Properties** > **Project References**. The projects that your integration project references are selected.

To convert an integration project to an application or library, see “Converting existing projects to applications and libraries” on page 1970.

Creating resources in an integration project

You can create resources such as message flows, maps, and ESQL files in an integration project.

Before you begin

Learn more about integration projects by reading “Integration projects” on page 1959.

This topic assumes that you have created an integration project. For more details, see “Creating an integration project” on page 1969.

About this task

An integration project is a specialized container in which you create and maintain all the resources that are associated with one or more message flows. To create resources in your integration project, complete the following steps.

Procedure

1. Click **File** > **New**.

   (Alternatively, expand the Independent Resources folder of the Application Development view, right-click the integration project, then click **New**.)
2. Select the resource to create.

   The appropriate wizard opens; for example, the **New Message Flow** wizard.
3. Follow the instructions in the wizard, then click **Finish**.

   The new resource is displayed in the Application Development view, under the integration project.

What to do next

You can also reference resources that exist outside the integration project (such as a Java project or Data Design project) by adding project references. Right-click the integration project, then click **Properties** > **Project References**. Select the projects that you want to reference in your integration project.

Converting existing projects to applications and libraries

Two options are available to convert existing projects to applications or libraries. Use **Convert Single Project** to convert a project with no references. Use **Analyse and Convert Multiple Projects** to convert one or more projects and any referenced resources.

Before you begin

- Read the concept information about applications, libraries, and integration projects in “Resource management overview” on page 1942.
- To convert projects from previous versions of IBM App Connect Enterprise, you must first import them. For instructions, see “Migrating development resources to IBM App Connect Enterprise 12.0” on page 62.

About this task

You can convert an integration project, Java project, or message set project into an application or static library. For example, you might want to convert a project in the following situations:

- You imported an existing project from a previous version of IBM App Connect Enterprise. You want to use that project as the basis for a new application. You can convert the project into an application, then add the rest of the resources that are required to complete your solution.

- You have an existing project that contains resources that you want to reuse in several solutions. You can convert the project into a static library, add any other required resources, then refer to that library from the appropriate applications.
- You imported your resources from a previous version of IBM App Connect Enterprise, and your message flow projects were migrated to integration projects. You can convert all or some of your projects (such as integration projects, Java projects, and message set projects) automatically to applications and static libraries.

To convert a project to an application or library, follow the appropriate instructions.

Procedure

- To convert a project that has no references to other resources, a simple conversion to an application or static library is sufficient; see "Converting a single project to an application or library" on page 1971.
- To convert all imported projects, or a project that contains references to other resources, a conversion wizard is provided, which uses rules to decide how to convert your resources. The wizard also converts associated projects, such as Java projects and message set projects, that are referenced by the selected projects; see "Converting one or more projects with the conversion wizard" on page 1972.
- By using the conversion wizards, you can convert a project to a static library. You can then convert a static library to a shared library manually; see "Converting a static library to a shared library" on page 1974.

Converting a single project to an application or library

Convert a project with no references to other resources by using the **Convert to Application or Library** wizard.

About this task

The following restrictions apply when you convert a single project to an application or library:

- You can convert only integration projects, Java projects, and message set projects.
- You can select multiple projects to convert to applications or static libraries, but you cannot convert more than one integration project at a time. To convert multiple integration projects, you must use the **Analyse and Convert Multiple Projects** wizard.
- You cannot convert a project that refers to a library.
- If an integration project is referenced by another integration project, you can convert it to a static library only.
- When you select the **Convert single project** option, no precondition checks are made, such as checking for references to projects that do not exist. If your project might contain references to other resources, use the **Analyse and Convert Multiple Projects** wizard to analyze all projects and resources. To complete precondition checks before you convert a project, select the option **Analyse and Convert Multiple Projects**.

To convert a single project to an application or library, without making precondition checks, complete the following steps.

Procedure

1. In the Application Development view, right-click the project or projects that you want to convert, then click **Convert to application or library** > **Convert single project**.
2. Select either **an application** or **a library**.
3. Click **Finish**.

Results

The project is converted into an application or static library and is shown in the Application Development view. The contents of the original project are now shown under the new application or library.

What to do next

After you create an application or library, you can continue with any of the following tasks:

- "Creating resources in an application" on page 1964
- "Creating resources in a library" on page 1965
- "Referencing resources in other libraries" on page 1976
- "Deployment rules and guidelines" on page 2465

If you converted an integration project that referred to a Java project, you can now convert the Java project to a library so that it can be used by other applications. In the Application Development view, right-click the Java project, click **Add project to existing container**, then select an existing shared library or other container.

You can also convert an application to a static library, or a shared or static library to an application, by following the instructions in "Converting between applications and libraries" on page 1974.

Converting one or more projects with the conversion wizard

Convert all imported projects, or a project that contains references to other resources, by using the **Convert Projects to Applications and Libraries** wizard.

About this task

To convert projects to applications or static libraries, including precondition checks, complete the following steps.

Procedure

1. In the Application Development view, select the resources that you want to convert.

   You can select multiple projects in the Independent Resources folder, or you can select all projects by right-clicking the Independent Resources folder.
2. Right-click the Independent Resources folder, or one of the selected projects, and click **Convert to application or library** > **Analyze and convert multiple projects**.

   The **Convert Projects to Applications and Libraries** wizard opens.
3. Projects that you can convert are listed. Projects that you selected in step 2 are preselected in the wizard. Select the projects to convert, then click **Next**.

   The wizard completes a precondition check. If any errors are detected that would prevent successful conversion, those errors are listed. For example, an integration project cannot be converted if it references a project that does not exist. You cannot continue with the conversion until all errors are fixed.
4. Select an error and click **Fix selected**.

   Alternatively, you can fix all the errors that are listed by clicking **Fix all**. If more than one solution is available for an error, you can select the solution from the Quick Fix dialog box that opens. An error that was fixed is indicated by a green tick.

   After you apply one or more fixes, if you change your mind, you can undo fixes. Click **Cancel**, then specify whether the fixes made during the precondition check are to be undone.

   After you apply fixes to the errors, the wizard runs the precondition check again. If new errors occur, they are listed so that you can fix them.

   When no errors exist, click **Next**.

5. Review the proposed conversion actions.

   The wizard analyzes the required conversion actions and shows a summary of changes that it will make. The proposed new applications and libraries are shown in tree form. Expand an application or library to see the resources that it references. The Conversion Actions pane lists the changes that will be made to convert the selected resource.

   The wizard applies the following rules to convert projects to applications or libraries:

   - A top-level integration project, or an integration project that is not referenced by another integration project, is converted to an application.
   - An integration project that is referenced by another integration project is converted to a static library.
   - If you choose to convert a referenced project that is not an integration project, it is converted to a static library, except for data design projects and adapter connection projects. These projects are unchanged and are referenced by the application or library. If you choose not to convert the referenced project, it remains unchanged, and the referencing project refers to the original project.

     For example, an integration project refers to a message set. If the integration project and the message set project are both selected for conversion, the integration project is converted to an application, and the message set project is converted to a static library. If, however, the integration project is selected for conversion, but the referenced message set project is not selected, the integration project is converted to an application that refers to the message set. The message set is not converted.
   - A project that is not an integration project, and that is referenced by multiple projects, is converted to a wrapper library. A wrapper library is a library that refers to the original project, such as a message set project. Project references from other projects are updated to refer to the wrapper library.
   - A stand-alone project that is not an integration project is converted to a static library.
   - An integration project that contains broken references is not converted. The broken references are reported so that you can fix them.
6. The conversion changes cannot be reversed. Therefore, you are prompted to back up your workspace by clicking **Export**.
7. Optional: For future reference, you can save the conversion actions for all converted projects by clicking **Save all conversion actions to file**. You can then save the single document as a `.txt` file.
8. To complete the proposed changes, click **Finish**.

Results

Your selected projects, and affected referenced projects, are converted to applications and static libraries and are shown in the Application Development view.

What to do next

After you create an application or library, you can continue with any of the following tasks:

- “Creating resources in an application” on page 1964
- “Creating resources in a library” on page 1965
- “Referencing resources in other libraries” on page 1976
- “Deployment rules and guidelines” on page 2465

If you converted an integration project that referred to a Java project, you can now convert the Java project to a library so that it can be used by other applications. In the Application Development view, right-click the Java project, click **Add project to existing container**, then select an existing shared library or other container.

You can also convert an application to a static library, or a shared or static library to an application, by following the instructions in “Converting between applications and libraries” on page 1974.

Converting a static library to a shared library

When you use the **Convert to Application or Library** wizards, you can convert one or more projects to static libraries. You can then convert a static library to a shared library manually

Before you begin

Before you convert a static library to a shared library, check that the resources in your static library are supported in a shared library. For more information, see "Resources that are not supported in a shared library" on page 1949.

About this task

When you convert a project or application to a library, that library is a static library. To convert a static library to a shared library, complete the following steps.

Procedure

1. Create a shared library in the IBM App Connect Enterprise Toolkit by clicking **File** > **New** > **Library**.
2. Enter a temporary name for the shared library, then click **Finish**.

   The name must be unique.
3. Move the contents of the static library to the shared library.

   You must preserve the folder structure when you move the contents from a static library to a shared library. To reveal all the folders that you must move, click **Hide Categories**  on the Application Development view toolbar.

   A message warns that moving resources to another location breaks project references. Accept this message. You will fix the broken references by renaming the libraries.
4. Rename the static library so that you can use the old name for the new shared library.

   Right-click the static library, click **Rename**, and enter a name.
5. Rename the shared library so that it has the old name of the static library.

   By renaming the shared library, broken project references are fixed.
6. After you have tested the shared library, delete the static library.

Results

The new shared library is shown in the Application Development view with the appropriate icon for a shared library (). If the shared library is referenced by another resource, it is shown in the Referenced Libraries folder for that resource.

Converting between applications and libraries

You can convert an application into a static library, or you can convert a static or shared library into an application.

Before you begin

- Read the concept information about applications, libraries, and integration projects in "Resource management overview" on page 1942.
- To convert projects from previous versions of IBM App Connect Enterprise, you must first import them. For instructions, see "Migrating development resources to IBM App Connect Enterprise 12.0" on page 62.
- To convert a project to an application or library, see "Converting existing projects to applications and libraries" on page 1970.

About this task

Applications are designed to contain all the resources that you need for a particular solution. Your main message flows are typically contained by an application. Libraries are designed to contain objects for reuse. Libraries typically contain reusable helper routines and resources such as subflows, ESQL modules, message definitions, and Java utilities. You might want to convert an application to a static library if it contains resources that you want to reuse for other solutions. You might want to convert a library to an application if it contains all the resources that are required to build your solution. If your application contains runnable message flows, a warning is displayed if you try to convert it to a library.

To convert an application or library to a different project type, complete the following steps.

Procedure

1. In the Application Development view, right-click the application or library that you want to convert, then click **Convert to Application** or **Convert to Library**.

   If you are converting a library to an application, conversion happens immediately. If necessary, you can rename the converted application by right-clicking it and selecting **Rename**.
2. If you are converting an application to a static library, and your application contains runnable flows, read the warning message. To leave the application as an application, click **Cancel**. If you still want to convert the application to a library, click **Convert**.

   The application is converted to a static library. To share the resources in this library between multiple solutions, you can convert the static library to a shared library (see "Converting a static library to a shared library" on page 1974).

Results

The converted application or library is displayed with its resources in the Application Development view.

Referencing resources from a container

To include resources in your application, library, or integration service, add references to libraries, or include projects in the container.

About this task

An application contains all the resources that you need to build a business solution. An application can use the resources that are stored directly in that application, and it can use resources that are stored in other libraries or projects. Resources in the IBM App Connect Enterprise Toolkit exist in specific types of project. Resources can refer to each other; for example, a message flow can refer to subflows or maps. Referenced resources can be in the same project, or in another referenced project. Applications, libraries, and integration services can refer to the resources in other libraries. Applications and libraries can also refer to resources in other projects, such as Java projects or data design projects.

For instructions about how to refer to resources in libraries, or include projects in containers, see the following topics:

- "Referencing resources in other libraries" on page 1976
- "Adding a project to an application, integration service, or library" on page 1979
- "Removing a project from a container" on page 1981

Referencing resources in other libraries

To include resources in your application, library, or integration service from other libraries, add references to those libraries.

About this task

The best way to make a resource available to multiple applications, libraries, or integration services is to store it in a shared library. For example, you might have some common error-handling code that you want to make available to multiple applications. You can store those common files in a shared library, then you can add a reference from your application to that shared library. A shared library can also reference another shared library. A shared library is deployed with or before the container that refers to it. If you update the contents of that library and redeploy it, those changes are available to all containers that refer to the library.

For examples of how to use shared libraries to share resources between multiple solutions, see the following topics:

- "Example: Sharing Java classes between solutions" on page 1976
- "Example: Sharing map files between solutions" on page 1978

If you reference a static library from an application, that static library is embedded in the application at deployment time. The library is effectively private and is not accessible to other applications or message flows outside the referring application.

A static library can reference another static library only. Similarly, a shared library can reference another shared library only.

The following steps describe how to add library references.

Procedure

1. In the Application Development view, right-click an application, library, or integration service and click **Manage library references**.
2. Select the libraries that you require and click **OK**.

   If the libraries that you select refer to other libraries, those dependent libraries are shown.
3. To check which resources will be deployed with your solution, look at the Prepare tab of the BAR file editor. When you expand the application, integration service, or library, library references are listed.

What to do next

To remove a reference to a library, right-click an application, library, or integration service and click **Manage library references**. Clear the check box next to the library references that you want to remove and click **OK**.

Example: Sharing Java classes between solutions

When you need to use the same Java classes in multiple solutions, store those Java classes in a shared library. You can access the Java classes in the shared library by using JavaCompute nodes in your applications.

About this task

If you update those Java classes and redeploy the shared library, those changes are automatically available to all applications that reference that shared library. You do not need to redeploy the referencing applications.

Java classes that are deployed in a shared library are not available to the integration server-wide class loader. When you deploy a shared library that contains Java files, a new class loader is created for that shared library. This class loader contains all Java classes in the shared library, as well as the Java classes

from all referenced shared libraries. Java classes in shared library class loaders are isolated from Java classes in the integration server-wide class loader.

A Java class can exist in multiple class loaders if that Java class is contained in a shared library that is referenced by other shared libraries. When you update that Java class by redeploying the shared library that contains it, all class loaders for all shared libraries that contain that Java class are deleted and re-created.

If you include a JavaCompute node in a subflow in a shared library, that node can access the Java classes in that shared library and any referenced shared libraries. If you include a JavaCompute node in a flow or subflow in an application, that node can access the Java classes in a shared library and any shared libraries that are referenced by that shared library. In this case, you must specify a shared library qualifier in the form `{shlib1}` as the Java classloader service. Java classes in applications, static libraries, or independent projects cannot access Java classes in shared libraries.

The order in which you create your resources is flexible. The following steps describe one way to share Java classes between multiple applications.

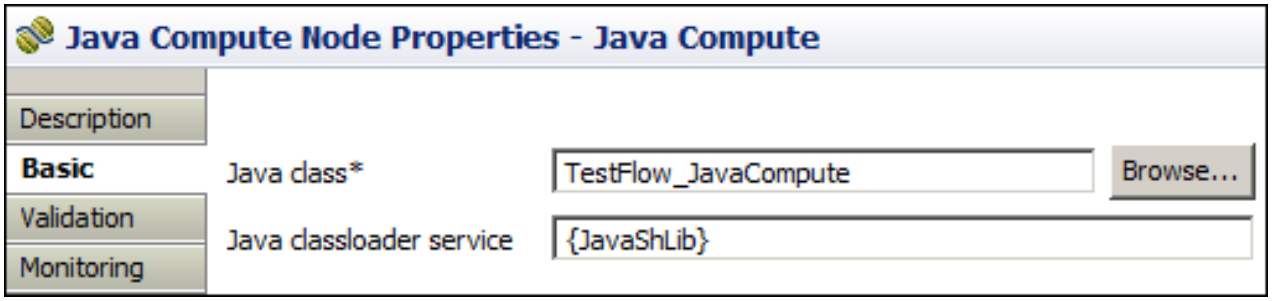
Procedure

1. In the IBM App Connect Enterprise Toolkit, create a shared library.
2. If you have existing Java classes, add them to the shared library. Otherwise, you can create your Java classes when you add a JavaCompute node to a message flow.
3. Create one or more applications to contain the message flows and other resources for your solutions.
4. Ensure that your applications refer to the shared library that contains the Java classes.
5. Create one or more message flows in your applications that contain JavaCompute nodes.
6. Configure each JavaCompute node to point to the Java classes in the shared library.

   Double-click the JavaCompute node and set the **Source folder** field to the shared library that contains the Java classes.
7. If you have existing Java classes, click **Finish**.
8. If you have not yet created your Java classes, click **Next** and select a template for your class. Define the Java build settings, then click **Finish**.

Results

The Java class file opens in the editor. If you view the basic properties for the JavaCompute node, the **Java class** field is populated with the location of the specified Java class. The **Java classloader service** field contains a qualifier for the shared library that contains the Java class in the form {*sharedLibraryName*}.



What to do next

After you create all the resources that your solution requires, deploy the shared library and the referencing applications.

You can deploy your resources by dragging the shared library and the applications onto the integration server. If you use this method, you must deploy the shared library before the applications that reference it. Alternatively, you can add the applications and shared library to a BAR file, then deploy that BAR file.

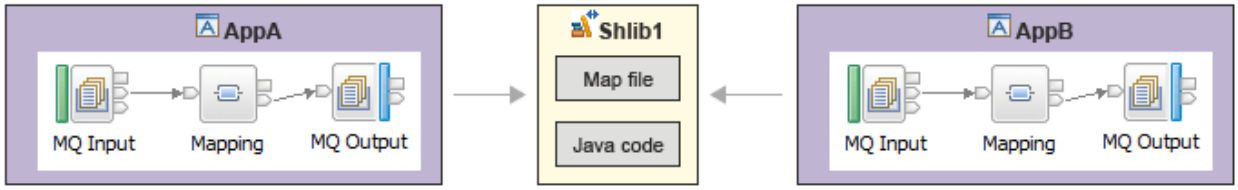
Example: Sharing map files between solutions

When you need to use the same map files in multiple solutions, store those map files in a shared library. You can access the map files in the shared library by using Mapping nodes in your applications.

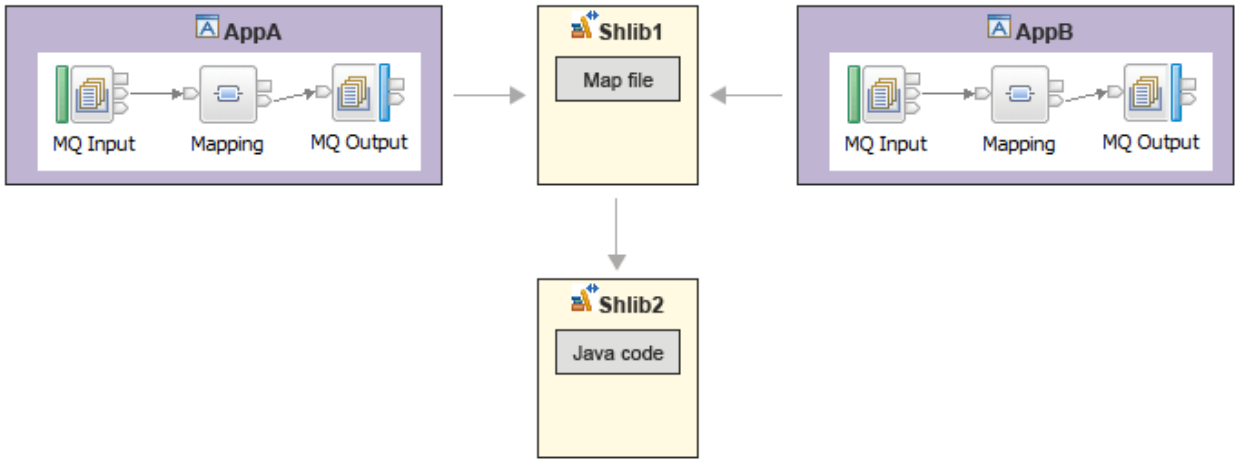
About this task

In this scenario, a map is used by multiple solutions. Therefore, the map is contained in a shared library so that multiple applications can reference it. This map uses a custom Java transformation, which is also used by multiple maps. Therefore, the Java code is also stored in a shared library, so that multiple shared libraries can reference it.

Example 1: The Mapping nodes in two different applications use the map file in a shared library. That map file uses a custom Java transformation, which is stored in the same shared library.



Example 2: The Mapping nodes in two different applications use the map file in a shared library. That map file uses a custom Java transformation, which is stored in another referenced shared library.



To create the scenario shown in example 2, complete the following steps. These steps assume that the Java code already exists in a shared library.

Procedure

1. In the IBM App Connect Enterprise Toolkit, create a message flow in an application and add a Mapping node.
2. Double-click the Mapping node. The **New Message Map** wizard opens.
3. In the **Container** field, click **New**.
4. Specify a name for the library, then click **Next**.
5. Select the shared library that contains the Java code that is required by the map, then click **Finish**.
6. To specify an alternative location for the mapping schema files, clear **Use default broker schema** and select the location of the mapping schema files. Click **Next**.
7. Select the mapping input and output models, then click **Next**.
8. The output domain is set automatically according to the selected output model. Click **Finish**.
9. Save the message flow.

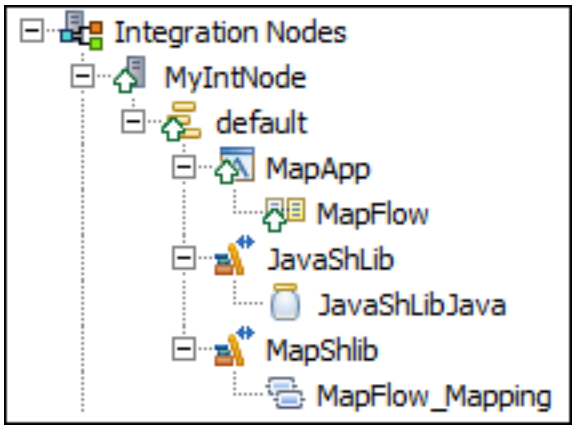
Results

You can view your resources in the Application Development view. An application contains the message flow. One shared library contains the message map, and another shared library contains the Java code that is required by that message map.

If you view the properties for the Mapping node, you can see that the **Mapping routine** field is set to the location of the map file. The location is in the following format: `{default}:MapFlow_Mapping in Shared Library MapShlib`. This value specifies that the map file is called `MapFlow_Mapping`, it uses the default broker schema, and it is contained in the shared library `MapShlib`.

What to do next

Deploy your resources. Shared libraries that are referenced by applications must be deployed with or before the applications that refer to them. You can deploy the shared libraries directly to the integration server before you deploy the applications. Alternatively, you can include the applications and shared libraries in a BAR file and deploy the BAR file.



If you update the map file or Java code in the shared libraries, those changes are available automatically to all applications that refer to those shared libraries.

Adding a project to an application, integration service, or library

If a project contains resources that are required for your solution, you can add that project to an application, integration service, or library.

Before you begin

- Read the concept information about applications, integration services, and libraries in "Resource management overview" on page 1942.
- To include projects from previous versions of IBM App Connect Enterprise, you must first import them.
- As an alternative to including a project in an application or library, you can convert a project to an application or library.

About this task

You can include the projects, such as Java projects, in an application, integration service, or library.

The following resources are not supported in shared libraries:

- WebSphere Adapters files
- Decision services
- IDL files
- Message flows

- Message sets
- Static libraries
- XSL files

You can add a project in an existing container in two ways:

- Begin with a project and choose which application or library to include it in.
- Begin with an application or library and choose which projects to include in it.

The following sections describe these methods.

Beginning with a project

Procedure

1. In the Application Development view, expand the Independent Resources folder and locate the relevant project.
2. Right-click the project and click **Add project to existing container**.

   A wizard of the same name opens. The wizard also lists any projects that are referenced by your selected project.
3. Select the application, integration service, or library in which you want to include the project, then click **OK**.

Beginning with an existing container

Procedure

1. In the Application Development view, right-click an application, integration service, or library, then click **Manage included projects**.

   A wizard lists all the projects that you can add to your application or library. The wizard does not list projects that are already included in other applications or libraries. Projects that refer to a project that is included in a different application or library are also not listed. If the project that you select refers to other projects, those projects are listed in the wizard for your information.
2. Select the project or projects that you want to include in the application or library, then click **OK**.
3. Eclipse also provides a method of managing project references. Right-click an application, library, or project in the Application Development view and click **Properties**, then **Project References**. However, use this method with caution. A list of all applications, libraries, and projects are listed, regardless of whether they can be referenced by the selected application, library, or project.
   For example, if you use this method to manage project references for a library, the interface allows you to select an application as a reference. However, a library cannot reference an application. Use this method only in the following circumstances:

   - If you want to refer to a project like a Java project or data design project from an integration project.
   - You can also use project references to enable content assist in the ESQL editor. (Content assist is context-sensitive help that displays valid ways in which a code statement can be completed.) If you set up a project reference from an integration project that contains ESQL code to a message model schema file, the ESQL editor can display a list of valid message references.

Results

The container now includes a reference to your selected project or projects. Those projects are no longer visible under the Independent Resources folder in the Application Development view, but are listed under the application, integration service, or library. To check which resources will be deployed with your solution, look at the Prepare tab of the BAR file editor. When you expand the application, integration service, or library, included projects are listed.

What to do next

To remove a project from a container, see "Removing a project from a container" on page 1981.

Removing a project from a container

If you solution no longer needs the resources in a project, you can remove that project from an application, integration service, or library.

Before you begin

- Read the concept information about applications, integration services, libraries, and integration projects in "Resource management overview" on page 1942.

This topic assumes that you have already included a project in an application or library. For more information, see "Adding a project to an application, integration service, or library" on page 1979.

About this task

You can remove the following types of project from an application or library:

- Java project
- Data design project
- Message set project

Procedure

To remove a project from a container, complete the following steps.

1. In the Application Development view, right-click an application or library, then click **Manage included projects**.

   A wizard lists all the projects that are in your application or library as well as all the projects that you can add to your application or library. The projects that are currently in the container are selected. The wizard does not list projects that are already included in other applications or libraries. Projects that refer to a project that is included in a different application or library are also not listed. If the project that you select refers to other projects, those projects are listed in the wizard for your information.
2. Clear the check boxes for the projects that you want to remove from the container, then click **OK**.

Results

The projects are removed from the application, integration service, or library. Those projects are no longer visible under the application, integration service, or library, but are listed under the Independent Resources folder.

Focusing on an application or library

Focus on an application or library to show only the resources that are associated with that container. You can also filter projects by using working sets.

Before you begin

This topic assumes that you have already created an application or library, as described in the following topics:

- "Creating an application" on page 1963
- "Creating a library" on page 1964

For more information about working sets, see Working sets.

About this task

If you focus on an application or library, the Application Development view shows only the selected container and its contents.

To focus on an application or library, complete the following steps.

Procedure

1. In the Application Development view, right-click an application or library, then click **Focus on Application** or **Focus on Library**.
2. To show all resources in the Application Development view, right-click the application or library, then click **Focus on Application** or **Focus on Library** again to deselect the option.

Deleting an integration project

An integration project is the container in which you create and maintain all the resources associated with one or more message flows. These resources are created as files, and are displayed in the project in the Application Development view. If you do not want to retain an integration project, you can delete it.

Before you begin

- The instructions in this topic assume that you have already created an integration project, as described in "Creating an integration project" on page 1969.
- Read the concept topic about "Integration projects" on page 1959

About this task

When you delete an integration project in the IBM App Connect Enterprise Toolkit, you can choose to delete the project and its resources. If you are using a shared repository, the repository might retain a copy of a deleted resource.

To delete an integration project, complete the following steps.

Procedure

1. In the Application Development view, select the integration project that you want to delete, and click **Edit** > **Delete**.

   You can also press Delete, or right-click the project and click **Delete**.
2. To delete the contents of the integration project, select **Also delete contents under *directory_name***.

   If you choose not to delete the contents of the integration project directory, all the files and the directory itself are retained. If you later create another project with the same name, and specify the same location for the project (or accept the location as the default value), you can access the files previously created.

   If you choose to delete all the contents, all files and the directory itself are deleted.
3. Click **Yes** to delete the integration project and selected resources.

Results

If you maintain resources in a shared repository, a copy is retained in that repository. You can follow the instructions provided by the repository supplier to retrieve the resource, if required.

If you are using the local drive or a shared drive to store your resources, no copy of the resource is retained. Be careful to select the correct resource when you complete this task.

Deleting a schema

You can delete a broker schema that you have created in an application or library if you no longer need it.

Before you begin

This topic assumes that you have already created a broker schema, as described in "Creating a broker schema" on page 1966. For more information about schemas, see "Broker schemas" on page 498.

About this task

The Application Development view is populated with all the applications and libraries to which you have access. A broker schema is contained in one of these containers.

To delete a broker schema, complete the following steps.

Procedure

1. In the Application Development view, expand the appropriate application or library.
2. If the schema contains resources, delete them.

   To delete the schema, it must be empty. The schema might not be visible in the Application Development view when it is empty. To show the new schema in the Application Development view, click **Hide Categories**  on the Application Development view toolbar.
3. Select the broker schema, then click **Edit** > **Delete**.

   A confirmation dialog box is displayed.
4. Click **Yes** to delete the broker schema directory or **No** to cancel the delete request.

   When you click **Yes**, the requested objects are deleted.

   If you maintain resources in a shared repository, a copy is retained in that repository. You can follow the instructions provided by the repository supplier to retrieve the resource, if required.

   If you are using the local file system or a shared file system to store your resources, no copy of the resource is retained. Be careful to select the correct resource when you complete this task.

Results

Exporting XSD schema files from an application or library

Export XSD schema (`.xsd`) files from an application or library for use in external tools.

About this task

You can export `.xsd` files without annotations specific to WebSphere Adapters from an application or library, so that you can use them in other programs.

Procedure

1. In the Application Development view:
   - Right-click your application and click **Export XSDs from Application**. The **Export XSDs from Application** window opens.
   - Right-click your library and click **Export XSDs from Library**. The **Export XSDs from Library** window opens.
2. Enter the directory that you want to export the `.xsd` files to, and click **OK**.

Results

Your `.xsd` files are exported from the application or library to the directory you selected.

Developing integration solutions by using integration services

To create web services solutions, create integration solutions by using integration services.

Before you begin

If you are not familiar with message flow concepts, message model concepts, and common tasks to manage message flow resources, see "Developing message flows" on page 482 and "Constructing message models" on page 2133.

About this task

In IBM App Connect Enterprise, an integration service is a specialized application that has a tightly defined interface and operations. You can configure the integration service so that you can call the operations from a web service (by using a SOAP/HTTP binding), or from a JavaScript program (by using a JavaScript API binding). For more information, see "Integration services" on page 1944.

Procedure

To build an integration service:

1. Create an integration service interface.

   You have the following options:

   - Create an integration service interface from scratch. For more information, see "Creating an integration service from scratch" on page 1986.
   - Create an integration service interface by importing an existing WSDL. For more information, see "Creating an integration service based on a WSDL file" on page 1987.
2. If your integration service is not based on imported WSDL or a Business Process Manager service, specify the interface by defining the operations. See "Defining the operations in a service interface" on page 1989.
3. Optional: Create a library to contain a logical grouping of related code, schemas, message models, and other resources that can be reused. For more information, see "Creating a library" on page 1964.
4. Optional: Define the required library references in the integration services, as described in "Referencing resources in other libraries" on page 1976. To include one or more libraries of resources in your integration service, you create references to those libraries.
5. Optional: Create other resources that you need in a library. These resources can be reused by other integration services or applications. For more information, see "Creating resources in a library" on page 1965.
6. Use the Service editor to implement each service operation as a subflow. See "Implementing an integration service operation" on page 1993.
7. Use the Service editor to implement a subflow for each available error handler. See "Implementing an integration service error handler subflow" on page 1994.
8. Generate your own HTTP binding for the service.

   See "Generating an integration service SOAP/HTTP binding" on page 1995. You can instead use the default HTTP binding that is generated when the service is created.
9. Optional: Generate a JavaScript client API so that you can call the integration service from a program that is running in a JavaScript environment. For more information about the JavaScript client API, see "Integration service JavaScript client API " on page 1995.

What to do next

- Deploy and test your integration service. For more information, see How do I deploy and test ?.
- View the deployed service by using the web user interface or the WebSphere Application Server administration console. For more information, see one of the following topics.
  - “Checking the results of deployment” on page 2485
  - web user interface

Integration service editor

The integration service editor is the default editor for viewing a graphical representation of a service and its operations, and for editing properties and implementing service operations. The integration service editor comprises a service overview and an interface editor. You can also define and implement operations.

Service overview

To start the integration service editor in the Editor view, open an integration service description in the Application Development view.

The **Service** tab provides a graphical overview of your integration service, showing:

- The service interface and the operations.
- The service endpoint and binding.
- The service error handlers.

The service endpoint and binding are shown on the left.

The service interface and operations are shown on the right.

Operations without an implementation are shown in the **Service** tab with a grayed-out icon.

By default, a SOAP over HTTP binding is generated when the integration service is created.

The following error handlers are created by default for each integration service:

- A Catch error handler.
- A Failure error handler.
- A Timeout error handler.

Service interface

The **Interface** tab shows the details of the operations that are defined for an integration service. Each of the operation inputs, outputs, and faults has a name and a type that is editable.

In the **Interface** tab, you can do any of the following actions:

- Define further operations. Add a new request-response or one-way operation in the Interface tab by using the controls in the Operations section. Alternatively, right-click anywhere in the editor pane.
- Remove existing operations.
- Specify names to existing operations.
- Add or remove inputs, outputs, and faults to an operation.
- Create a complex type for an input, output, or fault.

By default, a request-response operation is created when the integration service is created.

Operation implementation

You implement an operation in the integration service editor by clicking the operation that is shown in the **Service** tab. The embedded subflow editor opens for you to implement the operation as a subflow.

Use the breadcrumb navigation at the top of the editor to return to the integration service overview.

Creating an integration service from scratch

To create an integration service from scratch, define a service interface and implement its operations.

Before you begin

- Read the concept information about "Integration services" on page 1944.
- If you want to create an integration service definition that will be used by multiple integration services, create a shared library. You can then select this shared library when you complete the **New Integration Service** wizard.

If you have an existing interface that is specified in a WSDL file or designed in a Business Process Manager `.twx` file, complete the steps in one of the following topics:

- "Creating an integration service based on a WSDL file" on page 1987
- "Creating an integration service from a Business Process Manager integration service" on page 1988

About this task

To create an integration service by defining a new interface, complete the following steps:

Procedure

1. Open the **New Integration Service** wizard by using one of the following methods:
   - Click **File** > **New** > **Integration Service**.
   - In the Application Development view, click **New** > **Start by creating an integration service**.
   - Right-click the white space of the Application Development view then click **New** > **Integration Service**.
2. Enter a name for the integration service, and optionally a description.
3. To specify how you want to define the interface for your integration service, select **Define it myself using the integration service editor**.
4. Specify where you want to store your interface definition.
   - If the definition will be used by this integration service only, store the definition in the integration service project.
   - If the definition might be used by multiple integration services, store the definition in a shared library.
5. Click **Next**.
6. Optional: If the integration service requires resources that are stored in libraries, select those libraries. This step creates a reference to the libraries from the integration service.
7. Click **Finish**.

Results

An integration service is created and is shown in the Service editor. You can also expand the service in the Application Development view to view the integration service and its associated resources.

What to do next

1. Define the operations of the service interface by using the **Interface** tab of the service editor.

   Use the controls to add a request-response operation or a one-way (request) operation. You can define the inputs and outputs of each operation, and specify the name and type of each one. For more information, see "Defining the operations in a service interface" on page 1989.

2. Implement the operations that are defined in your service interface. For more information, see "Implementing an integration service operation" on page 1993.
3. Deploy and test an integration service. If you have stored your definition in a shared library, or referenced other resources in shared libraries, you must deploy the shared libraries with or before the integration service. If you update the resources in a shared library and redeploy it, those changes are available to all integration services that reference the shared library. For more information, see "Deployment rules and guidelines" on page 2465.

Creating an integration service based on a WSDL file

To create an integration service that is based on a WSDL file, define a service interface and implement its operations.

Before you begin

- Read the concept information about "Integration services" on page 1944.
- If multiple integration services might use the same WSDL file, store the WSDL file in a shared library. You can then select this shared library when you complete the **New Integration Service** wizard.

If you have an existing interface that is designed in a Business Process Manager `.twx` file, or you want to define your own interface, complete the steps in one of the following topics:

- "Creating an integration service from a Business Process Manager integration service" on page 1988
- "Creating an integration service from scratch" on page 1986

About this task

To create an integration service that is based on an existing WSDL file, complete the following steps:

Procedure

1. Open the **New Integration Service** wizard by using one of the following methods:
   - Click **File** > **New** > **Integration Service**.
   - In the Application Development view, click **New** > **Start by creating an integration service**.
   - Right-click the white space of the Application Development view, then click **New** > **Integration Service**.
2. Enter a name for the integration service, and optionally a description.
3. To specify how you want to define the interface for your integration service, select **Implement an interface already specified in an existing WSDL file**.
4. Specify how you want to use the WSDL file to implement the interface.
   - If the WSDL file will be used by this integration service only, import the file into the integration service project.
   - If you have a WSDL file that might be used by multiple integration services, use a WSDL file from a shared library.
5. Click **Next**.
6. Select the location of the WSDL file.
   - If you are importing a WSDL file, select the file from your workspace, or from an external location.
   - If you are using a WSDL file in a shared library, select the WSDL file from the relevant library in your workspace.
7. Click **Next**.
8. Select the WSDL bindings to import, and click **Next**.

   You can import only a SOAP over HTTP binding.

9. Optional: If your integration service requires resources that are stored in libraries, select the appropriate libraries, then click **Finish**.

   If, in Step 6, you decided to use a WSDL in a shared library, the reference to that library is created at that point. You do not need to refer to that library in this step.

Results

An integration service is created with the operations that are defined in the imported WSDL file. The integration service is shown in the Service editor. You can also expand the integration service in the Application Development view to view operations and associated resources.

What to do next

1. Implement the operations that are defined in your service interface. For more information, see "Implementing an integration service operation" on page 1993.
2. Deploy and test an integration service. If you have stored your WSDL file in a shared library, or referenced other resources in shared libraries, you must deploy the shared libraries with or before the integration service. If you update the resources in a shared library and redeploy it, those changes are available to all integration services that reference the shared library. For more information, see "Deployment rules and guidelines" on page 2465.

Creating an integration service from a Business Process Manager integration service

Use the **Create a new service interface from an IBM Business Process Manager integration service** option to create an integration service from a Business Process Manager `.twx` file.

Before you begin

Read the conceptual information about "Integration services" on page 1944.

If you have an existing interface that is specified in a WSDL file, or you want to define your own interface, complete the steps in one of the following topics:

- "Creating an integration service based on a WSDL file" on page 1987
- "Creating an integration service from scratch" on page 1986

Procedure

To create an integration service that is based on a Business Process Manager service, complete the following steps:

1. Open the **New Integration Service** wizard by using one of the following methods: ,
   - Click **File** > **New** > **Integration Service**.
   - In the Application Development view, click **New** > **Start by creating an integration service**.
   - Right-click the white space of the Application Development view, then click **New** > **Integration Service**.
2. Enter a name for the integration service, and optionally a description.
3. Select **Implement an interface already defined in Business Process Manager (.twx file)**, then click **Next**.
4. To select an Business Process Manager export (`.twx`) file, click **Browse** and locate the `.twx` file.
5. Select a Business Process Manager integration service, then click **Finish**.

Results

An integration service is created and is shown in the Service editor. You can also expand the service in the Application Development view to view operations and associated resources.

What to do next

1. Edit the operations that are defined in the service interface by using the **Interface** tab of the service editor.
2. Implement the operations that are defined in your service interface. For more information, see "Implementing an integration service operation" on page 1993.
3. Deploy and test an integration service. For more information, see "Deployment rules and guidelines" on page 2465.

Defining the operations in a service interface

Specify your service interface by defining the service operations, the operation types, and the operations inputs, outputs, and faults.

Before you begin

Create an integration service.

About this task

When you create an integration service in IBM App Connect Enterprise, the service opens in the service editor.

In the **Interface** tab:

- You can define further operations.
- You can remove existing operations.
- You can specify names to existing operations.
- You can add or remove inputs, outputs, and faults to an operation.
- You can create a complex type for an input, output, or fault.

For more information, see "Integration service editor" on page 1985.

Procedure

Complete the following steps to define an integration service interface:

1. Open your integration service in the Service editor by double-clicking the **Service Description** in the Application Development view, or by right-clicking and selecting **Open**.
2. Select the **Interface** tab to see the interface editor.
3. By default, a request-response operation is created when the integration service is created. Click the operation name to edit it.
4. Add or remove request-response operations and one-way operations by using the icons.
5. Add or remove inputs, outputs, and faults to operations by using the icons.

   In the **Properties** tab, click the name and type of an input, output, or fault to edit it. You can create a new complex type for an input, output, or fault by clicking the type and selecting **New...**.

Results

Your service interface is defined.

What to do next

Implement the operations that are defined in your integration service. For more information, see "Implementing an integration service operation" on page 1993.

Developing a service interface

An example of developing a service interface using the service editor.

Before you begin

Read the concept information about “Integration services” on page 1944, and create a service from scratch. See “Creating an integration service from scratch” on page 1986.

About this task

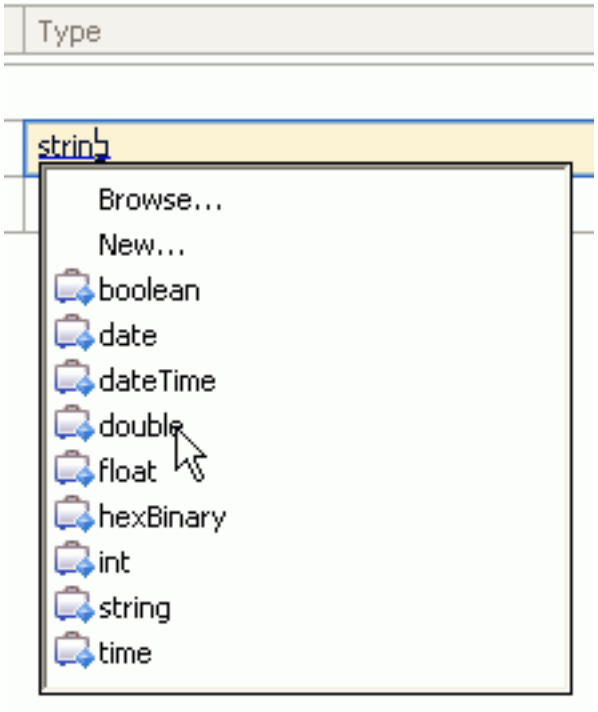
A service in IBM App Connect Enterprise is a specialized application that contains a web services solution. It defines an interface with operations that are implemented as separate subflows. The following example shows how to create an interface and define operations. The complete interface is explained in “Example of a service interface” on page 1992.

Procedure

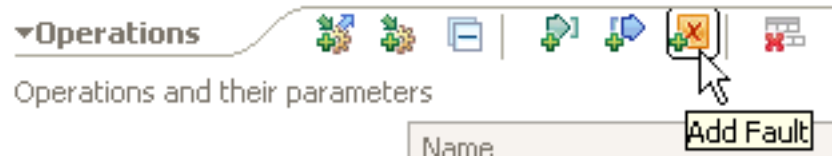
1. Open your integration service in the Service editor by double-clicking the **Service Description** in the Application Development view, or by right-clicking and selecting **Open**.
2. Display the service interface by switching to the **Interface** tab in the Service editor.
3. A default request-response operation, `operation1`, is created when the service is created. Rename `operation1` to `getApproval`.
4. Rename the inputs and outputs, and edit the types.
   a) Rename *input1* to *balance*. In the **Type** field, select the default, `string`. From the context menu, select `double`.

      The type is changed.

   b) Change *output1* to *approval* and the leave the type as `string`.



5. Add two faults to `getApproval` using the **Add Fault** icon: a *timeout* fault with a `string` type and *systemFailure*, also with a `string` type.



These faults will appear in the properties of bindings which use your interface. You can then implement the faults with fault selectors.

6. Add another request-response operation by clicking the **Add Request Response Operation** icon, or right-clicking and selecting from the context menu. A request-response operation with an input and an output is created. called `getHistory` with an input of *customerName* with a `string` type and an output of *customerHistory* with a `string` type. Select the `string` type of *customerHistory* and change the Name field to *customerPastHistory*.

7. Add the same *timeout* and *systemFailure* faults in this operation as the previous one. These faults would return error messages for timeout conditions or a system failure.
8. Add a one-way operation called `updateCreditRating`, either from the icons by selecting **Add One Way Operation** or right-clicking the canvas area in the interface editor and selecting from the context menu. Rename the input to *currentRating* with a `string` type. One-way operations send only an input as there is no response required.

	Name	Type
getApproval		
Inputs	balance	double
Outputs	approval	string
Fault	timeout	string
Fault	systemFailure	string
getHistory		
Inputs	customerName	string
Outputs	customerPastHistory	string
Fault	timeout	string
Fault	systemFailure	string
updateCreditRating		
Inputs	currentRating	string

What to do next

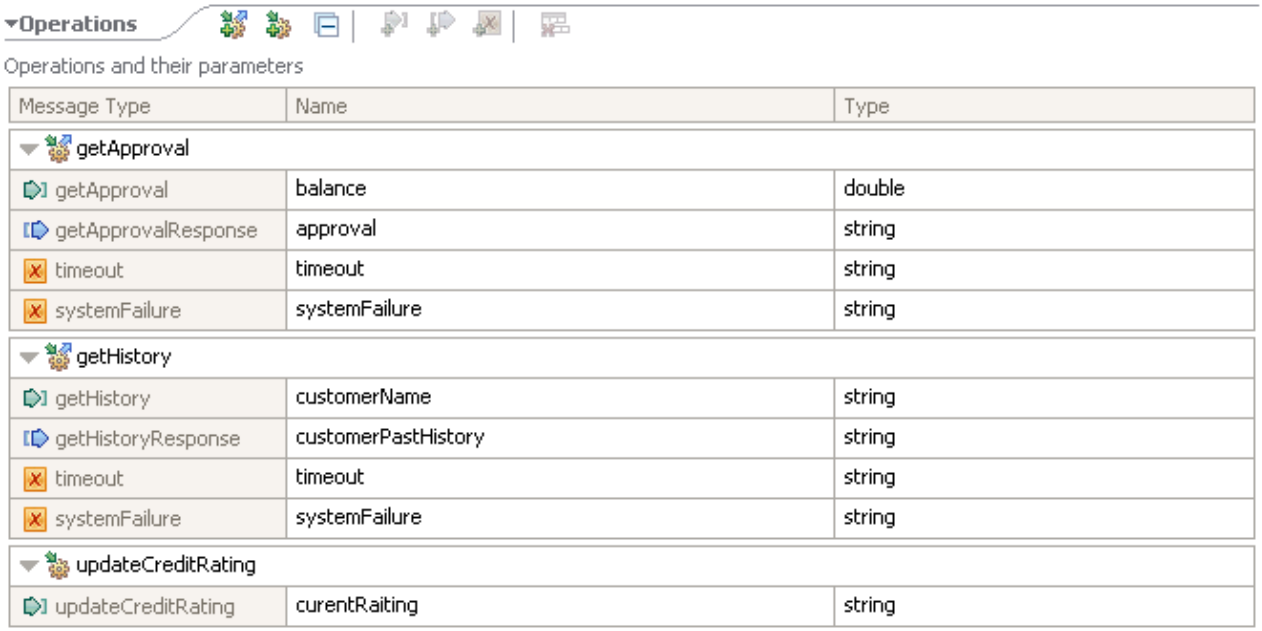
Implement the operations defined in the integration service as separate subflows. For more information, see “Implementing an integration service operation” on page 1993.

Example of a service interface

An integration service in IBM App Connect Enterprise is a specialized application with a well-defined interface, and implementation flows for each service operation. This example shows a service interface.

Read the concept information about “Integration services” on page 1944.

In the screen capture that follows, an interface has been created for a credit report. This is the interface to a component that will send a balance of a customer's account and get the approval for a transaction, get the history of the customer's account, and then update the customer's credit rating. `getApproval` and `getHistory` are request-response operations. `updateCreditRating` is a one-way operation.



Message Type	Name	Type
getApproval		
getApproval	balance	double
getApprovalResponse	approval	string
timeout	timeout	string
systemFailure	systemFailure	string
getHistory		
getHistory	customerName	string
getHistoryResponse	customerPastHistory	string
timeout	timeout	string
systemFailure	systemFailure	string
updateCreditRating		
updateCreditRating	curentRaiting	string

The following parts of the credit report interface are shown in the interface editor:

Request-response operation

`getApproval`, when invoked, sends the balance of customer account and gets the approval for a transaction. `getApproval` contains the following inputs, outputs, and faults:

- Input: `getApproval` sends as input the variable balance. The variable balance must have a double data type.
- Output: `getApproval` returns as output a variable named *approval*. The variable *approval* contains a string recommending approval (if funds are sufficient to justify granting credit) or rejection (if funds are not sufficient to extend credit to the applicant).
- Faults: `getApproval` may return one of two faults, both of which are strings describing an error condition: `timeout` is returned if the service waits for an excessive amount of time to determine approval; `systemFailure` is returned if there is communication or power failure.

Request-response operation

`getHistory`, when invoked, sends the name of a customer account and gets the history of the customer's transactions. `getHistory` contains the following inputs, outputs, and faults:

- Input: `getHistory` sends as input the variable *customerName*. The variable *customerName* must have a string data type.
- Output: `getHistory` returns as output a variable named *customerPastHistory*. The variable *customerPastHistory* contains a string with a record of past transactions.

- Fault: `getHistory` may return one of two faults, both of which are strings describing an error condition: `timeout` is returned if the service waits for an excessive amount of time to determine approval; `systemFailure` is returned if there is communication or power failure.

One-way operation

`updateCreditRating` when invoked sends the current credit rating of the customer. `updateCreditRating` has the following inputs:

- Input: `updateCreditRating` sends as input the variable *currentRating*. The variable *currentRating* must have a string data type.

By default, all added inputs and outputs of any simple type are mandatory fields. Selecting an input, output, or fault from the table opens further details about them in the properties view of the interface editor.

For an example of how to develop this interface from scratch, see "Developing a service interface" on page 1990.

Implementing an integration service operation

Implement the operations that are defined in your service interface.

About this task

You can use different editors to implement an integration service operation:

- You can implement a service operation by using the Service editor. For more information, see "Integration service editor" on page 1985.
- You can implement an operation by using the Message flow editor. For more information, see Message Flow editor.

Procedure

Complete the following steps to implement an operation:

1. Open the integration service.
   - In the Service editor, double-click the Service Description of the integration service in the Application Development view. The service **Overview** tab opens in the service editor.
   - In the Message flow editor, expand the integration service resources in the Application Development view.
2. Open the operation in an editor.
   - If you are using the Service editor, click an operation to open the embedded subflow editor.
   - If you are using the Message flow editor, double-click the subflow that represents the operation.
3. Implement the operation as a subflow. For more information, see "Developing message flows" on page 482.
   - A one-way operation has 1 input node by default.
   - A request-response operation has 1 input node and 1 output node by default.
   - Operation faults are displayed in the subflow as output nodes.

   Note: For the integration service to be called by using any binding, the response message that is built in the subflow must consist of the service payload in the XMLNSC domain. For example, if you are building a response in a Compute node, then you should write:

   ```
   SET OutputRoot.XMLNSC.NS1:echoResponse.data = 'response';
   ```

   instead of:

   ```
   SET OutputRoot.SOAP.Body.NS1:echoResponse.data = 'response';
   ```

4. Use the breadcrumb navigation at the top of the editor to return to the service overview.

What to do next

Implement the integration service error handlers. For more information, see "Implementing an integration service error handler subflow" on page 1994.

Implementing an integration service error handler subflow

Implement the error handlers that are defined in your service interface.

About this task

You edit a service interface by using the **Interface** tab of the service editor.

In the **Interface** tab:

- You can define further operations.
- You can specify names to existing operations.
- You can add inputs, outputs, and faults to an operation.
- You can implement an operation.

For more information, see "Integration service editor" on page 1985.

An integration service might encounter errors such as message failure or timeout.

IBM App Connect Enterprise provides the following error handlers to handle any errors that occur within your integration service:

- Catch error handler.
- Failure error handler.
- Timeout error handler.

You implement these error handlers as subflows:

- You implement the Catch error handler by developing the InputCatchHandler.subflow.
- You implement the Failure error handler by developing the InputFailureHandler.subflow.
- You implement the Timeout error handler by developing the InputHTTPTimeoutHandler.subflow.

Procedure

Complete the following tasks to implement an error handler subflow:

1. Open the integration service in the service editor by double-clicking the Service Description in the Application Development view.

   The service overview opens in the service editor.
2. Error handlers that are available to implement are displayed below the operations that are defined in your interface. Click on an error handler to open the embedded subflow editor and implement the error handler as a subflow.
3. Use the breadcrumb navigation at the top of the editor to return to the service overview.

What to do next

Generate a new integration service binding. For more information, see "Generating an integration service SOAP/HTTP binding" on page 1995.

Generating an integration service SOAP/HTTP binding

Learn the steps to generate a binding for your integration service.

About this task

When you create an integration service in IBM App Connect Enterprise, the service opens in the service editor. The service endpoint and binding are shown on the left of the integration service overview. The *Service Input* node represents the service endpoint. A default SOAP over HTTP binding is generated, shown next to the *Service Input* node icon.

You can also create your own binding. First, you delete the default binding, and then you can generate a new binding.

The integration service binding can be created and configured before or after you define and implement your operations.

Procedure

Complete the following steps to generate a binding:

1. In the IBM App Connect Enterprise Toolkit, open your integration service in the Service editor by double-clicking **Integration Service Description** in the Application Development view. Select the **Service** tab to see the service overview.
2. Delete the default SOAP/HTTP binding.

   Right-click the binding name and select **Remove Binding**.

   The existing binding is deleted. The service SOAPInput node icon changes to an Input node.
3. Right-click the Input node. Select **Generate** > **SOAP/HTTP Binding**. The **Generate SOAP/HTTP Binding wizard** launches.
4. Select a SOAP/HTTP binding type of either SOAP 1.1 or SOAP 1.2.
5. Enter the URL for the binding. Click **Finish**.

Results

A SOAP over HTTP binding is generated. The integration service input node icon is updated to a SOAPInput node icon, and the name of the binding is displayed next to it.

The properties of the binding are shown in the Properties view when the binding is selected in the Service editor. You can view and edit the binding properties in the Properties view.

Consumers can query your deployed integration service using a `?wsdl` query string to return the service interface. To disable this behavior, select the SOAP/HTTP binding in the Services editor, and clear `Enable support for ?wsdl` in the HTTP transport tab of the SOAP/HTTP service binding properties.

What to do next

Deploy the integration service to an integration server. For more information, see Chapter 7, “Deploying integration solutions,” on page 2463.

Integration service JavaScript client API

An integration service developer can generate a JavaScript client API from an existing integration service. The JavaScript client API provides operation functions that a JavaScript developer can call from an application that is running in a JavaScript environment.

When the integration service developer generates the JavaScript client API for an integration service, the following events occur:

- JavaScript client API code is generated from the definition of the existing integration service interface. You can use this code in JavaScript applications to call the integration service operations without

configuring the underlying communication mechanism. A JavaScript method is created for each integration service operation.

- A JSON/HTTP binding is added to the integration service so that JSON (JavaScript Object Notation) messages that are sent from the JavaScript client API can be processed by the integration service. The JSON/HTTP binding is intended for use only by the JavaScript client API.
- A web page that describes the JavaScript client API is generated. From the web page, the JavaScript developer can download or reference the JavaScript client API code and copy sample code directly into JavaScript client applications. The web page is accessed from the integration service URL.

Elements that are defined in the existing integration service, such as shared variables and Java statics, also apply to the integration service when the integration service is called by the JavaScript client API.

If the integration service is updated after the JavaScript client API is generated, then the JavaScript client API file and the associated web page are automatically updated when the integration service is saved.

Restrictions

The following restrictions apply to the JavaScript client API that is generated from an integration service description:

- Calling integration services by using the JavaScript client API is supported only from clients that are initiated either by Node.js, or by a Google Chrome web browser.
- JavaScript client API code can be generated only from an existing integration service.
- If you are deploying a web browser-based JavaScript application, then the IBM App Connect Enterprise HTTP proxy servlet must be deployed on the same web server as your JavaScript application. For information about the HTTP proxy servlet, see "HTTP proxy servlet overview" on page 141.
- The SOAP/HTTP binding is not required in order for the integration service to be called by the JavaScript client API. However, if the SOAP/HTTP binding is removed from an integration service, then the root URL for the integration service is not available and therefore the JavaScript client API code and associated web page are not accessible.

Configuring the environment for a web browser-based application that uses the JavaScript client API

To ensure that a web browser-based JavaScript application can receive messages from the integration service, you must deploy the IBM App Connect Enterprise HTTP proxy servlet onto the web application server that hosts the JavaScript application.

About this task

By default, direct communication between a web browser-based JavaScript application and an integration service is blocked by the web browser to prevent a potential cross-site scripting attack. To enable communication between the JavaScript application and an integration service, you must complete the following tasks to install and configure an HTTP proxy servlet:

Procedure

1. Configure the integration server that hosts the integration service to use the integration node listener for SOAP nodes.
2. Start an MQ listener (for example, the SYSTEM.DEFAULT.LISTENER.TCP listener) in the IBM MQ queue manager.

   For more information, search for *START LISTENER* in the IBM MQ product documentation.

3. Configure the HTTP proxy servlet with the following initialization parameters:

Parameter name	Value	Description
useClientMode	true	You should set this value to `true` even if the web application server is on the same machine as IBM App Connect Enterprise.
useQueueManagerDataInstead	*qmgr*OfConfigFile	*qmgr* is the name of your IBM MQ queue manager.
clientModeHostname	*hostname*	*hostname* is the host name or IP address for the queue manager. You can set this value to `localhost` if IBM MQ is installed on the same machine as IBM App Connect Enterprise.
clientModeChannelName	*channelname*	*channelname* is the name of the IBM MQ SVRCONN channel. The default value is SYSTEM.DEF.SVRCONN.
clientModePortNumber	*portnumber*	*portnumber* is the port number of the IBM MQ listener that you started in step 2. The default value for the SYSTEM.DEFAULT.LISTENER.TCP is 1414.

4. Deploy and configure the HTTP proxy servlet on the web application server that will host the JavaScript application.

Results

You have deployed the IBM App Connect Enterprise HTTP proxy servlet onto a web application server. A web browser-based JavaScript application (that is deployed on the same web application server as the HTTP proxy servlet) can now communicate with an integration service that is deployed on an IBM App Connect Enterprise integration server.

What to do next

"Generating a JavaScript client API for an integration service" on page 1997

Generating a JavaScript client API for an integration service

An IBM App Connect Enterprise integration service developer or administrator can generate a JavaScript client API for an existing integration service so that the integration service can be called from an application that is running in a JavaScript environment.

Before you begin

- You must have an existing integration service that uses the default SOAP/HTTP binding.
- Ensure that you are not referring to information from SOAP headers or SOAP attachments in your integration service, because this information is not available when the integration service is called by the JavaScript client API.
- If the JavaScript client API is being generated for use by a web browser-based JavaScript application, then you must configure the IBM App Connect Enterprise environment to support this usage, see "Configuring the environment for a web browser-based application that uses the JavaScript client API" on page 1996.

Procedure

Complete the following steps to generate a JavaScript client API from an existing integration service:

1. In the IBM App Connect Enterprise Toolkit, open your integration service in the integration service editor by double-clicking **Integration Service Description** in the Application Development view.
2. Click the **Service** tab.

   The integration service description is displayed, which includes the SOAP/HTTP binding.
3. Above the SOAP/HTTP binding, right-click the integration service name and click **Generate** > **JavaScript Client API**.

   The JavaScript client API for the integration service is generated and a reference to the JavaScript client API is displayed below the SOAP/HTTP binding.

   The properties of the JavaScript client API are shown in the **Properties** view when the JavaScript client API is selected in the integration service editor. You can view and edit the JavaScript client API properties from the **Properties** view.

   Note: The **Generate** > **JavaScript Client API** menu option is not available when the JavaScript client API already exists. In normal conditions, you should not need to regenerate the JavaScript client API. When you add new operations to the integration service, or update or delete existing operations, the API is automatically updated when you save the integration service. However, if you want to manually regenerate the JavaScript client API, you must remove the existing API first by right-clicking the **JavaScript Client API** entry and clicking **Remove**.

Results

- JavaScript client API files are generated from the definition of the existing integration service interface. The JavaScript client API files contain code that includes a JavaScript method for each integration service operation.
- A JSON/HTTP binding is added to the integration service so that JSON (JavaScript Object Notation) messages that are sent from the JavaScript client API can be processed by the integration service.
- A web page that describes the JavaScript client API is generated. From the web page, the JavaScript developer can download or reference the JavaScript client API code and copy sample code directly into JavaScript applications. The web page is accessed from the integration service URL.

What to do next

1. Deploy the integration service to an integration server. For more information, see Chapter 7, “Deploying integration solutions,” on page 2463.
2. Provide JavaScript developers with the integration service URL so that they can download or reference the JavaScript client API files and copy the sample code. The JavaScript developers can use the JavaScript client API to call the integration service. For more information, see “Calling an integration service by using a JavaScript client API” on page 1998.

Calling an integration service by using a JavaScript client API

When a JavaScript client API is generated from an integration service, a JavaScript developer can use the JavaScript client API to call the integration service from an application that is running in a JavaScript environment.

Before you begin

- A JavaScript client API must be generated from an existing integration service, see “Generating a JavaScript client API for an integration service” on page 1997.
- If you are developing a web browser-based JavaScript application, then you must configure your environment to use the HTTP proxy servlet, see “Configuring the environment for a web browser-based application that uses the JavaScript client API” on page 1996.

About this task

Complete the following steps to call an integration service from a JavaScript application:

Procedure

1. Understand the conventions that you must use, and the limitations that you must be aware of, when you write an application that uses the JavaScript client API to call an integration service; see "JSON conventions for calling an integration service by using a JavaScript client API" on page 2000.
2. Obtain the integration service URL from the IBM App Connect Enterprise integration service developer or administrator, or complete the following steps:
   a) In the IBM App Connect Enterprise Toolkit, click the deployed integration service in the **Integration Nodes** view.
   b) Click the **Properties** tab.

   The integration service URL is listed in the Info section.

   Note: The integration service URL is available only when the integration service has a SOAP/HTTP binding.
3. Access the integration service URL by using a web browser, and click the **JavaScript Client API** link.

   A web page is displayed. The web page contains the following items:

   - A link to the JavaScript client API file, which you can download (if you are developing a Node.js application) or reference (if you are developing a web browser-based JavaScript application). You can then use the JavaScript client API file to access the integration service.
   - Details of the JavaScript client API methods of the integration service operations, which include the input and output objects.
   - Details of the errors that might be returned from the integration service.
   - Sample code that you can add to your JavaScript application to call the JavaScript client API methods of the integration service operations, and to process any errors that are returned from the integration service.

   For more information about the contents of the web page, see "Integration service web page" on page 2001.
4. Optional: If you are developing a Node.js application, then complete the following steps:
   a) Use the Node.js package manager (npm) to install the Dojo package by changing to the Node.js installation directory and typing the following command on the command line:

   ```
   npm install dojo
   ```

   b) Download the *service_name*`.js` JavaScript client API file from the web page, where *service_name* is the name of the integration service.
   c) Create a Node.js application that imports the downloaded JavaScript client API file.
   d) Specify the host name and port of the integration service; see "Specifying the host name and port of the integration service" on page 2006.
5. Optional: If you are developing a web browser-based JavaScript application, then complete the following steps:
   a) Create a web browser-based JavaScript application.
   b) Reference the `dojo.js` module and the JavaScript client API file for the integration service; see "Referencing the dojo.js module and the JavaScript client API file" on page 2006.
6. Use the information on the integration service web page to help you complete the following tasks:
   - Create the input objects for the JavaScript client API methods of the integration service operations.
   - Use the sample code in your JavaScript application to access the JavaScript client API methods of the integration service operations.
   - Add code to your JavaScript application that handles the errors that might be returned from the integration service, and interrogates the errors for the information you require.

Results

You can write a JavaScript application to call an existing integration service.

JSON conventions for calling an integration service by using a JavaScript client API

It is possible for data to be lost when messages are automatically converted from JSON (JavaScript Object Notation) to XML, or from XML to JSON. However, you can minimize the potential for data loss during message transformation if you use documented conventions to declare and identify specific XML information within a JSON data structure definition.

When you use the JavaScript client API to call an integration service, the messages that are sent from the JavaScript client API must be converted from JSON to XML to be processed by the integration service. Messages from the integration service must be converted from XML to JSON to be retrieved by the JavaScript client API.

Since JSON has no equivalent concept for an XML attribute, conventions are used within JSON data structure definitions to distinguish between element values and attributes, and to specify how a JSON field name and associated value are represented as an XML attribute and associated value.

The following conventions are used in IBM App Connect Enterprise to handle attributes and element values:

Convention	Example

If an element has a value but no attributes, you can use standard JSON notation to indicate the value of the element.	`{"circle":"Red Circle"}`
	is equivalent to the XML string
	`<circle>Red Circle</circle>`

If an element has attributes, you must add `@` to the beginning of a JSON object name to indicate that the object is an attribute.	`{"circle":{"@color":"red"}}`
	is equivalent to the XML string
	`<circle color="red"/>`

If an element has both an attribute and a value, you must use the notation `#text` to indicate that an object is an element value.	`{"circle":{"@color":"red","#text":"Red Circle"}}`
	is equivalent to the XML string
	`<circle color="red">Red Circle</circle>`

If an element has a value but no attributes, you can use standard JSON notation to retrieve the element value.	`var myVar = {"circle":"Red Circle"};`
	`var circleValue = myVar.circle`
	The second line retrieves the value of the element "circle" from inside the JSON variable "myVar".

If an element has attributes, you must retrieve an attribute value by surrounding the attribute name with double quotation marks and square brackets.	`var myVar = {"circle":{"@color":"red"}};`
	`var circleColor = myVar.circle["@color"]`
	The second line retrieves the value of the attribute "color" from the element "circle" inside the JSON variable "myVar".

If an element has both an attribute and a value, you must retrieve the element value by using the notation `["#text"]`.	`var myVar = {"circle":`
	`{"@color":"red","#text":"Red Circle"}};`
	`var circleValue = myVar.circle["#text"]`
	The second line retrieves the value of the element "circle" from inside the JSON variable "myVar".

Limitations

Conversion of the following constructs between JSON and XML is not supported.

An XML element that contains mixed content

An output message that returns an XML element that contains an element value and nested elements cannot be converted to JSON. For example, the following XML message cannot be converted to JSON:

```
<shapes dimensions="2D">My Shapes
   <circle color="red">Red Circle</circle>
   <triangle color="yellow">Yellow Triangle</triangle>
</shapes>
```

However, the following XML message can be converted:

```
<shapes dimensions="2D">
   <circle color="red">Red Circle</circle>
   <triangle color="yellow">Yellow Triangle</triangle>
</shapes>
```

The JSON `_type` property

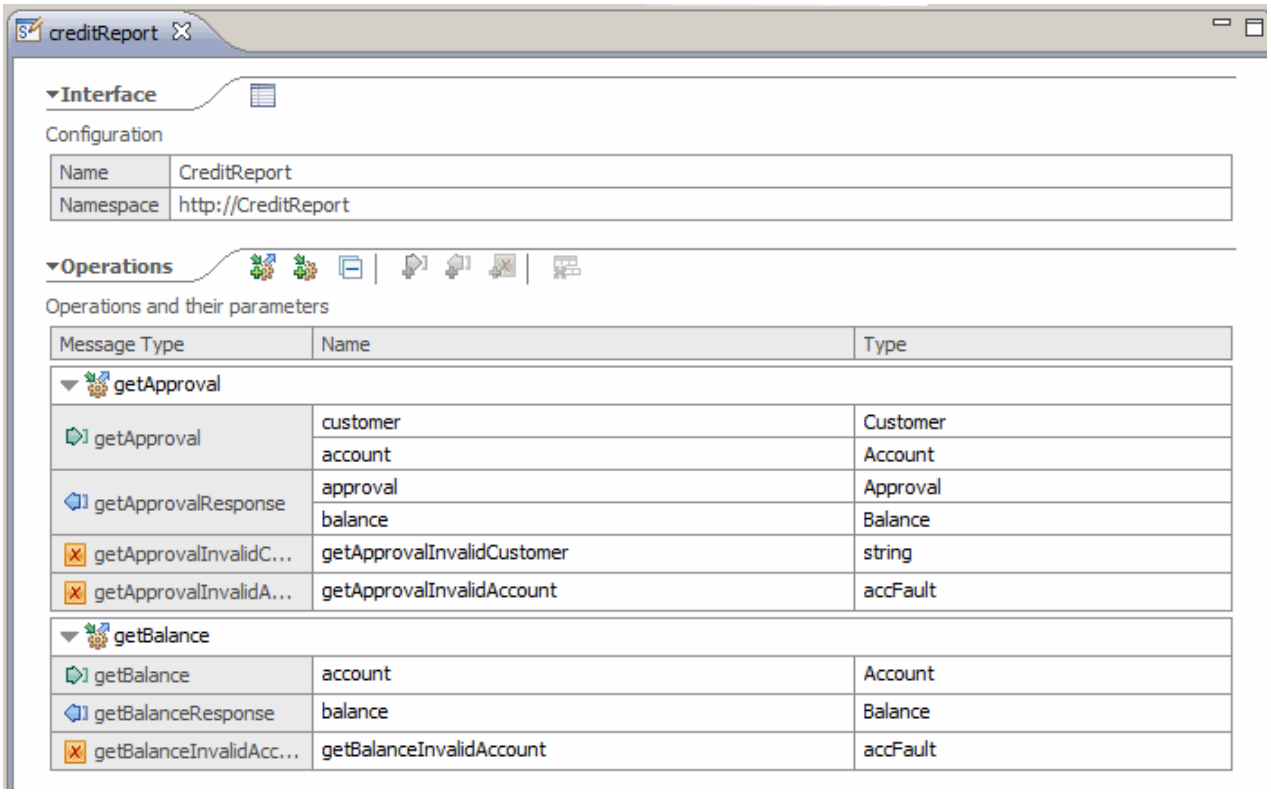
An input message that contains the JSON _type property cannot be converted to XML. For example, the following JSON message cannot be converted to XML. The integration service is still invoked, but with an XML message that does not contain anything for any JSON data that cannot be converted:

```
myCircle:{"__type":"Circle:http://www.example.org/primitiveTypesTest/",
   "x":2 ,
   "y":3 ,
   "radius":10
}
```

Integration service web page

The integration service web page contains links to the JavaScript client API file, details of the JavaScript client API methods, details of the errors that might be returned from the integration service, and sample code that a JavaScript developer can add to a JavaScript application to call the JavaScript client API.

The integration service web page is described using an example integration service. The following screen capture shows the configuration of the example integration service in the IBM App Connect Enterprise Toolkit.



When a JavaScript client API is generated, you can access the integration service URL by using a web browser, and then click the **JavaScript Client API** link to display the web page. The web page has two sections.

File

The File section contains a link to the *service_name*`.js` file, where *service_name* is the name of the integration service. In the example, the file is called `creditReport.js`. The file can be downloaded by clicking the link.

Note: You only need to download the file if you are developing a Node.js application.

Methods

The Methods section contains details of each method that is defined in the integration service. If there is more than one method that is defined in the integration service, then, at the top of the section, there are links to each method and you can click a link to navigate directly to the detail of the associated method.

For each method, there is a description, a list of the input and output objects, and any faults that are defined. The following image shows an example of a method, with the names of the input and output objects, and the names of two defined faults.

Method: IBMIntegration.creditReport.getApproval()

Description

None.

Input

customer : Customer
account : Account

Output

approval : Approval
balance : Balance

Fault

getApprovalFault1 : string

Fault

getApprovalFault2	identifier : string
	message : string

For each method, there is a coding sample that you can copy and paste into your JavaScript application. The coding sample includes the following elements:

- Sections that you might need to uncomment, depending on whether you are developing a JavaScript application for a Node.js environment, or for a web browser environment.
  - For more information about changing the host name and port that are associated with the integration service when you are developing an application for a Node.js environment, see "Specifying the host name and port of the integration service" on page 2006.
  - For more information about referencing the `dojo.js` module and the JavaScript client API file that are associated with the integration service when you are developing an application for a web browser-based environment, see "Referencing the dojo.js module and the JavaScript client API file" on page 2006.
- A comment that details the structure of the output variable, so that you know how to retrieve data from the integration service response.
- One or more comments that detail the structure of any possible faults, so that you know how to handle errors that are returned from the integration service.

  Note: There is always a fault definition (unexpected error JSON variable) to represent any exception that is generated by IBM App Connect Enterprise. For more information about the different types of exceptions you might receive, see Exception list structure and "Exception list tree" on page 516.

There might be one or more fault definitions (fault JSON variables) to represent any fault that is defined in the integration service.

- Code for the input JSON variable. You amend the values for each element to be the values that you want to send to the integration service.
- Code for the JavaScript routine that calls the integration service.

For information about the JSON conventions that are used in the JavaScript client API, and the limitations that are associated with the use of the API, see "JSON conventions for calling an integration service by using a JavaScript client API" on page 2000.

The following is the coding sample for one of the methods that is defined in the example integration service:

```
/* Uncomment these lines if you are developing in a Node.js environment.

require("http");
require("./creditReport");

IBMIntegration.creditReport.IBMContext.hostname = "myhost.company.com";
IBMIntegration.creditReport.IBMContext.port     = 7800;

*/

/* Uncomment these lines and put them in the <head> element of your HTML if you are
 developing in a browser environment.

<script type="text/javascript" src="/creditReport?resource=dojo.js"></script>
<script type="text/javascript" src="/creditReport?resource=creditReport.js"></script>

*/

/* This is an example of the output JSON variable.

var getApprovalResponseVar =
{
  "approval" :
  {
    "customer" :
    {
      "id" : "idValue" ,
      "fName" : "fNameValue" ,
      "lName" : "lNameValue"
    } ,
    "account" :
    {
      "sortCode" : "sortCodeValue" ,
      "accNo" : "accNoValue" ,
      "accType" : "accTypeValue"
    } ,
    "approved" : true
  } ,
  "balance" :
  {
    "customer" :
    {
      "id" : "idValue" ,
      "fName" : "fNameValue" ,
      "lName" : "lNameValue"
    } ,
    "account" :
    {
      "sortCode" : "sortCodeValue" ,
      "accNo" : "accNoValue" ,
      "accType" : "accTypeValue"
    } ,
    "balance" : 1.0
  }
};

*/

/*  This is an example of the unexpected error JSON variable.
    The penultimate property contains the actual exception thrown in IIB.
    Search the product documentation for 'exception list structure' to view
    the different types of exceptions and their contents.

var unexpectedErrorVar =
```

```
{
  "errName" : "Exception",
  ...
  "Label" : "{Label of the node where the exception occurred}",
  ...
  "{Exception name}" : {// penultimate property
      ... exception details ...
  },
  "Input" : {
      ... input message that caused this exception ...
  }
};

*/

/* This is an example of the fault JSON variable.

var getApprovalFault1Var =
{
  "errName" : "getApprovalFault1",
  "getApprovalFault1" : "getApprovalFault1Value"
};

*/

/* This is an example of the fault JSON variable.

var getApprovalFault2Var =
{
  "errName" : "getApprovalFault2",
  "getApprovalFault2" :   {
    "identifier" : "identifierValue" ,
    "message" : "messageValue"
  }

};

*/

/* This is an example of the input JSON variable. */

var getApprovalVar =
{
  "customer" :
  {
    "id" : "idValue" ,
    "fName" : "fNameValue" ,
    "lName" : "lNameValue"
  } ,
  "account" :
  {
    "sortCode" : "sortCodeValue" ,
    "accNo" : "accNoValue" ,
    "accType" : "accTypeValue"
  }
};

IBMIntegration.creditReport.getApproval( getApprovalVar, function( err,
 getApprovalResponseVar ){

  if (err) {
    console.log(" Failure for IBMIntegration.creditReport.getApproval() ");
    var errName = err.errName;
    if ( errName == "getApprovalFault1") {
      console.log("Fault getApprovalFault1 occurred.");
    }
    else if ( errName == "getApprovalFault2") {
      console.log("Fault getApprovalFault2 occurred.");
    }
    else if ( errName == "Exception") {
      console.log("Unexpected error occurred.");

      //To see the full details of the error, use JSON.stringify(err);

      //To retrieve only the exception, navigate to the penultimate property within the
 error
      var keys = Object.keys(err);
      console.log("Exception type: " + keys[keys.length-2]);
    }
  }
```

```
  else {
      console.log(" Success for IBMIntegration.creditReport.getApproval() ");
  }
} );
```

Specifying the host name and port of the integration service

If you are writing a JavaScript application for a Node.js client, then you must specify the host name and port that are used to call the integration service.

You must add the following lines of code to your JavaScript application, before the code that calls the integration service, so that your application can locate the integration service:

```
IBMIntegration.service_name.IBMContext.hostname = "host_name";
IBMIntegration.service_name.IBMContext.port = port;
```

where:

service_name
Specifies the name of the integration service.

host_name
Specifies the host name or IP address of the integration node where the integration service is deployed.

port
Specifies the port number of the listener that is used by the integration server where the integration service is deployed. For information about determining the listener that is used by an integration server, see “HTTP listeners” on page 795.

The lines of code are required only when the JavaScript application is run in a Node.js client. If the lines of code are included in an application that is run in a web browser, the code is ignored.

The following example shows a JavaScript application where the host name and port for an integration service named `OperationsService` are specified before the integration service is called:

```
IBMIntegration.OperationsService.IBMContext.hostname = "myhost.company.com";
IBMIntegration.OperationsService.IBMContext.port = 7800;

var multiInputVar =
{
    "input1" : "input1Value" ,
    "input2" : "input2Value"
};

IBMIntegration.OperationsService.multiInput( multiInputVar, function(errorObj, responseObj))
{
  console.log("IBMIntegration.OperationsService.multiInput()");
  console.log("Response "+JSON.stringify(responseObj));
  console.log("Response="+responseObj.output1);
});
```

Referencing the `dojo.js` module and the JavaScript client API file

If you are writing a JavaScript application for a web browser client, then you must reference the `dojo.js` module and the JavaScript client API file that are used to call the integration service.

You must add the following lines of code to your JavaScript application, before the code that calls the integration service, so that your application can locate the `dojo.js` module and the JavaScript client API file:

```
<script type="text/javascript" src="/context_root/namespace/service_name?resource=dojo.js"></
script>
<script type="text/javascript" src="/context_root/namespace/service_name?
resource=service_name.js"></script>
```

where:

context_root
Specifies the context root of the integration service (and the context root of the proxy servlet). If the context root is set to `/*`, then this entry and the preceding forward slash are omitted.

namespace
Specifies the namespace of the integration service. By default, the namespace is the name of the integration service.

service_name
Specifies the name of the integration service.

The lines of code are required only when the JavaScript application is run in a web browser client. If the lines of code are included in a Node.js application, the code is ignored.

The following example shows a JavaScript application where the `dojo.js` module and the JavaScript client API file for an integration service named `OperationsService` are specified before the integration service is called:

```
<script type="text/javascript" src="/OperationsService/OperationsService?resource=dojo.js"></
script>
<script type="text/javascript" src="/OperationsService/OperationsService?
resource=OperationsService.js"></script>

var multiInputVar =
{
    "input1" : "input1Value" ,
    "input2" : "input2Value"
};

IBMIntegration.OperationsService.multiInput( multiInputVar, function(errorObj, responseObj))
{
  console.log("IBMIntegration.OperationsService.multiInput()");
  console.log("Response "+JSON.stringify(responseObj));
  console.log("Response="+responseObj.output1);
});
```

Securing an integration service that uses a JavaScript client API

When an integration service is accessed by a JavaScript client API, you can ensure the integrity and confidentiality of the data that is sent between the integration service and the JavaScript application that calls the integration service.

Before you begin

Complete the following steps:

1. Generate a JavaScript client API for your integration service; see “Generating a JavaScript client API for an integration service” on page 1997.
2. Develop a JavaScript application that calls the integration service; see “Calling an integration service by using a JavaScript client API” on page 1998.

About this task

You can secure a SOAP/HTTP binding by using WS-Security (see “WS-Security” on page 2650), but this mechanism is not available for use by the JavaScript client API.

Note: If you developed a web browser-based JavaScript application, and IBM App Connect Enterprise and the web server that hosts the HTTP proxy servlet are on the same computer, you might want to secure only the connection between the web browser and the web server. However, if the HTTP proxy servlet receives data over SSL, then it must also forward the data to its destination over SSL. Therefore, to communicate with an integration service hosted on IBM App Connect Enterprise over a secure connection between a web browser and the HTTP proxy servlet, you must also secure the connection between the HTTP proxy servlet and the integration service.

If you want complete end-to-end security between the web browser and the integration service, you must also secure the connection to the IBM MQ queue manager. For more information about securing IBM MQ queue managers, search for *Data integrity* in the IBM MQ product documentation.

To secure the data that is sent between an integration service and a JavaScript application that calls the integration service, you must complete the following tasks:

Procedure

1. Obtain a certificate from a certificate authority, and ensure that the certificate is available in the following formats:
   - JKS format for IBM App Connect Enterprise.
   - PEM format, if you are securing a Node.js application.
   - The certificate formats that are supported by your web browser and web server, if you are securing a web browser-based JavaScript application.

   Note: You can use a self-signed server certificate for testing purposes. For more information about certificates and certificate authorities, see "Digital certificates" on page 2493.
2. Define a public key infrastructure (PKI) for IBM App Connect Enterprise and configure the PKI with the JKS keystore and truststore; see "Setting up a public key infrastructure" on page 2635.

   Note: If you have a web browser-based JavaScript application, you must define the PKI at the integration node level, or the integration node listener level (not at the integration server level or embedded listener level) because the HTTP proxy servlet is using the integration node listener.
3. Configure the integration service to use HTTPS; see "Securing integration services by using SSL" on page 2627.
4. Optional: If you are using a Node.js JavaScript application to call the integration service, then configure the Node.js application to use SSL; see "Configuring a Node.js application to access an integration service by using SSL" on page 2008.
5. Optional: If you are using a web browser-based JavaScript application to call the integration service, then configure the web browser-based application to use SSL; see "Configuring a web browser-based JavaScript application to access an integration service by using SSL" on page 2010.

Results

You have secured an integration service that uses a JavaScript client API.

Configuring a Node.js application to access an integration service by using SSL

If you are using the JavaScript client API with a Node.js application, then you can secure the data that is sent between an integration service and the JavaScript application.

Before you begin

Complete the following steps:

1. Define your public key infrastructure (PKI).
2. Configure the integration service to use SSL.

See "Securing an integration service that uses a JavaScript client API" on page 2007.

About this task

Complete the following steps to secure the data that is sent between an integration service and a Node.js application:

Procedure

1. Depending on your configuration requirements, add the following lines of code to your JavaScript application, where:

   service_name
   Specifies the name of your integration service.

   ca_cert
   Specifies the path to the CA certificate.

   client_key
   Specifies the path to the client key (the private key for your Node.js client).

   client_cert
   Specifies the path to the client certificate (the public key certificate for your Node.js client).

   client_cert_password
   Specifies the password for the client certificate.

Condition	**Add the following lines of code before you call the integration service**	**Comments**
All HTTPS configurations.	`IBMIntegration.`*`service_name`*`.IBMContext.protocol = "https";`	
The Node.js client must not check the credentials that are sent by the server.	`IBMIntegration.`*`service_name`*`.IBMContext.rejectUnauthorized = false;`	This is needed if the server provides a self-signed certificate or a CA-signed server certificate where the common name of the certificate does not match the domain name or host name of the server.

The Node.js client must validate the CA-signed certificate that is sent by the server.	`IBMIntegration.`*`service_name`*`.IBMContext.rejectUnauthorized = true;`
	
	`IBMIntegration.`*`service_name`*`.IBMContext.cacert = "`*`ca_cert`*`";`
		The Node.js client validates the CA-signed certificate by checking the CA-signed certificate against the public certificate of the CA.

The server is configured to require client authentication.	`IBMIntegration.`*`service_name`*`.IBMContext.key = "`*`client_key`*`";`
	
	`IBMIntegration.`*`service_name`*`.IBMContext.cert = "`*`client_cert`*`";`	

The client certificate uses a password.	`IBMIntegration.`*`service_name`*`.IBMContext.certpass = "`*`client_cert_password`*`";`	

For example, you might set the following properties in a Node.js client application that is using a CA-signed server certificate and a CA-signed client certificate with a password, to call an integration service named `TestService1`, where the certificates and key are stored in the Windows folder `C:\certs`.

```
IBMIntegration.TestService1.IBMContext.protocol = "https";
IBMIntegration.TestService1.IBMContext.rejectUnauthorized = true;
IBMIntegration.TestService1.IBMContext.cacert   = "C:\\certs\\ca.crt";
IBMIntegration.TestService1.IBMContext.key      = "C:\\certs\\client.key";
IBMIntegration.TestService1.IBMContext.cert     = "C:\\certs\\client.crt";
IBMIntegration.TestService1.IBMContext.certpass = "secret";
```

2. Change the port number that is associated with your integration service to the HTTPS port.

   The default HTTPS port is 7083 for the integration node listener and 7843 for the embedded listener.

   For example:

```
IBMIntegration.TestService1.IBMContext.hostname = "localhost";
IBMIntegration.TestService1.IBMContext.port = 7843;
```

Results

You have configured the Node.js client application to access the integration service by using SSL.

Configuring a web browser-based JavaScript application to access an integration service by using SSL

If you are using the JavaScript client API with a web browser-based JavaScript application, then you can secure the data that is sent between an integration service and the web browser-based JavaScript application.

Before you begin

Complete the following steps:

1. Define your public key infrastructure (PKI) at the integration node level, or the integration node listener level.
2. Configure the integration service to use SSL.

See "Securing an integration service that uses a JavaScript client API" on page 2007.

About this task

Complete the following steps to secure the data that is sent between an integration service and the browser-based JavaScript application:

Note: The steps assume that you are using the Google Chrome web browser and that the HTTP proxy servlet is deployed in an Apache Tomcat servlet container. However, the steps are similar for other web browsers and servlet containers. If you are running your servlet container behind a web server such as Apache HTTP Server, then, typically, you configure the web server to handle the SSL connections instead of configuring Apache Tomcat; see your web server documentation for information on how to configure SSL.

Procedure

1. Create a keystore for your servlet container.

   If your servlet container is on the same machine as IBM App Connect Enterprise and your servlet container uses the same certificate format, you can use the same keystore that you created for IBM App Connect Enterprise.
2. Configure the servlet container to use the keystore.

   For Apache Tomcat, complete the following steps:

   a) Edit the `server.xml` file.

      The file is found in:

      Tomcat_installation`\conf\server.xml`

      where *Tomcat_installation* is your Apache Tomcat installation directory.

   b) Uncomment the section titled `Define a SSL HTTP/1.1 Connector` and add the following lines to define the keystore and keystore password:

```
keystoreFile="keystore"
```

```
keystorePass="keystore_password"
```

where:

keystore
Specifies the path to the keystore.

keystore_password
Specifies the password of the keystore.

For example:

```
<!-- Define a SSL HTTP/1.1 Connector on port 8443
This connector uses the JSSE configuration, when using
APR, the connector should be using the OpenSSL style
configuration described in the APR documentation -->

<Connector port="8443" protocol="HTTP/1.1" SSLEnabled="true"
maxThreads="150" scheme="https" secure="true"

keystoreFile="c:\certs\keys.jks"
keystorePass="secret"

ReqClientAuth="false" sslProtocol="TLS" />
```

3. Save and close the `server.xml` file and restart Apache Tomcat.
4. Start the Google Chrome web browser and enter the URL for your integration service.

   Unless your keystore contains a CA certificate that the web browser can use to validate the client certificate, you get a warning message that the client certificate is untrusted.
5. To add the CA certificate, complete the following steps:
   a) Click **Settings** > **Show advanced settings** and click **Manage Certificates** in the HTTPS/SSL section.
   b) Select **Import** and use the wizard to add the PEM format of the CA certificate into the Trusted Root CA store.

Note: If you configured your integration node to support client authentication, you must also use the wizard to add the PFX format of your client certificate into the Personal store.

Results

You have configured the web browser-based JavaScript application to access the integration service by using SSL.

Developing integration solutions by using REST APIs

Use REST APIs to expose integrations as a RESTful web service that can be called by HTTP clients.

Before you begin

If you are not familiar with message flow concepts, message model concepts, and common tasks to manage message flow resources, see “Developing message flows” on page 482 and “Constructing message models” on page 2133.

About this task

In IBM App Connect Enterprise, a REST API is a specialized application. A REST API contains a set of resources, and a set of operations that can be called on those resources. The operations in a REST API can be called from any HTTP client, including client-side JavaScript code that is running in a web browser. For more information, see “REST APIs” on page 2013.

The definitions of the resources and operations that are available within a REST API are specified in Swagger or OpenAPI 3.0 documents, which are open specifications for defining REST APIs.

For more information about Swagger, see “Swagger” on page 2015.

For more information about OpenAPI 3.0, see “OpenAPI 3.0” on page 2018.

You can also learn about OpenAPI 3.0 by running the Product Tutorial "OpenAPI Specification v3 - Using an example REST API. " For more information about the product tutorials in IBM App Connect Enterprise, see Tutorials for.

IBM App Connect Enterprise also provides a set of REST nodes, which you can use to interact either synchronously or asynchronously with external REST APIs and IBM App Connect Enterprise REST APIs. For more information about using these REST nodes, see “Connecting to external REST APIs” on page 1032.

Procedure

1. Create a REST API in the IBM Integration Toolkit, by completing the steps in the relevant topic:
   - For a REST API based on Swagger, complete the steps in one of the following topics:
     - “Creating a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit” on page 2021.
     - “Creating a REST API from an imported Swagger document” on page 2023.
   - For a REST API based on OpenAPI 3.0, complete the steps in one of the following topics:
     - “Creating a REST API from scratch with OpenAPI 3.0 specifications by using the IBM App Connect Enterprise Toolkit” on page 2022.
     - “Creating a REST API from an imported OpenAPI 3.0 document” on page 2024

     If you are importing a Swagger document, ensure that you are aware of the restrictions on the format of Swagger documents that are used to create REST APIs, as described in “Restrictions on Swagger documents” on page 2018.

     If your REST API is based on an OpenAPI 3.0 document, ensure that you are aware of the restrictions on the format of OpenAPI 3.0 documents that are used to create REST APIs. For more information, see “Restrictions on OpenAPI 3.0 documents” on page 2019.
2. If you created the REST API from scratch by using the REST API Editor in the IBM App Connect Enterprise Toolkit, you must now define the resources, models, and operations in the REST API.
   - For a REST API based on Swagger, follow the steps in “Defining resources, models, and operations in a REST API by using the REST API Editor” on page 2025.
   - For a REST API based on OpenAPI 3.0, follow the steps in “Defining resources, models, and operations in a REST API by using the OpenAPI editor” on page 2029.

   However, if you created the REST API from an imported Swagger document, you can ignore this step and go to step “3” on page 2012
3. Implement each of the operations in the REST API as a subflow, as described in the relevant topic:
   - For REST APIs based on Swagger, follow “Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents” on page 2030.
   - For REST APIs based on OpenAPI 3.0, follow “Implementing an operation for REST APIs based on OpenAPI 3.0 documents” on page 2034.
4. Optional: Implement error handling for the REST API as a set of subflows, as described in “ Implementing an error handler in a REST API” on page 2038.
5. Optional: Secure your REST API by using HTTPS for encrypting communications between client and server, as described in “Securing a REST API by using HTTPS” on page 2041.
6. Optional: Secure your REST API by authenticating users with HTTP Basic Authentication, as described in “Securing a REST API by using HTTP Basic Authentication” on page 2042.
7. Optional: If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing (CORS). For more information, see “Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing” on page 2043.
8. Optional: REST APIs are configured by default to handle JSON data. If you want to handle non-JSON data in your REST API, see “Handling non-JSON data in a REST API” on page 2039.

Results

You develop an integration solution that uses a REST API.

What to do next

- Package and deploy your REST API to an integration server, as described in "Packaging and deploying a REST API" on page 2045.
- Optional: If you want to create multiple versions of an existing REST API, see "Creating a new REST API that uses artifacts from an existing REST API" on page 2044.
- Optional: You can enable JSON Validation for your REST API by using the "Message Validation" settings in the ACE REST API Editor. For more information about JSON Validation, see "JSON validation" on page 561.
- Optional: You can push (export) your deployed REST API to an IBM API Connect server. For more information, see "Pushing REST APIs to IBM API Connect " on page 2046.

REST APIs

In IBM App Connect Enterprise, a REST API is a specialized application that can be used to expose integrations as a RESTful web service that can be called by HTTP clients. IBM App Connect Enterprise also provides a set of REST nodes, which you can use to interact either synchronously or asynchronously with external REST APIs.

A REST API describes a set of resources, and a set of operations that can be called on those resources. The operations in a REST API can be called from any HTTP client, including client-side JavaScript code that is running in a web browser. You can also use the IBM App Connect Enterprise REST nodes to call and interact with external REST APIs. For information about using these REST nodes, see "Connecting to external REST APIs" on page 1032.

The REST API has a base path, which is similar to a context root. All resources in a REST API are defined relative to its base path. The base path can be used to provide isolation between different REST APIs, as well as isolation between different versions of the same REST API. For example, a REST API can be built to expose a customer database over HTTP. The base path for the first version of that REST API could be `/customerdb/v1`, while the base path for the second version of that REST API could be `/customerdb/v2`.

The REST API describes a set of resources. The HTTP client uses a path relative to the base path that identifies the resource in the REST API that the client is accessing. The paths to a resource can be hierarchical, and a well designed path structure can help a consumer of a REST API understand the resources available within that REST API. The following table lists some example resources for a customer database in the REST API:

Table 75. Example resources

Resource	Description
`/customers`	All the customers in the database
`/customers/12345`	Customer #12345
`/customers/12345/orders`	All orders for customer #12345
`/customers/12345/orders/67890`	Order #67890 for customer #12345

Each resource in the REST API has a set of operations that can be called by an HTTP client. An operation in a REST API has a name and an HTTP method (such as GET, POST, or DELETE). The name of the operation must be unique across all the resources in that REST API. Additionally, a single resource can have only one operation that is defined for a specific HTTP method. The combination of the path and the HTTP method that are specified by the HTTP client that is making the request is used to identify the resource and operation that is being called.

The following table lists example operations for the resource `/customers/12345`:

Table 76. Example operations		
HTTP Method	**Operation Name**	**Description**
GET	getCustomer	Retrieve the customer details from the database.
PUT	updateCustomer	Update the customer details in the database.
DELETE	deleteCustomer	Delete the customer from the database.

To call the updateCustomer operation, the HTTP client makes an HTTP PUT request to `/customerdb/v1/customers/12345`

Each operation in a REST API can also have a set of parameters that can be used by the HTTP client to pass arguments into the operation. Each parameter must be defined in the definitions for the REST API. Each parameter has a unique name and type. Several types of parameters are supported by REST APIs in IBM App Connect Enterprise:

Path parameters
Can be used to identify a particular resource. The value of the parameter is passed in to the operation by the HTTP client as a variable part of the URL, and the value of the parameter is extracted from the path for use in the operation. Path parameters are denoted by using the syntax `{paramName}` in the path to the resource. For example, the customer ID can be passed in as a path parameter named customerId:

```
/customers/{customerId}
```

Query parameters
The value of a query parameter is passed in to the operation by the HTTP client as a key value pair in the query string at the end of the URL. As an example, query parameters can be used to pass in a minimum and maximum number of results that should be returned by a particular operation:

```
/customers?min=5&max=20
```

Header parameters
The HTTP client can pass header parameters to an operation by adding them as HTTP headers in the HTTP request. As an example, header parameters might be used to pass in a unique identifier that identifies the HTTP client that is calling the operation:

```
Api-Client-Id: ff6e2c5d-42d5-4026-8f7f-d1e56da7f777
```

A single operation can define and accept multiple parameters of all three types. Additionally, depending on the HTTP method of the operation, the operation can accept data from the HTTP client in the request body. Operations can also send data back to the HTTP client in the response body. REST APIs in IBM App Connect Enterprise are configured by default to process JSON data, but it is possible to process data in various formats.

Each operation in the REST API must be implemented as a subflow. A subflow for an operation has a single input node, and a single output node. The implementer of the operation can build the subflow for the operation by using all of the standard message flow nodes available with IBM App Connect Enterprise.

When an HTTP client makes a call to an operation in a REST API that is deployed to an integration server, the request is automatically processed and routed to the input node in the corresponding subflow for that operation. When that subflow propagates a message to its output node, the message is automatically routed back to the HTTP client. The author of the REST API is not required to do anything to handle the HTTP transport.

To create a REST API in IBM App Connect Enterprise, you can define the models, resources, and operations from scratch, or you can use the IBM App Connect Enterprise Toolkit to import a Swagger document or an OpenAPI 3.0 document that describes the resources and operations that you want in the

REST API. For more information, see “Developing integration solutions by using REST APIs” on page 2011 and “Creating a REST API” on page 2019.

When you have created and deployed a REST API, you can push (export) the REST API definition to IBM API Connect. You can push one or more REST APIs to IBM API Connect by using either the IBM App Connect Enterprise web user interface or the **mqsipushapis** command. For more information, see “Pushing REST APIs to IBM API Connect ” on page 2046.

Swagger

Swagger is an open specification for defining REST APIs.

A Swagger document is the REST API equivalent of a WSDL document for a SOAP-based web service.

The Swagger document specifies the list of resources that are available in the REST API and the operations that can be called on those resources. The Swagger document also specifies the list of parameters to an operation, including the name and type of the parameters, whether the parameters are required or optional, and information about acceptable values for those parameters. Additionally, the Swagger document can include JSON Schema that describes the structure of the request body that is sent to an operation in a REST API, and the JSON schema describes the structure of any response bodies that are returned from an operation.

Swagger documents must be in either JSON format with a `.json` file extension, or YAML format with a `.yaml` or `.yml` file extension.

IBM App Connect Enterprise supports version 2.0 of the Swagger specification with some restrictions as described in “Restrictions on Swagger documents” on page 2018. For more information about Swagger, see Swagger. For more information about version 2.0 of the Swagger specification, see Swagger RESTful API Documentation Specification Version 2.0.

A range of third-party tools are available for you to use with Swagger documents:

Swagger Editor
: Assists you in building a Swagger document from a web browser by providing a side-by-side view of the Swagger document and the resulting REST API definitions. After you build your Swagger document, you can download it to use with IBM App Connect Enterprise. For more information, see GitHub: Swagger Editor.

Swagger UI
: Allows you to visualize and test a REST API that is defined with Swagger from any web browser. The built-in testing functions allow you to specify the inputs to an operation that is defined in that REST API, call that operation from the web browser, and inspect the results of calling that operation. For more information, see GitHub: Swagger UI.

Swagger Codegen
: Generates a Software Development Kit (SDK) in various languages, including Java, Objective-C, PHP, and Python, from a Swagger document for a REST API. The resulting SDK can be used to embed calls to the operations in that REST API into a software program that was written in one of the supported languages, without having to handle the underlying HTTP transport. For more information, see GitHub: Swagger Code Generator.

Most of the Swagger tools accept a Swagger document as a URL that points to a Swagger document that is hosted on an HTTP server. When you deploy REST APIs to IBM App Connect Enterprise, the Swagger document is published over HTTP for you to use with the Swagger tools. The scheme, host, and port number details of the Swagger document are automatically updated to match the details of the running REST API so that Swagger can be used to call the running REST API.

IBM App Connect Enterprise places some restrictions on Swagger documents, see “Restrictions on Swagger documents” on page 2018.

To see an example of a Swagger document, see Swagger petstore.

A copy of the following Swagger document, `<install root>/server/sample/restapis/swagger.json` is included with the product installation.

```
{
    "swagger": "2.0",
    "basePath": "/customerdb/v1",
    "info": {
        "title": "Customer Database",
        "description": "This is the customer database sample Swagger document included with IBM
 App Connect Enterprise.",
        "version": "1.0.0"
    },
    "definitions": {
        "Customer": {

                "operationId": "addCustomer",
                "summary": "Add a customer to the database",
                "parameters": [
                    {
                        "name": "body",
                        "in": "body",
                        "description": "The customer to add to the database",
                        "required": true,
                        "schema": {
                            "$ref": "#/definitions/Customer"
                        }
                    }
```

```
                ],
                "responses": {
                    "200": {
                        "description": "If the customer was successfully added to the database"
                    }
                },
                "tags": [
                    "customers"
                ]
            }
        },
        "/customers/{customerId}": {
            "get": {
                "operationId": "getCustomer",
                "summary": "Get a specified customer from the database",
                "parameters": [
                    {
                        "name": "customerId",
                        "in": "path",
                        "description": "The ID of the customer to get from the database",
                        "required": true,
                        "type": "integer"
                    }
                ],
                "responses": {
                    "200": {
                        "description": "The specified customer from the database",
                        "schema": {
                            "$ref": "#/definitions/Customer"
                        }
                    }
                },
                "tags": [
                    "customers"
                ]
            },
            "delete": {
                "operationId": "deleteCustomer",
                "summary": "Delete a specified customer from the database",
                "parameters": [
                    {
                        "name": "customerId",
                        "in": "path",
                        "description": "The ID of the customer to delete from the database",
                        "required": true,
                        "type": "integer"
                    },
                    {
                        "name": "Authorization-Key",
                        "in": "header",
                        "description": "Provide the authorization key that permits the customer
 to be deleted from the database",
                        "required": true,
                        "type": "string"
                    }
                ],
                "responses": {
                    "200": {
                        "description": "If the customer was successfully deleted from the
 database"
                    }
                },
                "tags": [
                    "customers"
                ]
            }
        }
    }
}
```

Restrictions on Swagger documents

IBM App Connect Enterprise has some restrictions on the Swagger documents that you can use to create a REST API that are in addition to the requirements that are specified in Swagger RESTful API Documentation Specification Version 2.0.

IBM App Connect Enterprise supports version 2.0 of the Swagger specification. For information about Swagger, see Swagger. For information about version 2.0 of the Swagger specification, see Swagger RESTful API Documentation Specification Version 2.0.

IBM App Connect Enterprise places certain restrictions on the format of Swagger documents that are used to create REST APIs:

- The Swagger document must be saved in either JSON format with a `.json` file extension, or in YAML format with a `.yaml` or `.yml` file extension.
- You must enter a value for the **operationId** field in the Operation Object, and the value of the **operationId** field must be unique across all operations that are defined in this REST API. IBM App Connect Enterprise uses the operation ID as a unique name to refer to the operation.
- The base paths of all REST APIs deployed to a single integration server must be unique. You cannot deploy a REST API to an integration server if there is already another REST API deployed with the same base path.
- Form data parameters:
  - When IBM App Connect Enterprise is implementing a REST API, form data parameters are permitted in Swagger documents, but no support is provided for parsing form data parameters.
  - When a REST API is being consumed through a RESTRequest node, form data parameters are not supported.
- The `"file"` JSON schema type is permitted in Swagger documents but is not supported by IBM App Connect Enterprise; you cannot import a Swagger document that includes a reference to the `"file"` JSON schema type.
- The JSON schema **`"$ref"`** keyword is supported with the following restrictions:
  - Only internal file references that have the form `"$ref" : "#/definitions/Pet"` are allowed.
  - Recursive self references can be imported into the IBM App Connect Enterprise Toolkit. However, if you use a Mapping node, the Graphical Data Mapping editor cannot be used to dynamically discover the depth of recursion. If recursive self references have been imported, use mapping only when you want to move the structure, by using a **Move** transform, from input to output.

When you are using a Swagger document in a message map, ensure that you satisfy the requirements described in JSON schema requirements for message maps.

OpenAPI 3.0

OpenAPI 3.0 is an open specification for defining REST APIs.

The OpenAPI 3.0 Specification (OAS) defines a standard, language-agnostic interface to RESTful APIs, which allows both humans and computers to discover and understand the capabilities of the service without access to source code, documentation, or through network traffic inspection. When properly defined, a consumer can understand and interact with the remote service with a minimal amount of implementation logic.

An OpenAPI 3.0 definition can then be used by documentation generation tools to display the API, code generation tools to generate servers and clients in various programming languages, testing tools, and many other use cases.

IBM App Connect Enterprise supports version 3.0 of the OpenAPI specification with some restrictions. For more information, see https://github.com/OAI/OpenAPI-Specification/blob/main/versions/3.0.0.md and “Restrictions on OpenAPI 3.0 documents” on page 2019.

Restrictions on OpenAPI 3.0 documents

IBM App Connect Enterprise has some restrictions on the OpenAPI 3.0 documents that you can use to create a REST API. These restrictions are in addition to the requirements that are specified in the OpenAPI 3.0 specification.

Consider the following limitations and restrictions when you use OpenAPI 3.0 REST APIs:

- You can import and implement OpenAPI 3.0 documents that contain external references, but you cannot edit these documents by using theIBM App Connect Enterprise Open API Editor.
- You can use the IBM App Connect Enterprise Toolkit to edit only one OpenAPI 3.0 document at a time.
- The base paths of all REST APIs deployed to a single integration server must be unique. You cannot deploy a REST API to an integration server if another REST API is deployed with the same base path.
- When the OpenAPI Editor is open, the REST API Editor is set to 'read only' mode. Only the **Create**, **Edit**,and **Delete** subflow buttons in the OpenAPI Editor are active.
- You can use OpenAPI 3.0 documents that contain multiple server objects, but the base URL in each object must be the same. You cannot use server templating, in which server variables are used to replace values in a URL template in the server object.
- Some aspects of the OpenAPI 3.0 specification are not currently supported by the user interface. In these circumstances, you can use the **source view** of the Open API editor to edit the specification text directly.
- The user interface does not currently support referencing a request body component from the request body of an operation. If you want to reference a request body component, add the reference to the request body of the operation directly in the OpenAPI source, as shown in the following example:

  ```
  requestBody: $ref: '#/components/requestBodies/request_body_component_name'
  ```

  The reference is confirmed on the details page for the request body in the user interface.
- Some OpenAPI 3.0 objects are ignored when you create REST API projects in App Connect Enterprise.
  - Cookie data parameters are allowed in OpenAPI 3.0 documents by IBM App Connect Enterprise, but no support is provided for parsing the HTTP Input header **Cookie** field into `LocalEnvironment.REST.Input.Parameters`.
  - Parameters of complex type are allowed in OpenAPI 3.0 documents, but IBM App Connect Enterprise does not currently support parsing or mapping complex type parameters.

Creating a REST API

To create a REST API in IBM App Connect Enterprise, you can define the models, resources, and operations in the REST API Editor, or the OpenAPI editor. Alternatively, you can use the IBM App Connect Enterprise Toolkit to import a Swagger document or an OpenAPI 3.0 document that describes the resources and operations that you want in the REST API.

About this task

Both methods of creating a REST API have advantages, and the most appropriate method depends on your circumstances.

Creating a REST API from scratch by using Swagger specifications

You can use the REST API editor that is integrated into the IBM App Connect Enterprise Toolkit to create a REST API from scratch. The REST API editor enables you to graphically create a REST API by defining the resources, operations, and parameters for that REST API. You can also use the REST API editor to define models that represent the structure of JSON request and response bodies for the operations in the REST API. The models that you define with the REST API editor can then be used by the Graphical Data Mapping editor to implement the operations in the REST API.

The REST API editor creates and modifies a Swagger document that is compliant with version 2.0 of the Swagger specification. The Swagger document can be used with the Graphical Data Mapping editor to

implement operations in the REST API as well as a wide range of external tools. For example, Swagger UI, Swagger Codegen, and IBM API Management. However, the REST API editor does not support the full Swagger specification, and cannot be used to set some properties, such as validation attributes, on objects in the Swagger document.

Use the REST API editor to create a REST API from scratch in the following circumstances:

- You have limited or no knowledge of the Swagger specification.
- You prefer to use the graphical tools that are integrated into the IBM Integration Toolkit, rather than using an external editor to create a Swagger document.

Creating a REST API from scratch by using OpenAPI 3.0 specifications

You can use the OpenAPI editor that is integrated into the IBM App Connect Enterprise Toolkit to create a REST API from scratch. By using the OpenAPI editor, you can graphically create a REST API by defining the resources, operations, and parameters for that REST API. You can also use the OpenAPI editor to define models that represent the structure of JSON request and response bodies for the operations in the REST API. The models that you define with the OpenAPI editor can then be used by the Graphical Data Mapping editor to implement the operations in the REST API.

The OpenAPI editor creates and modifies an OpenAPI 3.0 document. The OpenAPI 3.0 document can be used with the Graphical Data Mapping editor to implement operations in the REST API.

Use the OpenAPI editor to create a REST API from scratch by using OpenAPI 3.0 specifications in the following circumstances:

- You have limited or no knowledge of the OpenAPI 3.0 specification.
- You prefer to use the graphical tools that are integrated into the IBM Integration Toolkit, rather than using an external editor to create an OpenAPI 3.0 document.

Creating a REST API by importing a Swagger document

You can use an external editor, such as Swagger Editor, to create a Swagger document that defines the REST API that you want to implement. You can then create a REST API by importing this Swagger document by using the IBM App Connect Enterprise Toolkit. All the resources, operations, and parameters are loaded from the Swagger document and are viewable from the REST API editor in the IBM App Connect Enterprise Toolkit. The models are also loaded from the Swagger document, and those models can then be used with the Graphical Data Mapping editor to implement operations in the REST API.

The REST API editor in the IBM Integration Toolkit also allows you to modify the REST API, such as adding new resources, and it modifies the imported Swagger document automatically. However, the REST API editor does not support the full Swagger specification, and might be unable to display or modify the full contents of an imported Swagger document.

Create a REST API by importing a Swagger document in the following circumstances:

- You have good knowledge of the Swagger specification, and you create a Swagger document for the REST API that you plan to implement in IBM App Connect Enterprise.
- A separate member of your team, such as an API Designer, is creating a Swagger document for the REST API that you plan to implement in IBM App Connect Enterprise.
- You require the use of all properties in the Swagger specification; for example, the validation attributes such as maxLength, uniqueItems, and allOf, which are available when you define models.

Creating a REST API by importing an OpenAPI 3.0 document

You can use an external editor to create an OpenAPI 3.0 document that defines the REST API that you want to implement. You can then create a REST API by importing this OpenAPI 3.0 document by using the IBM App Connect Enterprise Toolkit. All the resources, operations, and parameters are loaded from the OpenAPI 3.0 document and are viewable from the OpenAPI editor in the IBM App Connect Enterprise Toolkit. The models are also loaded from the OpenAPI 3.0 document, and those models can then be used with the Graphical Data Mapping editor to implement operations in the REST API.

The OpenAPI editor in the IBM Integration Toolkit also allows you to modify the REST API, such as adding new resources, and it modifies the imported OpenAPI 3.0 document automatically.

Create a REST API by importing an OpenAPI document in the following circumstances:

- You have good knowledge of the OpenAPI 3.0 specification, and you create an OpenAPI 3.0 document for the REST API that you plan to implement in IBM App Connect Enterprise.
- A separate member of your team, such as an API Designer, is creating an OpenAPI 3.0 document for the REST API that you plan to implement in IBM App Connect Enterprise.
- You require the use of all properties in the OpenAPI 3.0 specification.

Procedure

Complete the steps in one of the following tasks to create a REST API in IBM App Connect Enterprise:

- "Creating a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit" on page 2021
- "Creating a REST API from scratch with OpenAPI 3.0 specifications by using the IBM App Connect Enterprise Toolkit" on page 2022
- "Creating a REST API from an imported Swagger document" on page 2023.
- "Creating a REST API from an imported OpenAPI 3.0 document" on page 2024.

  If you are importing a Swagger document, ensure that you are aware of the restrictions on the format of Swagger documents that are used to create REST APIs, as described in "Restrictions on Swagger documents" on page 2018.

What to do next

- If you created the REST API from scratch by defining resources, models, and operations in the IBM App Connect Enterprise Toolkit, you must now define the operations in the REST API Editor or the OpenAPI editor before you implement them. For information, see "Defining resources, models, and operations in a REST API by using the REST API Editor" on page 2025, and "Defining resources, models, and operations in a REST API by using the OpenAPI editor" on page 2029.
- If you create the REST API from an imported Swagger document, you must then implement the operations, as described in "Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents" on page 2030.

Creating a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit

You can create a REST API by defining the resources, models, and operations in the IBM App Connect Enterprise Toolkit.

About this task

You can use the REST API editor to create a REST API from scratch with Swagger specifications. Alternatively, you can Create a REST API from scratch with OpenAPI specifications by using the IBM App Connect Enterprise Toolkit.

You can also Create a REST API by importing a Swagger document or Create a REST API by importing an OpenAPI document.

Procedure

To create a REST API by defining the resources, models, and operations, complete the following steps:

1. Open the **Create a REST API** wizard by clicking **File** > **New** > **REST API** .

2. Enter a name for the REST API.

   The name that you specify is used as the name of the project in the IBM App Connect Enterprise Toolkit.
3. Select **Create a REST API and define resources and operations yourself**.
4. Select **Swagger 2.0** from the drop-down menu.

   The **API base path** field and the **Version** field are completed automatically.
5. To finish creating the REST API, click **Finish**.

   The **REST API Editor** for the new REST API opens automatically, which you must now use to define resources, models, and operations, as described in "Defining resources, models, and operations in a REST API by using the REST API Editor" on page 2025.

Results
The REST API is created.

What to do next
Define the operations in the REST API and then implement them, by completing the steps in the following topics:

1. "Defining resources, models, and operations in a REST API by using the REST API Editor" on page 2025
2. "Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents" on page 2030

Creating a REST API from scratch with OpenAPI 3.0 specifications by using the IBM App Connect Enterprise Toolkit

You can create a REST API from scratch with OpenAPI 3.0 specifications by defining the resources, models, and operations in the OpenAPI editor that is integrated with the IBM App Connect Enterprise Toolkit.

About this task
You can use the OpenAPI editor to create a REST API from scratch with OpenAPI 3.0 specifications. Alternatively, you can Create a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit.

You can also Create a REST API by importing a Swagger document, or Create a REST API by importing an OpenAPI3 document.

Procedure
To create a REST API by defining the resources, models, and operations, complete the following steps:

1. Open the **Create a REST API** wizard by clicking **File** > **New** > **REST API** .
2. Enter a name for the REST API.

   The name that you specify is used as the name of the project in the IBM App Connect Enterprise Toolkit.
3. Select **Create a REST API and define resources and operations yourself**.
4. Select **OpenAPI3** from the menu.

   The **API base path** field and the **Version** field are completed automatically.
5. To finish creating the REST API, click **Finish**.

   The REST API Editor for the new REST API opens automatically, but you can edit the generated values. You must now use the OpenAPI editor to define resources, models, and operations, as described in "Defining resources, models, and operations in a REST API by using the OpenAPI editor" on page 2029.

Results
The REST API is created.

What to do next
Define the operations in the REST API and then implement them, by completing the steps in the following topics:

1. "Defining resources, models, and operations in a REST API by using the OpenAPI editor" on page 2029
2. "Implementing an operation for REST APIs based on OpenAPI 3.0 documents" on page 2034

Creating a REST API from an imported Swagger document

To create a REST API in IBM App Connect Enterprise, you can import a Swagger document by using the IBM App Connect Enterprise Toolkit.

Before you begin
Create a Swagger document that describes the resources and operations that you want in the REST API. Ensure that the Swagger document adheres to the guidelines in the Swagger specification, and that it satisfies the requirements of IBM App Connect Enterprise. For more information, see Swagger RESTful API Documentation Specification Version 2.0 and "Restrictions on Swagger documents" on page 2018.

About this task
To create a REST API in IBM App Connect Enterprise, you can use the **Create a REST API** wizard in the IBM App Connect Enterprise Toolkit to import a Swagger document. You must then create the REST API and other project artifacts that are needed to implement and deploy the new REST API. Alternatively, you can create a REST API by defining the models, resources, and operations from scratch, as described in "Creating a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit" on page 2021.

Procedure
To create a REST API by importing a Swagger document, complete the following steps:

1. Open the **Create a REST API** wizard by clicking **File** > **New** > **REST API** .
2. Enter a name for the REST API.

   The name that you specify is used as the name of the project in the IBM App Connect Enterprise Toolkit.
3. Select **Import resources and operations defined in a Swagger document** and then click **Next**.
4. Select the path to the Swagger document that describes the resources and operations that you want in the REST API.

   You can import the Swagger document from the file system or from an existing project in the workspace.

   The file is validated for use in a REST API. If any errors are found while the selected Swagger document is validated, those validation errors are displayed in the wizard. If validation errors are found in the selected Swagger document, you cannot proceed.
5. Optional: To review the list of resources and operations that are contained in the selected Swagger document, click **Next**.
6. To finish creating the REST API, click **Finish**.

   The **REST API Description** for the new REST API opens automatically, which you can use to implement operations as described in "Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents" on page 2030.

Results
The REST API is created.

What to do next

Implement each of the operations in the REST API as a subflow, see "Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents" on page 2030.

Creating a REST API from an imported OpenAPI 3.0 document

To create a REST API in IBM App Connect Enterprise, you can import an OpenAPI 3.0 document by using the IBM App Connect Enterprise Toolkit.

Before you begin

Create an OpenAPI 3.0 document that describes the resources and operations that you want in the REST API. Ensure that the OpenAPI 3.0 document adheres to the guidelines in the OpenAPI 3.0 specification, and that it satisfies the requirements of IBM App Connect Enterprise. For more information, see https://github.com/OAI/OpenAPI-Specification/blob/main/versions/3.0.0.md and "Restrictions on OpenAPI 3.0 documents" on page 2019.

About this task

To create a REST API in IBM App Connect Enterprise, you can use the **Create a REST API** wizard in the IBM App Connect Enterprise Toolkit to import an OpenAPI 3.0 document. You must then create the REST API and other project artifacts that are required to implement and deploy the new REST API. Alternatively, you can create a REST API by defining the models, resources, and operations from scratch, as described in "Creating a REST API from scratch with OpenAPI 3.0 specifications by using the IBM App Connect Enterprise Toolkit" on page 2022.

Procedure

To create a REST API by importing an OpenAPI 3.0 document, complete the following steps:

1. Open the **Create a REST API** wizard by clicking **File** > **New** > **REST API** .
2. Enter a name for the REST API.

   The name that you specify is used as the name of the project in the IBM App Connect Enterprise Toolkit.
3. Select **Import resources and operations defined in a RESTAPI document** and then click **Next**.
4. Click **Next**.
5. Select the path to the OpenAPI 3.0 document that describes the resources and operations that you want in the REST API.

   You can import the OpenAPI 3.0 document from the file system or from an existing project in the workspace.

   The file is validated for use in a REST API. If any errors are found while the selected OpenAPI 3.0 document is validated, those validation errors are displayed at the top of the wizard. You cannot proceed if validation errors are found in the selected OpenAPI 3.0 document.
6. Optional: To review the list of resources and operations that are contained in the selected OpenAPI 3.0 document, click **Next**.
7. To finish creating the REST API, click **Finish**.

   The **REST API Description** for the new REST API opens automatically, which you can use to implement operations as described in "Implementing an operation for REST APIs based on OpenAPI 3.0 documents" on page 2034.

Results

The REST API is created.

What to do next

Implement each of the operations in the REST API as a subflow, see "Implementing an operation for REST APIs based on OpenAPI 3.0 documents" on page 2034.

Defining resources, models, and operations in a REST API by using the REST API Editor

Use the **REST API Editor** to graphically define resources, models, and operations in a REST API.

Before you begin

Create a REST API in the IBM App Connect Enterprise Toolkit, as described in "Creating a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit" on page 2021.

About this task

Use the sections in the **REST API Editor** to define your REST API.

Procedure

1. In the IBM App Connect Enterprise Toolkit, navigate to your REST API project.
2. Open the REST API Description by double-clicking the REST API project or by right-clicking and selecting **Open**.

   The REST API editor for Swagger documents opens and provides a view of the API details, it Resources and Operations, Error handling, Security, and Message Validation Settings.

To define resources, models, and operations in a REST API, complete the following steps:

3. Use the **Header** section of the REST API Editor to display and modify general information about the REST API.

   The **REST API base URL** field displays the current base path for the REST API. All resources in a REST API are defined relative to its base path. You can edit this field to modify the base path of the REST API. The value of this field must be a valid URL path segment, and must not contain any variable elements.

   The `Title` field displays the current title of the REST API. The Title is distinct from the REST API project name, and is defined as a property in the Swagger document. The Title is used when you push a REST API into IBM API Management.

   The `Version` field displays the current version of the REST API. It is defined as a property in the Swagger document. The Version is used when you push a REST API into IBM API Management.

   The header section also includes an example REST API base URL. The *hostname* and *port number* portions of this URL must be replaced with the hostname and port number of the integration server that the REST API is deployed to. To start an operation that is defined in this REST API by using an HTTP client, you must combine the REST API base URL, the path of the operations resource, and the HTTP method for the operation that you are starting. Depending on the operation that is being started, you might also need to pass extra parameters, or a request body.
4. Use the **Resources** section to manipulate the resources for your REST API:

   

   Use this button to create a new resource in your REST API. When you click this button, a dialog is displayed in which you can specify the resource path and select the operations that you

want to add to the resource: GET, POST, PUT, DELETE, OPTIONS, HEAD, and PATCH. When you click **OK**, the new resource and the operations for that resource are added to the REST API.

You can also add and remove operations from a resource after it is created. Use the  button on the right side of the resource to add more operations to an existing resource. Use the  button on the right side of the operation to remove that operation from its resource.

 Use this button to modify your resource path. When you click this button, a dialog is displayed in which you can modify the resource path.

 Use this button to expand all operations under each resource.

 Use this button to collapse all operations under each resource.

5. When you add an operation under a resource, you can manipulate it.

   An operation can have several different kinds of parameters, and 0 or more responses, which are shown in the following sections:

   - **Path, Query, and Header parameter**

     Use the Add button  and the Delete button  to add or delete Header and Query parameters, and then set their Name, Type, and Data Type, and optionally, the Format, Required, and Description values.

     The `Name` and `Type` fields of a Path parameter cannot be changed, and the name must match the path template in the resource. Path parameters can be added or removed only by editing the path template in the Resource.

     The Data Type of a Path, Query, or Header parameter can be set only to a primitive data type, such as string, number, integer, or Boolean. These primitive data types correspond with those in the Swagger specification, and map to the possible primitive types in a JSON document. You cannot set the Data Type of a Path, Query, or Header parameter to that of a Model defined in the REST API. The Data Type of a Path, Query, or Header parameter is not currently used by the IBM App Connect Enterprise run time, and the parameters are provided to the nodes in the subflow as character data. The Graphical Data Map models them as strings. However, it is advisable to set the parameter correctly for use with Swagger tooling.

     The `Format` field is an optional free-form description of the format of the data that is expected for values of this parameter. For example, you can use formats that are mentioned in the Swagger specification such as `int32`, `double`, or `date-time`. Alternatively, you can include your own format names, such as `customer-id`. The Format of a Path, Query, or Header parameter is not currently used by the IBM App Connect Enterprise run time; however, it is advisable to set it correctly for use with Swagger tooling.

     The `Required` field states whether the parameter must be specified by HTTP clients that start this operation. Path parameters must always be specified in the request URL by an HTTP client. This field cannot be changed for Path parameters. Query and Header parameters can be marked as optional by deselecting this checkbox. The presence of a Query or Header parameter is not currently validated

by the IBM App Connect Enterprise run time. However, it is advisable to set it correctly for use with Swagger tooling.

The Swagger Form parameter type is not supported in IBM App Connect Enterprise.

- **Request Body**

  Use the Add request button  and the Delete button  to add or delete a request body, if a request body is allowed for the HTTP method of the selected operation. For example, `GET`, `HEAD`, `DELETE`, and `OPTIONS` requests do not permit request bodies.

  A request body is usually a JSON document, and the structure of that JSON document can be defined in a Model. The structure of a request body is not currently validated by the IBM App Connect Enterprise run time. However, the Model definition can be used with a Mapping node to graphically implement the REST API operation. It is advisable to define Models for all of the possible JSON request bodies in the API, for use with Swagger tooling.

  The `Schema type` for Request includes all primitive data types, such as `string`, `number`, `integer`, or `boolean`, plus all models defined in the API.

- **Response Body**

  Use the Add response button  and the Delete button  to add or delete a response, if a response body is permitted for the HTTP method of the selected operation. For example, `HEAD` requests do not return a response body.

  Set the HTTP `status code number` for this response as the value of the `Response Status` field. The HTTP status code must be a valid HTTP status code as described by RFC 7231 or the IANA Status Code Registry. You can define multiple responses for a single operation, but the HTTP status code of a response must be unique within that operation.

  A response body is usually a JSON document, and the structure of that JSON document can be defined in a Model. The structure of a response body is not currently validated by the IBM App Connect Enterprise run time. However, the Model definition can be used with a Mapping node to graphically implement the REST API operation. It is advisable to define Models for all of the possible JSON request bodies in the API for use with Swagger tooling.

  The `Schema type` for Response includes all primitive data types, such as `string`, `number`, `integer`, or `boolean`, plus all models defined in the API. Additionally, you can specify if this operation returns an array of values, where the type of each item in that array is defined by the **Schema type** field. If you specify that the response is an array, and the Schema type refers to a Model that is itself an array, the Response is defined as returning an array of arrays.

6. Use the **Model Definitions** section of the editor to define the JSON data that you can use for the Request and Response `Schema type` in your operations.

   To create a new Model data type, click the Add button next to the **Model Definitions** field, and enter a name for your new JSON data type:

   
   You can define models of type `object`, `string`, `integer`, `number`, `boolean`, and `null`.

   Note: The file data type is not supported by IBM App Connect Enterprise; you cannot set a parameter or model type as `file`.

   To create an object Model when you have entered its name, use the **Add a child for selection** button

   

   , located in the **Model Definitions** section, to add the first child. You can then add more children to build up the required structure:

   

   You can specify if the data type must be an array, whether it is required, whether it allows null, and you can specify a format. **Format** is a free form text field, which you can use to describe the format of the data. For example, you can have a string with a format of `date`. For more information, see http://swagger.io/specification/#dataTypeFormat.

   The following example shows the definition of a *Pet* schema type:

   
   This *Pet* Model schema type could be used in a GET operation to produce a JSON data message with the following format:

```
{
 "id": 1001,
 "category": {
  "id": 10,
  "name": "Cat"
 },
 "name": "Moggy",
 "photoUrls": ["http:\/\/something.com\/images?q=tbn:XmoggyJjB2XhAqq97VzJP"],
 "tags": [{
  "id": 11,
  "name": "Moggy"
 }],
 "status": "pending"
```

```
}
```

You can also define a GET for returning multiple Pets by setting the operation Schema type to *Pet* and checking the `Array` option:

While the Open API editor is active in a separate window to allow editing the resources, models, and operations theIBM App Connect Enterprise Toolkit REST API editor for Swagger documents is in a read-only mode. You must close the REST API API editor to re-enable the ACE Toolkit REST API editor for Swagger documents.

Results

The resources, models, and operations are defined in the REST API.

What to do next

Implement each of the operations in the REST API as a subflow, as described in "Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents" on page 2030.

Defining resources, models, and operations in a REST API by using the OpenAPI editor

Use the **OpenAPI Editor** to graphically define resources, models, and operations in a REST API.

Before you begin

Create a REST API in the IBM App Connect Enterprise Toolkit, as described in "Creating a REST API" on page 2019.

About this task

Use the sections in the **OpenAPI Editor** to define your REST API.

The **OpenAPI Editor** has a **Navigation view** to position into the various objects of the OAI3 document and to create and delete those objects. Selecting an object in the Navigation view displays a **Form View** where you can view, create, and change the content of that object. There is also a **Source View**, which you can use to display the raw OpenAPI 3.0 document. The Source View is accessed by clicking the **Source View** icon.

Procedure

To define resources, models, and operations in a REST API, complete the following steps:

1. Click **Edit API document in OpenAPI Editor** to open the OpenAPI editor in a separate window.
2. Click the '+' sign next to **Path** to open the **Path editor**
3. Enter a path name into the **Path** field.
4. Optional: Enter a summary in the **Summary** field.
5. Optional: Enter a description in the **Description** field.
6. Click **Create** to create the OpenAPI 3.0 document.
7. Click the '+' sign next to **Operations** to add an operation.
8. Select an operation from the menu.
9. Optional: Enter a summary in the **Summary** field.
10. Optional: Enter a description in the **Description** field.
11. Click **Create** to create the operation.

12. Click **Save** to save the operation.
13. Continue to update the REST API by adding items from the list of components, such as Servers, Tags, Parameters.
14. When you finish updating the RESTAPI, click **Save**.
15. Close the OpenAPI editor.

    If you return to the IBM App Connect Enterprise Toolkit, you can see that the **Resources and Operations** section of the RESTAPI is now populated.

Results

The resources, models, and operations are defined in the REST API.

What to do next

Implement each of the operations in the REST API as a subflow, as described in "Implementing an operation for REST APIs based on OpenAPI 3.0 documents" on page 2034.

Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents

Use the **REST API Editor** in the Application Development view to implement operations in a REST API.

Before you begin

- Create a REST API based on a Swagger 2.0 specification document in the IBM App Connect Enterprise Toolkit, as described in "Creating a REST API" on page 2019.
- If you created the REST API from scratch by defining resources, models, and operations (as described in "Creating a REST API from scratch with Swagger specifications by using the IBM App Connect Enterprise Toolkit" on page 2021, you must also define the operations in the REST API Editor. For more information, see "Defining resources, models, and operations in a REST API by using the REST API Editor" on page 2025.

About this task

Operations in a REST API are implemented as a subflow, and you must use the REST API editor to create an empty subflow for each operation. You can then implement the operation by adding any of the standard IBM App Connect Enterprise message flow nodes to the subflow.

If you do not implement an operation, you can still deploy the REST API to an integration server. However, when an HTTP client attempts to call an operation that is not implemented, an `HTTP 501 Not Implemented` status code is returned to the client.

Procedure

To implement an operation in a REST API, complete the following steps:

1. Open the REST API that contains the operation that you want to implement.

   The **REST API Editor** is in the Application Development view under the REST API project.
2. Locate the operation in the **REST API Editor**. Operations are listed under the Operations heading, and are grouped by resource.
3. The **Header** section shows the details for the REST API base URL.
4. The **Resources** section shows the operations for each resource.

   Click this button to create a subflow for the operation:  . If you already defined a subflow for the operation, that subflow is opened. When you click this button, you are prompted to confirm that you want to save the REST API. Saving the RESTAPI ensures that the nodes that you add to the subflow are

correctly defined with the current definition of the REST API. The subflow is opened in the Message Flow Editor, and it is brought to the front.

Use the hover-help that is provided for each button to get information about the associated action.

5. Implement the operation by adding any of the standard IBM App Connect Enterprise message flow nodes to the subflow.

   For more information, see Implementing a REST API operation by using a message map.

6. Access the REST API operation information, REST API operation parameters, and REST API request and response body, as described in "Implementing REST API operation processing in the subflow by using message flow nodes" on page 2031.

Results

The operation is implemented in the REST API.

What to do next

You must package and deploy your REST API to an integration server, as described in "Packaging and deploying a REST API" on page 2045.

You can also complete the following optional tasks:

- Implement error handling for the REST API as a set of subflows. For more information, see " Implementing an error handler in a REST API" on page 2038.
- Secure your REST API by using HTTPS for encrypting communications between client and server. For more information, see "Securing a REST API by using HTTPS" on page 2041.
- Secure your REST API by authenticating users with HTTP Basic Authentication. For more information, see "Securing a REST API by using HTTP Basic Authentication" on page 2042.
- If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing, as described in "Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing" on page 2043.
- You can enable JSON Validation for your REST API by using the "Message Validation" settings in the ACE REST API Editor. For more information about JSON Validation, see "JSON validation" on page 561.
- REST APIs are configured by default to handle JSON data. If you want to handle non-JSON data, see "Handling non-JSON data in a REST API" on page 2039.

Implementing REST API operation processing in the subflow by using message flow nodes

Access the REST API operation information, REST API operation parameters, and REST API request and response body.

Accessing the REST API operation information

Information about the current operation is automatically placed into the local environment tree. You can use this information in your implementation if you want to determine which operation in the REST API was called, which HTTP method was used, the request path, or the request URI. For example, if you are sharing transformation logic across multiple operations, you can use this information to determine in which operation the REST API was called.

Accessing current operation information in a message map

You can access the current operation information in a message map. The current operation information is available as a set of elements, which are named Method, Operation, Path, and URI, in a Message Assembly that includes the Local Environment, under **Local Environment** > **REST** > **Input folder**. For more information, see Mapping data in the local environment tree.

When you create the message map by using the option **Message map with input and output for REST API operation**, the local environment is automatically added to the map input and any path or query parameters are added. A Task transform is pre-wired to **Local Environment** > **REST** > **Input**,

to help you locate this information. For more information, see Implementing a REST API operation by using a message map.

Accessing current operation information in ESQL

Check to see if the current operation was called by using an HTTP GET.

```
IF InputLocalEnvironment.REST.Input.Method = 'GET' THEN
  -- Executed only if the current operation was called using an HTTP GET.
END IF;
```

Check to see if the current operation is the getAllCustomers operation.

```
IF InputLocalEnvironment.REST.Input.Operation = 'getAllCustomers' THEN
  -- Executed only if the current operation is the getAllCustomers operation.
END IF;
```

Create a log message with the request path.

```
DECLARE logMessagePath CHARACTER 'Received request on path ' ||
 InputLocalEnvironment.REST.Input.Path;
```

Create a log message with the request URI.

```
DECLARE logMessageURI CHARACTER 'Received request on URI  ' ||
 InputLocalEnvironment.REST.Input.URI;
```

Accessing current operation information in Java

Check to see if the current operation was called by using an HTTP GET.

```
MbMessage inLocalEnvironment = inAssembly.getLocalEnvironment();
MbElement leRestInput = inLocalEnvironment.getRootElement().getFirstElementByPath("/REST/
Input");

if (leRestInput.getFirstElementByPath("Method").getValueAsString().equals("GET")) {
  // Executed only if the current operation was called using an HTTP GET.
}
```

Check to see if the current operation is the getAllCustomers operation.

```
if
 (leRestInput.getFirstElementByPath("Operation").getValueAsString().equals("getAllCustomers"))
 {
  // Executed only if the current operation is the getAllCustomers operation.
}
```

Create a log message with the request path.

```
String logMessagePath = "Received request on path " +
 leRestInput.getFirstElementByPath("Path").getValueAsString();
```

Create a log message with the request URI.

```
String logMessageURI = "Received request on URI  " +
 leRestInput.getFirstElementByPath("URI").getValueAsString();
```

Accessing current operation information in .NET (C#)

Check to see if the current operation was called by using an HTTP GET.

```
NBMessage inLocalEnvironment = inputAssembly.LocalEnvironment;
NBElement leRestInput = inLocalEnvironment.RootElement["REST"]["Input"];

if (((String) leRestInput["Method"]) == "GET"){
  // Executed only if the current operation was called using an HTTP GET.
}
```

Check to see if the current operation is the getAllCustomers operation.

```
if (((String) leRestInput["Operation"]) == "getAllCustomers") {
  //Executed only if the current operation is the getAllCustomers operation.
}
```

Create a log message with the request path.

```
String logMessagePath = "Received request on path " + ((String) leRestInput["Path"]);
```

Create a log message with the request URI.

```
String logMessageURI = "Received request on URI  " + ((String)leRestInput["URI"]);
```

Accessing the REST API operation parameters

If the definition of an operation includes one or more parameters, the names and values of those parameters are automatically placed into the local environment tree, but only if those parameters are provided by the HTTP client that is calling the operation. Optional or missing parameters are not placed into the local environment tree. Parameters are always placed into the local environment tree as character (string) elements, where the name of each element is the name of the parameter and the value of the element is the value of the parameter.

Accessing parameter values in a message map

You can access parameter values in a message map. All parameters are available as set of elements, where the elements have the same name as the parameter name, in a Message Assembly that includes the Local Environment, under **Local Environment** > **REST** > **Input** > **Parameters** folder.

When you create the message map by using the option **Message map with input and output for REST API operation**, the local environment is automatically added to the map input and any path or query parameters are added under **Local Environment** > **REST** > **Input** > **Parameters**, ready for you to connect transforms. A `Task` transform is pre-wired to **Local Environment** > **REST** > **Input** , to help you locate this information. For more information, see Implementing a REST API operation by using a message map. If you update the REST API and change the path or query parameters, the message map is updated with the new definitions when it is reopened. If there were existing transforms wired to the parameters, they might need to be modified.

If you do not use the option **Message map with input and output for REST API operation**, you must add the local environment manually, and in the **Parameters** folder use the `any` element to add user-defined elements. For more information, see Mapping data in the local environment tree and Defining user-defined elements.

Accessing parameter values in ESQL

Check to see if the parameter named 'max' is supplied.

```
DECLARE max INTEGER -1;
IF FIELDTYPE(InputLocalEnvironment.REST.Input.Parameters.max) IS NOT NULL THEN
  SET max = InputLocalEnvironment.REST.Input.Parameters.max;
END IF;
```

Accessing parameter values in Java

Check to see if the parameter named 'max' is supplied.

```
MbElement maxElement = inLocalEnvironment.getRootElement().getFirstElementByPath("/REST/
Input/Parameters/max");
int max = -1;
if (maxElement != null) {
  max = Integer.valueOf(maxElement.getValueAsString());
}
```

Accessing parameter values in .NET (C#)

Check to see if the parameter named 'max' is supplied.

```
NBElement maxElement = inLocalEnvironment.RootElement["REST"]["Input"]["Parameters"]["max"];
int max = -1;
if (max != null){
  max = (int) maxElement;
}
```

Accessing the REST API request and response body

Depending on the HTTP method of the operation, the operation can accept data from the HTTP client in the request body. REST APIs in IBM App Connect Enterprise are configured by default to process JSON data. For more information about processing JSON data that was passed in the request body, and creating JSON data to send as the response body, see “JSON parser and domain” on page 553. You can also use a message map to process JSON data. For more information, see Creating or transforming a JSON output message by using a message map.

Implementing an operation for REST APIs based on OpenAPI 3.0 documents

Use the REST API Editor in the Application Development view or the **OpenAPI Editor** to implement operations in a REST API.

Before you begin

- Create a REST API based on an OpenAPI 3.0 specification document in the IBM App Connect Enterprise Toolkit, as described in “Creating a REST API” on page 2019.
- If you created the REST API from scratch, as described in “Creating a REST API from scratch with OpenAPI 3.0 specifications by using the IBM App Connect Enterprise Toolkit” on page 2022, you must also define the resources, models, and operations in the OpenAPI editor . For more information, see “Defining resources, models, and operations in a REST API by using the OpenAPI editor” on page 2029.

About this task

Operations in a REST API are implemented as a subflow, and you can use the RESTAPI Editor or the OpenAPI editor to create an empty subflow for each operation. You can then implement the operation by adding any of the standard IBM App Connect Enterprise message flow nodes to the subflow.

If you do not implement an operation, you can still deploy the REST API to an integration server. However, when an HTTP client attempts to call an operation that is not implemented, an `HTTP 501 Not Implemented` status code is returned to the client.

You can use the OpenAPI Editor to create, edit, and delete subflows for operations for OpenAPI 3.0 based REST APIs.

Procedure

To implement an operation in a REST API, complete the following steps:

1. Open the REST API Description by double-clicking the REST API project or by right-clicking and selecting **Open**.

   The REST API editor for OpenAPI 3.0 documents opens and provides a view of the API details, its Resources and Operations, Error handling, Security, and Message Validation Settings.
2. In the RESTPI Editor, open the REST API that contains the operation that you want to implement.
3. In the REST API Editor for OpenAPI 3.0, locate the operation in the **Resources and Operations** section and click **Create Subflow**. Alternatively, if you are working with the REST API in the OpenAPI editor , locate the operation and click **Create Subflow**.

   The new subflow is opened. You are prompted to confirm that you want to save the REST API. Saving the RESTAPI ensures that the nodes that you add to the subflow are correctly defined with the current

definition of the REST API. The subflow is opened in the Message Flow Editor, and it is brought to the front. If you already created a subflow, the actions **Edit Subflow** and **Delete Subflow** are provided instead of **Create Subflow**.

4. Implement the operation by adding any of the standard IBM App Connect Enterprise message flow nodes to the subflow.

   For more information, see Implementing a REST API operation by using a message map.

5. Access the REST API operation information, REST API operation parameters, and REST API request and response body, as described in "Implementing REST API operation processing in the subflow by using message flow nodes" on page 2031.

Results

The operation is implemented in the REST API.

What to do next

You must package and deploy your REST API to an integration server, as described in "Packaging and deploying a REST API" on page 2045.

You can also complete the following optional tasks:

- Implement error handling for the REST API as a set of subflows. For more information, see " Implementing an error handler in a REST API" on page 2038.
- Secure your REST API by using HTTPS for encrypting communications between client and server. For more information, see "Securing a REST API by using HTTPS" on page 2041.
- Secure your REST API by authenticating users with HTTP Basic Authentication. For more information, see "Securing a REST API by using HTTP Basic Authentication" on page 2042.
- If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing, as described in "Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing" on page 2043.
- You can enable JSON Validation for your REST API by using the "Message Validation" settings in the ACE REST API Editor. For more information about JSON Validation, see "JSON validation" on page 561.
- REST APIs are configured by default to handle JSON data. If you want to handle non-JSON data, see "Handling non-JSON data in a REST API" on page 2039.

Implementing REST API operation processing in the subflow by using message flow nodes

Access the REST API operation information, REST API operation parameters, and REST API request and response body.

Accessing the REST API operation information

Information about the current operation is automatically placed into the local environment tree. You can use this information in your implementation if you want to determine which operation in the REST API was called, which HTTP method was used, the request path, or the request URI. For example, if you are sharing transformation logic across multiple operations, you can use this information to determine in which operation the REST API was called.

Accessing current operation information in a message map

You can access the current operation information in a message map. The current operation information is available as a set of elements, which are named Method, Operation, Path, and URI, in a Message Assembly that includes the Local Environment, under **Local Environment** > **REST** > **Input folder**. For more information, see Mapping data in the local environment tree.

When you create the message map by using the option **Message map with input and output for REST API operation**, the local environment is automatically added to the map input and any path or query parameters are added. A Task transform is pre-wired to **Local Environment** > **REST** > **Input**,

to help you locate this information. For more information, see Implementing a REST API operation by using a message map.

Accessing current operation information in ESQL

Check to see if the current operation was called by using an HTTP GET.

```
IF InputLocalEnvironment.REST.Input.Method = 'GET' THEN
  -- Executed only if the current operation was called using an HTTP GET.
END IF;
```

Check to see if the current operation is the getAllCustomers operation.

```
IF InputLocalEnvironment.REST.Input.Operation = 'getAllCustomers' THEN
  -- Executed only if the current operation is the getAllCustomers operation.
END IF;
```

Create a log message with the request path.

```
DECLARE logMessagePath CHARACTER 'Received request on path ' ||
 InputLocalEnvironment.REST.Input.Path;
```

Create a log message with the request URI.

```
DECLARE logMessageURI CHARACTER 'Received request on URI  ' ||
 InputLocalEnvironment.REST.Input.URI;
```

Accessing current operation information in Java

Check to see if the current operation was called by using an HTTP GET.

```
MbMessage inLocalEnvironment = inAssembly.getLocalEnvironment();
MbElement leRestInput = inLocalEnvironment.getRootElement().getFirstElementByPath("/REST/
Input");

if (leRestInput.getFirstElementByPath("Method").getValueAsString().equals("GET")) {
  // Executed only if the current operation was called using an HTTP GET.
}
```

Check to see if the current operation is the getAllCustomers operation.

```
if
 (leRestInput.getFirstElementByPath("Operation").getValueAsString().equals("getAllCustomers"))
 {
  // Executed only if the current operation is the getAllCustomers operation.
}
```

Create a log message with the request path.

```
String logMessagePath = "Received request on path " +
 leRestInput.getFirstElementByPath("Path").getValueAsString();
```

Create a log message with the request URI.

```
String logMessageURI = "Received request on URI  " +
 leRestInput.getFirstElementByPath("URI").getValueAsString();
```

Accessing current operation information in .NET (C#)

Check to see if the current operation was called by using an HTTP GET.

```
NBMessage inLocalEnvironment = inputAssembly.LocalEnvironment;
NBElement leRestInput = inLocalEnvironment.RootElement["REST"]["Input"];

if (((String) leRestInput["Method"]) == "GET"){
  // Executed only if the current operation was called using an HTTP GET.
}
```

Check to see if the current operation is the getAllCustomers operation.

```
if (((String) leRestInput["Operation"]) == "getAllCustomers") {
  //Executed only if the current operation is the getAllCustomers operation.
}
```

Create a log message with the request path.

```
String logMessagePath = "Received request on path " + ((String) leRestInput["Path"]);
```

Create a log message with the request URI.

```
String logMessageURI = "Received request on URI  " + ((String)leRestInput["URI"]);
```

Accessing the REST API operation parameters

If the definition of an operation includes one or more parameters, the names and values of those parameters are automatically placed into the local environment tree, but only if those parameters are provided by the HTTP client that is calling the operation. Optional or missing parameters are not placed into the local environment tree. Parameters are always placed into the local environment tree as character (string) elements, where the name of each element is the name of the parameter and the value of the element is the value of the parameter.

Accessing parameter values in a message map

You can access parameter values in a message map. All parameters are available as set of elements, where the elements have the same name as the parameter name, in a Message Assembly that includes the Local Environment, under **Local Environment** > **REST** > **Input** > **Parameters** folder.

When you create the message map by using the option **Message map with input and output for REST API operation**, the local environment is automatically added to the map input and any path or query parameters are added under **Local Environment** > **REST** > **Input** > **Parameters**, ready for you to connect transforms. A `Task` transform is pre-wired to **Local Environment** > **REST** > **Input** , to help you locate this information. For more information, see Implementing a REST API operation by using a message map. If you update the REST API and change the path or query parameters, the message map is updated with the new definitions when it is reopened. If there were existing transforms wired to the parameters, they might need to be modified.

If you do not use the option **Message map with input and output for REST API operation**, you must add the local environment manually, and in the **Parameters** folder use the `any` element to add user-defined elements. For more information, see Mapping data in the local environment tree and Defining user-defined elements.

Accessing parameter values in ESQL

Check to see if the parameter named 'max' is supplied.

```
DECLARE max INTEGER -1;
IF FIELDTYPE(InputLocalEnvironment.REST.Input.Parameters.max) IS NOT NULL THEN
  SET max = InputLocalEnvironment.REST.Input.Parameters.max;
END IF;
```

Accessing parameter values in Java

Check to see if the parameter named 'max' is supplied.

```
MbElement maxElement = inLocalEnvironment.getRootElement().getFirstElementByPath("/REST/
Input/Parameters/max");
int max = -1;
if (maxElement != null) {
  max = Integer.valueOf(maxElement.getValueAsString());
}
```

Accessing parameter values in .NET (C#)

Check to see if the parameter named 'max' is supplied.

```
NBElement maxElement = inLocalEnvironment.RootElement["REST"]["Input"]["Parameters"]["max"];
int max = -1;
if (max != null){
  max = (int) maxElement;
}
```

Accessing the REST API request and response body

Depending on the HTTP method of the operation, the operation can accept data from the HTTP client in the request body. REST APIs in IBM App Connect Enterprise are configured by default to process JSON data. For more information about processing JSON data that was passed in the request body, and creating JSON data to send as the response body, see “JSON parser and domain” on page 553. You can also use a message map to process JSON data. For more information, see Creating or transforming a JSON output message by using a message map.

Implementing an error handler in a REST API

Use the REST API Description view to implement error handlers in a REST API.

Before you begin

You must create a REST API in the REST API Description, see “Creating a REST API” on page 2019.

About this task

Three types of error handler are available for a REST API:

Catch
If an exception is thrown when you process a request in a subflow for an operation and that exception is not handled by that subflow, a message is routed to the Catch error handler. For example, if a JavaCompute node in the subflow for an operation throws an exception and that exception is not caught by a TryCatch node, that exception is passed to the Catch error handler.

Timeout
If a subflow for an operation is processing a message and that subflow does not respond to the client within the expected time limit, a message is routed to the Timeout error handler. The Timeout error handler can then be used to pass a response back to the client to inform that client that the operation timed out. If this situation occurs, the subflow for an operation continues to process the message. The processing of that message is not cancelled. However, a response to the client cannot be sent.

Note: Depending on the client, the client might time out without receiving a response from calling the operation, in which case, any response that is sent is not received.

Failure
If an error occurs while the request from the client is being processed and that error is not handled by the Catch or Timeout error handlers, a message is routed to the Failure error handler.

Error handlers in a REST API are implemented as a subflow. You must use the IBM App Connect Enterprise Toolkit to create an empty subflow for each error handler. You can then implement the error handler by adding any of the standard message flow nodes that are available in IBM App Connect Enterprise to the subflow.

If you do not implement an error handler, default error handling behavior is used. If you do not implement the Catch error handler or the Failure error handler, the exception is thrown back to the client with an HTTP 500 Internal Server Error status code. If you do not implement the Timeout error handler, a timeout exception is thrown back to the client with an HTTP 504 Gateway Timeout status code.

Procedure

To implement an error handler in a REST API, complete the following steps:

1. Open the `REST API Description` for the REST API for which you want to implement an error handler.

   The `REST API Description` is in the Application Development view under the REST API project.
2. Locate the error handler in the `REST API Description`.

   Error handlers are listed under the Error Handling heading.

Complete one of the following steps depending on whether you created the RESTAPI with a Swagger document or an OpenAPI3 document.

3. Optional: If you created the RESTAPI with a Swagger document, click the **Implement the *<error_handler_type>*** error handler link, where *<error_handler_type>* is the error handler type.

   A new subflow is automatically created and opened. The link on the `REST API Description` changes to **Open the <error_handler_type>** error handler, and if you click the link, the existing subflow reopens.
4. Optional: If you created the REST API with an OpenAPI 3.0 document, click **Create subflow** to create a subflow.

   You can also use the OpenAPI Editor **Configuration** tab to implement error handlers for REST APIs based on OpenAPI 3.0.

Results

The error handler is implemented in the REST API.

What to do next

You must package and deploy your REST API to an integration server, see “Packaging and deploying a REST API” on page 2045.

You can also complete the following optional tasks:

- Use the `REST API Description` view to implement operations in a REST API, see “Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents” on page 2030 or “Implementing an operation for REST APIs based on OpenAPI 3.0 documents” on page 2034.
- Secure your REST API by using HTTPS for encrypting communications between client and server, see “Securing a REST API by using HTTPS” on page 2041.
- Secure your REST API by authenticating users with HTTP Basic Authentication, see “Securing a REST API by using HTTP Basic Authentication” on page 2042.
- If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing, see “Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing” on page 2043.
- You can enable JSON Validation for your REST API by using the "Message Validation" settings in the ACE REST API Editor. For more information about JSON Validation, see “JSON validation” on page 561.
- REST APIs are configured by default to handle JSON data. If you want to handle non-JSON data, see “Handling non-JSON data in a REST API” on page 2039.

Handling non-JSON data in a REST API

REST APIs are set up by default to handle JSON data, but can also handle other data formats.

Before you begin

You must complete the following tasks:

1. You must create a REST API in the IBM App Connect Enterprise Toolkit, see “Creating a REST API” on page 2019.

2. You must implement at least one operation in the REST API, see “Implementing an operation in a REST API by using the REST API Editor for Swagger 2 documents” on page 2030.

About this task

When a message arrives on the Input node of a subflow for an implemented operation, the message domain of that message is set to JSON. You can handle other types of data in a subflow for an implemented operation by using a ResetContentDescriptor node to change the message domain of the message before any message parsing is performed.

You can also use a Route node to handle multiple types of data in the same subflow. You can configure the Route node to route data to a ResetContentDescriptor node based on the Content-Type header in the request message. The Content-Type header can be added to the request by the HTTP client, and is used to describe the type of the data in the request.

Procedure

To handle non-JSON data in a REST API, complete the following steps:

1. Open the `REST API Description`, for the implemented operation that you want to modify, click the **Open the Operation** link.
2. Optional: If you want to handle multiple types of data in this subflow, complete the following steps:
   a) Add a Route node to the canvas.
   b) Connect the **Out** terminal of the subflow Input node to the **In** terminal of the Route node.
   c) Add Output terminals to the Route node for each message domain and type of data that you want to process by right-clicking the Route node and clicking **Add Output Terminal**.
   d) Route to the new terminals on the Route node by adding entries to the **Filter** table.
   e) To route on Content-Type, use the following XPath expression as an example for handling XML request messages by using the XMLNSC domain:

   ```
   starts-with($Root/HTTPInputHeader/Content-Type,'application/xml')
   ```

   Use the starts-with function in your XPath expression because HTTP clients might send in an optional character set parameter following the type and subtype.
3. Add a ResetContentDescriptor node to the canvas.
   - If you added a Route node in the previous step, you must add a ResetContentDescriptor node for each message domain and type of data that you want to process. If you are processing JSON data, you do not require a ResetContentDescriptor node.
   - If you did not add a Route node in the previous step, connect the **Out** terminal of the subflow Input node to the **In** terminal of the ResetContentDescriptor node.
   - If you added a Route node in the previous step, then connect the terminal that you added in the previous step to the corresponding ResetContentDescriptor node for that message domain and type of data.
4. For each ResetContentDescriptor node that you added in the previous step, configure the ResetContentDescriptor node by specifying the value of the **Message domain** property. You must also select **Reset message domain**.
5. You can now continue to implement the operation by using any of the standard message flow nodes that are included in IBM App Connect Enterprise. Connect any new message flow nodes to the **Out** terminal of the IBM App Connect Enterprise nodes that you added in the previous steps.

Results

Your REST API is set up to handle non-JSON data.

What to do next

You must package and deploy your REST API to an integration server, see "Packaging and deploying a REST API" on page 2045.

You can also complete the following optional tasks:

- Implement error handling for the REST API as a set of subflows, see " Implementing an error handler in a REST API" on page 2038.
- Secure your REST API by using HTTPS for encrypting communications between the client and server, see "Securing a REST API by using HTTPS" on page 2041.
- Secure your REST API by authenticating users with HTTP Basic Authentication, see "Securing a REST API by using HTTP Basic Authentication" on page 2042.
- If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing, see "Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing" on page 2043.

Securing a REST API by using HTTPS

Secure the communications between a REST API and an HTTP client by enabling HTTPS.

Before you begin

- Create a REST API in the IBM App Connect Enterprise Toolkit. Follow the instructions in "Creating a REST API" on page 2019. This makes the REST API available to be configured for HTTPS.
- Create the integration server to which you want to deploy the REST API. Follow the instructions in "Creating an integration server" on page 168.
- Decide which HTTP Listener you want to use for HTTPS messages. For information about which listener to use for HTTPS messages, see "HTTP listeners" on page 795.
- Set up a public key infrastructure (PKI) to configure the keystores, truststores, passwords, and certificates to enable SSL communication. Follow the instructions in "Setting up a public key infrastructure" on page 2635. This results in the integration server or integration node being configured for the PKI.

About this task

Secure the communications between a REST API and an HTTP client by enabling HTTPS. You can enable HTTPS just for encryption, or you can also configure a REST API for client authentication (mutual authentication).

This task uses some of the same substeps as enabling a message flow with HTTPInput and HTTPReply nodes to use HTTPS, as described in "Configuring HTTPInput and HTTPReply nodes to use SSL (HTTPS)" on page 2619.

Procedure

To enable HTTPS for a REST API, complete the following steps:

1. Configure the integration server or integration node to use SSL.

   Complete one of the following substeps, depending on which HTTP listener you have chosen to use for HTTPS messages:

   - If you are using the integration node listener: Configure the integration node to use SSL
   - If you are using the integration server listener: Configure the integration server to use SSL
2. In the Application Development view, which is under the REST API project, open the REST API `Description` for the REST API for which you want to enable HTTPS.
3. Under Security Options, select **Enable HTTPS** in the REST API Description.

Results

Your REST API is secured by using HTTPS.

What to do next

1. You can complete the following optional tasks:
   - Secure your REST API by authenticating users with HTTP Basic Authentication, see "Securing a REST API by using HTTP Basic Authentication" on page 2042.
   - If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing, see "Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing" on page 2043.
2. Package and deploy your REST API to an integration server, see "Packaging and deploying a REST API" on page 2045.

Securing a REST API by using HTTP Basic Authentication

Authenticate HTTP clients that want to call a REST API by enabling HTTP Basic Authentication.

Before you begin

You must create a REST API in the IBM App Connect Enterprise Toolkit, see "Creating a REST API" on page 2019.

About this task

You can authenticate HTTP clients that want to call a REST API by enabling HTTP Basic Authentication. IBM App Connect Enterprise supports several authentication providers that can be used for this purpose, including Lightweight Directory Access Protocol (LDAP), any WS-Trust V1.3 compliant Security Token Service (STS), and Tivoli Federated Identity Manager.

Procedure

To enable HTTP Basic Authentication for a REST API by using Lightweight Directory Access Protocol (LDAP), any WS-Trust V1.3 compliant Security Token Service (STS), or Tivoli Federated Identity Manager, complete the following steps:

1. Create a security profile that you can use for authentication, see "Creating a security profile for LDAP" on page 2584, "Creating a security profile for WS-Trust V1.3 (TFIM V6.2)" on page 2588 and "Creating a security profile for TFIM V6.1" on page 2589.
2. Configure the security profile that you created in the previous step on the REST API:
   a) In the **BAR file** editor, open the BAR file that contains the REST API.
   b) Click the **Manage** tab.
   c) Locate the automatically generated message flow in the REST API.
      The automatically generated message flow is named `gen/<name_of_REST API>`, where *<name_of_REST API>* is the name of the REST API.
   d) In the **Properties** view for the automatically generated message flow, in the **Security Profile Name** field, specify the name of the security profile that you created in the previous step. Save the BAR file.
3. Deploy the BAR file to an integration server.
   HTTP clients that want to call the REST API must provide a user name and password. If authentication information is not supplied by the HTTP client, or authentication fails, an `HTTP 401 Unauthorized` status code is returned to the client.

Results

You have secured a REST API by using HTTP Basic Authentication.

What to do next

You must package and deploy your REST API to an integration server, see "Packaging and deploying a REST API" on page 2045.

You can also complete the following optional tasks:

- Secure your REST API by using HTTPS, see "Securing a REST API by using HTTPS" on page 2041.
- If your REST API is going to be used by client-side code that is running in a web browser, you might have to configure Cross-Origin Resource Sharing, see "Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing" on page 2043.

Permitting web browsers to access a REST API by using Cross-Origin Resource Sharing

Permit web pages that are running in a web browser to make requests to a REST API that is running in IBM App Connect Enterprise by enabling Cross-Origin Resource Sharing (CORS).

Before you begin

You must create a REST API in the IBM App Connect Enterprise Toolkit, see "Creating a REST API" on page 2019.

About this task

You can permit a web browser to access a REST API by using CORS. When you enable CORS on an integration server, it is enabled for all REST APIs and any other HTTP services that are running on that integration server. You are not required to configure CORS for each REST API that you deploy.

Procedure

To permit a web browser to access a REST API, complete the following steps:

1. Configure the integration server HTTP listener to enable CORS.
2. Ensure that the CORS configuration meets the requirements for all operations that are deployed in the REST API.

   To permit cross-origin requests for additional HTTP methods, additional HTTP headers, or to allow authentication information to be passed into the REST API, you might have to change some extra parameters.

Results

Your web browser can access a REST API by using CORS.

What to do next

You must package and deploy your REST API to an integration server, see "Packaging and deploying a REST API" on page 2045.

You can also complete the following optional tasks:

- Secure your REST API by using HTTPS for encrypting communications between client and server, see "Securing a REST API by using HTTPS" on page 2041.
- Secure your REST API by authenticating users with HTTP Basic Authentication, see "Securing a REST API by using HTTP Basic Authentication" on page 2042.

Creating a new REST API that uses artifacts from an existing REST API

Deploy multiple versions of the same REST API simultaneously by copying REST API artifacts into a new REST API project.

Before you begin

You must create a REST API in the IBM App Connect Enterprise Toolkit, see "Creating a REST API" on page 2019.

About this task

To create multiple versions of the same REST API, you can copy artifacts from an existing REST API into a new REST API.

Note: If you want to deploy the new and existing REST APIs on the same integration server, you must specify a different base path for each of them. Use the Modify button () in the REST API editor to modify the resource paths.

Procedure

To create a new REST API that uses artifacts from an existing REST API complete the following steps.

1. Create a REST API project in the IBM App Connect Enterprise Toolkit.

   If the existing REST API project is in the currently open workspace, you must specify a different name for the new REST API project. If you modified the REST API project, modify the resource path by using the Modify button in the REST API editor.
2. Open the `REST API Description` for the new REST API project.

Complete one of the following steps depending on whether you created the REST API with a Swagger document or an OpenAPI 3.0 document.

3. Optional: In the `REST API Description`, implement operations and error handlers from the existing REST API project.
   a) for all operations that you want to implement, click the **Implement the Operation** link.
   b) If you created the REST API with a Swagger document, then for all error handlers that you want to implement, click the **Implement the Error Handler** link.

   This action creates the connections from the REST API project to the subflows.

   Note: Do not add any message flow nodes to the generated subflows.
4. Optional: In the `REST API Description`, implement operations and error handlers from the existing REST API project.
   a) If you created the REST API with an OpenAPI 3.0 document, then for all operations that you want to implement, click the **Create subflow** button.
   b) If you created the REST API with an OpenAPI 3.0 document, then, for all error handlers that you want to implement, click the **Create subflow** button.

   This action creates the connections from the REST API project to the subflows.

   Note: Do not add any message flow nodes to the generated subflows.
5. Copy the subflows for implemented operations and error handlers from the existing REST API project into the new REST API project.

   Copying subflows from the existing REST API overwrites the subflows that are generated in the previous step.
6. Reference any static or shared libraries in the new REST API project that are referenced by the existing REST API, see "Referencing resources in other libraries" on page 1976.

7. Copy all other artifacts, for example, subflows, schemas, and maps, from the existing REST API project into the new REST API project.

Results

You have created a new REST API by reusing artifacts from an existing REST API.

What to do next

You must package and deploy your REST API to an integration server, see "Packaging and deploying a REST API" on page 2045.

Packaging and deploying a REST API

Package your REST API into a BAR file and deploy it to an integration server.

Before you begin

You can create a REST API in the IBM App Connect Enterprise Toolkit, as described in "Creating a REST API" on page 2019.

About this task

REST APIs can be deployed to integration servers that are configured to use the integration server HTTP listener.

If you plan to deploy more than one REST API to an integration server, the REST APIs must have different base paths.

Procedure

To package a REST API into a BAR file and deploy it to an integration server, complete the following steps:

1. Package the REST API into a BAR file.

   You can use either the **BAR file editor**, or you can use the command line. Both the **mqsicreatebar** and **mqsipackagebar** commands package a REST API into a BAR file. When you use these commands, pass the name of the REST API in as the application name.

   For example:

   ```
   mqsicreatebar -data workspaceDirectory -b restApiName.bar -a restApiName
   ```

   ```
   mqsipackagebar -a restApiName.bar -k restApiName
   ```

2. Deploy the REST API to the integration server.

   You can use the IBM App Connect Enterprise Toolkit, the web user interface, or the **mqsideploy** command; for example:

   ```
   mqsideploy integrationNodeName -e integrationServerName -a restApiName.bar
   ```

   ```
   mqsideploy -i ipAddress -p port -a C:\myworkspace\myapi1\restApiName.bar
   ```

   If another REST API is deployed to the integration server and that REST API has a clashing base path, the deployment of the REST API fails. You cannot deploy REST APIs that have clashing base paths to the same integration server.

Results

Your REST API is deployed.

Pushing REST APIs to IBM API Connect

Create or update a definition for your deployed REST APIs on IBM API Connect.

Before you begin

You must complete the following tasks:

- Register or update credentials for the API owner with IBM API Connect:
  - For Version 5 and Version 5 on IBM Cloud, see Administering Developer organizations in the IBM API Connect product documentation.
  - For Version 2018, see Administering Consumer organizations in the IBM API Connect product documentation.
  - For Version 10, see Working with consumer organizations in the IBM API Connect product documentation.
- If you intend to stage the REST API to a catalog, ensure that the IBM API Connect server has a catalog to which you can stage a product that includes the REST API.
- Ensure that any firewalls allow the following connections:
  - IBM App Connect Enterprise can connect to the IBM API Connect server by using HTTPS.
  - The IBM API Connect server can connect to the integration server by using HTTP or HTTPS.
- Create a REST API in the IBM App Connect Enterprise Toolkit; see “Creating a REST API” on page 2019.
- Deploy the REST API to the integration server; see “Packaging and deploying a REST API” on page 2045.

About this task

You can push the definition of deployed REST APIs into IBM API Connect, which you can then use to manage and publish your APIs. Use IBM API Connect to promote and monitor the usage of the REST APIs, and to secure and authenticate access requests from users and applications to your IBM App Connect Enterprise application. It also provides monitoring and fine-grained control over access and workload management, such as the ability to control the number of requests per second for a client application. For information about supported versions of IBM API Connect, see the IBM App Connect Enterprise system requirements web page.

IBM API Connect works with an IBM DataPower® Gateway appliance. IBM API Connect pushes configuration to the IBM DataPower Gateway, which in turn proxies the requests back to the IBM App Connect Enterprise integration server that hosts the deployed REST API, as shown in the following diagram.

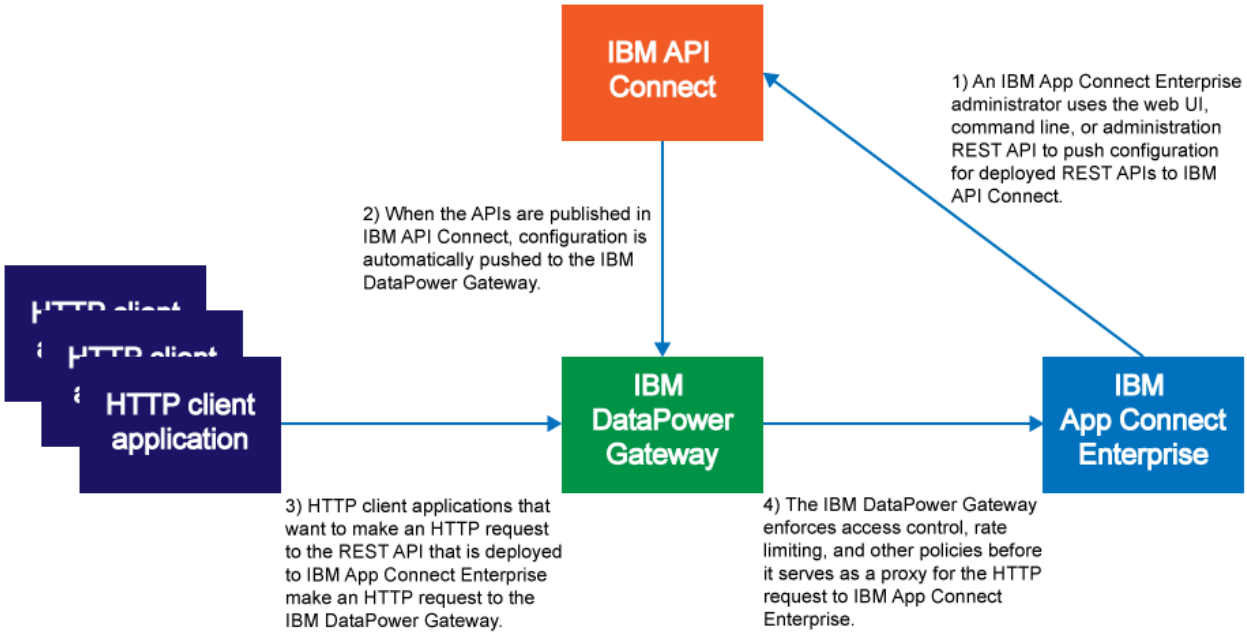

Figure 35. The interaction between IBM App Connect Enterprise, IBM API Connect, IBM DataPower Gateway, and HTTP client applications.

When you push a REST API to IBM API Connect, you can either create a new REST API definition or, if the REST API definition exists on the IBM API Connect system, you can replace the latest version of the definition with the new definition of your REST API. The title and version of the REST API are used to identify the REST API definition on the IBM API Connect system.

You can push one or more deployed REST APIs to IBM API Connect by using the IBM App Connect Enterprise web user interface, the **mqsipushapis** command, or the administration REST API, as described in the following topics:

- "Pushing REST APIs to IBM API Connect by using the web user interface" on page 2047
- "Pushing REST APIs to IBM API Connect by using the mqsipushapis command" on page 2052

Pushing REST APIs to IBM API Connect by using the web user interface

Use the web user interface to create or update a definition for one or more deployed REST APIs in IBM API Connect.

Before you begin

Complete the following tasks:

- Register or update credentials for the API owner with IBM API Connect:
  - For Version 5 and Version 5 on IBM Cloud, see Administering Developer organizations in the IBM API Connect product documentation.
  - For Version 2018, see Administering Consumer organizations in the IBM API Connect product documentation.
  - For Version 10, see Working with consumer organizations in the IBM API Connect product documentation.
- If you intend to stage the REST API to a catalog, ensure that the IBM API Connect server has a catalog to which you can stage a product that includes the REST API. If a current version of the REST API exists in the catalog, staging a new version of the REST API unpublishes the current version and changes it to staged state.

- Ensure that any firewalls allow the following connections:
  - IBM App Connect Enterprise can connect to the IBM API Connect server by using HTTPS.
  - The IBM API Connect server can connect to the integration server by using HTTP or HTTPS.
- Create a REST API in the IBM App Connect Enterprise Toolkit; see "Creating a REST API" on page 2019.
- Deploy the REST API to the integration server; see "Packaging and deploying a REST API" on page 2045.

About this task

You can use the IBM App Connect Enterprise web user interface to push one or more REST APIs to IBM API Connect. If the REST API definition exists on the IBM API Connect system, you replace the REST API definition with the new definition of your REST API.

Procedure

To push one or more REST APIs to IBM API Connect, complete the following steps.

1. In the web user interface, click the **Open List of Options** icon for the required integration server.
   - If you are viewing all the available servers under the **Servers** tab, the **Open List of Options** icon appears within the tile for each integration server.
   - If you are viewing the content of an integration server under the **Contents** tab, the **Open List of Options** icon appears in the title bar for the integration server.
2. Click **Share REST APIs to API Connect**.

   The **Push REST APIs to API Connect** dialog box opens for you to define your connection to the IBM API Connect system.
3. Select the version of the IBM API Connect system that you are connecting to.

   You can choose from Version 5, Version 5 on IBM Cloud, Version 2018, or Version 10.
4. Enter the connection details for the IBM API Connect management cluster or server in the **Host** and **Port** fields.
   - For **Version 5**, enter the values of the host and port for the IBM API Connect management server or cluster.
   - For **Version 5 on IBM Cloud**, enter the values of the host and port for the IBM API Connect management server or cluster:
     a. Enter the URL of the IBM API Connect system in the **Host** field, omitting the `http://` or `https://` protocol but including the region code; for example:

     ```
     apimanager.eu-gb.apiconnect.cloud.ibm.com
     ```

     In this example, `eu-gb` is the region code for London. The regions that you can specify are:
     - Sydney: `au-syd`
     - Frankfurt: `eu-de`
     - London:`eu-gb`
     - Tokyo: `jp-tok`
     - Washington DC:`us-east`
     - Dallas: `us-south`

     For more information about region codes, see Updated global location names for IBM Cloud.
     b. Enter the port number in the **Port** field; for example, 443.
   - For **Version 2018** or **Version 10**, enter the values of the host and port for the IBM API Connect management server or cluster.

5. Enter your credentials for accessing the IBM API Connect system.

   Note:

   If the IBM API Connect environment is configured with self-signed certificates, or if the certificate configuration does not match the domain of the IBM API Connect environment, the first stage of the **Push REST APIs to API Connect** process fails. If you select **Disable certificate verification when connecting**, App Connect Enterprise ignores the errors. This property is not required when you connect to IBM API Connect Version 5 on IBM Cloud.

   - For **Version 5**, enter your username and password.
   - For **Version 5 on IBM Cloud**, enter the API key that is specified in your service credentials in IBM API Connect. To generate an API key, complete these steps:
     a. Open the IBM Cloud Dashboard at https://cloud.ibm.com and log in if necessary.
     b. From the menu, click **Manage** > **Access (IAM)**.
     c. In the Access (IAM) contents pane, click **IBM Cloud API Keys**.
     d. Click **Create an IBM Cloud API Key**, then follow the on-screen instructions.
   - For **Version 2018** or **Version 10**, enter your username and password, together with the realm, client ID, and client secret.

     You can obtain the values for the client ID and client secret by registering App Connect Enterprise as a client application that can access the IBM API Connect environment. To register a client app from the IBM API Connect toolkit command-line interface (CLI), complete the following steps:

     a. Create a file called `ace-registration.json`, which will be used as the input for creating a registration object. Add the following JSON object as the file content, where *clientID* and *clientSecret* represent appropriate secure values of your choice.

```
{
  "name": "ace-registration",
  "client_id": "clientID",
  "client_secret": "clientSecret",
  "client_type": "toolkit"
}
```

     Example:

```
{
  "name": "ace-registration",
  "client_id": "aceappid4321",
  "client_secret": "aceapptopsecret",
  "client_type": "toolkit"
```

```
}
```

b. If you don't already have a local installation of the IBM API Connect toolkit that provides CLI commands for IBM API Connect, download and install the toolkit. For more information, see Installing the toolkit in the IBM API Connect documentation.

c. From a command prompt, log in to the IBM API Connect management server by using either of the following toolkit CLI commands. Ensure that you log in as an admin with the authority to create registrations.

Interactive login:

```
apic-slim login
```

(You will be prompted to enter your IBM API Connect credentials.)

Non-interactive login:

```
apic-slim login --username userID --password userPassword --server mgmtServerEndpoint
 --realm realm
```

For example:
`apic-slim login --username joebloggs --password mysecretpwd --server mycloudmanager.mydomain.com --realm admin/default-idp-1`

For more information about these login credentials, see Logging in to a management server in the IBM API Connect documentation.

d. Create an IBM API Connect registration for App Connect Enterprise by running the following command, which supplies the `ace-registration.json` file that you created earlier, as input.

```
apic-slim registrations:create --server mgmtServerEndpoint ace-registration.json
```

If you specify an existing `client_id` value in the `ace-registration.json` file, the registration process silently generates a new client ID. You must therefore verify the `client_id`

value for the registration before you specify it in the **Push REST APIs to API Connect** dialog box. (See the next step for details.)

e. Confirm the registration by running the following command:

```
apic-slim registrations:get ace-registration --server mgmtServerEndpoint --output -
```

For example:
`apic-slim registrations:get ace-registration --server mycloudmanager.mydomain.com --output -`

You should see output similar to this:

```
type: registration
api_version: 2.0.0
id: 6a45ed7e-d461-4ea7-89fa-f2a84b2f28ed
name: ace-registration
title: ace-registration
state: enabled
client_type: toolkit
client_id: d2ddd06b-679b-4e84-a7db-c3a18aa3da52
client_secret: '********'
scopes:
  - 'cloud:view'
  - 'cloud:manage'
  - 'provider-org:view'
  - 'provider-org:manage'
  - 'org:view'
  - 'org:manage'
  - 'product-drafts:view'
  - 'product-drafts:edit'
  - 'api-drafts:view'
  - 'api-drafts:edit'
  - 'child:view'
  - 'child:create'
  - 'child:manage'
  - 'product:view'
  - 'product:stage'
  - 'product:manage'
  - 'approval:view'
  - 'approval:manage'
  - 'api-analytics:view'
  - 'api-analytics:manage'
  - 'consumer-org:view'
  - 'consumer-org:manage'
  - 'app:view:all'
  - 'app:manage:all'
  - 'my:view'
  - 'my:manage'
  - 'webhook:view'
created_at: '2021-01-25T14:38:49.000Z'
updated_at: '2021-01-25T14:38:49.000Z'
url: >-
  https://mycloudmanager.mydomain.com/api/cloud/registrations/6a45ed7e-d461-4ea7-89fa-
f2a84b2f28ed
```

If the `client_id` value in the output is different from the value that you specified in the `ace-registration.json` file, this indicates that a new client ID was generated by the registration process. Make a note of this new `client_id` value because it takes precedence over the value in your `ace-registration.json` file.

Tip: You can alternatively confirm the registration by running this command, which writes the output to a file named `ace-registration.yaml`:

```
apic-slim registrations:get ace-registration --server mgmtServerEndpoint
```

f. In the **Push REST APIs to API Connect** dialog box, enter the `client_id` value (from the **`apic-slim registrations:get`** output) into the **Client ID** field, and enter the `client_secret` value from the `ace-registration.json` file into the **Client secret** field.

For more information about creating a JSON object for the `ace-registration.json` file and a client registration, see Obtaining a Client ID and Secret in the Open API Explorer Documentation.

6. After you enter your credentials, click **Connect to API Connect**.

   A connection is established to the IBM API Connect server and you are prompted to specify the target organization, product, and catalog.
7. Select the target organization where you want to push the REST APIs.

   The **Organization** menu shows a list of organizations on the IBM API Connect server to which you have access.
8. Specify the name of the product that you want to update or create, then click **Continue**.

   You can specify an existing product or you can create a new product. Specify the title, name, and version of the product. If you want to stage the product, specify the name of the catalog in which you want it to be staged.

   Available REST APIs are listed.
9. Select the REST APIs that you want to push to IBM API Connect and add to the product, then click **Continue**.

   You are given the option to specify the endpoint that IBM API Connect uses to call the REST API that is hosted by App Connect Enterprise.
10. Choose to either override the hostname and port number that are used by IBM API Connect to call the pushed APIs, or allow IBM API Connect to call the APIs directly.

    If you choose to override the hostname and port number, you can specify HTTP proxy details, HTTPS proxy details, or both.

    - To complete the process of pushing the REST APIs to IBM API Connect by using the web user interface, click **Push APIs**.
    - Optionally, you can copy the properties that you set through the web user interface to the clipboard, in command format, by clicking **Copy command**. You can then use this output to modify and run the **mqsipushapis** command to push the REST APIs to IBM API Connect. For more information, see "Pushing REST APIs to IBM API Connect by using the mqsipushapis command" on page 2052.
11. You can view progress as the selected REST APIs are pushed to IBM API Connect.

    - If an API definition exists on the IBM API Connect server, the existing definition is replaced by the definition of your REST API. If no API definition exists on the server, a new API definition is created for your REST API.
    - If the specified product exists, it is updated. If the specified product does not exist, a new product is created.
    - If a catalog is selected, the product is staged in the catalog.
12. Click individual tasks to see a detailed breakdown of the progress of each task.

    When the REST APIs are pushed to IBM API Connect, close the wizard by clicking **Done**.

Results

Your REST API definition is created or updated on the IBM API Connect server.

Pushing REST APIs to IBM API Connect by using the `mqsipushapis` command

Use the **mqsipushapis** command to create or update the definition of one or more deployed REST APIs on IBM API Connect.

Before you begin

You must complete the following tasks:

- Register or update credentials for the API owner with IBM API Connect:
  - For Version 5 and Version 5 on IBM Cloud, see Administering Developer organizations in the IBM API Connect product documentation.
  - For Version 2018, see Administering Consumer organizations in the IBM API Connect product documentation.
  - For Version 10, see Working with consumer organizations in the IBM API Connect product documentation.
- If you intend to stage the REST API to a catalog, ensure that the IBM API Connect server has a catalog to which you can stage a product that includes the REST API. If a current version of the REST API exists in the catalog, then staging a new version of the REST API unpublishes the current version and changes it to staged state.
- Ensure that any firewalls allow the following connections:
  - IBM App Connect Enterprise can connect to the IBM API Connect server by using HTTPS.
  - The IBM API Connect server can connect to the integration server by using HTTP or HTTPS.
- Create a REST API in the IBM App Connect Enterprise Toolkit; see “Creating a REST API” on page 2019.
- Deploy the REST API to the integration server; see “Packaging and deploying a REST API” on page 2045.

About this task

You can use the **mqsipushapis** command to push the definition of one or more REST APIs to IBM API Connect. If the REST API definition exists on the IBM API Connect system, you replace the REST API definition with the new definition of your REST API.

Procedure

Follow these steps to push one or more deployed REST APIs to the IBM API Connect server:

1. Optional: Construct the **mqsipushapis** command in the web user interface by using the **Push REST APIs to API Connect** dialog and then clicking **Copy command** to copy the output to the clipboard. For more information, see step “1” on page 2048 to step “10” on page 2052 in “Pushing REST APIs to IBM API Connect by using the web user interface” on page 2047. You can use the output to modify the **mqsipushapis** command and then run it at step “2” on page 2053.
2. Use the **mqsipushapis** command to create or update the definition of your deployed REST APIs to an IBM API Connect server. Ensure that you have the correct parameters for the version of IBM API Connect that you want to use.
   - **Version 5**. The following example shows how you can use the command to push REST APIs to IBM API Connect Version 5 and stage the product in the catalog:

     ```
     mqsipushapis INODE --integration-server default --apic-host mysystem
      --apic-port 443 --apic-version v5 --apic-username testuser --apic-password mypassword
      --apic-org myOrg –-apic-catalog-title MyCatalog --apic-product-title MyProduct
      –-apic-product-name ProdName –-apic-product-version 2.0.0 --rest-apis myapi1:myapi2:myapi3
     ```

     You can choose to be prompted for the IBM API Connect password rather than entering it in the command, by specifying `--apic-password ""` (an empty string in double quotes).
   - **Version 5 on IBM Cloud**. The following example shows how you can use the **mqsipushapis** command to push REST APIs to IBM API Connect Version 5 on IBM Cloud and stage the product in the catalog:

     ```
     mqsipushapis --admin-host localhost --admin-port 7600
     --apic-host apimanager.eu-gb.apiconnect.cloud.ibm.com --apic-port 443
     --apic-version v5-on-ibm-cloud --apic-api-key ab209e28-6ajd-1965-8916-7457d176b0c7
     --apic-org myOrg –-apic-catalog-title MyCatalog --apic-product-title MyProduct
     ```

```
 --rest-apis myapi4:myapi5 --apic-disable-certificate-verification
```

In this example, the product name and version are not specified, so the product name is derived from the product title, and the product version defaults to `1.0.0`.

For the parameter **`--apic-host`**, enter the URL of the API Connect system. Omit the `http://` or `https://` protocol, but include the region code. In this example, the **`--apic-host`** value includes `eu-gb`, the region code for London. For more information about region codes, see https://cloud.ibm.com/docs/overview?topic=overview-whatsnew#updated-global-location-names.

- **Version 2018**. The following example shows how you can use the **`mqsipushapis`** command to push REST APIs to IBM API Connect Version 2018 and stage the product in the catalog:

```
mqsipushapis --admin-host localhost --admin-port 4415 --apic-version v2018
--apic-host myhost --apic-port 443 --apic-org v2018-org --apic-product-title myProduct2
--apic-product-name my-product-2 --rest-apis myapi1 --apic-username v2018-user --apic-
password ""
--apic-realm provider/default-idp-2 --apic-client-id clientid --apic-client-secret
 clientsecret
--apic-catalog-title Sandbox --integration-server CVS --apic-disable-certificate-
verification
```

In this example, an empty string is specified for the password parameter (`--apic-password ""`), so the system prompts for the IBM API Connect password.

The command must also include parameters for the realm, client ID, and client secret.

Client ID and Client Secret: To obtain a Client ID & Secret, you have to register a client application with the IBM API Connect environment by using the IBM API Connect command-line interface. The client application in this case is IBM App Connect Enterprise. Follow these steps to obtain a Client ID and Client Secret:

a. Create a JSON object with the following fields:

   - name
   - client_id
   - client_secret
   - client_type

   Example JSON:

```
ace-registration.json
{
  "name": "ace-registration",
  "client_id": "clientid",
  "client_secret": "clientsecret",
  "client_type": "toolkit"
```

```
}
```

b. Download and install the **CLI** version of the IBM API Connect command-line interface, as described at https://www.ibm.com/docs/en/api-connect/2018.x?topic=environment-installing-toolkit.

c. Log in to the IBM API Connect command-line interface.

```
./apic-slim login
```

d. Create an IBM API Connect registration for IBM App Connect Enterprise by running the following command in the IBM API Connect command-line interface. Specify the JSON object that you created as the input file.

```
./apic-slim registrations:create --server mycloudmanager.mydomain.com ace-
registration.json
```

If you specify an existing client_id in the JSON object, the registration process silently generates a new client_id.

e. Confirm the registration by running the following command:

```
./apic-slim registrations:get --server mycloudmanager.mydomain.com ace-reg
```

- **Version 10**. The following example shows how you can use the **mqsipushapis** command to push REST APIs to IBM API Connect Version 10 and stage the product in the catalog:

```
mqsipushapis --admin-host localhost --admin-port 4415 --apic-version v10
--apic-host myhost --apic-port 443 --apic-org v10-org --apic-product-title myProduct2
--apic-product-name my-product-2 --rest-apis myapi1 --apic-username v10-user --apic-
password ""
--apic-realm provider/default-idp-2 --apic-client-id clientid --apic-client-secret
 clientsecret
--apic-catalog-title Sandbox --integration-server CVS --apic-disable-certificate-
verification
```

In this example, an empty string is specified for the password parameter (`--apic-password ""`), so the system prompts for the IBM API Connect password.

The command must also include parameters for the realm, client ID, and client secret.

Client ID and Client Secret: To obtain a Client ID & Secret, you have to register a client application with the IBM API Connect environment by using the IBM API Connect command-line interface. The client application in this case is IBM App Connect Enterprise. Follow these steps to obtain a Client ID and Client Secret:

a. Create a JSON object with the following fields:

- name
- client_id
- client_secret
- client_type

Example JSON:

```
ace-registration.json
{
  "name": "ace-registration",
  "client_id": "clientid",
  "client_secret": "clientsecret",
  "client_type": "toolkit"
```

```
}
```

b. Download and install the **CLI** version of the IBM API Connect command-line interface, as described at https://www.ibm.com/docs/en/api-connect/10.0.x?topic=configuration-installing-toolkit.

c. Log in to the IBM API Connect command-line interface.

```
./apic-slim login
```

d. Create an IBM API Connect registration for IBM App Connect Enterprise by running the following command in the IBM API Connect command-line interface. Specify the JSON object that you created as the input file.

```
./apic-slim registrations:create --server mycloudmanager.mydomain.com ace-
registration.json
```

If you specify an existing client_id in the JSON object, the registration process silently generates a new client_id.

e. Confirm the registration by running the following command:

```
./apic-slim registrations:get --server mycloudmanager.mydomain.com ace-reg
```

For more information about creating the JSON object and client registration, see https://apic-api.apiconnect.ibmcloud.com/v10/#/documentation/authentication/auth_clientid_secret.

Note: If the IBM API Connect environment is configured with self-signed certificates or if the certificate configuration does not match the domain of the IBM API Connect environment, the command fails. Include the parameter **`--apic-disable-certificate-verification`** to instruct IBM App Connect Enterprise to ignore the errors. This parameter is not required when you connect to API Connect Version 5 on IBM Cloud.

3. When the command is run, the selected REST APIs are pushed to the IBM API Connect server:

- If there is an existing API definition on the IBM API Connect server, the existing definition is replaced by the definition of your REST API. If there is no existing API definition on the server, a new API definition is created for your REST API.
- If the specified product exists, it is updated. If the specified product does not exist, a new product is created.
- If a catalog is selected, the product is staged in the catalog.

Results

Your REST API definition is created or updated on an IBM API Connect server.

Developing integration solutions by using patterns

Create integration solutions that are used to solve a specific business problem by using patterns.

Before you begin

If you are not familiar with message flow concepts, message model concepts, and common tasks to manage message flow resources, see “Developing message flows” on page 482 and “Constructing message models” on page 2133.

About this task

A catalog of IBM App Connect Enterprise patterns, which is available on a GitHub repository, provides reusable solutions that encapsulate a tested approach to solving a common architecture, design, or deployment task in a particular context. Much of the work of design and development has been done for you when you use a pattern.

You can use these patterns unchanged, or modify them to meet your own requirements. You must create additional resources to complement the pattern and complete the solution.

Read the following sections to learn more about developing integration solutions by using patterns:

- "Patterns" on page 2057
- "Using patterns" on page 2058
- "Getting patterns from the GitHub repository" on page 2067

Patterns

A *pattern* is a reusable solution that encapsulates a tested approach to solving a common architecture, design, or deployment task in a particular context.

A pattern captures a tested solution to a commonly recurring problem, addressing the objectives that you want to achieve. The specification of a pattern describes the problem that is being addressed, why the problem is important (the value statement), and any constraints for the solution. Patterns typically emerge from common usage and the application of a particular product or technology.

An IBM App Connect Enterprise pattern can be used to generate customized solutions to a recurring problem in an efficient way. IBM App Connect Enterprise patterns are provided to encourage the adoption of preferred techniques in message flow design, to produce efficient and reliable flows. Patterns provide the following benefits:

- Give you guidance for the implementation of solutions
- Increase development efficiency, because resources are generated from a set of predefined templates
- Result in higher-quality solutions, through reuse of assets and common implementation of programming approaches, such as error handling and logging

A catalog of IBM App Connect Enterprise patterns is provided in a repository on GitHub that is accessible from the **Patterns Explorer** view in the IBM App Connect Enterprise Toolkit. The patterns are divided into pattern categories. *Pattern categories* are categories that are based on the pattern classification and structure the display in the Patterns Explorer. The catalog provides detailed help that guides you toward a suitable IBM App Connect Enterprise pattern to create resources that are used to solve a specific business problem.

You can also create your own *user-defined patterns*.

Each pattern has values that are known as pattern parameters. *Pattern parameters* are parameters that customize and configure an IBM App Connect Enterprise pattern. The pattern parameters that you configure depend on the particular pattern, and on the options that you enable for that pattern. An example of a pattern parameter is a queue name from where messages are read.

The IBM App Connect Enterprise patterns provide defaults for most pattern parameters, and help is provided to explain them. After you have configured the pattern parameters, you generate a *pattern instance project*, which contains references to all other projects in the workspace that relate to your pattern instance. A pattern instance project also contains a pattern instance configuration file that stores the pattern parameter values. This configuration file stores the pattern parameters that you configured. Generating a pattern instance project also creates one or more additional IBM App Connect Enterprise projects that typically contain message flows and other IBM App Connect Enterprise resources that implement the pattern.

You can open the pattern instance configuration file at any time to see the values of the pattern parameters. When a pattern configuration file has been reopened, you can regenerate the IBM App Connect Enterprise projects. Regeneration deletes the generated IBM App Connect Enterprise projects and re-creates them from scratch. The pattern instance project contains an HTML summary file and a pattern instance configuration file. The summary file has a section that explains additional tasks that might be required, such as creating queues.

You can create resources from each IBM App Connect Enterprise pattern more than once to give you unique pattern instances, each with a different configuration. The pattern parameters that you can configure depend on the particular pattern, and also the options that you enable for that pattern.

Some of the pattern parameter settings can affect the resources that are generated. For example, if you enable logging and error handling, the generated projects contain additional message flows and ESQL scripts.

In all cases, the specification of both the problem and the solution are indispensable parts of the pattern definition.

Using patterns

Use patterns that are supplied with the IBM App Connect Enterprise Toolkit to create resources that are used to solve a specific business problem.

Each IBM App Connect Enterprise *pattern* is designed to address a specific business problem. To find out about the IBM App Connect Enterprise patterns that are supplied on GitHub, see "Getting patterns from the GitHub repository" on page 2067.

Each pattern has values known as *pattern parameters* that you use to create the pattern resources for use in your environment. The pattern parameters that you can configure depend on the specific pattern, and also the options that you enable for that pattern; for example, logging.

When you select a pattern from the Patterns Explorer, the **Pattern Specification** tab gives details about the purpose and configuration of each pattern parameter associated with a pattern, the effects and consequences of changing them, and any postrequisite tasks. All patterns have pattern parameter properties that distinguish one application of a pattern template from another.

All patterns are either abstract or implementations and as you move down the tree the patterns become more specific. At any level in a tree a pattern can be an implementation.

You can apply pattern implementations only. Pattern implementations map to a complete specification with prerequisite and postrequisite tasks, and pattern parameter details. Pattern implementations have a **Create New Instance** button in the **Pattern Specification** tab. *Abstract* patterns, which cannot be applied, do not have a **Create New Instance** button in the **Pattern Specification** tab.

You can create resources from each pattern more than once to give unique *pattern instances* with different configurations. The configuration for each pattern instance is contained within a single *pattern instance project*. The pattern instance project contains links to all projects containing the resources that are created as a result of generating a pattern instance from your configuration, such as message flows, Java classes for JavaCompute nodes, ESQL modules, message maps, test client, XML files, and style sheet files.

Choosing a pattern

Select a pattern in the **Patterns Explorer** view to create resources to solve a specific business problem.

Before you begin

Before you complete this task, read the following overview topics about patterns:

- "Patterns" on page 2057
- "Using patterns" on page 2058

About this task

To create resources by using a pattern, complete the following steps:

Procedure

1. Open the **Patterns Explorer** view by using one of the following methods:
   - In the Application Development view, click **New pattern instance** in the **Pattern Instances** section.
   - Click the **Patterns Explorer** tab.
   - Click **Quick Starts**, then click **Start from patterns**.
   - Click the **Open Patterns Explorer** icon in the task bar ().

   The **Patterns Explorer** view is displayed.
2. In the **Patterns Explorer** view, click **Patterns**.

   The **Pattern Specification** tab displays information about the patterns. For example, to find out about message-based integration patterns, complete the following steps:

   a) Click **Message-based Integration**.

   The **Pattern Specification** tab displays information about the selected pattern, and because it is an abstract pattern the **Create New Instance** button is not displayed.

   b) Under **Message-based Integration** click another pattern, for example **Message Correlator**.

   The **Pattern Specification** tab displays information about the selected pattern, and because it is an abstract pattern the **Create New Instance** button is not displayed.

   c) Under **Message Correlator** click another pattern, for example **MQ request-response with persistence**.

   The **Pattern Specification** tab displays information about the selected pattern, and because it is a pattern implementation the **Create New Instance** button is displayed.
3. Before you use your pattern, read "Tasks to complete before applying the pattern" and "Constraints on the use of the pattern".
4. To use a pattern implementation from the **Pattern Specification** tab, click **Create New Instance**.

   The **Create New Instance** window opens.
5. Enter a new pattern instance name.

   You cannot use the following names:
   - The name of an existing project in the current workspace.
   - On Windows only: MS-DOS device driver names. For more information, see the article on the Microsoft support site: MS-DOS device driver names cannot be used as file names.
6. Click **OK**. If you click **Cancel**, no changes are made to the workspace.

   The **Configure Pattern Parameters** page is displayed.
7. On the **Configure Pattern Parameters** page, complete all required pattern parameter fields.

   Configure pattern parameters by entering the appropriate values. If you do not want to generate the pattern immediately, save the parameters to edit later. Before you apply a pattern, enter a value for each pattern parameter. You can accept a default value, if one is offered. Empty strings are permitted for some fields.

   You can reuse a saved configuration by editing the parameters, see “Editing and regenerating a pattern” on page 2065.

   Parameter groups might be marked with error markers. You can click the error marker to move to the first field that has an error.

What to do next

Now complete the following task:

- “Generating a pattern instance” on page 2064

Working with patterns in the Application Development view

Using the Application Development view to create patterns.

Before you begin

Before completing this task, read the following overview topics about patterns:

- "Patterns" on page 2057
- "Using patterns" on page 2058

About this task

Pattern instances are shown under the Pattern Instances folder in the Application Development view. If you have not created any pattern instances yet, the folder is not visible. Similarly, pattern authoring projects are shown under the Pattern Authoring folder.

The Patterns Explorer is a separate tab. When you select a pattern from the Patterns Explorer, the specification for that pattern is shown in the editor view. When you click **Create New Instance**, a pattern configuration opens in the editor. You configure your parameters for the pattern, then click **Generate**. A pattern instance is created, and is shown under the Pattern Instances folder in the Application Development view. A working set is also created for the pattern and is immediately active, so that you can see only the resources that are associated with your pattern. To see all resources in your workspace, click the **Remove all filters** icon  on the toolbar of the Application Development view.

What to do next

Now complete the following task:

- "Choosing a pattern" on page 2058

Adding or removing project references in a pattern instance project

A pattern instance project contains references to regular projects and they are listed in the Project References category of a pattern instance project.

About this task

The Project References category under a pattern instance project in the Application Development view shows the same project references as the Project References page in the Properties window.

To add another project to the list of project references for your pattern instance project, complete the following steps:

Procedure

1. Expand the Pattern Instances folder in the Application Development view.
2. Open the pattern instance project and select the **Project References**.
3. Right-click the **Project References** and then select **Properties**.
4. Add projects by selecting them in the **Project References**.
   You can remove projects in the same way by deselecting them.

Going to a referenced project

How to display your pattern instance project in the Application Development view.

About this task

To display your pattern instance project complete the following steps.

Procedure

1. Expand the Pattern Instances folder in the Application Development view.
2. Expand your pattern instance project, and expand **Project References**.
3. Right-click your pattern instance project reference.
4. Select **Go to Referenced Project**.
   The referenced flows project is selected in the Application Development view.

Showing a working set for a pattern instance project

When a pattern instance project is created by the Patterns Explorer, a working set of the same name is generated, and all projects that are part of that pattern instance are placed inside it.

About this task

To view all of the projects in your pattern instance:

Procedure

1. Click the arrow on the toolbar of the Application Development view, then click **Select Working Set**.
   All working sets are displayed, including those for pattern instances.
2. Select the relevant working sets and click **OK**.
   Only the resources associated with the selected working sets are shown in the Application Development view.
3. To see all resources in the workspace, click the arrow on the Application Development view toolbar, then click **Deselect Working Set**.
   Alternatively, click the **Remove all filters** icon  on the toolbar of the Application Development view.

Focusing on a pattern instance

Several ways are available for you to focus on a particular pattern instance.

Procedure

To focus on your pattern you can use one of the following methods:

- In the Pattern Instances section, right-click your pattern instance project, select **Focus on Pattern Instance**.
- In the toolbar of the Application Development view, click the down arrow and select your pattern instance name from the menu.

The navigator refreshes to show the currently selected working set and its associated projects.

To confirm that your pattern instance project is currently in focus, right-click your pattern instance project, ensure that the check box to the left of the **Focus on Pattern Instance** menu item is selected. If you clear this check box, the navigator shows all of the projects.

If the navigator has focus on your working set, if you click the down arrow in the IBM App Connect Enterprise Development toolbar, your working set menu item is selected in the menu.

Creating a working set and focus on a pattern instance

Creating a working set for an imported project interchange file that contains a pattern instance project and its associated projects.

About this task

If you import a project interchange file that contains a pattern instance project and its associated projects, a working set is not automatically created for the pattern instance project. Therefore, you must create a working set.

Procedure

In the Pattern Instances section of the Application Development view, right-click the pattern instance project, and select **Create Working Set and Focus on Pattern Instance** in the menu.

When this item is selected, a working set is created with the same name as the pattern instance project, the pattern instance project and its associated projects are added to that working set, and the working set is given focus in the navigator.

Deleting a pattern instance project

Pattern instance projects typically contain references to regular projects. Therefore, when you select a pattern instance project for deletion you must decide whether to delete all of the referenced projects from the file system. Some pattern instance projects have no project references.

About this task

Use the following instructions depending on the type of pattern instance that you want to delete:

- "Deleting a pattern instance project with project references" on page 2062
- "Deleting a pattern instance project with no project references" on page 2063

Deleting a pattern instance project with project references

Pattern instance projects typically contain references to regular projects. Therefore, when you select a pattern instance project for deletion you must decide whether to delete all of the referenced projects from the file system.

About this task

Pattern authors can configure projects in a pattern authoring project so that they are not overwritten when a pattern instance is regenerated. Projects that have been configured in this way are not deleted when a pattern instance is deleted.

Use the following steps to delete a pattern instance project that has project references:

Procedure

1. In the Application Development view, open the Pattern Instances section.
2. Right-click the pattern instance project, or projects, that you want to delete, click **Delete**.

   The **Confirm Project Delete** window opens, displaying any projects that are referenced by the pattern instance project. The **Also delete the projects referenced by this pattern instance project** check box is selected and the **Also delete contents in the file system** check box is cleared by default.
3. Choose one of the following options:
   - To delete the pattern instance project, or projects, and the project references, but leave the contents in the file system, keep the default settings, click **Yes**. The pattern instance project, or projects, and the project references still exist in the file system.
   - To delete the pattern instance project, or projects, and the project references from the workspace and the file system, ensure that **Also delete the projects referenced by this pattern instance project** and **Also delete contents in the file system** are both selected, click **Yes**. The working set is deleted.
   - To delete your pattern instance project, or projects, from the workspace but not from the file system and to keep the project references in the workspace and file system, ensure that **Also delete the projects referenced by this pattern instance project** and **Also delete contents in the file system** are both cleared. The working set is deleted.
   - If you decide not to delete the pattern instance project, or projects, click **No**.

Deleting a pattern instance project with no project references
Decide whether to delete your pattern instance project, which has no project references, from both the workspace and the file system.

About this task

Use the following steps to delete a pattern instance project that has no project references:

Procedure

1. In the Application Development view, open the Pattern Instances section.
2. Right-click the pattern instance project, or projects, that you want to delete, click **Delete**. The **Confirm Project Delete** window opens, displaying the pattern instance project. The **Also delete contents under *pattern _instance_name*** check box is cleared by default. The default is to delete the pattern instance project from the workspace, but not to delete it from the file system.
3. Choose one of the following options:
   - To delete the pattern instance project, or projects, from the workspace, but not from the file system, click **Yes**. The working set is also deleted.
   - To delete the pattern instance project, or projects, from the workspace and from the file system, select the **Also delete contents under *pattern_instance_name*** check box, click **Yes**. The working set is also deleted.
   - If you decide not to delete the pattern instance project, or projects, click **No**.

Deleting projects

If you want to delete a project, you must take into account whether it is referenced by a pattern instance project.

About this task

Use the following instructions depending on whether the project that you want to delete is referenced by a pattern instance project:

- "Deleting projects that are referenced by a pattern instance project" on page 2063
- "Deleting projects that are not referenced by a pattern instance project" on page 2063

Deleting projects that are referenced by a pattern instance project
If you want to delete an application, library, or integration project, you must take into account whether it is referenced by a pattern instance project.

About this task

If you delete an application, library, or integration project that is referenced by a pattern instance project, the project reference is removed from the pattern instance project. Therefore, before you delete an application, library, or integration project, ensure that it is not referenced by another project.

Deleting projects that are not referenced by a pattern instance project
If you want to delete a project, you must take into account whether it is referenced by a pattern instance project.

About this task

Complete the following steps to delete your project if it is not referenced by a pattern instance project:

Procedure

1. In the Application Development view, select the project that you want to delete, then click **Delete**.

   The **Confirm Project Delete** window opens asking whether you are sure that you want to delete the project. The default action is to delete the project from the workspace, but not to delete it from the file system. Therefore, by default, the **Also delete content under *project_name*** check box is cleared.
2. Choose one of the following options:
   - To delete the projects from the workspace, but not to delete it from the file system, ensure that the **Also delete content under *project_name*** check box is cleared.
   - To delete the projects from the workspace and delete it from the file system, ensure that the **Also delete content under *project_name*** check box is selected.
   - If you decide not to delete the projects, click **No**.

Generating a pattern instance

Generate resources from the pattern.

Before you begin

You must have chosen pattern. For more details, see "Choosing a pattern" on page 2058.

About this task

The **Generate** button is unavailable until all required parameters are complete.

To generate the IBM App Connect Enterprise Toolkit resources for the pattern, complete the following steps.

Procedure

On the **Configuration** page, click **Generate**.

Focus is automatically moved to the Application Development view, which lists all the new resources that have been generated.

All of the other resources are filtered out in this view.

Results

Following a successful **Generate** action:

- A pattern instance project is created in your workspace and is displayed in the Application Development view. The pattern instance project contains a pattern instance configuration file and a summary file. The summary file describes the tasks that have been generated, and the tasks that are still required.
- All the resources generated for a pattern instance are packaged into their own working set and the Application Development view displays only the resources in this working set. The name of the working set is always the same as the pattern instance name provided. This name must always be unique within the workspace.
- You can regenerate the pattern by using the same instance name, but, if you confirm the regeneration, existing projects are deleted, see "Editing and regenerating a pattern" on page 2065.

What to do next

Now complete the following task:

- "Reviewing the pattern instance summary and tasks" on page 2065

Editing and regenerating a pattern

You can regenerate a pattern instance after you have edited a saved configuration in a pattern instance project.

About this task

Before you begin:

You must be in the IBM App Connect Enterprise Toolkit and have an existing pattern configuration file in a pattern instance project.

Procedure

1. Open an existing pattern configuration by double-clicking the configuration XML file in a pattern instance project.

   The **Configure Pattern Parameters** page of the editor displays parameter values for that configuration instance. The Integration node navigation pane is in focus. The title of the **Configure Pattern Parameters** page for the parameter reflects the pattern instance name (not the pattern name).
2. View and edit the pattern parameters. You can now choose either of the following options:
   - Close the editor without saving the changes.
   - Select **Generate**. Resources, such as projects, already exist in the workspace. You are warned that these resources will be deleted and you can choose whether to continue. If you continue, the resources are regenerated; the existing resources are deleted and re-created. If you decide not to continue, the pattern configuration remains open and no changes are made to the pattern resources.

     When you make changes in the Pattern Configuration editor, the summary file and configuration XML file might be out of date because the *instance_name*`_configuration.xml` and the *instance_name*`_summary.html` files do not match the generated resources. The **Problems** view displays any warning messages. Double-click the warning message to open the relevant editor for the resource.

What to do next

Now complete the following task:

- “Reviewing the pattern instance summary and tasks” on page 2065

Reviewing the pattern instance summary and tasks

Showing the summary page for your pattern instance project.

Before you begin

You must have completed the following tasks:

- “Generating a pattern instance” on page 2064

About this task

After generating the pattern instance, you might have to do additional tasks to complete your solution and to support its operation following instance. These tasks are located in a summary file that is created in the pattern reference project, which has the same name as the instance name.

The summary file lists the resources that were created for the pattern instance, based on the pattern parameter values that you entered in the **Configure Pattern Parameters** page. The summary also lists any outstanding tasks that you must complete to make the solution operational. For example, you might have to configure the message set details that are required by one or more input nodes that form part of the overall solution, or create IBM MQ queues for the nodes.

When a pattern has been configured and generated once, it contains both a configuration file and a summary file. If you edit and save the configuration file, both the configuration and the summary files display a warning symbol and a warning also shows in the **Problems** window indicating that the two files are out of sync. To get the files back in sync, regenerate the pattern.

To view the summary and tasks:

Procedure

1. Click **Windows** > **Show view** > **Tasks** to open the **Task** view.
2. In the **Path** column, find your pattern instance project name, which includes the pattern instance name that you used when you created the pattern instance.
3. To open the Summary page, double-click anywhere on the task, or right-click and select **Go To**.
4. Complete the tasks that are shown in the summary file.

What to do next

Now complete the following task:

- "Adding resources to a BAR file" on page 2470

Importing an existing configuration

You can import a pattern configuration XML file from the workspace or file system and populate your current pattern instance with its values.

Before you begin

Before you start:

Before completing this task, you must have a compatible pattern configuration.

You must be in the IBM App Connect Enterprise Toolkit and have a pattern instance open.

Procedure

1. Open your current configuration. On the **Configure Pattern Parameters** page, click the **Open existing configuration** icon.

   The **Open Pattern Configuration** window opens.
2. You can select an existing pattern XML configuration file either from a workspace or file system location.

   Only configuration files created by the same pattern can be imported.

   - To select from a list of compatible XML configuration files that are already in the workspace, click **Workspace**. If you select a valid XML configuration file, the editor is configured with the values from the existing configuration file. You can then choose one of the following options:
     - Save the changes by clicking **OK**.
     - Return to the **Configure Pattern Parameters** page and discard the changes by clicking **Cancel**.
   - To select an XML configuration file from the file system by using a standard file system window, click **File System**. Select the file that you want to use, click **Open**.

   The configuration XML is validated against the corresponding pattern schema, if you select a configuration that is not valid, for example, from a different pattern, you receive notification. You can then either select the correct file, or cancel the action.
3. Share the pattern instance projects.

   To share pattern instance projects between IBM App Connect Enterprise Toolkit workspaces, you can export the pattern instance project into a directory in the file system or into a Project Interchange File (PIF). You can then import the pattern instance project into another workspace.

What to do next

Now complete the following task:

- "Generating a pattern instance" on page 2064

Getting patterns from the GitHub repository

You can download and install existing patterns from the OT4I GitHub Pattern Repository by using the IBM App Connect Enterprise Toolkit.

About this task

From the **Patterns Explorer** in the IBM App Connect Enterprise Toolkit, complete the following steps to download and install a pattern:

Procedure

1. Right-click **OT4I GitHub Pattern Repository** under **Pattern Repositories**, and click **Connect** to display the categories of the patterns that are available in the repository.
2. Expand a pattern category to list the patterns that are available in that category.

   Each pattern name in the list is appended with **[Not Installed]** if the pattern is not installed in the IBM App Connect Enterprise Toolkit, or **[Installed]** if the pattern is already installed.
3. Right-click the pattern that you want to download and click **Download and Install**.

   This menu option is available only if the pattern is not already installed.
4. When the security warning is displayed, click **OK**.

   The pattern is downloaded and installed, the pattern name in the list is appended with **[Installed]**, and the pattern is listed under **Patterns** in the **Patterns Explorer**.
5. Optional: If you want to uninstall and remove a pattern from the IBM App Connect Enterprise Toolkit, right-click the pattern name in **Pattern Repositories** > **OT4I GitHub Pattern Repository** and click **Uninstall**.

   The pattern is uninstalled and removed from the list of patterns under **Patterns**, and the pattern name in the repository is appended with **[Not Installed]**.

   Note: Uninstalling a pattern from the IBM App Connect Enterprise Toolkit does not affect any instances that are created from the pattern.

What to do next

Read the pattern documentation and create a pattern instance to explore the pattern functionality; see "Using patterns" on page 2058

Note: From the **Patterns Explorer** you also have access to the **Experimental OT4I GitHub Pattern Repository**. The **Experimental OT4I GitHub Pattern Repository** contains patterns that are available for testing but are not fully-supported.

User-defined patterns

A *user-defined pattern* extends the function of IBM App Connect Enterprise so that you are able to create patterns that you can reuse within your organization.

The *pattern author* creates a user-defined pattern to meet a business or technical requirement, and the *pattern user* configures a user-defined pattern that the pattern author has created. The user-defined pattern is available to a pattern user in the Patterns Explorer view in the Integration Development perspective of the IBM App Connect Enterprise Toolkit.

To create user-defined patterns, you must provide the implementation of the solution that reflects good practice in your organization. This implementation is known as an *exemplar*. An exemplar is a project that holds content for a pattern. An exemplar contains message flows and other resources, such as source

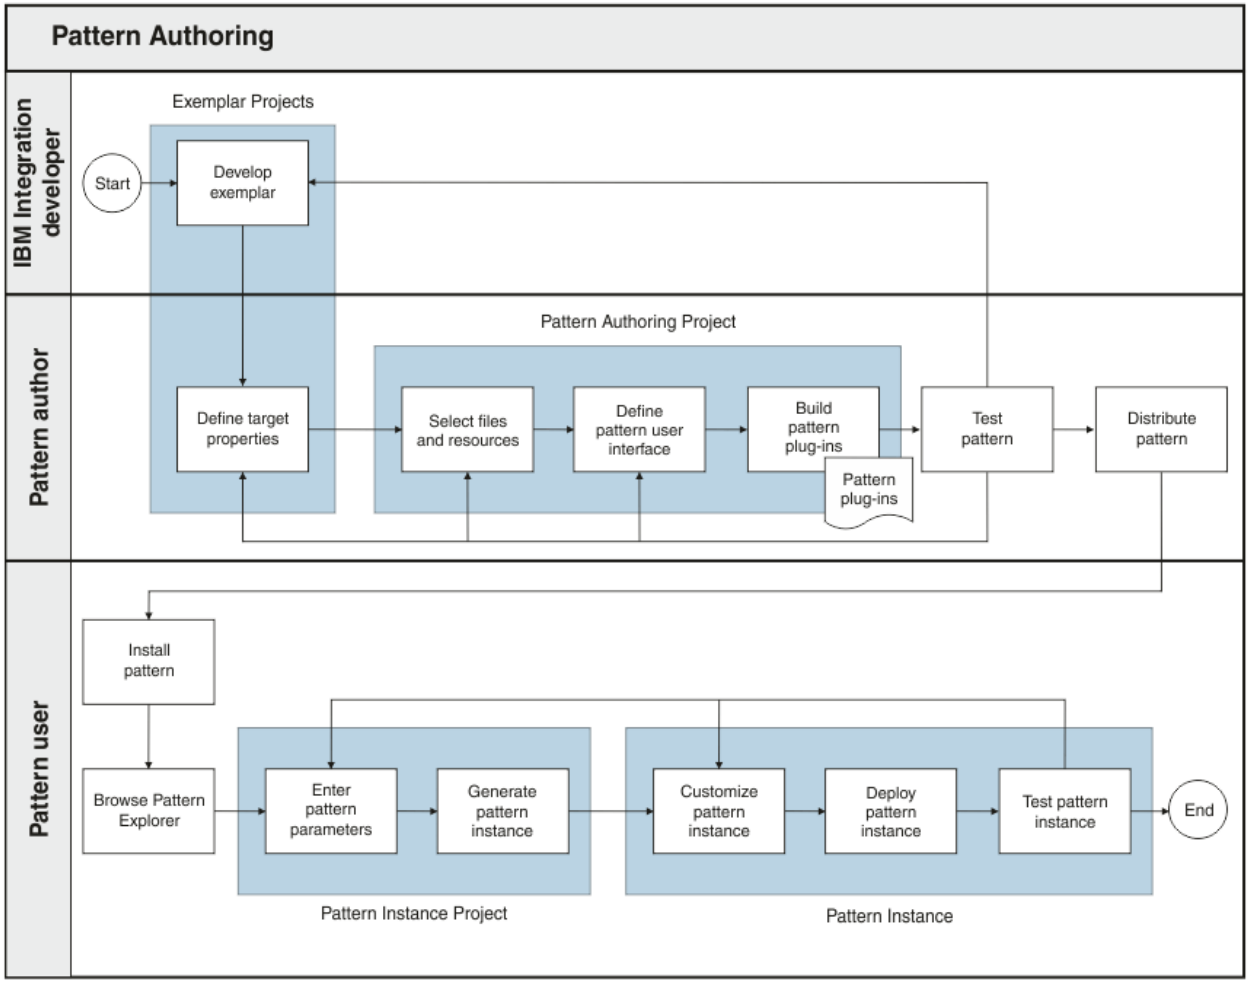
code, Java classes for JavaCompute nodes, ESQL modules, message maps, test client, XML files, and style sheet files. Exemplars are used to create pattern plug-ins by configuring a *pattern authoring project*.

You can use the Pattern Authoring editor to configure a pattern and create the pattern plug-ins that implement the pattern. You can distribute the pattern plug-ins so that other people can use your pattern. Your pattern is displayed in the **Patterns Explorer** view and can be used in the same way as the built-in patterns.

To create a user-defined pattern, see "Creating a user-defined pattern" on page 2068.

Creating a user-defined pattern

The workflow showing the actions required for pattern authoring.



The three stages of creating a user-defined pattern are performed by the IBM App Connect Enterprise developer, the pattern author, and the pattern user.

1. The IBM App Connect Enterprise developer develops the exemplar. The exemplar is fundamental to the pattern authoring process. It assumes that the exemplar is the starting point for a pattern. Some modifications might be required to the exemplar to prepare it for pattern authoring.
2. The pattern author creates a pattern plug-in from the exemplar. Authoring a pattern is a design activity. Some of the pattern authoring focuses on the resources in IBM App Connect Enterprise, for example, defining the target properties for the pattern and configuring the user interface that is presented to the pattern user. The pattern author ensures that the pattern can be customized by pattern users, if required, and that these customizations are not overwritten if the pattern user regenerates an instance of the pattern. One possible approach to customization is to include in the message flows of the pattern one or more subflows that are intended to be customized by pattern users. The pattern author

includes these subflows in a separate project within the pattern and configures the project so that it is not overwritten when a pattern instance is regenerated.

The pattern author then shares the user-defined pattern with the pattern user. Patterns are most useful when they are shared with a user base. This user base can be within an organization, or a broader community, for example, open source licensing.

3. The pattern user receives a user-defined pattern, customizes it, and uses it in accordance with the requirements of the organization.

Pattern authoring

To create a user-defined pattern, complete the following tasks. "Extending a user-defined pattern" is an optional set of tasks that you can use to add features to your user-defined pattern. For example, by extending a user-defined pattern you can create user-defined patterns that include parameters that pattern users can modify.

1. “Creating a pattern authoring project” on page 2069
2. “Selecting the source files to use for a user-defined pattern” on page 2070
3. Optional: “Adding and removing the project references for a user-defined pattern” on page 2070
4. Optional: “Configuring a project used in a user-defined pattern” on page 2071
5. Optional: “Extending a user-defined pattern” on page 2072
6. “Building pattern plug-ins” on page 2126
7. “Testing a user-defined pattern” on page 2126
8. “Packaging and distributing pattern plug-ins” on page 2127

When you have created pattern plug-ins for your user-defined pattern, pattern users can install them to use in IBM App Connect Enterprise projects, see “Downloading and installing a pattern archive” on page 2130.

Creating a pattern authoring project

Create a pattern authoring project and choose an exemplar for the project.

About this task

Procedure

To create a pattern authoring project:

1. Click **File** > **New** > **Other**.

   A window opens in which you can select a wizard.
2. Expand **Integration Bus - Application Development**, select **Pattern Authoring Project**, then click **Next**.

   The **New Pattern Authoring Project** wizard opens.
3. Enter a pattern name and a project name for your pattern, then click **Next**.
4. Select the project references that you require.

   These references are the exemplars for the user-defined pattern.
5. Click **Finish**.

Results

Your pattern is displayed under the Pattern Authoring folder in the Application Development view, and is opened in the Pattern Authoring editor.

What to do next

Select the source files. For more information, see "Selecting the source files to use for a user-defined pattern" on page 2070.

Selecting the source files to use for a user-defined pattern

Select the source files to include in your pattern.

Before you begin

Complete the following task:

- "Creating a pattern authoring project" on page 2069

Procedure

To select the source files to use in the user-defined pattern:

1. In the Pattern Authoring editor, click the **Source Files** tab.
2. In the **Select Source Files** section, select the source files in the referenced projects that you want to include in your pattern.

What to do next

- Extend the pattern, see "Extending a user-defined pattern" on page 2072.
- Change the project references, see "Adding and removing the project references for a user-defined pattern" on page 2070.
- Build the pattern, see "Building pattern plug-ins" on page 2126.

Adding and removing the project references for a user-defined pattern

Change the project references for a user-defined pattern so that you can change the source files in the user-defined pattern.

Before you begin

Complete the following task:

- "Creating a pattern authoring project" on page 2069

Procedure

To add or remove project references:

1. In the Pattern Authoring editor, click the **Source Files** tab. Click **Change Project References**.
2. To add a new project reference, select the project reference that you want to add and click **OK**.

   If you add a new project reference, none of the source files within the project reference are selected. To select source files for the new project reference, see "Selecting the source files to use for a user-defined pattern" on page 2070. If your user-defined pattern requires referenced projects but they are not included as source files in the pattern, you must distribute the referenced projects to pattern users to ensure the user-defined pattern works.
3. To remove a project reference, clear the project reference that you want to remove and click **OK**.

   If you remove a referenced project from the workspace, the source files are removed from the pattern authoring project but the project reference remains. If you later add the project back into the workspace, the source files are added to the pattern authoring project.

What to do next

- You can extend the pattern; see "Extending a user-defined pattern" on page 2072.
- If the pattern is complete, you can now build the pattern; see "Building pattern plug-ins" on page 2126.

Configuring a project used in a user-defined pattern

Configure a project that is included in a user-defined pattern to control whether the project is overwritten when a pattern user regenerates a pattern, and to set the name of the project.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Adding and removing the project references for a user-defined pattern" on page 2070

About this task

When a pattern user generates a user-defined pattern, copies of projects that are selected as source files in the pattern authoring project are created in the pattern instance. By default, if a pattern user customizes the projects in an instance of a user-defined pattern and then regenerates the pattern instance, those customizations are overwritten. As a pattern author, you can configure projects in a user-defined pattern project so that they are not regenerated when a pattern user regenerates a pattern instance. Pattern users can then customize these projects and regenerate pattern instances without losing the customizations. Projects that are configured so they are not overwritten are also not overwritten if a new version of the pattern is installed before the pattern user regenerates a pattern instance.

As a pattern author, you can specify how a project that is contained in a user-defined pattern is named when a pattern instance is generated. By default, the pattern instance name is added as a prefix to the project name. You can turn off this prefix. If you generate more than one instance of a user-defined pattern that contains a project name without a prefix, all instances of the pattern use the same copy of the project.

As a pattern author, you can name a project in a user-defined pattern by using the value of a pattern parameter. The project name is determined after all transformation expressions are calculated.

Procedure

To configure a project used in a user-defined pattern:

1. In the Pattern Authoring editor, in the **Select Source Files** section, select the project you want to configure and click **Edit**, or double-click the project you want to configure.

   The **Edit Project** window opens.
2. To configure a project so that when a pattern user regenerates a pattern instance it is not overwritten, select **Pattern users will modify this project**.

   If the project does not exist, it is generated when a pattern user generates an instance of the pattern. If the project exists it is not overwritten. If the project exists, but files within it have been deleted, these files are created.
3. To configure a project so that when a pattern user generates a pattern instance the project name does not start with the name of the pattern instance, clear **Prefix the project name with the pattern instance name**.
4. To configure a project so that when a pattern user generates a pattern instance the project name is set to the value of a pattern parameter, click **Select**. In the **Select Pattern Parameter** window, select the parameter you want to use to set the project name, then click **OK**.
5. Click **OK**.

What to do next

- Extend the pattern, see "Extending a user-defined pattern" on page 2072
- Build the pattern, see "Building pattern plug-ins" on page 2126

Extending a user-defined pattern

Extend a user-defined pattern to customize its behavior so that it is easier to use or to provide guidance to pattern users.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070

About this task

A basic user-defined pattern is a copy of an existing message flow, but by extending a user-defined pattern you can allow the pattern user to customize the pattern.

Procedure

You can extend a user-defined pattern in the following ways:

- Create documentation for the pattern.

  Creating documentation provides guidance to your pattern users. To update the pattern documentation, see "Creating documentation for a pattern" on page 2073.
- Define the target properties.

  A user-defined pattern can change the value of user-defined properties, promoted node properties, and node properties in a message flow. A property that is changed by a pattern is called a target property. Pattern users create a pattern instance by configuring pattern parameters. The values of the pattern parameters that are configured by a pattern user can be used to configure the target properties in the pattern instance. To define target properties, see "Defining the target properties" on page 2074.
- Define the user interface.

  You can customize how the pattern parameters are displayed to pattern users by defining the user interface. For example, you can rename or group pattern parameters, and you can define default values for pattern parameters. To define the user interface, see "Defining the user interface" on page 2074, "Adding and editing parameter groups" on page 2076, and "Enabling parameter groups" on page 2077.
- Configure the categories in the Patterns Explorer view.

  When a pattern user imports a user-defined pattern, it is shown in the Patterns Explorer view. You can select which category the user-defined pattern is assigned to in the Patterns Explorer view and create new categories. To configure the categories, see "Creating and configuring categories" on page 2079.
- Configure the SOAP nodes.

  To use SOAP nodes in user-defined patterns, see "Configuring SOAP nodes for user-defined patterns" on page 2080.
- Change pattern parameter IDs.

  Pattern parameter IDs are used to refer to pattern parameters in XPath, Java, and PHP code. You can write the code to modify pattern parameters or pattern instances. Default parameter IDs are assigned, but you can change them to custom IDs. To change parameter IDs, see "Changing pattern parameter IDs" on page 2081.
- Control the creation of projects in the pattern.

  You can use XPath expressions to control whether a project in a user-defined pattern is created based on the values of pattern parameters. To set up project creation expressions and then test the expressions, see "Creating a project used in a user-defined pattern" on page 2082 and "Testing a project creation expression" on page 2083.

- Transform the pattern parameters.

  You can calculate values for pattern parameters from other pattern parameters by using XPath expressions. To set up transformations for pattern parameters and then test the transformations, see “Transforming pattern parameters” on page 2084 and “Testing a transformation expression” on page 2085.
- Enable or disable the pattern parameters.

  You can use XPath expressions to control whether a pattern parameter can be modified by a pattern user based on the values of other pattern parameters. To set up enabling expressions for pattern parameters and then test the expressions, see “Enabling pattern parameters” on page 2086 and “Testing an enabling expression” on page 2087.
- Use enumerated values for the pattern parameters.

  You can set up enumerated types for pattern parameters so that pattern users have a predefined list of values for the pattern parameters. If a target property has a list of possible values, the pattern authoring tool generates an enumerated type for that target property. You can modify the enumerated type that is automatically created. To use enumerated types see “Using enumerated values for pattern parameters” on page 2088 and “Creating enumerated types for pattern parameters” on page 2088.
- Use tables for the pattern parameters.

  You can set up table types for pattern parameters by defining the columns for the table. Pattern users can then enter one or more rows of data in the table in your user-defined pattern. To use table types see “Using tables for pattern parameters” on page 2091 and “Adding pattern parameter table types” on page 2091.
- Use user-defined editors for the pattern parameters.

  You can create user-defined editors for pattern parameters in your user-defined patterns. Pattern users use these editors when they enter values for pattern parameters in an instance of your user-defined pattern. To use user-defined editors, see “Using user-defined editors for pattern parameters” on page 2093.
- Modify pattern instances by using Java or PHP.

  You can write code in Java or PHP that modifies pattern instances when a pattern user generates an instance of a user-defined pattern. For example, you can write code to modify the structure of a message flow based on the values of pattern parameters. To use Java or PHP in user-defined patterns, see “Modifying pattern instances by using Java or PHP” on page 2105.

What to do next

After extending your user-defined pattern, you must build the pattern plug-in, see “Building pattern plug-ins” on page 2126.

Creating documentation for a pattern

When you create a pattern authoring project, a default HTML pattern specification is created as part of the project. You can edit this pattern specification to document your user-defined pattern.

Before you begin

Complete the following task:

- “Creating a pattern authoring project” on page 2069

About this task

Procedure

To edit the pattern specification, complete the following steps.

1. Expand the Pattern Authoring folder in the Application Development view.
2. Expand your pattern authoring project, and expand **Pattern Specification**.

3. Right-click `overview.htm` and select **Open With** > **HTML Editor**.

   The default user-defined pattern specification is shown in the HTML editor.
4. Edit the content of the pattern specification in the HTML editor.

   The default specification contains example links to suggested HTML files. To ensure that these links work correctly, you must create the required files and edit the links in the default specification. If you do not require these additional pages, delete the example links from the default specification.
5. To save the changes, click **File** > **Save**.
6. To view the updated pattern specification, click the **Categories** tab of the Pattern Authoring editor.

Defining the target properties

Identify the target properties in the workspace project so that you can define the pattern interface and pattern users can modify the pattern parameters.

Before you begin

Create the pattern authoring project and select the source files. For information about creating a pattern authoring project, see "Creating a pattern authoring project" on page 2069. For information about selecting the source files, see "Selecting the source files to use for a user-defined pattern" on page 2070.

Procedure

To identify the target properties that you want to use in the workspace project:

1. In the Application Development view, double-click the message flow that you want to use.
2. Open the **Select Target Properties** window by completing one of the following steps:
   - To select a node property as a target property, in the Message Flow editor, right-click the node that you want to use and click **Pattern** > **Select Target Properties**.
   - To select a user-defined property as a target property, in the Message Flow editor, right-click the canvas and click **Pattern** > **Select Target Properties**.
3. In the **Select Target Properties** window, select the target properties that you want to use in the pattern.
4. Close the **Select Target Properties** window.
5. Save the message flow.

Results

The selected target properties are displayed in the Target Properties panel of the **Source Files** tab in the Pattern Authoring editor.

What to do next

Define the user interface; see "Defining the user interface" on page 2074.

Defining the user interface

To control how pattern users view and edit pattern parameters in the Pattern Instance editor after the pattern user has created an instance of a user-defined pattern, you must define the user interface.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

When a pattern user creates an instance of a user-defined pattern, the parameter groups and pattern parameters that are defined in the **Pattern Configuration** tab of the Pattern Authoring editor are displayed in the Pattern Instance editor. If the **Pattern Configuration** tab displays groups or parameters that you do not want in the final pattern, you must delete them from the **Pattern Configuration** tab before building the pattern plug-ins.

To define the user interface, open the **Pattern Configuration** tab of the Pattern Authoring editor. In the **Groups and Parameters** list, entries are shown in a hierarchy in which groups contain pattern parameters, and pattern parameters contain target properties.

Procedure

To define the user interface, choose one or more of the following options:

1. You can define the groups in which pattern parameters are displayed and assign target properties to pattern parameters:
   a) To define the groups in which pattern parameters are displayed in the Pattern Instance editor, drag pattern parameters to groups.

      To add new groups or edit existing groups, see "Adding and editing parameter groups" on page 2076. To control whether parameter groups are enabled by using XPath expressions, see "Enabling parameter groups" on page 2077.

   b) To assign target properties to pattern parameters, drag target properties to pattern parameters.

      If the target property and pattern parameter do not use a compatible editor, an error message is displayed; see step "5" on page 2076 to change the parameter editor. If you drag multiple target properties to one pattern parameter, all target properties in that pattern parameter are populated with the same value that is entered for the pattern parameter by the pattern user.
2. To add a new pattern parameter, click **Add Parameter**, and click **OK**.

   To configure the new parameter, see steps "4" on page 2075 and "5" on page 2076.
3. To remove a pattern parameter or parameter group, select the pattern parameter or parameter group to remove and click **Delete**.
   - To remove a parameter group it must have no pattern parameters assigned to it.
   - To remove a pattern parameter it must have no target properties assigned to it. To remove a target property so that you can remove a pattern parameter, clear the target property in the Message Flow editor of the Application Development view. For more information about defining target properties, see "Defining the target properties" on page 2074. When you remove a target property in the Message Flow editor, the associated pattern parameter and parameter group are not automatically deleted in the **Pattern Configuration** tab of the Pattern Authoring editor.
4. You can change the name of a pattern parameter, create help text, create a field prompt, and configure parameter options in the **Basic** tab. In the **Groups and Parameters** list, select the pattern parameter and click **Edit**, or double-click the pattern parameter. The **Edit Parameter** window opens.
   - To change the name of the pattern parameter, enter a name for the pattern parameter in the **Display Name** field and click **OK**. The name for the pattern parameter is changed to the new name.
   - To change parameter options, select or clear the **Hide the parameter** and **Mandatory parameter** check boxes, as required.
   - To enter a field prompt, type a text into the **Field prompt** field.
   - To provide help text for the pattern parameter, type the text in the **Help Text (HTML)** field.
   - To close the **Edit Parameter** window after you have completed your changes, click **OK**.

5. You can change the parameter editor, and set a default value for a pattern parameter in the **Editor** tab. In the **Groups and Parameters** list, select the pattern parameter and click **Edit**, or double-click the pattern parameter. The **Edit Parameter** window opens. Click the **Editor** tab.
   - To change the parameter editor, select the required editor in the **Parameter editor** list.
     - To use an enumerated type for the parameter, select **Drop Down Selection** in the **Parameter editor** list, then select an enumerated type for the parameter in the **Type selection** field. For more information, see "Using enumerated values for pattern parameters" on page 2088.
     - To use a table type for the parameter, select **Table Editor** in the **Parameter editor** list, then select a table type for the parameter in the **Type selection** field. For more information, see "Using tables for pattern parameters" on page 2091.
     - To use a user-defined editor for the parameter, select **User-Defined Editor** in the **Parameter editor** list. For more information, see "Using user-defined editors for pattern parameters" on page 2093.
   - To enter a default value for a pattern parameter, if **Parameter editor** is `Drop Down Selection` or `Check Box`, select a value from the **Default value** list. Otherwise, enter a value in the **Default value** field.
   - To close the **Edit Parameter** window after you have completed your changes, click **OK**.

What to do next

You can build the pattern plug-ins, see "Building pattern plug-ins" on page 2126.

Adding and editing parameter groups

Edit parameter groups to control how pattern parameters are displayed to pattern users when they create pattern instances from a user-defined pattern.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

After defining target properties, a default list of parameter groups is created. You can edit the default groups or add new groups.

Procedure

- To add a new group:
  a) In the **Pattern Configuration** tab of the Pattern Authoring editor, click **Add Group**.
     The **Add Group** window opens.
  b) Enter a display name for the group in the **Display name** field.
  c) Enter a description for the group in the **Description** field.
  d) The **Generate help documentation** check box is selected by default. If you do not want to show the help documentation for the parameters in the group, clear the **Generate help documentation**

check box. To add help documentation for pattern parameters, see "Defining the user interface" on page 2074.

e) If you do not want the group to display with a surrounding box in the Configure Pattern Parameters page, clear the **Display parameters in a group box** check box.

If a group is displayed in a group box, pattern users can expand or collapse the group box to display or hide the parameters in that group. Parameters in a group that is not shown in a group box are always visible.

f) Click **OK**.

The new group is shown in the Groups and Parameters list.

- To edit an existing group:

a) In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click the group name that you want to edit, or select the group name and click **Edit**.

The **Edit Group** window opens.

b) To change the display name, enter a display name for the group in the **Display name** field.

c) To change the description, enter a description for the group in the **Description** field.

d) If you want to show help documentation for the parameters in the group, ensure the **Generate help documentation** check box is selected. To add help documentation for pattern parameters, see "Defining the user interface" on page 2074.

e) If you want the group to display with a surrounding box in the Configure Pattern Parameters page, ensure the **Display parameters in a group box** check box is selected.

If a group is displayed in a group box, pattern users can expand or collapse the group box to display or hide the parameters in that group. Parameters in a group that is not shown in a group box are always visible.

f) Click **OK**.

The modified group is shown in the Groups and Parameters list.

What to do next

You can choose whether a parameter group is enabled based on the value of pattern parameters; see "Enabling parameter groups" on page 2077.

Enabling parameter groups

In a user-defined pattern, control whether parameter groups are enabled based on the values of pattern parameters.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

By default, when pattern users configure an instance of a user-defined pattern, all the parameter groups that are defined in the user-defined pattern are enabled. Enabled parameter groups and pattern parameters within those groups are visible to pattern users in the Configure Parameters page. You can control whether a parameter group in an instance of a user-defined pattern is enabled by using an XPath expression:

- If the expression evaluates to Boolean **true**, the parameter group is enabled. When a pattern user configures an instance of a user-defined pattern, the parameter group and pattern parameters within that group are visible to pattern users in the Configure Parameters page. The values of pattern

parameters within enabled parameter groups populate the target properties of the user-defined pattern.

- If the expression evaluates to Boolean `false`, the parameter group is disabled. When a pattern user configures an instance of a user-defined pattern, the parameter group is not shown to pattern users in the Configure Parameters page. Pattern parameters within disabled groups are not shown to pattern users and the values of those parameters do not populate the target properties in an instance of the user-defined pattern.

If no XPath expression is entered for a parameter group, the parameter group is enabled. For XPath reference information, including information about XPath functions, see W3C XPath 1.0 Specification.

The `pp:getValue()` function is included, in addition to the functions in the XPath 1.0 Specification. The `pp:getValue()` function takes the parameter ID of a pattern parameter and returns the value of that pattern parameter. To see the parameter ID for a pattern parameter:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click a parameter group, or select a parameter group and click **Edit**. The **Edit Group** window opens.
2. Click the **Visibility** tab. The parameter IDs for pattern parameters are shown in the **Parameter ID** column of the Pattern Parameters table. To change parameter IDs, see "Changing pattern parameter IDs" on page 2081.

Procedure

To control whether a pattern parameter group is enabled by using an XPath expression:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click the parameter group that you want to control, or select the parameter group and click **Edit**.

   The **Edit Group** window opens.
2. Click the **Enable** tab. Create an XPath expression for your chosen parameter group:
   - To select a function:
     a. Expand **Boolean**, **Number**, **Pattern**, or **String** in the Functions section, then click a function. The function is displayed in the **Function name** field.
     b. Click **Use**. The function is inserted into the **Expression** field at the cursor.
   - To select an operator:
     a. Click an operator in the Operators section. The operator is displayed in the **Operator** field.
     b. Click **Use**. The operator is inserted into the **Expression** field at the cursor.
   - To select a pattern parameter:
     a. Click a pattern parameter in the Pattern Parameters table. The parameter ID shown in the **Parameter ID** column of the Pattern Parameters table for the chosen parameter is displayed in the **Parameter ID** field.

        You cannot select a pattern parameter that uses a table type.
     b. Click **Use**. The parameter ID is inserted into the **Expression** field at the cursor. To change parameter IDs, see "Changing pattern parameter IDs" on page 2081.
   - You can also edit the expression directly in the **Expression** field.
3. Repeat the actions in step "2" on page 2078, as required, to create your XPath expression.
4. You can now choose whether to test your expression:
   - To test your expression, see "Testing a group enabling expression" on page 2079.
   - To accept the expression without testing it, click **OK**. The **Edit Group** window closes.

Testing a group enabling expression
In a user-defined pattern, test an XPath expression that is used for enabling parameter groups.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074
- "Enabling parameter groups" on page 2077

Procedure

To test your XPath expression:

1. If the **Enable** tab in the **Edit Group** window is not already open, complete the following steps to open the tab:
   a) In the **Pattern Configuration** tab of the Pattern Authoring editor, select the parameter group containing the XPath expression that you want to test and click **Edit**.
      The **Edit Group** window opens.
   b) Click the **Enable** tab.
2. To test the expression, click **Evaluate**.
   The expression is evaluated by using the values in the **Test Values** column of the Pattern Parameters section, and the result is shown in the **Result** field. The result shows whether the parameter group is enabled or disabled, and the value of the expression is shown in parentheses. If the value is `true`, the associated group is enabled; if the value is `false`, the group is disabled. Use the following table to determine the value of your XPath expression.

Result data type	Evaluates to true	Evaluates to false
Boolean	`true`	`false`
Numeric	Any non-zero value	`0` or `0.0`
String	Any string that returns `true` with a match that is not case-sensitive	Any string that does not return `true` with a match that is not case-sensitive

3. To change the test value for a parameter, select the parameter in the Pattern Parameters section and enter the required test value in the **Test value** field. Click **Set**.
   The new test value is shown in the Pattern Parameters section.
4. Repeat steps "2" on page 2079 and "3" on page 2079, as required, to test the XPath expression.
   If you want to modify the expression, see "Enabling parameter groups" on page 2077.
5. When you have finished testing the expression, click **OK**.
   The **Edit Group** window closes.

Creating and configuring categories

Configure categories to which to assign user-defined patterns in the Patterns Explorer view.

Before you begin

Complete the following task:

- "Creating a pattern authoring project" on page 2069

About this task

You can drag your user-defined pattern into any existing category, or you can create a new category. If you create a category, you can write a category specification that provides information about the category for other users. User-defined patterns are shown within these categories in the Patterns Explorer view.

Procedure

To create a new category, update the category specification, assign your pattern to a category, rename a category, or remove a category, begin by opening the **Categories** tab of the Pattern Authoring editor. You can now choose one or more of the following options:

- To create a new category as a subcategory of an existing category:
  a) Select an existing category.
  b) Click **Add Category**.
     The **Add Category** window opens.
  c) Enter the name of your new category and click **OK**.
     The new category is added to the category list under the category previously selected. The **Save Your Pattern File** window opens, asking you to confirm whether you want to save your patterns file. Click **Yes**.
- To edit the category specification for a category:
  a) Double-click the category.
     The HTML editor opens containing the default category specification.
  b) Update the category specification to describe the category, and click **File** > **Save** to save any changes.
- To assign your user-defined pattern to a category, drag your user-defined pattern to your chosen category.
- To rename a category:
  a) Click **Rename Category**.
     The **Edit Category** window opens.
  b) Enter the new name, click **OK**.
     The **Save Your Pattern File** window opens, asking you to confirm whether you want to save your patterns file.
- To remove a category, click **Remove category**.
  The **Save Your Pattern File** window opens, asking you to confirm whether you want to save your patterns file. Click **Yes**.

Configuring SOAP nodes for user-defined patterns

Configure the target properties on SOAPInput, SOAPRequest, and SOAPAsyncRequest nodes by using a WSDL file.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- “Creating a pattern authoring project” on page 2069

Procedure

To configure target properties on SOAP nodes by using a WSDL file:

1. Select an exemplar that uses a SOAPInput, SOAPRequest, or SOAPAsyncRequest node.
   See “Selecting the source files to use for a user-defined pattern” on page 2070.

2. Define the target properties and ensure that the `WSDL file name` target property is selected as a target property in the SOAPInput, SOAPRequest, or SOAPAsyncRequest node.

   See "Defining the target properties" on page 2074.

What to do next

When the pattern user generates an instance of the user-defined pattern, the WSDL file name is presented as a pattern parameter. After the pattern user inputs the WSDL file name, the properties in the WSDL file are used to configure the SOAP node target properties. Examples of WSDL properties are the port type, binding, and service port values.

The target properties are configured with the first occurrence of each WSDL property.

Changing pattern parameter IDs

Change default pattern parameter IDs to make it easier to write XPath, Java, and PHP code that uses parameter IDs.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

Pattern parameter IDs uniquely identify pattern parameters. As a pattern author, you use pattern parameter IDs when writing XPath expressions to transform or enable pattern parameters, or when writing Java or PHP code to modify pattern instances. Every pattern parameter in a user-defined pattern has a default pattern parameter ID assigned, but you can change pattern parameter IDs from the default values so that they are easier to identify in your code.

Procedure

To change pattern parameter IDs from the default values:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click the parameter for which you want to change the parameter ID, or select the parameter and click **Edit**.

   The **Edit Parameter** window opens.
2. In the **Parameter ID** field of the **Basic** tab, enter your new parameter ID.

   The new parameter ID can be made up of ASCII characters, but must start with a non-numeric character.
3. Click **OK**. The **Edit Parameter** window closes.

What to do next

- To use the new parameter ID in an XPath expression to transform pattern parameters, see "Transforming pattern parameters" on page 2084.
- To use the new parameter ID in an XPath expression to enable pattern parameters, see "Enabling pattern parameters" on page 2086.
- To use the new parameter ID in Java or PHP code to modify pattern instances, see "Modifying pattern instances by using Java or PHP" on page 2105.

Creating a project used in a user-defined pattern

Use the values of pattern parameters to control whether a project is created when a pattern user generates an instance of a user-defined pattern.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

You can control whether projects that are selected as source files in a user-defined pattern are created by using XPath expressions. For XPath reference information, including information about XPath functions, see W3C XPath 1.0 Specification.

- The `pp:getValue()` function is included, in addition to the functions in the XPath 1.0 Specification. The `pp:getValue()` function takes the parameter ID of a pattern parameter and returns the value of that pattern parameter. To see the parameter ID for a pattern parameter:
  1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click a parameter, or select a parameter and click **Edit**. The **Edit Parameter** window opens.
  2. Click the **Transform** tab. The parameter IDs for pattern parameters are shown in the **Parameter ID** column of the Pattern Parameters table.
- When a pattern instance is generated by a pattern user, transformation expressions are processed before any Java and PHP code that has been added to modify pattern instances. Transformation of pattern parameters is processed in the following sequence:
  1. Every parameter that has an XPath transformation expression is evaluated.
  2. The value of each parameter that has an XPath transformation expression is updated with the result of its evaluation, overwriting the value entered by the pattern user.
  3. The parameters are evaluated in top to bottom order, as they are listed in the **Pattern Configuration** tab of the Pattern Authoring editor.

Procedure

To control project creation by using an XPath expression:

1. Open the Pattern Authoring editor.
2. In the **Source** tab, in the Select Source Files section, double-click the project that you want to control, or select the project and click **Edit**.

   The **Edit Project** window opens.

3. Click the **Create** tab. Create an XPath expression for your chosen project:
   - To select a function:
     a. Expand **Boolean**, **Number**, **Pattern**, or **String** in the Functions section, then click a function. The function is displayed in the **Function name** field.
     b. Click **Use**. The function is inserted into the **Expression** field at the cursor.
   - To select an operator:
     a. Click an operator in the Operators section. The operator is displayed in the **Operator** field.
     b. Click **Use**. The operator is inserted into the **Expression** field at the cursor.
   - To select a pattern parameter:
     a. Click a pattern parameter in the Pattern Parameters table. The parameter ID shown in the **Parameter ID** column of the Pattern Parameters table for the chosen parameter is displayed in the **Parameter ID** field.

        You cannot select a pattern parameter that uses a table type.
     b. Click **Use**. The parameter ID is inserted into the **Expression** field at the cursor.
   - You can also edit the expression directly in the **Expression** field.
4. Repeat the actions in step "3" on page 2083, as required, to create your XPath expression.
5. You can now choose whether to test your expression:
   - To test your expression, see "Testing a project creation expression" on page 2083.
   - To accept the expression without testing it, click **OK**. The **Edit Project** window closes.

Testing a project creation expression
Test your XPath project creation expression created in a user-defined pattern to check that it works correctly.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074
- "Creating a project used in a user-defined pattern" on page 2082

Procedure

To test your XPath expression:

1. If the **Create** tab in the **Edit Project** window is not already open, complete the following steps to open the tab:
   a) Open the Pattern Authoring editor.
   b) In the **Source Files** tab, in the Select Source Files section, double-click the project containing the XPath expression that you want to test, or select the project and click **Edit**.

      The **Edit Project** window opens.
   c) Click the **Create** tab.
2. To change the test value for a parameter, select the parameter in the Pattern Parameters section and enter the required test value in the **Test value** field. Click **Set**.

   The new test value is shown in the Pattern Parameters section.

3. To test the expression, click **Evaluate**.

   The expression is evaluated by using the values in the **Test Values** column of the Pattern Parameters section and the result is shown in the **Result** field. If the expression is not valid an error message is displayed in the **Result** field.
4. Repeat steps "2" on page 2083 and "3" on page 2084, as required, to test the XPath expression.

   If you want to modify the expression, see "Creating a project used in a user-defined pattern" on page 2082.
5. When you have finished testing the expression, click **OK**.

   The **Edit Project** window closes.

Transforming pattern parameters

Calculate a pattern parameter value from the values entered for other pattern parameters.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

You can transform pattern parameters by using XPath expressions; for example, to calculate a pattern parameter value from the values entered for other pattern parameters. IBM App Connect Enterprise supports XPath 1.0. For XPath reference information, including information about XPath functions, see W3C XPath 1.0 Specification.

- The `pp:getValue()` function is included, in addition to the functions in the XPath 1.0 Specification. The `pp:getValue()` function takes the parameter ID of a pattern parameter and returns the value of that pattern parameter. To see the parameter ID for a pattern parameter:
  1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click a parameter, or select a parameter and click **Edit**. The **Edit Parameter** window opens.
  2. Click the **Transform** tab. The parameter IDs for pattern parameters are shown in the **Parameter ID** column of the Pattern Parameters table.
- When a pattern instance is generated by a pattern user, transformation expressions are processed before any Java and PHP code that has been added to modify pattern instances. Transformation of pattern parameters is processed in the following sequence:
  1. Every parameter that has an XPath transformation expression is evaluated.
  2. The value of each parameter that has an XPath transformation expression is updated with the result of its evaluation, overwriting the value entered by the pattern user.
  3. The parameters are evaluated in top to bottom order, as they are listed in the **Pattern Configuration** tab of the Pattern Authoring editor.

Procedure

To transform a pattern parameter by using an XPath expression:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click the parameter that you want to transform, or select the parameter and click **Edit**. The **Edit Parameter** window opens.

   You cannot transform a parameter that uses a table type.

2. Click the **Transform** tab. Create an XPath expression for your chosen parameter:
   - To select a function:
     a. Expand **Boolean**, **Number**, **Pattern**, or **String** in the Functions section, then click a function. The function is displayed in the **Function name** field.
     b. Click **Use**. The function is inserted into the **Expression** field at the cursor.
   - To select an operator:
     a. Click an operator in the Operators section. The operator is displayed in the **Operator** field.
     b. Click **Use**. The operator is inserted into the **Expression** field at the cursor.
   - To select a pattern parameter:
     a. Click a pattern parameter in the Pattern Parameters table. The parameter ID shown in the **Parameter ID** column of the Pattern Parameters table for the chosen parameter is displayed in the **Parameter ID** field.

        You cannot select a pattern parameter that uses a table type.
     b. Click **Use**. The parameter ID is inserted into the **Expression** field at the cursor.
   - You can also edit the expression directly in the **Expression** field.
3. Repeat the actions in step "2" on page 2085, as required, to create your XPath expression.
4. You can now choose whether to test your expression:
   - To test your expression, see "Testing a transformation expression" on page 2085.
   - To accept the expression without testing it, click **OK**. The **Edit Parameter** window closes.

Testing a transformation expression
Test your XPath transformation expression created in a user-defined pattern to check that it works correctly.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074
- "Transforming pattern parameters" on page 2084

Procedure

To test your XPath expression:

1. If the **Transform** tab in the **Edit Parameter** window is not already open, complete the following steps to open the tab:
   a) In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click the parameter containing the XPath expression that you want to test, or select the parameter and click **Edit**.

      The **Edit Parameter** window opens.
   b) Click the **Transform** tab.
2. To change the test value for a parameter, select the parameter in the Pattern Parameters section and enter the required test value in the **Test value** field. Click **Set**.

   The new test value is shown in the Pattern Parameters section.
3. To test the expression, click **Evaluate**.

   The expression is evaluated by using the values in the **Test Values** column of the Pattern Parameters section and the result is shown in the **Result** field. If the expression is not valid an error message is displayed in the **Result** field.

4. Repeat steps “2” on page 2085 and “3” on page 2085, as required, to test the XPath expression.
   If you want to modify the expression, see “Transforming pattern parameters” on page 2084.
5. When you have finished testing the expression, click **OK**.
   The **Edit Parameter** window closes.

Enabling pattern parameters

You can control whether pattern parameters can be edited by pattern users based on the values of other pattern parameters.

Before you begin

Complete the following tasks:

- “Creating a pattern authoring project” on page 2069
- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Defining the target properties” on page 2074

About this task

By using XPath expressions you can control whether pattern users can edit pattern parameters in the Pattern Instance editor . If an expression evaluates to Boolean **true**, the pattern user can configure the parameter in the **Configure Pattern Parameters** page; if an expression evaluates to Boolean `false`, the parameter is read-only, and the pattern user cannot configure it. When the pattern user configures pattern parameters, expressions are evaluated whenever any of the pattern parameters used in an expression change.

IBM App Connect Enterprise supports XPath 1.0. For XPath reference information, including information about XPath functions, see W3C XPath 1.0 Specification.

The `pp:getValue()` function is included, in addition to the functions in the XPath 1.0 Specification. The `pp:getValue()` function takes the parameter ID of a pattern parameter and returns the value of that pattern parameter. To see the parameter ID for a pattern parameter:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, double-click a parameter, or select a parameter and click **Edit**. The **Edit Parameter** window opens.
2. Click the **Enable** tab. The parameter IDs for pattern parameters are shown in the **Parameter ID** column of the Pattern Parameters table.

Procedure

To define an XPath expression to control whether a pattern parameter can be edited:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, select the parameter that you want to configure. Click **Edit**.
   The **Edit Parameter** window opens.

2. Click the **Enable** tab. Create an XPath expression for your selected parameter by applying the following operations as required:
   - To select a function:
     a. Click a function in the Functions section. The function is displayed in the **Function name** field.
     b. Click **Use**. The function is inserted into the **Expression** field at the cursor.
   - To select an operator:
     a. Click an operator in the Operators section. The operator is displayed in the **Operator** field.
     b. Click **Use**. The operator is inserted into the **Expression** field at the cursor.
   - To select a pattern parameter:
     a. Click a pattern parameter in the Pattern Parameters table. The ID shown in the **Parameter ID** column of the Pattern Parameters table for the selected parameter is displayed in the **Parameter ID** field.

        You cannot select a pattern parameter that uses a table type.
     b. Click **Use**. The parameter ID is inserted into the **Expression** field at the cursor.
   - You can also edit the expression directly in the **Expression** field.

   A common requirement is for a pattern parameter to be read-only. To ensure that a pattern parameter is read-only, set the XPath expression for the pattern parameter to `false()`.
3. You can now choose whether to test your expression:
   - To test your expression, see "Testing an enabling expression" on page 2087.
   - To accept the expression without testing it, click **OK**. The **Edit Parameter** window closes.

Testing an enabling expression
Test an XPath enabling expression that you created in a user-defined pattern to check that it works correctly.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074
- "Enabling pattern parameters" on page 2086

Procedure

To test your XPath expression:

1. If the **Enable** tab in the **Edit Parameter** window is not already open, complete the following steps to open the tab:
   a) In the **Pattern Configuration** tab of the Pattern Authoring editor, select the parameter containing the XPath expression that you want to test and click **Edit**.

      The **Edit Parameter** window opens.
   b) Click the **Enable** tab.
2. To test the expression, click **Evaluate**.

   The expression is evaluated by using the values in the **Test Values** column of the Pattern Parameters section, and the result is shown in the **Result** field. The result shows whether the parameter is enabled or disabled, and the value of the expression is shown in parentheses. If the value is `true`, the

associated parameter is enabled; if the value is `false`, the parameter is disabled. Use the following table to determine the value of your XPath expression.

Result data type	Evaluates to True	Evaluates to False
Boolean	`true`	`false`
Numeric	Any non-zero value	`0` or `0.0`
String	Any string that returns `true` with a match that is not case-sensitive	Any string that does not return `true` with a match that is not case-sensitive

3. To change the test value for a parameter, select the parameter in the Pattern Parameters section and enter the required test value in the **Test value** field. Click **Set**.

   The new test value is shown in the Pattern Parameters section.
4. Repeat steps "2" on page 2087 and "3" on page 2088, as required, to test the XPath expression.

   If you want to modify the expression, see "Enabling pattern parameters" on page 2086.
5. When you have finished testing the expression, click **OK**.

   The **Edit Parameter** window closes.

Using enumerated values for pattern parameters

Use enumerated types to provide predefined values for the pattern parameters in your user-defined patterns.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074

About this task

You can use enumerated types to provide pattern users with a predefined list of pattern parameter values to select from. For enumerated types that you create, you can add, remove, and edit values. As part of the pattern authoring process, any target properties that use a list of values have enumerated types created for them automatically. You can remove values from this automatically generated list, but you cannot add new values or change existing values.

Procedure

- Create your own enumerated types.

  See "Creating enumerated types for pattern parameters" on page 2088.
- Edit enumerated types.

  See "Editing enumerated types for pattern parameters" on page 2089.
- Assign enumerated types to pattern parameters.

  See "Defining the user interface" on page 2074.

Creating enumerated types for pattern parameters

Define enumerated types to provide predefined values for pattern parameters in your user-defined patterns.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069

- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Defining the target properties” on page 2074

About this task

Enumerated types give pattern users a predefined list of values to select from when they choose values for pattern parameters after generating a new pattern instance.

Procedure

To create a new enumerated type:

1. In the Pattern Authoring editor, click the **Pattern Configuration** tab. Click **Enumerated Types**.
   The **Configure Enumerated Types** window opens.
2. Click the **Add** button that is under the **Enumerated type** field.
   The **Enter New Enumeration** window opens.
3. Enter a name for the enumeration in the **Enter a name for the enumeration** field. Click **OK**.
   The new enumeration is displayed in the table of values, and a display name and default value are entered in the table.
4. For manipulating values, either adding or editing, use the following options:
   - To add a new value, click the **Add** button that is next to the table of values. A new display name and value are added to the table.
   - To edit a display name or value, double-click the display name or value in the table. Type a new entry and then press Enter to save the new display name or value.
5. When you have finished adding values and editing display names and values, click **OK**.
   The **Configure Enumerated Types** window closes.

What to do next

You can now assign your enumerated type to a pattern parameter, see “Defining the user interface” on page 2074.

Editing enumerated types for pattern parameters

Edit enumerated types to add, remove or rename values in existing enumerated types, or to rename an enumerated type. You can edit an existing user-generated enumerated type to add, remove, or change values and display names within the enumerated type, or to change the name of the enumerated type.

Before you begin

Complete the following tasks:

- “Creating a pattern authoring project” on page 2069
- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Defining the target properties” on page 2074
- “Creating enumerated types for pattern parameters” on page 2088

About this task

As part of the pattern authoring process, target properties that use a list of values have enumerated types automatically created for them. You can remove values from this automatically generated list or regenerate the original list of values, but you cannot add new values or edit existing values.

You can duplicate or remove user-generated enumerated types and enumerated types created from target properties.

For enumerated types that you create, you can add, remove, and edit values.

Procedure

To edit enumerated types:

1. In the Pattern Authoring editor, click the **Pattern Configuration** tab. Click **Enumerated Types**. The **Configure Enumerated Types** window opens.
2. In the **Enumerated type** field, select the enumerated type to edit.
3. You can make the following changes to user-generated enumerated types:
   - Rename the enumerated type. To rename the enumerated type, click **Rename**. The **Rename Enumeration** window opens. Enter a name for the enumeration and click **OK**. The **Rename Enumeration** window closes.
   - Add new values. To add a new value, click the **Add** button that is next to the table of values. A new value and display name are added to the table.
   - Remove values. To remove a value, select the value to remove and click the **Remove** button that is next to the table of values. The value is removed from the table.

     If a value is the only entry in the table, you cannot remove it.
   - Change existing values and display names. To edit a value or display name, double-click the value or display name in the table. Type a new entry and then press Enter to save the new display name or value.
   - Duplicate the enumerated type. To duplicate an enumerated type, click **Duplicate**. The duplicate enumerated type is displayed. The name of the duplicate enumerated type is the same as the original, but with _1 added to the end.
   - Remove the enumerated type. To remove an enumerated type, click **Remove**. The enumerated type is removed.

     If an enumerated type is being used by a pattern parameter it cannot be removed. You can check if an enumerated type is being used by a parameter in the **This enumerated type is used by the following parameter** field. To modify a parameter so that it does not use an enumerated type, see "Defining the user interface" on page 2074.
4. You can make the following changes to enumerated types that are created from target properties:
   - Rename the enumerated type. To rename the enumerated type, click **Rename**. The **Rename Enumeration** window opens. Enter a name for the enumeration and click **OK**. The **Rename Enumeration** window closes.
   - Remove values. To remove a value, select the value to remove and click the **Remove** button that is next to the table of values. The value is removed from the table.

     If a value is the only entry in the table, you cannot remove it.
   - Reset the original values. To restore values you have removed from the list, click **Reset Values**. The original list is displayed.
   - Duplicate the enumerated type. To duplicate an enumerated type, click **Duplicate**. The duplicate enumerated type is displayed. The name of the duplicate enumerated type is the same as the original, but with _1 added to the end.
   - Remove the enumerated type. To remove an enumerated type, click **Remove**. The enumerated type is removed.

     If an enumerated type is being used by a pattern parameter it cannot be removed. You can see if an enumerated type is being used by a parameter in the **This enumerated type is used by the following parameter** field. To modify a parameter so that it does not use an enumerated type, see "Defining the user interface" on page 2074.
5. Repeat the tasks in steps "3" on page 2090 and "4" on page 2090 until your changes are complete. Click **OK**.

   The **Configure Enumerated Types** window closes.

What to do next

You can now build your pattern; see “Building pattern plug-ins” on page 2126.

Using tables for pattern parameters

Use table parameter types to create tables of pattern parameters in your user-defined patterns.

Before you begin

Complete the following tasks:

- “Creating a pattern authoring project” on page 2069
- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Defining the target properties” on page 2074

About this task

You can add tables to your user-defined patterns, into which pattern users can enter rows of data. To add a table, you must define a table parameter type by specifying the columns you want in the table. You must then assign this parameter type to a pattern parameter when you define the user interface for the user-defined pattern.

When a pattern user configures an instance of your user-defined pattern, the table columns are displayed and the pattern user can enter one or more rows of data into the table. You can write Java or PHP code to use the values entered in parameter tables to modify the pattern instance.

When you use tables in your user-defined patterns, consider the following points:

- Values entered in parameter tables are handled as strings.
- Values entered in parameter tables cannot be transformed by using XPath expressions and cannot be used in XPath expressions.
- You can use enabling XPath expressions to enable a pattern parameter that uses a parameter table type.

Procedure

- To create a table parameter type, see “Adding pattern parameter table types” on page 2091.
- To edit a table parameter type, see “Editing pattern parameter table types” on page 2092.
- To assign a table parameter type to a parameter, see “Defining the user interface” on page 2074.
- To write Java or PHP code to read the values entered in a parameter table, see “Reading table values” on page 463 or “Examples of PHP API code” on page 2123.

Adding pattern parameter table types

Add table parameter types to include tables of pattern parameters in your user-defined patterns.

Before you begin

Complete the following tasks:

- “Creating a pattern authoring project” on page 2069
- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Defining the target properties” on page 2074

About this task

Create pattern parameter table types to add parameter tables to your user-defined patterns. To define a table parameter type you must specify the columns of the table. For every column, you must specify a display name and a column ID.

Procedure

To create a table parameter type:

1. In the Pattern Authoring editor, click the **Pattern Configuration** tab. Click **Tables**.
   The **Configure Tables** window opens.
2. Click the **Add** button that is next to the **Table** field.
   The **Enter New Table** window opens.
3. Enter a name for the table in the **Enter a name for the table** field. Click **OK**.
   The new table name is displayed in the **Table** field.
4. Define the columns you want to include in the table:
   - To add a new column, click the **Add** button that is next to the table of column entries. A new display name and column ID are added to the table.
   - To edit a display name, column ID, default value, or width, double-click the entry you want to edit. Type a new entry, then press Enter to save the new value.
5. To make a table column mandatory, select the required column in the table of column entries and select **Mandatory column**.
6. To enter help text for a table column, select the required column in the table of column entries and type the text in the **Enter any HTML or text that you want to display as help text for this column** field.
7. Click **OK**.

What to do next

To add a table to your user-defined pattern you must assign your parameter table type to a pattern parameter; see "Defining the user interface" on page 2074.

Editing pattern parameter table types

Edit pattern parameter table types in your user-defined pattern to add, remove, rename, or duplicate the table type, or to add, remove, or edit columns in the table type.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Defining the target properties" on page 2074
- "Adding pattern parameter table types" on page 2091

About this task

Procedure

To edit pattern parameter table types:

1. In the Pattern Authoring editor, click the **Pattern Configuration** tab. Click **Tables**.
   The **Configure Tables** window opens.
2. In the **Table** field, select the table type you want to edit.

3. You can make the following changes to table types:
   - Remove the table type. To remove the table type, click **Remove**.

     If a table type is used by a pattern parameter it cannot be removed. You can check if a table type is used by a parameter in the **This table is used by the following parameters** field. To modify a parameter so that it does not use a table type, see "Defining the user interface" on page 2074.
   - Rename the table type. To rename the table type, click **Rename**. The **Rename Table** window opens. Enter a new name for the table and click **OK**.
   - Duplicate the table type. To duplicate the table type, click **Duplicate**. The duplicate table type is displayed. The name of the duplicate table type is the same as the original, but with _1 added to the end.
   - Add columns to your table type. To add a new column, click the **Add** button that is next to the table of column entries. A new display name and column ID are added to the table.
   - Remove columns from your table type. To remove a column, click the **Remove** button that is next to the table of column entries.

     If a column entry is the only entry in the table, you cannot remove it.
   - Edit the display name, column ID, default value, or width for a column in your table type. To edit a display name, column ID, default value, or width, double-click the entry you want to edit. Type a new entry, then press Enter to save the new value.
   - Specify that a column in your table type is mandatory. To make a table column mandatory, select the required column in the table of column entries and select **Mandatory column**.
   - Enter help text for a column in your table type. To enter help text for a table column, select the required column in the table of column entries and type the text in the **Enter any HTML or text that you want to display as help text for this column** field.
4. When you have finished editing your pattern parameter table type, click **OK**.

   The **Configure Tables** window closes.

What to do next

You can now build your pattern; see "Building pattern plug-ins" on page 2126.

Using user-defined editors for pattern parameters

Create and configure a user-defined editor, which is used by pattern users to enter the value for a pattern parameter in your user-defined pattern.

About this task

When you define the user interface for your user-defined pattern, you must assign an editor to every pattern parameter. In addition to the built-in editors, you can create user-defined editors. The appearance and function of a user-defined editor is defined by Java code that you must write.

Procedure

To use a user-defined editor for a pattern parameter in a user-defined pattern:

1. Select the user-defined editor type for the required pattern parameter when you define the user interface for your user-defined pattern; see "Defining the user interface" on page 2074.
2. Configure the user-defined editor; see "Configuring a user-defined editor" on page 2094. When you configure the user-defined editor, you must specify the Java class that runs when the editor is used. For more information about writing Java code for user-defined editors, see "Writing Java code for a user-defined editor" on page 2095.

Configuring a user-defined editor
Configure a user-defined editor to specify the Java code that the editor uses and to specify configuration values and notifications used by the code.

Before you begin

Assign a user-defined editor to a pattern parameter; see "Defining the user interface" on page 2074.

About this task

To configure a user-defined editor for a pattern parameter, select a Java code project and a Java class within that project. The code in the Java class is run when the editor is used by a pattern user. You can create a new code project and Java class if required.

You can use your code project for user-defined editor code and for Java and PHP code to modify pattern instances. For more information about using Java and PHP to modify pattern instances, see "Modifying pattern instances by using Java or PHP" on page 2105. By including user-defined editor and pattern instance modification code in the same code project for patterns that use both types of code, you need to distribute fewer projects to pattern users.

You can specify configuration values when you configure your user-defined editor. These values can be used by your user-defined editor code. For example, you can enter a list of configuration values that are used to populate a list in your user-defined editor.

You can select parameters in your user-defined pattern that send change notifications to the user-defined editor. Your editor code can use change notifications to update the value of the parameter to which the user-defined editor is assigned when other pattern parameter values change.

Procedure

To configure a user-defined editor, complete the following steps:

1. In the **Pattern Configuration** tab of the Pattern Authoring editor, select the parameter to which you have assigned a user-defined editor. Click **Edit**.

   The **Edit parameter** window opens.
2. Click the **Editor** tab. In the **Parameter editor** field, confirm that **User-Defined Editor** is selected, then click **Configure Editor**.
3. In the **Project name** field, select the project that contains the Java code for your user-defined editor. To create a new code project, click **New Project** and complete the following steps:
   a) Enter a plug-in ID for the new code plug-in.

      After the plug-in is created, the plug-in ID is shown in the **Projects** section of the Application Development view. The plug-in ID is also used to identify the plug-in when you distribute it to pattern users.
   b) Clear **Add an example pattern authoring Java class to the project**.
   c) Clear **Add PHP support to the project**.
   d) Click **Finish**.
4. In the **Class name** field, select the class in the code project you want to run when the user-defined editor is used.

5. Optional: You can create a new Java class by completing the following steps:
   a) Click **New Java Class**.
      The **New Pattern Authoring Property Editor** window opens.
   b) In the **Source folder** field, click **Browse** and select the folder in which to store the new Java class file.
   c) Optional: In the **Package** field, enter the name of the Java package for the new class.
      If you leave this field blank, the default package is used.
   d) Optional: To add an interface for the new Java class, click **Add**. The **Implemented Interfaces Selection** window opens. In the **Choose interfaces** field, enter the name of the interface that you want to add, select the interface in the **Matching items** list and click **OK**. The **Implemented Interfaces Selection** window closes.
   e) Optional: To remove an interface for the Java class, select the interface in the **Interfaces** list and click **Remove**.
   f) Optional: Click **Next** to view information about the Pattern Authoring Property Editor template, which is used to create the Java class.
   g) Click **Finish**.
6. In the **Configuration values** field, enter any values that you want to be available in the Java code for your user-defined editor.
   For example, if your editor displays a list of values to a pattern user, you can enter the list of values in this field. Your editor code can then use the configuration values to display them in the editor.
7. In the **Select the visible parameters which will send change notifications to this user-defined editor** field, select all parameters in your user-defined pattern from which you want change notifications to be sent.
8. Click **OK**.

What to do next

Write the Java code for your user-defined editor; see "Writing Java code for a user-defined editor" on page 2095.

Writing Java code for a user-defined editor
Write Java code to define the appearance and function of your user-defined editor.

Before you begin

Create a code project and a Java class. You can create a code project and an example Java class for a user-defined editor when you configure your user-defined editor; see "Configuring a user-defined editor" on page 2094.

Read the reference information about the Java interfaces required to write code for user-defined editors; see Java interfaces for user-defined editors.

About this task

Enter Java code for your user-defined editor in the Java class you want to use. You must assign the Java class and the code project to your user-defined editor when you configure the editor; see "Configuring a user-defined editor" on page 2094. Pattern users edit an instance of your user-defined pattern by using the pattern instance editor. The code for your user-defined editor passes values to and receives values from the pattern instance editor by using two Java interfaces, `PatternPropertyEditor` and `PatternPropertyEditorSite`. You must write code to override the methods in these interfaces.

If an exception is thrown by user-defined editor code, the exception is caught and displayed in the **Pattern Instance Editor Exception** window, which opens automatically.

Procedure

To write the code for your user-defined editor:

1. Write code for your main user-defined editor class. Be aware of the following points:
   - The user-defined editor main class is created when the pattern user opens an instance of your user-defined pattern.
   - Your user-defined editor must extend the `BasePatternPropertyEditor` super class.
   - The main class must provide a default public constructor with no arguments.
2. In your main user-defined editor class, write code to override the `configureEditor()` method. Use this method to set up your user-defined editor after it is created. Be aware of the following points:
   - The `configureEditor()` method takes a `PatternPropertyEditorSite` object, a boolean value, and a string value. These values are passed automatically from the pattern instance editor.
   - The `PatternPropertyEditorSite` object acts as the interface between your user-defined editor code and the pattern instance editor. You can access this object by using the `getSite()` method anywhere in your user-defined editor code.
   - The boolean value indicates whether the pattern parameter for the user-defined editor has been flagged as mandatory. If it has, your code must set a value for the pattern parameter.
   - The string value contains the configuration values that are entered when configuring the user-defined editor. If required, you can write code to parse this string to use the values in your editor code.
   - In your `configureEditor()` method, call `configureEditor()` on the superclass, and pass the `PatternPropertyEditorSite` object, boolean value, and string value that were passed to your `configureEditor()` method. For example:

     ```
     @Override
      public void configureEditor(PatternPropertyEditorSite site, boolean required, String
      configurationValues) {
         super.configureEditor(site, required, configurationValues);
      }
     ```
3. In your main user-defined editor class, write code to override the `createControls()` method. Use this method to define the controls of your user-defined editor. Be aware of the following points:
   - You can create the controls in the `createControls()` method or write one or more new classes for the controls and instantiate these new classes from the `createControls()` method.
   - You must call the `valueChanged()` method on the `PatternPropertySite` object when the value of your pattern parameter changes. This call notifies the pattern instance editor of the change, which then updates any XPath expressions or user-defined editors which use this pattern parameter. You can access the `PatternPropertySite` object for your user-defined editor by using the `getSite()` method, for example, `PatternPropertyEditorSite site = getSite()`.
   - In the `createControls()` method, you must initialize your controls before defining any listeners for those controls.
4. In your main user-defined editor class, write code to override the `setValue()` method. Use this method to set initial values in your user-defined editor, for example, to populate a text box with the default value of the pattern parameter. The `setValue()` method takes a string value that is the current value of the pattern parameter, which is passed automatically from the pattern instance editor. The value passed from the pattern instance editor is the default value of the parameter, or the value that was saved after the pattern instance is configured.
5. In your main user-defined editor class, write code to override the `getValue()` method. Use this method to provide the value of the pattern parameter to the pattern instance editor. The `getValue()` method is automatically called after the `valueChanged()` method is called.
6. In your main user-defined editor class, write code to override the `setEnabled()` method. Use this method to enable or disable your user-defined editor. The `setEnabled()` method is passed a boolean value from the pattern instance editor to indicate whether the pattern parameter is enabled or

disabled by an enabling XPath expression. When the parameter is enabled, the value is *true*; when the parameter is disabled the value is *false*.

7. Optional: In your main user-defined editor class, write code to override the `isValid()` method. Use this method to validate entries in your editor and return an error message to the pattern instance editor if required. The error message is displayed to pattern users in the pattern instance editor.
8. Optional: In your main user-defined editor class, write code to override the `notifyChanged()` method. Use this method to handle change notifications from other parameters in your user-defined pattern and change the value of your pattern parameter or the behavior of your editor, if required. The `notifyChanged()` method takes the parameter ID of the changed parameter and the new value of that parameter.

Example

See the following examples of Java code for user-defined editors:

- For an example of user-defined editor code that uses one class, see "User-defined editor code example that uses one Java class" on page 2097.
- For an example of user-defined editor code that uses two classes, see "User-defined editor code example that uses two Java classes" on page 2099.
- For an example of a user-defined editor that handles change notifications from pattern parameters, see "User-defined editor code example for handling change notifications" on page 2101.

What to do next

If you have not configured your user-defined editor, see "Configuring a user-defined editor" on page 2094.

User-defined editor code example that uses one Java class
Use the example Java code to create a user-defined editor to display a text box, by using one Java class.

About this task

The following example code shows you how to use one Java class to display a text box user-defined editor to a pattern user. The `MyEditor` class extends the `BasePatternPropertyEditor` class and is specified as the user-defined editor class in the user-defined editor configuration; see "Configuring a user-defined editor" on page 2094. An instance of the `MyEditor` class is created automatically when the pattern user opens the pattern instance editor.

1. The `configureEditor()` method is called automatically after the user-defined editor class is created. This method sets up the editor.
2. The `createControls()` method is called to create the user interface for the editor:
   a. The SWT toolkit object, `Composite`, is used for the user interface.
   b. A text box control is created and the SWT layout information for the text box is defined.
   c. A listener on the text box is defined, which calls the `valueChanged()` method of the PatternPropertyEditorSite object for the editor. This ensures that when the selected value in the text box is changed, change notifications are sent to any XPath expressions or editors that use the value of this parameter.
3. The `setValue()` method sets the initial value for the text box. In this example, the code filters out blank values. The code also filters out values that start with <, to remove watermark values. This assumes watermark values are enclosed in angle brackets.
4. The `getValue()` method reads the current value of the text box and returns the value to the pattern instance editor. The pattern instance editor uses this returned value as the value of the pattern parameter.
5. The `setEnabled()` method enables or disables the text box control, depending on whether the pattern parameter is enabled or disabled. The parameter can be enabled or disabled by using an XPath expression; see "Enabling pattern parameters" on page 2086. When the result of an XPath expression

enables or disables the parameter, a boolean value is passed from the pattern instance editor to the `setEnabled()` method. If the parameter is enabled, the boolean value is *true*; if the parameter is disabled the boolean value is *false*.

```
package com.your.company.domain.MyPattern.code;

import org.eclipse.swt.SWT;
import org.eclipse.swt.layout.GridData;
import org.eclipse.swt.widgets.Composite;
import org.eclipse.swt.widgets.Event;
import org.eclipse.swt.widgets.Listener;
import org.eclipse.swt.widgets.Text;

import com.ibm.broker.config.appdev.patterns.ui.*;

public class MyEditor extends BasePatternPropertyEditor {

   private Text text;

   @Override
   public void configureEditor(PatternPropertyEditorSite site, boolean required, String
 configurationValues) {
      super.configureEditor(site, required, configurationValues);
 }

   @Override
   public void createControls(Object parent) {
      Composite composite = (Composite) parent;

      text = new Text(composite, SWT.BORDER);

      GridData textLayoutData = new GridData(GridData.FILL_HORIZONTAL);
      textLayoutData.horizontalIndent = 0;
      text.setLayoutData(textLayoutData);

      text.addListener(SWT.Modify, new Listener() {
         @Override
         public void handleEvent(Event event) {
            PatternPropertyEditorSite site = getSite();
            site.valueChanged();
         }
      });
   }

   @Override
   public void setValue(String value) {

      if (value != null) {
         if (value.startsWith("<") == false) {
            text.setText(value);
         }
      }
   }

   @Override
   public String getValue() {
      String value = text.getText();
      if (value.length() > 0) {
         return value;
      }
      return null;
   }

   @Override
   public void setEnabled(boolean enabled) {
      text.setEnabled(enabled);
   }
}
```

User-defined editor code example that uses two Java classes
Use the example Java code to create a user-defined editor to display a list of values by using two Java classes.

About this task

The following example code shows you how to use two Java classes to display a list of values to a pattern user.

The MyEditor class controls the function of the editor. The MyComposite class controls the appearance of the editor by using the SWT toolkit.

The example assumes that the following steps are completed:

- The values shown in the list in the user-defined editor are entered as configuration values in the **Configure User-Defined Editor** window. The values must be entered as a comma-separated string, for example, `Apple,Orange,Pear,Lemon`. For more information about entering configuration values, see "Configuring a user-defined editor" on page 2094.
- The `MyEditor` class is entered in the **Configure User-Defined Editor** window, in the **Class name** field. For more information about specifying the class name for your user-defined editor code, see "Configuring a user-defined editor" on page 2094.

MyEditor class

The `MyEditor` class extends the `BasePatternPropertyEditor` class. An instance of the `MyEditor` class is created automatically when the pattern user opens the pattern instance editor.

1. The `configureEditor()` method is called automatically after the `MyEditor` class is created. This method reads the configuration values string for the user-defined editor and stores each of the comma-separated values.
2. The `createControls()` method is called to create the user interface for the editor. The controls are defined in the `MyComposite` class.
3. The `isValid()` method is called automatically after the `valueChanged()` method is called. In this example, `isValid()` checks the current value of the pattern parameter and returns an error message if no value is selected. The error message is displayed to the pattern user in the pattern instance editor. If the parameter value is valid, the method returns `null`.
4. The `setValue()`, `getValue()`, and `setEnabled()` methods are defined in the `MyComposite` class:
   a. The `setValue()` method sets the initial value in the user-defined editor.
   b. The `getValue()` method returns the current value of the pattern parameter to the pattern instance editor.
   c. The `setEnabled()` method is called when the pattern parameter is enabled or disabled by an XPath expression.

```
package com.your.company.domain.MyPattern.code;

import org.eclipse.swt.SWT;
import org.eclipse.swt.widgets.Composite;

import com.ibm.broker.config.appdev.patterns.ui.BasePatternPropertyEditor;
import com.ibm.broker.config.appdev.patterns.ui.PatternPropertyEditorSite;

public class MyEditor extends BasePatternPropertyEditor {
   private MyComposite composite;
   private String configurationValues;
   private String[] items;

   @Override
   public void configureEditor(PatternPropertyEditorSite site, boolean required, String
 configurationValues) {
      super.configureEditor(site, required, configurationValues);
      this.configurationValues = configurationValues;
      this.items = configurationValues.split("\\,");
      if (this.items == null) {
         this.items = new String[] { };
      }
```

```
   }

   @Override
   public void createControls(Object parent) {
      Composite parentComposite = (Composite) parent;
      PatternPropertyEditorSite site = getSite();
      composite = new MyComposite(parentComposite, SWT.NONE, items, site);
   }

   @Override
   public String isValid() {
      String selection = getValue();
      if (selection != null) {
         return null;
      }
      return "Nothing currently selected..!";
   }

   @Override
   public void setValue(String value) {
      composite.setValue(value);
   }

   @Override
   public String getValue() {
      return composite.getValue();
   }

   @Override
   public void setEnabled(boolean enabled) {
      composite.setEnabled(enabled);
   }
}
```

MyComposite class

The `MyComposite` class creates the user interface controls for the user-defined editor. The `MyComposite` class extends the SWT toolkit `Composite` class.

1. The layout of the controls is set and a new list control is created.
2. The `valueChanged()` method is used in a listener on the list control. This ensures that when the selected value in the list is changed, change notifications are sent to any XPath expressions or editors that use the value of this parameter.
3. The `setValue()`, `getValue()`, and `setEnabled()` methods are defined in the `MyComposite` class, but are called from the `MyEditor` class:
   a. The `setValue()` method takes the value of the pattern parameter and updates the list control to show the selected value.
   b. The `getValue()` method retrieves the currently selected value from the list control and, if it is not blank, returns it to `MyEditor`.
   c. The `setEnabled()` method uses the boolean value passed to it to enable or disable the list control.

```
package com.your.company.domain.MyPattern.code;

import org.eclipse.swt.SWT;
import org.eclipse.swt.events.SelectionAdapter;
import org.eclipse.swt.events.SelectionEvent;
import org.eclipse.swt.layout.GridData;
import org.eclipse.swt.layout.GridLayout;
import org.eclipse.swt.widgets.Composite;
import org.eclipse.swt.widgets.List;

import com.ibm.broker.config.appdev.patterns.ui.PatternPropertyEditorSite;

public class MyComposite extends Composite {
   private List list;
   private PatternPropertyEditorSite site;

   public MyComposite(Composite parent, int style, String[] items, final
 PatternPropertyEditorSite site) {
      super(parent, SWT.NONE);
      this.site = site;
```

```
      GridLayout gridLayout = new GridLayout(1, false);

      gridLayout.marginWidth = 1;
      gridLayout.marginHeight = 1;
      gridLayout.horizontalSpacing = 0;
      gridLayout.verticalSpacing = 0;
      setLayout(gridLayout);

      setLayoutData(new GridData(SWT.FILL, SWT.FILL, true, true));

      list = new List(this, SWT.BORDER);
      list.setItems(items);
      GridData listLayoutData = new GridData(GridData.FILL_HORIZONTAL);
      listLayoutData.horizontalIndent = 0;
      list.setLayoutData(listLayoutData);

      list.addSelectionListener(new SelectionAdapter() {
         @Override
         public void widgetSelected(SelectionEvent event) {
            site.valueChanged();
         }
      });
   }

   public void setValue(String value) {
      if (value != null) {
         list.setSelection(new String[] { value });
      }
   }

   public String getValue() {
      String[] selection = list.getSelection();
      if (selection.length > 0) {
         return selection[0];
      }
      return null;
   }

   public void setEnabled(boolean enabled) {
      list.setEnabled(enabled);
   }
}
```

User-defined editor code example for handling change notifications
Use the example Java code to create a user-defined editor that updates the value of the parameter when there are changes to other pattern parameters.

About this task

The following example code shows you how to write user-defined editor code to handle change notifications from other pattern parameters. The user-defined editor, assigned to pattern parameter *months*, displays a list of the months of the year, one or more of which the pattern user can select by using check boxes. A second pattern parameter, *uncheck month*, displays a list of the months of the year in a drop-down list. When the pattern user selects a month in the *uncheck month* parameter, the user-defined editor code receives a change notification from *uncheck month* and that month is cleared in the list of months in the user-defined editor.

The `MyEditor` class controls the function of the editor. The `MyComposite` class controls the appearance of the editor by using methods and objects from the SWT toolkit.

The example assumes that the following steps are completed:

1. The pattern parameters, *months* and *uncheck month* are added to the user-defined pattern. To add pattern parameters, see “Defining the user interface” on page 2074.
2. An enumerated type is created that contains the months of the year. The enumerated type is assigned to pattern parameter, *uncheck month*. To use enumerated types, see “Using enumerated values for pattern parameters” on page 2088.
3. The pattern parameter, *months*, is configured to use a user-defined editor; see “Defining the user interface” on page 2074.

4. The user-defined editor for pattern parameter, *months*, is configured by completing the following steps. For more information about configuring a user-defined editor, see "Configuring a user-defined editor" on page 2094.
   a. The `MyEditor` class is entered in the **Configure User-Defined Editor** window, in the **Class name** field.
   b. The pattern parameter, *uncheck month*, is selected in the **Configure User-Defined Editor** window, in the **Select the visible parameters which will send change notifications to this user defined editor** field.

MyEditor class

The `MyEditor` class extends the `BasePatternPropertyEditor` class. An instance of the `MyEditor` class is created automatically when the pattern user opens the pattern instance editor.

1. The `configureEditor()` method is called automatically after the `MyEditor` class is created.
2. The `createControls()` method is called to create the user interface for the editor. The controls are defined in the `MyComposite` class.
3. The `isValid()` method is called automatically after the `valueChanged()` method is called. In this example, `isValid()` checks the current value of the pattern parameter and returns an error message if no value is selected. The error message is displayed to the pattern user in the pattern instance editor. If the parameter value is valid, the method returns `null`.
4. The `setValue()`, `getValue()`, and `setEnabled()` methods are defined in the `MyComposite` class:
   a. The `setValue()` method sets the initial value in the user-defined editor.
   b. The `getValue()` method returns the current value of the pattern parameter to the pattern instance editor.
   c. The `setEnabled()` method is called when the pattern parameter is enabled or disabled by an XPath expression.
5. The `notifyChanged()` method calls the `uncheckMonth()` method in the MyComposite class, passing the value of the parameter, *uncheck month*. The `notifyChanged()` method also takes the ID of the updated pattern parameter, but this is not used in this example.

```
package com.your.company.domain.MyPattern.code;

import org.eclipse.swt.SWT;
import org.eclipse.swt.widgets.Composite;

import com.ibm.broker.config.appdev.patterns.ui.BasePatternPropertyEditor;
import com.ibm.broker.config.appdev.patterns.ui.PatternPropertyEditorSite;

public class MyEditor extends BasePatternPropertyEditor {
   private MyComposite composite;

   @Override
   public void configureEditor(PatternPropertyEditorSite site, boolean required, String
 configurationValues) {
      super.configureEditor(site, required, configurationValues);
   }

   @Override
   public void createControls(Object parent) {
      Composite parentComposite = (Composite) parent;
      PatternPropertyEditorSite site = getSite();
      composite = new MyComposite(parentComposite, SWT.NONE, site);
   }

   @Override
   public String isValid() {
      String selection = getValue();
      if (selection != null) {
         return null;
      }
      return "Nothing currently selected..!";
   }

   @Override
```

```
    public void setValue(String value) {
       if (value != null) {
          composite.setValue(value);
       }
    }

    @Override
    public String getValue() {
       return composite.getValue();
    }

    @Override
    public void setEnabled(boolean enabled) {
       composite.setEnabled(enabled);
    }

    @Override
    public void notifyChanged(String parameterId, String value) {
       composite.uncheckMonth(value);
    }
}
```

MyComposite class

The `MyComposite` class creates the user interface controls for the user-defined editor. The `MyComposite` class extends the SWT toolkit `Composite` class.

1. The layout of the controls is set and a new table control is created.
2. The `valueChanged()` method is used in a listener on the table control. This ensures that when the selected values in the table are changed, change notifications are sent to any XPath expressions or editors that use the value of this parameter.
3. A table item is created for each month of the year.
4. The `setValue()`, `getValue()`, and `setEnabled()` methods are defined in the `MyComposite` class, but are called from the `MyEditor` class:
   a. The `setValue()` method takes the value of the pattern parameter and updates the table control to show the selected values. The value of the parameter is stored as an XML document in string format that contains the list of months and information about whether each month is selected. The `setValue()` method reads each month, whether it is selected, and updates the check boxes in the table.
   b. The `getValue()` method retrieves the currently selected values from the table in the user-defined editor. The list of months and the check box status of each month is stored in an XML document, which is saved as a string value. This string is returned to the `MyEditor` class and then to the pattern instance editor. The string is stored as the current value of the parameter.
   c. The `uncheckMonth()` method takes the value of the parameter, *uncheck month*, passed from the `MyEditor` class. The month is checked against the list of months in the table and when a match is found, the check box for that month is cleared in the user-defined editor.
   d. The `setEnabled()` method uses the boolean value passed to it to enable or disable the table control.

```

      for (TableItem tableItem : table.getItems()) {
         String itemName = tableItem.getText();
         if (itemName.equals(monthName) == true) {
            tableItem.setChecked(false); break;
         }
      }
   }

   public void setEnabled(boolean enabled) {
      table.setEnabled(enabled);
   }
}
```

Modifying pattern instances by using Java or PHP

Use Java or PHP code to modify pattern instances when the pattern user generates an instance of a user-defined pattern. For example, you can use Java or PHP code to modify the structure of a message flow based on the values of pattern parameters.

When you author user-defined patterns, you can include Java or PHP code to modify pattern instances. This code is run when the pattern user generates an instance of a user-defined pattern and can be used to carry out a number of actions on the pattern.

By using the IBM Integration API, you can access all the nodes, connections, and pattern parameters in a user-defined pattern. Examples of changes that you can make by using Java code are:

- Adding, removing, and copying nodes
- Changing connections between nodes
- Renaming nodes
- Changing pattern parameter values and user-defined property values
- Renaming message flows

By using the PHP API for user-defined patterns, you can access the pattern parameters and the pattern instance name of a user-defined pattern. Examples of changes that you can make by using PHP code are:

- Marking up ESQL files to change the operation of the ESQL file depending on the value of pattern parameters
- Taking values from an XML file and using them as pattern parameters
- Changing pattern parameter values
- Renaming message flows
- Running other PHP scripts or Java code

Do not use Java or PHP API code to set the `WSDL file name` property, or any of the properties set by the WSDL file, on a SOAPInput, SOAPRequest, or SOAPAsyncRequest node in your user-defined pattern. To set the `WSDL file name` property, see “Configuring SOAP nodes for user-defined patterns” on page 2080. To modify other properties on these nodes, select the properties as target properties when you

create your user-defined pattern. To select target properties, see “Defining the target properties” on page 2074.

Choosing between Java and PHP

IBM App Connect Enterprise contains a Java to PHP bridge, therefore you can complete some pattern authoring tasks by using either Java or PHP. You can choose which language to use based on the existing skills, assets, or libraries within your organization. The IBM App Connect Enterprise Toolkit includes code completion and a debugger for Java, which make Java a good choice for longer or more complex code. PHP written in the IBM App Connect Enterprise Toolkit can be changed and tested without relaunching the workbench, which makes PHP a good choice if you want to change your code and view the results quickly. If you do not have a preference between Java and PHP after considering the skills and assets of your organization and the testing approach, use Java for changes to the structure of the message flow and use PHP to modify text files.

Plug-in packaging

The code you write to modify pattern instances is contained in a separate plug-in from the user-defined pattern. When you create a pattern archive, your code plug-ins are automatically packaged with the generated pattern plug-ins. For more information about packaging user-defined patterns, see “Packaging and distributing pattern plug-ins” on page 2127.

Sequence of actions when a pattern user generates a pattern instance

When a pattern user generates an instance of a user-defined pattern, the following actions occur in sequence:

1. The pattern instance projects are created and all non-message flow files are copied into the workspace.
2. The message flows in the pattern plug-ins are loaded into memory.
3. Pattern parameters that are transformed by using XPath expressions are evaluated. If a pattern parameter is disabled by using an XPath expression, its parameter values are not changed. All target properties are set in all message flows within the user-defined pattern based on pattern parameter values.
4. The Java and PHP code targets are run in top-to-bottom order as they are listed in the Pattern Authoring editor.
5. The message flows are saved into the pattern instance projects.

Creating a code plug-in project
Create a Java and PHP plug-in project to contain pattern instance modification code.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- “Creating a pattern authoring project” on page 2069
- “Selecting the source files to use for a user-defined pattern” on page 2070

About this task

You must create a code plug-in project to contain the Java and PHP pattern instance modification code that you write. You can distribute the Java and PHP code plug-in project in the pattern archive for the associated user-defined pattern to pattern users. See “Packaging and distributing pattern plug-ins” on page 2127.

Procedure

To create a Java and PHP code plug-in project:

1. Open the **Pattern Configuration** tab of the Pattern Authoring editor.
2. Click **Add**.

   The **Add Java or PHP Code** window opens.
3. Click **New Project**.

   The **New Pattern Authoring Java and PHP Project** window opens.
4. Enter a plug-in ID for the new code plug-in.

   After the plug-in is created, the plug-in ID is shown in the **Projects** section of the Application Development view. The plug-in ID is also used to identify the plug-in when you distribute it to pattern users.
5. Optional: If you want to include PHP code in the code plug-in, select **Add PHP support to the project**.

   If you select this option a `main.php` template and example PHP scripts are added to the code plug-in.
6. Optional: If you want to include a Java class in the code plug-in, complete the following steps:
   a) Select **Add an example pattern authoring Java class to the project**.
   b) Enter a package name for the Java class in the **Package name** field.
   c) Enter a class name for the Java class in the **Class name** field.
7. Click **Finish**.

   The **New Pattern Authoring Java and PHP Project** window closes.
8. You can now add Java or PHP code to a user-defined pattern:
   - To add Java code to a user-defined pattern, see "Modifying pattern instances by using the IBM Integration API" on page 2107.
   - To add PHP code to a user-defined pattern, see "Modifying pattern instances by using PHP" on page 2121.
   - To return to pattern authoring without adding code, in the **Add Java or PHP Code** window, click **Cancel**.

Modifying pattern instances by using the IBM Integration API
Add Java code to a code plug-in project to modify a pattern instance when the pattern instance is generated by a pattern user.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Creating a code plug-in project" on page 2106

About this task

You can add Java code to a code plug-in project so that it runs when a pattern instance is generated. To add the Java code, select the Java class that you want to run.

The Java class you select can be created in the following ways:

- If you added a Java class when you created the code plug-in, then a template Java class is created and added to the project. This class is based on the Pattern Authoring Class template and contains the basic structure required to function correctly.
- When you follow the steps in this topic to select a Java class, you can optionally create a new Java class. A class created in this way is based on the Pattern Authoring Class template and contains the basic structure required to function correctly.
- You can write your own Java class. This class must implement the `GeneratePatternInstanceTransform` interface.

Regardless of how the class is created, you must add your own code within the class to complete the steps you require when the pattern instance is generated. For examples of IBM Integration API code for completing common tasks, see "Developing applications using the IBM Integration API: Example code" on page 455. For reference information about the IBM Integration API, see IBM Integration API.

Procedure

To select a Java class to run when a pattern instance is generated:

1. If the **Add Java or PHP Code** window is not open, in the **Pattern Configuration** tab of the Pattern Authoring editor, click **Add**.

   The **Add Java or PHP Code** window opens.
2. In the **Type of code** list, select Java.
3. In the **Class name** list, select the name of the class that you want to run when a pattern instance is generated.

   A class is shown in the **Class name** list if it is in the current workspace and if it implements the `GeneratePatternInstanceTransform` interface.
4. Optional: You can create a new Java class:
   a) Click **New Java Class**.

      The **New Pattern Authoring Java Class** window opens.
   b) In the **Source folder** field, click **Browse** and select the folder in which to store the new Java class file.
   c) Optional: In the **Package** field, enter the name of the Java package for the new class.

      If you leave this field blank, the default package is used.
   d) Optional: Select **Enclosing type** and enter an enclosing type in the **Enclosing type** field.
   e) Enter a name for the new Java class in the **Name** field.
   f) Optional: Change the Superclass for the new Java class in the **Superclass** field.
   g) Optional: To add an interface for the new Java class, click **Add**. The **Implemented Interfaces Selection** window opens. In the **Choose interfaces** field, enter the name of the interface that you want to add, select the interface in the **Matching items** list and click **OK**. The **Implemented Interfaces Selection** window closes.
   h) Optional: To remove an interface for the Java class, select the interface in the **Interfaces** list and click **Remove**.
   i) Optional: Click **Next** to view information about the Pattern Authoring Class template, which is used to create the Java class.
   j) Click **Finish**.
5. Click **OK**.

   The **Add Java or PHP Code** window closes and the Java class is shown in the Java and PHP Code section of the **Pattern Configuration** tab.
6. Optional: The Java and PHP code listed in the Java and PHP Code section of the **Pattern Configuration** tab runs from top to bottom when a pattern instance is generated. To change the order in which the code is run, select the entry you want to move in the **Java and PHP Code** section and click the **Up** or **Down** button to change the position of the entry in the list.

What to do next

In the Java class that you selected to run when the pattern instance is generated, you must now write the code to perform the steps you require. For examples of IBM Integration API code for completing common tasks, see "Developing applications using the IBM Integration API: Example code" on page 455. For information about the Java development views and editors within the IBM App Connect Enterprise Toolkit, see Java Development User Guide - Views and Editors.

Developing applications using the IBM Integration API: Example code
Examples of IBM Integration API code for common tasks, to help you write your own Java code to develop message flow applications or modify user-defined patterns.

About this task

The IBM Integration API uses the `com.ibm.broker.appdev.*` classes in the `IntegrationAPI.jar` file.

The following topics show examples of Java code that you can use to complete common tasks:

Procedure

Loading an existing message flow into memory
Use the IBM Integration API when developing message flow applications to load a message flow into memory. You can then access the message flow in your Java code.

You must load a message flow into memory to use it with the IBM Integration API methods within your Java code. To load a message flow into memory, create a `File` object and use the `read()` method of the `FlowRendererMSGFLOW`, which makes the message flow available for your Java code. The `read()` method takes the message flow project that contains the required message flow file and the relative path to the message flow file from this project.

The following example shows how to load a message flow that is in the `mqsi` directory:

```
import java.io.File;
import java.io.IOException;
import com.ibm.broker.MessageBrokerAPIException;
import com.ibm.broker.config.appdev.MessageFlow;
import com.ibm.broker.config.appdev.FlowRendererMSGFLOW;

public class LoadMessageFlow {
    public static void main(String[] args) {
        File msgFlow = new File("../mqsi/main.msgflow");
        try {
            MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
        } catch (IOException e) {
            // Add your own code here
            e.printStackTrace();
        } catch (MessageBrokerAPIException e) {
            // Add your own code here
```

```
            e.printStackTrace();
        }
    }
}
```

Pattern authoring

When you create patterns with the pattern authoring tool, use the `getMessageFlow()` method of the `PatternInstanceManager` object, which is automatically passed to your Java code. Modify a pattern instance to load a message flow into memory and make it available to other IBM Integration API methods.

The following example shows how to load a message flow that is in the default schema:

```
public class MyJava implements GeneratePatternInstanceTransform {
    public void onGeneratePatternInstance(PatternInstanceManager patternInstanceManager) {
        MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject",
 "main.msgflow");
        if (mf1 != null) {
           // Message flow was found
        }
        else {
           // Message flow was not found
        }
    }
}
```

The following example shows how to load a message flow that is in the `mqsi` schema:

```
public class MyJava implements GeneratePatternInstanceTransform {
    public void onGeneratePatternInstance(PatternInstanceManager patternInstanceManager) {
        MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "mqsi/
main.msgflow");
        if (mf1 != null) {
           // Message flow was found
        }
        else {
           // Message flow was not found
        }
    }
}
```

Renaming a node
Use the IBM Integration API when developing message flow applications to rename a node.

To rename a node, you must first access the required node. You can access the node by using the existing name of the node and the `getNodeByName()` method. You can then rename the node by using the `setNodeName()` method, which takes the new node name as a parameter.

The following example shows how to rename a node that is named `My Input Node`:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
Node mqinNode = mf1.getNodeByName("My Input Node");
mqinNode.setNodeName("New Input Node");
```

Pattern authoring

The following example shows how to rename the previous example node for a pattern:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
Node mqinNode = mf1.getNodeByName("My Input Node");
mqinNode.setNodeName("New Input Node");
```

Adding a node and a subflow node
Use the IBM Integration API when developing message flow applications to add a new node or subflow node to a message flow.

You can add a new built-in node, or a new subflow node to a message flow.

- When you add a subflow node by using the IBM Integration API, you must link the subflow node with the subflow message flow by using the `setSubFlow()` method of the subflow node object. For example, if you have assigned your subflow message flow to message flow instance *sub1* and you have assigned your subflow node to subflow node instance *sfNode*, you must use the following statement to link the subflow node with the subflow message flow:

```
sfNode.setSubFlow(sub1);
```

- If you want to set a node property on a subflow node, use the `addNodeProperty()` method to set the property before you link the node to the subflow by using the `setSubFlow()` method. If you use `addNodeProperty()` after `setSubFlow()`, the node property might not be stored.

The following example shows you how to add a new built-in node:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("INPUTQ");
mf1.addNode(mqinNode);
```

The following example shows you how to add a new subflow node to a message flow:

1. The new subflow node is added to the message flow held in object `mf1`.
2. The subflow node is linked to the subflow message flow by using the setSubFlow() method.
3. The subflow node name is set to `My Sub Flow Node`.
4. A new subflow node is created and assigned to object `sfNode`.

The subflow can be stored in a `.msgflow` format:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
File subFlow = new File("subflow.msgflow");
MessageFlow sub1 = FlowRendererMSGFLOW.read(subFlow);
SubFlowNode sfNode = new SubFlowNode();
sfNode.setNodeName("My Sub Flow Node");
sfNode.setSubFlow(sub1);
mf1.addNode(sfNode);
```

The subflow can be stored in a `.subflow` format:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
sFile subFlow = new File("subflow.subflow");
MessageFlow sub1 = FlowRendererMSGFLOW.read(subFlow);
SubFlowNode sfNode = new SubFlowNode();
sfNode.setNodeName("My Sub Flow Node");
sfNode.setSubFlow(sub1);
mf1.addNode(sfNode);
```

Pattern authoring

The following example shows you how to add a new built-in node to a pattern instance:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("INPUTQ");
mf1.addNode(mqinNode);
```

The following example shows you how to add a new subflow node to a message flow:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
MessageFlow sub1 = patternInstanceManager.getMessageFlow("MyFlowProject", "subflow.msgflow");
SubFlowNode sfNode = new SubFlowNode();
sfNode.setNodeName("My Sub Flow Node");
sfNode.setSubFlow(sub1);
mf1.addNode(sfNode);
```

Setting the position of a node
Use the IBM Integration API to set the position of a node on the canvas in the Application Development view.

Set the position of a node on the canvas by using the `setLocation()` method of the node object. The following example sets the position of a new MQOutput node to coordinates x=300 pixels, y=100 pixels:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
MQOutputNode mqoutNode = new MQOutputNode();
mqoutNode.setLocation(300, 100);
```

Pattern authoring

The following example is the same as the previous, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
MQOutputNode mqoutNode = new MQOutputNode();
mqoutNode.setLocation(300, 100);
```

Copying a node
Use the IBM Integration API to copy a node or subflow node to a message flow.

You can copy a built-in or subflow node by using the `clone()` method. In the following example, a new MQInput node *mqinNode* is created and properties on the node are set. A new MQInput node *mqinNode1* is then created by copying *mqinNode* by using the `clone()` method. When the node is copied, the node properties are also copied.

Example:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("INPUTQ");
MQInputNode mqinNode1 = (MQInputNode) mqinNode.clone();
mqinNode1.setNodeName("Copy of My Input Node");
mf1.addNode(mqinNode1);
```

Pattern authoring

The following example is the same as the previous, but for pattern authoring:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("INPUTQ");
MQInputNode mqinNode1 = (MQInputNode) mqinNode.clone();
mqinNode1.setNodeName("Copy of My Input Node");
mf1.addNode(mqinNode1);
```

Removing a node
Use the IBM Integration API when developing message flow applications to remove a node from a message flow.

To remove a node, you must first get the required node from the message flow object. In the following example, the `getNodeByName()` method is used to get the required node from message flow object *mf1*. The node is then removed by using the `removeNode()` method. When a node is removed, any connections to or from the node are also removed.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
Node mqinNode = mf1.getNodeByName("My Input Node");
mf1.removeNode(mqinNode);
```

Pattern authoring

The following example is the same as the previous, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
Node mqinNode = mf1.getNodeByName("My Input Node");
mf1.removeNode(mqinNode);
```

Adding connections between nodes
Use the IBM Integration API when developing message flow applications to add connections between nodes.

Pattern authoring

You can connect both subflow and built-in nodes. The first example shows you how to connect two built-in nodes. The second example shows you how to connect a built-in node to a subflow node.

To use the terminals of a subflow node, you must link the subflow node with the subflow message flow by using the `setSubFlow()` method of the subflow node object. For example, if you have assigned your subflow message flow to message flow instance *sub1* and you have assigned your subflow node to subflow node instance *sfNode*, you must use the following statement to link the subflow node with the subflow message flow:

```
sfNode.setSubFlow(sub1);
```

The following example shows you how to connect two built-in nodes:

1. A MQInput node and a Collector node are created.
2. The `getInputTerminal()` method is used to create a dynamic Input terminal called *NEWIN* on the Collector node.
3. The Input terminal is connected to the Output terminal of the MQInput node by using the `connect()` method of the message flow object *mf1*.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("INPUTQ");
CollectorNode colNode = new CollectorNode();
colNode.getInputTerminal("NEWIN");
mf1.connect(mqinNode.OUTPUT_TERMINAL_OUT, colNode.getInputTerminal("NEWIN"));
```

To use a static terminal on a node, you must use the appropriate constant defined for it in the IBM Integration API. These constants are listed in the IBM Integration API javadoc, see IBM Integration API.

The following example shows you how to connect a subflow node to a built-in node. You must load the subflow message flow and link it to a subflow node. You must use the `getInputTerminal()`, `getInputTerminals()`, `getOutputTerminal()` or `getOutputTerminals()` method to access the terminal on the subflow node to which you want to connect. The example code completes the following steps:

1. The main message flow, `main.msgflow`, and a Compute node in the main message flow are loaded into memory.
2. The subflow message flow, subflow.msgflow, and the subflow node in the main message flow are loaded into memory.
3. The `setSubFlow()` method of the subflow node is used to link the subflow message flow *sub1* to the subflow node *sfNode*.
4. The `getOutputTerminal()` method is used to get the Process terminal of the subflow node. The `connect()` method of the message flow object is used to connect this terminal to the Input terminal of the Compute node.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
```

```
ComputeNode compNode = (ComputeNode)mf1.getNodeByName("My Compute Node");
File subFlow = new File("subflow.msgflow");
MessageFlow sub1 = FlowRendererMSGFLOW.read(subFlow);
SubFlowNode sfNode = (SubFlowNode)mf1.getNodeByName("My Subflow Node");
sfNode.setSubFlow(sub1);
mf1.connect(sfNode.getOutputTerminal("Process"), compNode.INPUT_TERMINAL_IN);
```

The following example is the same as the previous example for connecting two build-in nodes, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("INPUTQ");
CollectorNode colNode = new CollectorNode();
colNode.getInputTerminal("NEWIN");
mf1.connect(mqinNode.OUTPUT_TERMINAL_OUT, colNode.getInputTerminal("NEWIN"));
```

The following example is the same as the previous example for using static terminals on a node, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
ComputeNode compNode = (ComputeNode)mf1.getNodeByName("My Compute Node");
MessageFlow sub1 = patternInstanceManager.getMessageFlow("MyFlowProject", "subflow.msgflow");
SubFlowNode sfNode = (SubFlowNode)mf1.getNodeByName("My Subflow Node");
sfNode.setSubFlow(sub1);
mf1.connect(sfNode.getOutputTerminal("Process"), compNode.INPUT_TERMINAL_IN);
```

Adding and connecting user-defined nodes
Use the IBM Integration API to add user-defined nodes and to connect user-defined nodes to other nodes.

The code required to add and connect user-defined node is different to the code required for built-in nodes and subflow nodes.

When you write Java code for user-defined nodes you must be aware of the following information:

- User-defined nodes are supported by instances of the `GenericNode` class. To add user-defined nodes to message flows, create instances of `GenericNode` and add them to the message flow instance.
- To retrieve existing instances of a user-defined node, call `getNodeByName()` and cast the returned object to a `GenericNode` object.
- The terminals defined on your user-defined nodes are not automatically available in the API. If you create an instance of a `GenericNode` class, it does not have any input or output terminals listed. The methods `getInputTerminals()` and `getOutputTerminals()` return empty lists.
- To get an input terminal for a `GenericNode`, call `getInputTerminal()` and pass the terminal name that exists on the generic node. This method returns the input terminal and makes it available in the message flow object that contains your generic node. After you have used `getInputTerminal()` with a known terminal name, this input terminal is returned if `getInputTerminals()` is used.
- To get an output terminal for a `GenericNode`, call `getOutputTerminal()` and pass the terminal name that exists on the generic node. This method returns the output terminal and makes it available in the message flow object that contains your generic node. After you have used `getOutputTerminal()` with a known terminal name, this output terminal is returned if `getOutputTerminals()` is used.

The following example shows how you can add a user-defined node to a message flow and connect it to a built-in node:

1. An MQInput node is created and added to the message flow.
2. A user-defined node is created by using the `GenericNode` class and is added to the message flow object.
3. The static output terminal of the MQInput is assigned to the variable *outputTerminal*.
4. The input terminal of the user-defined node is assigned to the variable *inputTerminal* by using the `getInputTerminal()` method with the known terminal name *In*.
5. The nodes are connected by using the `connect()` method.

6. The final section of code shows that the input node is now available for use in the message flow, by using the `getInputTerminals()` method of the user-defined node instance.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);

MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("IN");
mf1.addNode(mqinNode);

GenericNode myNode = new GenericNode("MyUserDefinedNode");
myNode.setNodeName("MyNode");
mf1.addNode(myNode);

OutputTerminal outputTerminal = mqinNode.OUTPUT_TERMINAL_OUT;
InputTerminal inputTerminal = myNode.getInputTerminal("In");
mf1.connect(outputTerminal, inputTerminal);

InputTerminal[] inputTerminals = myNode.getInputTerminals();
System.out.println("Input terminals on my node:");
for (int i = 0; i < inputTerminals.length; i++) {
   InputTerminal inputTerminal = inputTerminals[i];
   System.out.println(inputTerminal.getName());
}
```

Pattern authoring

The following example is the same as the previous example, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");

MQInputNode mqinNode = new MQInputNode();
mqinNode.setNodeName("My Input Node");
mqinNode.setQueueName("IN");
mf1.addNode(mqinNode);

GenericNode myNode = new GenericNode("MyUserDefinedNode");
myNode.setNodeName("MyNode");
mf1.addNode(myNode);

OutputTerminal outputTerminal = mqinNode.OUTPUT_TERMINAL_OUT;
InputTerminal inputTerminal = myNode.getInputTerminal("In");
mf1.connect(outputTerminal, inputTerminal);

InputTerminal[] inputTerminals = myNode.getInputTerminals();
System.out.println("Input terminals on my node:");
for (int i = 0; i < inputTerminals.length; i++) {
   InputTerminal inputTerminal = inputTerminals[i];
   System.out.println(inputTerminal.getName());
}
```

Removing connections between nodes

Use the IBM Integration API to remove connections between nodes.

You can disconnect two nodes by using the `disconnect()` method of the message flow object. You must provide this method with the names of the terminal instances that you want to disconnect.

The following example shows how you can disconnect two nodes:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
MQInputNode mqinNode = (MQInputNode)mf1.getNodeByName("My Input Node");
MQOutputNode mqoutNode = (MQOutputNode)mf1.getNodeByName("My Output Node");
mf1.disconnect(mqinNode.OUTPUT_TERMINAL_OUT, mqoutNode.INPUT_TERMINAL_IN);
```

Pattern authoring

The following example is the same as the previous example, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
MQInputNode mqinNode = (MQInputNode)mf1.getNodeByName("My Input Node");
```

```
MQOutputNode mqoutNode = (MQOutputNode)mf1.getNodeByName("My Output Node");
mf1.disconnect(mqinNode.OUTPUT_TERMINAL_OUT, mqoutNode.INPUT_TERMINAL_IN);
```

Creating or changing user-defined properties
Use the IBM Integration API to create or change user-defined properties (UDPs).

You can create new UDPs and add them to the message flow, or you can discover existing UDPs and modify them.

The following example shows you how to create a UDP and add it to a message flow:

1. A UDP called `Property1` is created in parameter group `Group1`. The data type of the UDP is defined as a string, and the UDP is given the default value `Hello World!`
2. The UDP is then added to the message flow by using the `addFlowProperty()` method.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
UserDefinedProperty udp = new UserDefinedProperty("Group1", "Property1",
 UserDefinedProperty.Usage.MANDATORY, UserDefinedProperty.Type.STRING, "Hello World!");
mf1.addFlowProperty(udp);
```

In the following example, the existing UDPs in a message flow are discovered by using the `getFlowProperties()` method on the message flow. The `setName()` method is then used to set the name of the first UDP to `Property3`:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
Vector<FlowProperty> flowProperties = mf1.getFlowProperties();
flowProperties.get(0).setName("Property3");
```

You can also modify user-defined properties by using the administration REST API, as described in "Setting message flow user-defined properties at run time by using the administration REST API" on page 436.

Pattern authoring

The following examples are the same as the previous UDP examples, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
UserDefinedProperty udp = new UserDefinedProperty("Group1", "Property1",
 UserDefinedProperty.Usage.MANDATORY, UserDefinedProperty.Type.STRING, "Hello World!");
mf1.addFlowProperty(udp);
```

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
Vector<FlowProperty> flowProperties = mf1.getFlowProperties();
flowProperties.get(0).setName("Property3");
```

Changing pattern parameter values
Use the IBM Integration API to modify a pattern instance to change pattern parameter values.

You can change a pattern parameter value by using the `PatternInstanceManager` object.

The following example sets the value of the pattern parameter with the pattern parameter ID pp1 to `true`:

```
patternInstanceManager.setParameterValue("pp1", "true");
```

Reading table values
Use the IBM Integration API to read table values by accessing and extracting table values.

To read table values, you must first access the table and then extract the data from each row. To read the table values, use one of the following examples:

Use this example to access and extract the table values by providing the name of the columns. In this example, *noRows* is the number of rows in the table, *value* is the parameter that stores the table value, *column* is the name of the column in the table, and *pp3* is the parameter ID.

```
PatternParameterTable paramtable = pim.getParameterTable("pp3");
int noRows = paramtable.getRowCount();
String value;
PatternParameterRow row;
for(int i=0; i<noRows; i++) {
    row = paramtable.getRow(i);
    value = row.getValue("column");
    //insert your code here
}
```

Alternatively, if you do not provide the name of the columns, you can use this example to access and extract the table values by using the `getColumns()` method. In this example, *noColumns* is the number of columns in the table, *value* is the parameter that stores the table value, *columns* is an array containing the names of the columns in the table, and *pp3* is the parameter ID.

```
PatternParameterTable paramtable = pim.getParameterTable("pp3");
int noRows = paramtable.getRowCount();
PatternParameterRow row;
String[] columns;
String value;
for(int i=0; i<noRows; i++) {
    row = paramtable.getRow(i);
    columns = row.getColumns();
    int noColumns = columns.length;
    for(int j=0; j<noColumns; j++) {
        value = row.getValue(columns[j]);
        //insert your code here
    }
```

Creating ESQL modules

Use the IBM Integration API when developing message flow applications to create ESQL modules. You can then associate ESQL modules with nodes that use ESQL. For example, if you create a Compute node, you can write Java code to create an ESQL module and then associate that module with the node.

Examples of nodes that use ESQL are Compute, Database, DatabaseInput, and Filter nodes. If you are using a non-default broker schema, you must set the schema by using the `setBrokerSchema()` method.

The following example shows you how to create an ESQL module in the `mqsi` schema. The module is then assigned to a new Compute node by using the `setComputeExpression()` method:

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
ESQLModule module = new ESQLModule();
module.setBrokerSchema("mqsi");
module.setEsqlMain("MyESQLMain");
ComputeNode compNode = new ComputeNode();
compNode.setNodeName("My Compute Node");
compNode.setComputeExpression(module);
mf1.addNode(compNode);
```

The following example shows you how to create an ESQL module in the default schema. The `setBrokerSchema()` method is not required.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
File esql = new File("FileBatchProcessingSample_Branch.esql");
ESQLFile esqlFile = new ESQLFile(esql);
Vector<ESQLModule> esqlModules = esqlFile.getEsqlModules();
ComputeNode compNode = new ComputeNode();
compNode.setNodeName("My Compute Node");
compNode.setComputeExpression(esqlModules.get(0));
mf1.addNode(compNode);
```

The following example shows you how to discover an ESQL module from within an ESQL file by using the `getEsqlModules()` method. You can then use the ESQL module to set the compute expression on a Compute node by using the `setComputeExpression()` method.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
File esql = new File("FileBatchProcessingSample_Branch.esql");
ESQLFile esqlFile = new ESQLFile(esql);
Vector<ESQLModule> esqlModules = esqlFile.getEsqlModules();
ComputeNode compNode = new ComputeNode();
compNode.setNodeName("My Compute Node");
compNode.setComputeExpression(esqlModules.get(0));
mf1.addNode(compNode);
```

Pattern authoring

The following examples are the same as the three previous examples, but tailored for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
ESQLModule module = new ESQLModule();
module.setBrokerSchema("mqsi");
module.setEsqlMain("MyESQLMain");
ComputeNode compNode = new ComputeNode();
compNode.setNodeName("My Compute Node");
compNode.setComputeExpression(module);
mf1.addNode(compNode);
```

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
ESQLModule module = new ESQLModule();
module.setEsqlMain("MyESQLMain");
ComputeNode compNode = new ComputeNode();
compNode.setNodeName("My Compute Node");
compNode.setComputeExpression(module);
mf1.addNode(compNode);
```

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
File esql = new File("FileBatchProcessingSample_Branch.esql");
ESQLFile esqlFile = new ESQLFile(esql);
Vector<ESQLModule> esqlModules = esqlFile.getEsqlModules();
ComputeNode compNode = new ComputeNode();
compNode.setNodeName("My Compute Node");
compNode.setComputeExpression(esqlModules.get(0));
mf1.addNode(compNode);
```

Renaming a message flow

Use the IBM Integration API when developing message flow applications to rename message flows.

You can write code to rename a message flow by using the `setName()` method. In the following example, a message flow file called `main.msgflow` is renamed to `mainGenerated.msgflow`.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
mf1.setName(mf1.getName()+"Generated");
```

Pattern authoring

The following example is the same as the previous example, but for pattern authoring:

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
mf1.setName(mf1.getName()+"Generated");
```

Updating filter tables on Route nodes

Use the IBM Integration API to update filter tables on Route nodes.

You can add and update rows on the filter table of a Route node.

Adding a new row

The following example shows you how to add a new row to a filter table by using the `createRow()` method:

1. The message flow and the Route node are loaded into memory.
2. The filter table of the Route node is loaded into memory by using the `getFilterTable()` method of the RouteNode object.
3. A new filter table row is created by using the `createRow()` method.
4. The value of the `filter pattern` property on this new row is set to `value="123"` by using the `setFilterPattern()` method.
5. The `routing output terminal` property is set to NEWOUT by using the `setRoutingOutputTerminal()` method.
6. The new row is then added to the filter table by using the `addRow()` method.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
RouteNode routeNode = (RouteNode)mf1.getNodeByName("My Route Node");
RouteNode.FilterTable filterTable = (RouteNode.FilterTable)routeNode.getFilterTable();
RouteNode.FilterTableRow newRow = filterTable.createRow();
newRow.setFilterPattern("value=\"123\"");
newRow.setRoutingOutputTerminal("NEWOUT");
filterTable.addRow(newRow);
```

Updating a row

The following example shows you how to update rows on the filter table of a Route node.

1. The message flow, Route node, and filter table of the Route node are loaded into memory.
2. The rows of the filter table are loaded into memory by using the `getRows()` method.
3. The `filter pattern` property of the first row of the filter table is set to `value2="456"`.
4. The `routing output terminal` property of the first row of the filter table is set to NEWOUT2.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
RouteNode routeNode = (RouteNode)mf1.getNodeByName("My Route Node");
RouteNode.FilterTable filterTable = (RouteNode.FilterTable)routeNode.getFilterTable();
Vector<RouteNode.FilterTableRow> filterTableRows = filterTable.getRows();
filterTableRows.get(0).setFilterPattern("value2=\"456\"");
filterTableRows.get(0).setRoutingOutputTerminal("NEWOUT2");
```

Pattern authoring

The following examples are the same as the previously described examples, but for pattern authoring:

Adding a new row

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
RouteNode routeNode = (RouteNode)mf1.getNodeByName("My Route Node");
RouteNode.FilterTable filterTable = (RouteNode.FilterTable)routeNode.getFilterTable();
RouteNode.FilterTableRow newRow = filterTable.createRow();
newRow.setFilterPattern("value=\"123\"");
newRow.setRoutingOutputTerminal("NEWOUT");
filterTable.addRow(newRow);
```

Updating a row

```
MessageFlow mf1 = patternInstanceManager.getMessageFlow("MyFlowProject", "main.msgflow");
RouteNode routeNode = (RouteNode)mf1.getNodeByName("My Route Node");
RouteNode.FilterTable filterTable = (RouteNode.FilterTable)routeNode.getFilterTable();
Vector<RouteNode.FilterTableRow> filterTableRows = filterTable.getRows();
filterTableRows.get(0).setFilterPattern("value2=\"456\"");
filterTableRows.get(0).setRoutingOutputTerminal("NEWOUT2");
```

Running PHP code
Use the IBM Integration API to modify a pattern instance to run PHP scripts from within your Java code.

You can run PHP scripts from within the IBM Integration API by using the `runScript()` method of the PatternInstanceManager object. In the following example, the IBM Integration API runs a PHP script in the `com.your.company.domain.code` plug-in, `templates/script.php`.

```
@Override
public void onGeneratePatternInstance (PatternInstanceManager patternInstanceManager) {
 patternInstanceManager.runScript("com.your.company.domain.code", "templates/script.php");
}
```

Saving a message flow file from memory
Use the IBM Integration API when developing message flow applications to save a message flow from memory.

Save a message flow to a message flow file to preserve additions and modifications that you have made. To save a message flow from memory, use the `write()` method of the `FlowRendererMSGFLOW` object. The `write()` method writes all the changes made using the IBM Integration API to the specified message flow file.

The schema for a message flow is stored in the message flow, and cannot be modified by using the IBM Integration API. When you save your message flow file by using the IBM Integration API, the file is saved to a directory that has the same name as the schema. If the directory does not exist, it is created. For example, if your message flow is part of the `mqsi` schema, when you save the message flow file it is saved to the `mqsi` directory.

The following example shows how to save a message flow in the specified directory by using the `write()` method. On Windows, if the message flow is part of the `mqsi` schema, the message flow file is saved to `C:\MB\mqsi\main.msgflow`.

```
File msgFlow = new File("main.msgflow");
MessageFlow mf1 = FlowRendererMSGFLOW.read(msgFlow);
FlowRendererMSGFLOW.write(mf1,"C:\MB");
```

Testing Java code
After writing Java code to modify pattern instances, test the code to check that it works correctly.

Before you begin

Before you test your Java code, you must build the pattern plug-ins; see “Building pattern plug-ins” on page 2126.

About this task

You can test your Java code either by creating an instance of a pattern and checking that it is modified as you expect or by using the Java debugger to step through the code.

Procedure

- To test your user-defined pattern by creating an instance of the pattern, see “Testing a user-defined pattern” on page 2126.

- To use the Java debugger, you must open a temporary workspace to generate an instance of your user-defined pattern, then return to the original workspace to step through the code. To use the Java debugger, complete the following steps:
  a) In your Java code file, add a breakpoint to the required line of code. To add a breakpoint, right-click the marker bar (vertical ruler) to the left of the required code and click **Toggle Breakpoint**.
  b) In the Pattern Authoring editor, click the **Create Pattern** tab.
  c) Click **Debug Pattern**.
     The **Workspace Launcher** window opens.
  d) Select the temporary workspace in which to generate an instance of your user-defined pattern. Click **Browse** and select a workspace or enter a workspace in the **Workspace** field. Click **OK**.
     The selected workspace opens.
  e) In the temporary workspace, you must generate an instance of your user-defined pattern. In the Application Development view, click the **Patterns Explorer** tab and select your user-defined pattern.
  f) In the **Pattern Specification** tab, click **Create New Instance**. Enter a name for the instance of your user-defined pattern and click **OK**.
  g) Enter any mandatory pattern parameters and click **Generate**.
     The generation of the pattern instance stops when it reaches the breakpoint in your Java code.
  h) In the original workspace, in the **Confirm Perspective Switch** window, click **Yes**.
     The original workspace switches to debug mode and shows the code paused at your breakpoint.
  i) You can now use the Java debugger to test your code; see "Java Debugger" on page 664.
  j) When you have finished testing the code in the Java debugger, close the temporary workspace and switch back to the Integration Development perspective in the original workspace; see perspectives.

What to do next

You can either change your Java code and retest it or you can package and distribute your user-defined pattern:

- To change and retest your Java code, edit the code file and then repeat the steps in this topic.
- To package and distribute your user-defined pattern, see "Packaging and distributing pattern plug-ins" on page 2127

To ensure that changes in your Java code are included in your generated pattern, change the version number of the Java plug-in, as described in the following steps.

1. Update the version number of the Java plug-in in `manifest.mf`.
2. Update the version number of the pattern on the **Create Pattern** tab.
3. Re-create the pattern plug-ins and pattern archive, as described in "Building pattern plug-ins" on page 2126.
   To check that the pattern archive contains the correct versions of the plug-ins, you can look at the `feature.xml` file.
4. Install the pattern.

Modifying pattern instances by using PHP

Add PHP code to a code plug-in project to modify a pattern instance when the pattern instance is generated by a pattern user.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- "Creating a pattern authoring project" on page 2069

- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Creating a code plug-in project” on page 2106

About this task

You can add PHP code to a code plug-in project by selecting a PHP script, which runs when a pattern instance is generated. You can choose whether to write the output of this script to a file. For example, you can write a PHP script that creates an ESQL file that is used in your user-defined pattern.

If you added PHP support when you created the code plug-in, a PHP template and example scripts are created and added to the project. Alternatively, you can write your own PHP script. Regardless of how the script is created, you must add your own code within the script to complete the steps you require when the pattern instance is generated. For examples of PHP code for completing common tasks, see “Examples of PHP API code” on page 2123. For reference information about the PHP pattern authoring API, see PHP API for user-defined patterns.

Procedure

To select a PHP script to run when a pattern instance is generated:

1. If the **Add Java or PHP Code** window is not open, in the **Pattern Configuration** tab of the Pattern Authoring editor, click **Add**.

   The **Add Java or PHP Code** window opens.
2. In the **Type of code** list, select PHP.
3. In the **Project name** list, select the project or plug-in that contains the PHP script that you want to run when a pattern instance is generated. If the required plug-in is installed, but is not in your workspace, click **Browse** and select the required plug-in.
4. In the **PHP file name** list, select the name of the script you want to run when a pattern instance is generated.

   The **PHP file name** list shows all the PHP scripts in the project or plug-in that you selected.
5. Optional: To write the output of the PHP script to a file, select **Write the output from the PHP file into an output file**.
   a) In the **Pattern instance project** list, select the pattern instance project in which you want to include the output file.
   b) In the **Output file name** field, enter a name for the output file.

      You can include a path in this field, for example `scripts/example.mqsc` to write the output to the `scripts` folder.
6. Click **OK**.

   The **Add Java or PHP Code** window closes and the PHP script that you selected is shown in the **Java and PHP Code** section of the **Pattern Configuration** tab.
7. Optional: The Java and PHP code listed in the Java and PHP Code section of the **Pattern Configuration** tab runs from top to bottom when a pattern instance is generated. To change the order in which the code runs, select the entry you want to move in the Java and PHP Code section and click the **Up** or **Down** button to change the position of the entry in the list.

What to do next

In the PHP script that you selected to run when the pattern instance is generated, you must now write the code to perform the steps you require. For examples of PHP code for completing common tasks, see “Modifying pattern instances by using PHP” on page 2121. For reference information about the PHP pattern authoring API, see PHP API for user-defined patterns.

Examples of PHP API code
Use the following examples of PHP API code for common tasks to help you write your own PHP code to modify pattern instances.

About this task

The following examples show PHP code that you can use to complete common tasks when you are creating user-defined patterns:

Procedure

- Running additional PHP scripts.
  The following example shows how to use a PHP script to run another PHP script, by using the `mb_pattern_run_template()` function. The `mb_pattern_run_template()` function uses the following parameters:

  1. The first parameter required by `mb_pattern_run_template()` is the name of the project containing the PHP template; `Transform` in this example.
  2. The second parameter required by `mb_pattern_run_template()` is the name of the PHP script to run; in this example `example.esql.php`, which is in a subfolder called `mqsi`.
  3. The third parameter required by `mb_pattern_run_template()` is the name of the file to which the output is written; in this example `example.esql`, in subfolder `mqsi`.

  The user-defined pattern in this example contains a Boolean pattern parameter called `includeErrorHandling`. This pattern parameter is used to create a check box in the pattern:

```
<?php
    if ($_MB['PP']['includeErrorHandling'] == 'true') {
        mb_pattern_run_template("Transform", "mqsi/example.esql.php", "mqsi/example.esql");
    }
?>
```

- Using PHP scripts with markup for ESQL.
  In the following example, the user-defined pattern contains a pattern parameter called `errorQueue`, which can contain the values none or `errorAction`:

```
BROKER SCHEMA mqsi
<?php
    if ($_MB['PP']['errorAction'] == 'errorQueue') {
        echo "DECLARE ErrorAction EXTERNAL CHARACTER '".$_MB['PP']['errorAction']."';";

        echo <<<ESQL

        CREATE FILTER MODULE CheckErrorAction
            CREATE FUNCTION Main() RETURNS BOOLEAN
            BEGIN
                IF ErrorAction = 'errorQueue' THEN
                    RETURN TRUE;
                ELSE
                    RETURN FALSE;
                END IF;
            END;
        END MODULE;

ESQL;
    }
?>
```

- Using PHP scripts to remove files from a project. In the following example, the script first checks the value of the check box pattern parameter, which has the pattern parameter ID pp1. If this parameter is set to `false`, the script deletes the `Log.msgflow` and `Log.esql` files from the pattern instance project. Message flow files must be deleted by using the `removeMessageFlow()` function. Non-message flow files can be deleted by using the standard PHP function `unlink()`:

```
if ($_MB['PP']['pp1'] == 'false') {

    $pim = $_MB["PATTERN_INSTANCE_MANAGER"];
```

```
    $logmsgflow = $pim->getMessageFlow("Example_Flows", "mqsi/Log.msgflow");
    $pim->removeMessageFlow($logmsgflow);

    $piworkspace = $pim->getWorkspaceLocation();
    $piname = $pim->getPatternInstanceName();
    $logesql = $piworkspace . "/" . $piname . "_Example_Flows/mqsi/Log.esql";
    unlink($logesql);
}
```

- Running Java code from PHP by using a static Java method. The following example shows a Java class, *MyClass*, that can be run from within a PHP script. The class contains a static method:

```
package com.your.company.domain.code;

import com.ibm.broker.config.appdev.MessageFlow;
import com.ibm.broker.config.appdev.patterns.GeneratePatternInstanceTransform;
import com.ibm.broker.config.appdev.patterns.PatternInstanceManager;

public class MyClass implements GeneratePatternInstanceTransform {

    public static void doSomethingUseful(String message) {
        System.out.println("Message received [" + message + "]");
    }

    @Override
    public void onGeneratePatternInstance(PatternInstanceManager patternInstanceManager) { }
}
```

You can run the *MyClass* class from PHP as shown in the following example. In the line `$class = $pim->getPluginClass("com.your.company.domain.code", "com.your.company.domain.code.MyClass")`, the first argument, `com.your.company.domain.code`, is the ID of the plug-in that contains the Java class. The second argument, `com.your.company.domain.code.MyClass`, is the name of the class.

```
<?php
    $pim = $_MB["PATTERN_INSTANCE_MANAGER"];
    $class = $pim->getPluginClass("com.your.company.domain.code",
 "com.your.company.domain.code.MyClass");
    java_import("com.your.company.domain.code.MyClass");
    MyClass::doSomethingUseful("Hello!");
?>
```

- Running Java code from PHP by using a non-static Java method. The following example shows a Java class, *MyClass*, that can be run from within a PHP script. The class contains a method that is not static:

```
package com.your.company.domain.code;

import com.ibm.broker.config.appdev.MessageFlow;
import com.ibm.broker.config.appdev.patterns.GeneratePatternInstanceTransform;
import com.ibm.broker.config.appdev.patterns.PatternInstanceManager;

public class MyClass implements GeneratePatternInstanceTransform {

   public void doSomethingUseful(String message) {
      System.out.println("Message received [" + message + "]");
   }

   @Override
   public void onGeneratePatternInstance(PatternInstanceManager patternInstanceManager) { }
}
```

You can run the *MyClass* class from PHP as shown in the following example. In the line `$class = $pim->getPluginClass("com.your.company.domain.code", "com.your.company.domain.code.MyClass")`, the first argument, `com.your.company.domain.code`, is the ID of the plug-in that contains the Java class. The second argument, `com.your.company.domain.code.MyClass`, is the name of the class. A new instance of the class is created in the line `$obj = $class->newInstance()`. In the last line of the example, the `doSomethingUseful()` method of the class is run.

```
<?php
    $pim = $_MB["PATTERN_INSTANCE_MANAGER"];
```

```
    $class = $pim->getPluginClass("com.your.company.domain.code",
 "com.your.company.domain.code.MyClass");
    $obj = $class->newInstance();
    $obj->doSomethingUseful("Hello!");
?>
```

- Using PHP scripts to read table values. In the following example, the PHP script extracts the values from an array stored in the superglobal variable *$_MB*. First the script searches inside the array for any values stored in the *event* and *response* variables, and then returns the values:

```
<?php
 $pim = $_MB["PATTERN_INSTANCE_MANAGER"];
 $table = $pim->getParameterTable("table1");
 $count = $table->getRowCount();
 for ($j=0;$j<$count ;$j++ ) {
  echo "".$_MB['PP']['table1'][$j]['event']."';\n";
  echo "".$_MB['PP']['table1'][$j]['response']."';\n";
 }
?>
```

  The array has the following structure:

```
array(4) {
 ["PATTERN_INSTANCE_MANAGER"]=>
 object(Java)#1 (0) {
 }
 ["PP"]=>
  array(10) {
   ["queueName"]=>string(11) "QP.QUEUE.QS"
   ["configurePrefixSuffix"]=>string(5) "false"
   ["queuePrefix"]=>string(3) "QP."
   ["queueSuffix"]=>string(3) ".QS"
   ["logging"]=>string(5) "queue"
   ["generateMessageSet"]=>string(4) "true"
   ["table1"]=>
   array(2) {
     [0]=>
      array(2) {
     ["event"]=>string(6) "event1"
     ["response"]=>string(9) "response1"
      }
     [1]=>
      array(2) {
     ["event"]=>string(6) "event2"
     ["response"]=>string(9) "response2"
      }
   }
 }
```

Testing PHP API code
After writing PHP code to modify pattern instances, test the code to check that it works correctly.

Before you begin

Before you test your PHP code, you must build the pattern plug-ins; see “Building pattern plug-ins” on page 2126.

About this task

You can check that your PHP scripts work correctly by creating an instance of your user-defined pattern. When you test your user-defined pattern, a new workspace is opened in which to create the instance of your pattern. If you want to change your PHP code and retest it, you are not required to open a new workspace after each change. If you make any other changes to the pattern authoring project, you must rebuild the pattern plug-ins and launch a new workspace.

Procedure

To test your user-defined pattern, see “Testing a user-defined pattern” on page 2126. A new workspace is opened in which you generate an instance of your user-defined pattern. After the pattern instance is

generated, check that your PHP code has worked correctly. For example, if you write PHP code to remove files from a pattern instance project, check that the files are deleted.

What to do next

You can either change your PHP code and retest it or you can package and distribute your user-defined pattern:

- To change and retest your PHP code, repeat the following steps until all your changes are complete. You can keep the test workspace open and continue to change your code and generate pattern instances without closing and relaunching the test workspace after each change:
  1. Edit the PHP code file in your main workspace and save the file.
  2. In the test workspace, generate a new instance of your user-defined pattern and check the results.
- To package and distribute your user-defined pattern, see "Packaging and distributing pattern plug-ins" on page 2127.

Building pattern plug-ins

You must build the pattern plug-ins before you can distribute user-defined patterns to pattern users.

Before you begin

Complete the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070

About this task

Procedure

To build the pattern plug-ins:

1. In the Pattern Authoring editor, click the **Create Pattern** tab.
2. Enter values in the **Plug-in ID** and **Version** fields for your plug-in according to the naming and version numbering conventions within your organization.

   For more information about naming conventions for Eclipse plug-ins, see http://wiki.eclipse.org/Naming_Conventions. For more information about version numbering conventions for Eclipse plug-ins, see http://wiki.eclipse.org/Version_Numbering.
3. Optional: Select **Create translation plug-ins**, if required.
4. Click **Create Pattern Plug-ins**.

   The plug-ins for your user-defined pattern are created and displayed under the Pattern Authoring folder in the Application Development view. The plug-ins are named *PluginID*, and *PluginID*.doc, where *PluginID* is the value entered in the **Plug-in ID** field in the **Create Pattern** tab. If **Create translation plug-ins** is selected, two additional plug-ins are created, named *PluginID*.nl1 and *PluginID*.nl1.doc.

What to do next

You must now test the pattern, see "Testing a user-defined pattern" on page 2126.

Testing a user-defined pattern

Ensure that you test your user-defined pattern before you share it with your pattern users.

Before you begin

Complete the following tasks:

- “Creating a pattern authoring project” on page 2069
- “Selecting the source files to use for a user-defined pattern” on page 2070
- “Building pattern plug-ins” on page 2126

About this task

Before you distribute your user-defined pattern, you can test it to ensure that it works correctly. To test your user-defined pattern, the Pattern Authoring editor opens a temporary workspace in which you can generate an instance of your user-defined pattern. You can then check that your user-defined pattern works correctly. If your user-defined pattern contains Java pattern authoring API code, see “Testing Java code” on page 2120. If your user-defined pattern contains PHP pattern authoring API code, see “Testing PHP API code” on page 2125.

Procedure

To test your user-defined pattern:

1. In the Pattern Authoring editor, click the **Create Pattern** tab.
2. Click **Test Pattern**.

   The **Workspace Launcher** window opens.
3. Select the temporary workspace in which to generate an instance of your user-defined pattern. Click **Browse**. Select a workspace or enter a workspace in the **Workspace** field. Click **OK**.

   The selected workspace opens.
4. Click the **Patterns Explorer** tab in the Application Development view.

   Your new user-defined pattern is shown in the **Patterns Explorer** view.
5. Test your pattern by generating a new pattern instance.

   See “Using patterns” on page 2058.
6. If you want to change your pattern, change the pattern authoring project and then rebuild the pattern plug-ins.

   If you are changing only Java or PHP pattern authoring API code, you do not have to rebuild the pattern plug-ins; see “Testing Java code” on page 2120 and “Testing PHP API code” on page 2125.

What to do next

After you have tested the pattern, you can share it with the pattern users, see “Packaging and distributing pattern plug-ins” on page 2127.

Packaging and distributing pattern plug-ins

Package the plug-ins for your user-defined pattern into a pattern archive so that pattern users can download and install the pattern on their own system.

Before you begin

Before you can complete this task, you must have completed the following tasks for your user-defined pattern:

1. “Creating a pattern authoring project” on page 2069
2. “Selecting the source files to use for a user-defined pattern” on page 2070
3. “Building pattern plug-ins” on page 2126
4. “Testing a user-defined pattern” on page 2126

About this task

To enable pattern users to use your user-defined pattern, you must create a pattern archive from the pattern plug-ins. The pattern archive is published to a pattern community site, which is either a website

or shared file system directory. The pattern user can download and install the pattern archive from the pattern community site. The following tasks describe this process:

- The pattern author creates a pattern archive, see "Creating a pattern archive" on page 2128.
- The pattern author uploads the pattern archive to a patterns community site, see "Uploading a pattern archive" on page 2129.
- The pattern user downloads and installs the pattern archive, see "Downloading and installing a pattern archive" on page 2130.

If you want to uninstall a user-defined pattern, see "Uninstalling a pattern archive" on page 2133.

Creating a pattern archive

Package your user-defined pattern as a pattern archive so that you can distribute it to pattern users.

Before you begin

Before you can complete this task, you must have completed the following tasks:

- "Creating a pattern authoring project" on page 2069
- "Selecting the source files to use for a user-defined pattern" on page 2070
- "Building pattern plug-ins" on page 2126
- "Testing a user-defined pattern" on page 2126

About this task

When you have tested your user-defined pattern and you are satisfied with its content and quality, package it into a pattern archive so that you can distribute it to your pattern users.

You can include additional plug-in projects in your pattern archive. For example, if your user-defined pattern includes a user-defined editor, you can include the code plug-in project that contains the code for the editor in your pattern archive. If you want to include a JAR archive package in your pattern archive, you must first convert the JAR file to a plug-in. To convert a JAR file to a plug-in, complete the following steps:

1. Click **File** > **New** > **Other**.
2. Expand **Plug-in Development** and select **Plug-in from Existing JAR Archives**.
3. Click **Next** to start the **New Plug-in from Existing JAR Archives** wizard. Navigate through the wizard, completing the fields as required. Click **Finish**.

If the code in the JAR plug-in is required by a code plug-in in your user-defined pattern, you must ensure that the `MANIFEST.MF` file of your code plug-in includes a dependency to the JAR plug-in.

Procedure

To package your user-defined pattern into a pattern archive, complete the following tasks:

1. Open your pattern instance project, click the **Create Pattern** tab.
2. In the Pattern Distribution section, click **Create Pattern Archive**.

   The **"Create a Pattern Archive"** window opens.

   The **File name** defaults to the first segment of the pattern project name appended by `.patternzip`
3. To select a location, click **Browse**, and navigate to the required location.

   The **Location** is the file system location to which the pattern archive is saved. If you want to publish the pattern archive directly to a pattern community shared file system location to which you have write access, select that location.
4. Select any additional plug-in projects from your workspace that you want to include in the pattern archive.

   Only plug-in projects are displayed in the list.

5. Click **Finish**.

   A progress monitor is displayed at the bottom of the window.

   - If you click **Cancel** while the creation process is being run, the progress monitor stops and a warning message is displayed saying that the operation has stopped and the pattern archive will not be created. You can choose to restart the creation process by clicking **Finish**, or cancel the creation process by clicking **Cancel**. If the pattern archive has already been created, it is removed from the target location and its resources are deleted from the workspace. If you click **Cancel** again, the window is closed.
   - If an error occurs during the creation process, for example, the disk is full, or a write access permissions problem has occurred, an error message is displayed. You can correct the problem without exiting the window, and try again.

   If the process completes successfully, the window closes.

Results

The pattern plug-ins and features are generated in the workspace. If the plug-ins already exist in the workspace, you are asked if you want to overwrite them; if you have already created the `.doc` plug-in or your translated files, you might choose not to overwrite the plug-ins. The pattern is temporarily displayed in the **Patterns Explorer** view. A pattern archive with the extension `.patternzip` is created in the target location.

What to do next

- If you published the pattern archive directly to a pattern community shared file system location, pattern users can now download the pattern archive, see "Downloading from a shared file system" on page 2132.
- If you did not publish the pattern archive directly to a pattern community shared file system location, you can upload the pattern archive to a pattern community site to distribute the pattern archive to pattern users, see "Uploading a pattern archive" on page 2129.

Uploading a pattern archive

The pattern author can upload a pattern archive to a pattern community site so that it can be distributed to pattern users.

Before you begin

Before you can complete this task, the pattern author must have completed the following task:

- "Creating a pattern archive" on page 2128

About this task

To publish a user-defined pattern, the pattern author must upload the pattern archive to a pattern community site, which is either a pattern community website or a pattern community shared file system location. To upload to a pattern community website, the pattern author must have write access to the website.

Procedure

- To upload to a pattern community website:
  - If the pattern community website supports the upload interface, the pattern author can specify the pattern metadata, for example, category, icon, and description, and then upload the pattern archive to the pattern community website.
  - If the pattern community website does not support the upload interface, the pattern archive must be passed to the administrator of the pattern community website so that it can be published.

- To upload to a pattern community shared file system location:
  - If the pattern author has write access to the shared file location, that location can be selected when the pattern archive is created. See “Creating a pattern archive” on page 2128.
  - If the pattern author does not have write access to the shared file location, the pattern archive must be passed to the administrator of the shared file location so that it can be published.

What to do next

The pattern user can now download and install the pattern archive, see “Downloading and installing a pattern archive” on page 2130.

Downloading and installing a pattern archive

To use a user-defined pattern, download and install the pattern archive for the user-defined pattern.

Before you begin

Before you can complete this task, you must decide which user-defined pattern you want to use from a pattern community site.

About this task

Before you can update a pattern archive to a newer version of an installed pattern archive, you must uninstall the current version of the pattern archive, see “Uninstalling a pattern archive” on page 2133.

When you have chosen a user-defined pattern that you want to use from a pattern community site, download and install the pattern archive for that user-defined pattern to your local system by using one of the following methods:

- “Downloading from a pattern community website” on page 2130
- “Downloading from a pattern community website by using a helper application” on page 2131
- “Downloading from a shared file system” on page 2132

What to do next

You can now use the user-defined pattern in your projects, see “Using patterns” on page 2058.

Downloading from a pattern community website

To use a user-defined pattern in your IBM App Connect Enterprise projects, download and install the pattern archive for the user-defined pattern from a pattern community website.

Before you begin

Before you can complete this task, you must have the URL of the user-defined pattern that you want to download.

In this installation use case, only HTTP URLs that have no security are supported.

About this task

If you want to stop the download process, click **Cancel**, the pattern is not installed and the tasks are rolled back. If you click **Cancel** again, the **Download Pattern** window closes.

Procedure

1. In the **Patterns Explorer** view, click **Download**.
   The **Download and Install Pattern** window opens.

2. Type in, or copy and paste, the complete URL for the pattern archive into the **File Location** field, click **Download**.

   The progress monitor starts to run and the status line shows the individual tasks that are being performed.

Results

The new user-defined pattern is displayed in the **Patterns Explorer** view.

What to do next

You can now use the user-defined pattern in your projects. See “Using patterns” on page 2058.

Downloading from a pattern community website by using a helper application
To use a user-defined pattern in your IBM App Connect Enterprise projects, download and install the pattern archive for the user-defined pattern from a pattern community website by using a helper application.

Before you begin

Before you can complete this task, you must be on the pattern community website that contains the pattern archive that you want to download.

About this task

You can install a pattern archive directly from a pattern community website by using a helper application.

Procedure

1. Navigate to the pattern archive that you want to download.
2. Click the link for the required pattern archive.

   A new window opens. The content of the window depends on your browser, but the typical options are to either open the file or save the file.
3. Install the pattern archive:

   - Windows On Windows:

     Select the option to open the pattern archive. The **Install Pattern Archive** window opens and shows a progress monitor.

     If you have more than one IBM App Connect Enterprise Toolkit installed on your workstation, the helper application is for the IBM App Connect Enterprise Toolkit that you most recently installed. If you want to control which IBM App Connect Enterprise Toolkit is extended with your pattern, download the file to disk, follow the instructions in “Downloading from a shared file system” on page 2132, then start the IBM App Connect Enterprise Toolkit that you want to extend.

   - Linux On Linux:

     The exact steps you must complete to install the pattern archive depend on your Linux distribution and the file explorer and browser you use. Use the following steps as a guide.

     a. Save the pattern archive to your local file system. Select the option in your browser window to save the pattern archive to your local file system. Choose a location for the file and start the download.

     b. After the download completes, open the pattern archive with the **`MBPatternInstaller`** helper application. Open a file explorer and navigate to the pattern archive. Use the **Open with** menu option on the pattern archive and select `MBPatternInstaller.bin`. The MBPatternInstaller

application is located in the IBM App Connect Enterprise Toolkit installation directory, for example:

- On Windows: `C:\Program Files\IBM\ACE\12.0.n.0\tools`
- On Linux: *`install_dir`*`/ace-12.0.n.0/tools` where *install_dir* is the directory into which the installation file was uncompressed.

. The **Install Pattern Archive** window opens and shows a progress monitor.

4. Close and relaunch the IBM App Connect Enterprise Toolkit.

Results

The new user-defined pattern is displayed in the **Patterns Explorer** view.

What to do next

You can now use the user-defined pattern in your projects. See "Using patterns" on page 2058.

Downloading from a shared file system
To use a user-defined pattern in your IBM App Connect Enterprise projects, download and install the pattern archive for the user-defined pattern from a pattern community site that is a shared file system by using the file URL or by browsing for a file.

Before you begin

Before you can complete this task, you must have access to the pattern community site that contains the pattern archive that you want to download.

About this task

- If you want to download and install the pattern archive for the user-defined pattern from a pattern community website by using a helper application and you have more than one IBM App Connect Enterprise Toolkit installed on your workstation, the helper application is for the IBM App Connect Enterprise Toolkit that you most recently installed. If you want to control which IBM App Connect Enterprise Toolkit is extended with your pattern, download the file to disk, complete the following instructions, then start the IBM App Connect Enterprise Toolkit that you want to extend.
- If you want to stop the download process, click **Cancel**, the pattern is not installed and the tasks are rolled back. If you click **Cancel** again, the **Download and Install Pattern** window closes.

Procedure

In the **Patterns Explorer** view, click **Download**.

The **Download and Install Pattern** window opens.

- If you want to download the pattern by using the file URL, type in, or copy and paste, the complete URL for the pattern archive into the **File Location** field, click **Download**. The progress monitor starts to run and the status line shows the individual tasks that are being performed.
- If you want to download the pattern by browsing your local file system:
  a. Click **Browse**. The **Select The Pattern Archive To Install** window opens.
  b. Navigate to the pattern archive that you want to use, click **Open**.
  c. Click **Download**. The progress monitor starts to run and the status line shows the individual tasks that are being performed.

Results

The new user-defined pattern is displayed in the **Patterns Explorer** view.

What to do next

You can now use the user-defined pattern in your projects; see “Using patterns” on page 2058.

Uninstalling a pattern archive

Uninstall the pattern archive to remove a user-defined pattern from the Patterns Explorer view.

Before you begin

Before you can complete this task, you must have completed the following task:

- “Downloading and installing a pattern archive” on page 2130

Each user-defined pattern archive has one pattern feature, the name of which is based on the name of the main pattern plug-in. If the name of the plug-in is *com.your.company.Test*, the name of the pattern feature is *com.your.company.Test.Feature_<plug-in version>*. If translation was selected by the pattern author, the pattern archive has a second pattern feature, *com.your.company.Test.Feature_NL.<plug-in version>*. To uninstall a pattern archive you must know the feature name of the pattern archive to ensure that the correct user-defined pattern is removed.

About this task

You can uninstall a pattern archive for a user-defined pattern that you have previously installed. Uninstalling a pattern archive removes the associated user-defined pattern from the Patterns Explorer view.

Procedure

To uninstall the pattern archive:

1. Click **Help** > **About**.
2. Click the **Installation Details** button.
3. Click the **Installed Software** tab.
4. Browse to and select the pattern feature. If translation was selected by the pattern author, two pattern features exist and both must be selected.
5. Click **Uninstall**.

   The **"Uninstall"** window opens.
6. Select the pattern feature and click **Finish**. The pattern feature is uninstalled.
7. You can either restart the workspace, or click **Apply Changes**.
8. Click **OK** to close the window.

Results

The pattern archive is removed and the user-defined pattern is removed from the Patterns Explorer view.

Constructing message models

You can model a wide variety of message formats by using XML Schema files, DFDL schema files, message sets, and WebSphere Adapters.

About this task

Tip: In IBM App Connect Enterprise, *message model schema* files contained in applications, integration services, and libraries are the preferred way to model messages for most data formats. Message sets are required if you use the MRM or IDOC domains. For more information about message modeling, see “Message modeling concepts” on page 2134.

This topic area describes the concepts behind message modeling and the tasks that are involved in working with message models. If you are unfamiliar with message models, read the topics that describe

the concepts, starting with “Message modeling overview” on page 2134. These topics explain when you might want to model messages, and describe the message modeling objects that you can use, such as message model schema files, message sets, and message definition files.

The following tasks are provided for developing message models:

- “Modeling different data formats” on page 2207
- “Working with DFDL schema files” on page 2220
- “Working with XML schema files” on page 2242
- “Message Sets: Working with message sets” on page 2247
- “Applying a Quick Fix to a task list error” on page 2318
- “Importing files from the file system into the IBM App Connect Enterprise Toolkit” on page 2319

Message modeling overview

Much of the business world relies on the exchange of information between applications. This information is contained in messages that have a defined structure that is known and agreed by the sender and the receiver.

Applications typically use a combination of message formats, including those message formats that are defined by the following structures or standards:

- Comma Separated Values (CSV)
- COBOL, C, PL/I, and other language data structures
- Industry standards such as SWIFT, X12 or HL7
- XML including SOAP

You can model a wide variety of message formats so that they can be understood by IBM App Connect Enterprise message flows.

When the message format is known, the integration node can parse an incoming message bit stream and convert it into a logical message tree for manipulation by a message flow. After the message has been processed by the message flow, the integration node converts the message tree back into a message bit stream. Conversion to and from a bit stream is performed by a parser. IBM App Connect Enterprise supplies several parsers, each suited to a particular class of message formats called a domain.

The following topics together give an overview of Message modeling:

- “Message modeling concepts” on page 2134
- “Why model messages?” on page 2138
- “Message domains and parsers” on page 2146
- “The message model” on page 2147

Message modeling concepts

Message modeling is a way of predefining the message formats that are used by your applications.

Modeling your message formats is necessary for IBM App Connect Enterprise to understand some data formats, but simplifies the development of message flows regardless of the data format that you are processing. For a full description of the advantages of using message models, see “Why model messages?” on page 2138

When you model messages, you must understand the following concepts:

- Message models
- Schema files
- Domains and parsers
- New Message Model wizard

- Model editors
- Model generators
- Model validator

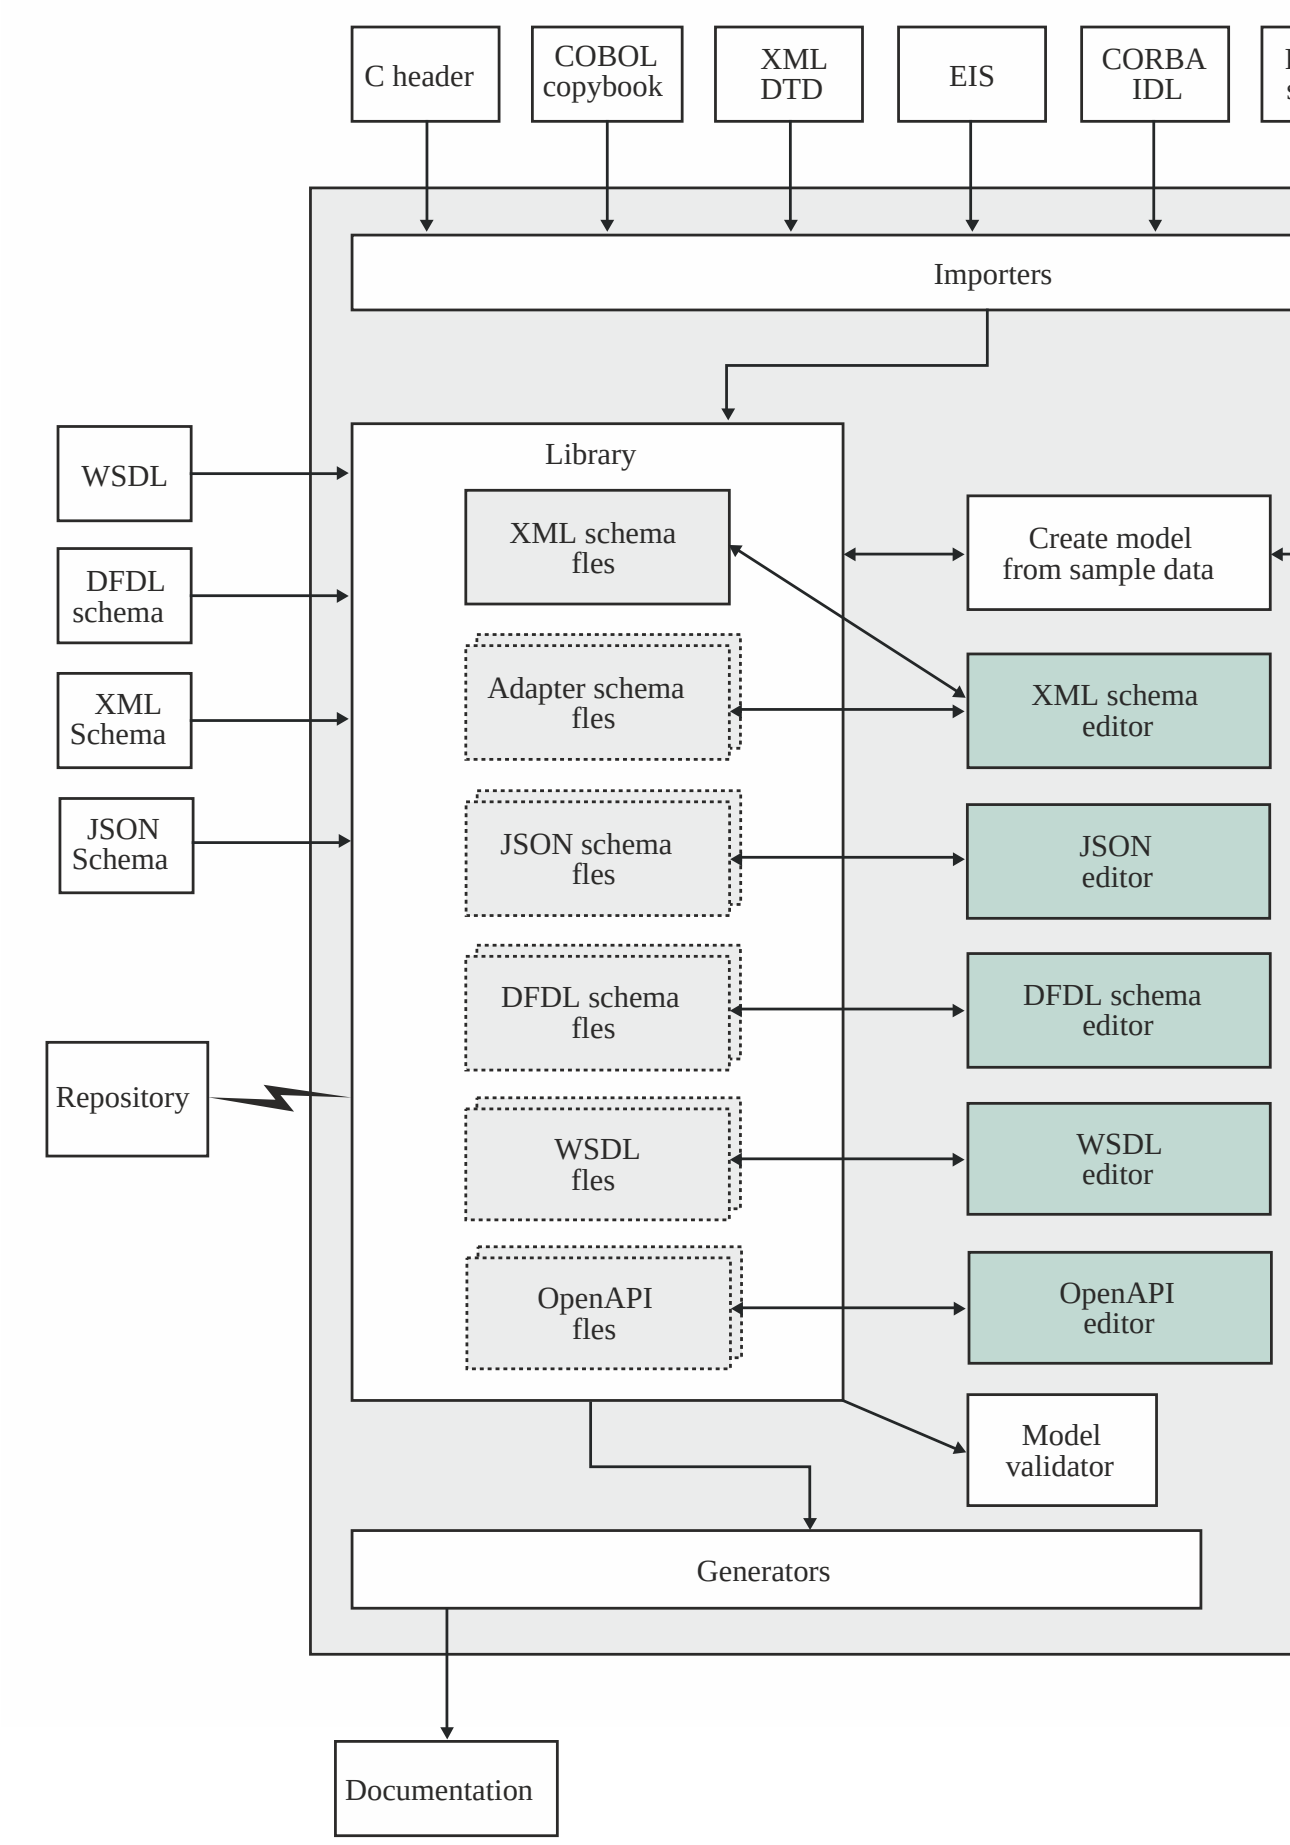
Additionally, you might have to understand the following concept:

- Message sets

Tip: A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see “Enabling message set development” on page 2248 .

For more information about applications and libraries, see “Resource management overview” on page 1942. For a description of message sets, see “Message Sets: Message sets overview” on page 2169. The remainder of this topic describes message model schema files.

The following figure shows the different types of files that comprise a message model in a library or application. It shows the formats that can be imported by using the New Message Model wizard.



C header
COBOL copybook
XML DTD
EIS
CORBA IDL
Importers
Library
WSDL
DFDL schema
XML Schema
JSON Schema
Repository
XML schema fles
Adapter schema fles
JSON schema fles
DFDL schema fles
WSDL fles
OpenAPI fles
Create model from sample data
XML schema editor
JSON editor
DFDL schema editor
WSDL editor
OpenAPI editor
Model validator
Generators
Documentation

A message model is used by IBM App Connect Enterprise to model a message format. The message models used by IBM App Connect Enterprise are based on W3C XML Schema or the JSON Schema.

The following table shows the different message formats supported by IBM App Connect Enterprise, and the message model schema file that is used to model each format:

Format	**Message model schema file**
SOAP XML	XML Schema 1.0 and WSDL 1.0
Other XML	XML Schema 1.0
CSV	Data Format Description Language 1.0
Other delimited	Data Format Description Language 1.0
Industry standard text or binary data	Data Format Description Language 1.0
Custom text or binary data	Data Format Description Language 1.0
COBOL structure	Data Format Description Language 1.0
C structure	Data Format Description Language 1.0
PL/I structure	Data Format Description Language 1.0
CORBA IDL	XML Schema 1.0
SAP	WebSphere Adapter Schema or message sets
Siebel	WebSphere Adapter Schema
PeopleSoft	WebSphere Adapter Schema
JDEdwards	WebSphere Adapter Schema
Database record	XML Schema 1.0
JSON	JSON Schema
MIME	The MIME parser does not use a model.

XML Schema 1.0 (XSD) is an open standard modeling language from the World Wide Web Consortium (W3C) that was designed to model and validate XML documents. However, it can also be used to express the logical structure of many data formats. For more information about XML Schema, see “XML Schema” on page 2148.

Data Format Description Language 1.0 (DFDL) is an open standard modeling language from the Open Grid Forum (OGF) that builds upon the features of XSD 1.0 in order to model and validate all kinds of general text and binary data. It uses standard XSD model objects to express the logical structure of the data, together with DFDL annotations to describe the text or binary physical representation. For more information about DFDL, see “Data Format Description Language (DFDL)” on page 2162.

WebSphere Adapter Schema is an IBM extension to XSD 1.0. It uses the standard XSD model objects to express the logical structure of data, along with special annotations that are used when exchanging data with EIS systems that use the WebSphere Adapters of the integration node.

JSON Schema is a vocabulary that is designed to model and validate JSON documents. For more information about JSON Schema, see json-schema.org. There are several drafts of the JSON Schema specification; currently supported drafts are draft 4 and draft 5.

When you have created an IBM App Connect Enterprise application or library, you can add existing DFDL schema, XSD schema (and any associated WSDL files), JSON schema (and any associated OpenAPI definition files), and WebSphere Adapter schema files directly into your application or library, or add them to a folder within your project. Alternatively, you can create message model schema files by any of the following methods:

- o Using the XSD, DFDL, or JSON editors in the IBM App Connect Enterprise Toolkit

- o Importing from other files (for example XML DTD or COBOL copybooks)
- o Generating a model from an example data stream (XML only)
- o Connecting direct to EIS systems or databases
- o Running a tutorial that includes a schema

When a message model schema has been created, it can be edited to refine the model. Specific editors are provided for XSD schema and DFDL schema. Adapter schemas are edited using the XSD schema editor. JSON schemas are edited using the JSON editor. WSDL and OpenAPI definition editors are also provided. For more information about the available editors and their functions, see Editors.

A message model schema consists of a number of different model objects. For more information about message model objects, see “Message model objects” on page 2148.

When your message model schemas are complete, you can use them in developing your message flow. For more information, see “Why model messages?” on page 2138

Why model messages?

IBM App Connect Enterprise supplies a range of parsers to parse and write message formats. Some message formats are self-defining and can be parsed without reference to a model. However, most message formats are not self-defining, and a parser must have access to a predefined model that describes the message, if it is to parse the message correctly.

An example of a self-defining message format is XML. In XML, the message itself contains metadata in addition to data values, and it is this metadata that enables an XML parser to understand an XML message even if no model is available. Another example of a self-defining format is JSON.

Examples of messages that do not have a self-defining message format are CSV text messages, binary messages that originate from a COBOL program, and SWIFT formatted text messages. None of these message formats contain sufficient information to enable a parser to fully understand the message. In these cases, a model is required to describe them.

Even if your messages are self-defining, and do not require modeling, message modeling has the following advantages:

- Runtime validation of messages. Without a message model, a parser cannot check whether input and output messages have the correct structure and data values.
- Enhanced parsing of XML messages. Although XML is self-defining, all data values are treated as strings if a message model is not used. If a message model is used, the parser is provided with the data type of data values, and can cast the data accordingly.
- Improved productivity when writing ESQL. When you are creating ESQL programs for IBM App Connect Enterprise message flows, the ESQL editor can use message models to provide code completion assistance.
- Drag-and-drop operations on message maps. When you are creating message maps for IBM App Connect Enterprise message flows, the Graphical Data Mapping editor uses the message model to populate its source and target views.
- Reuse of message models, in whole or in part, by creating additional messages that are based on existing messages.
- Generation of documentation.
- Provision of version control and access control for message models by storing them in a central repository.

To make full use of the facilities that are offered by IBM App Connect Enterprise, model your message formats.

To speed up the creation of message models, importers are provided to read metadata such as C header files, COBOL copybooks, and EIS metadata, and to create message models from that metadata. Additionally, predefined models are available for common industry standard message formats such as SWIFT, EDIFACT, X12, FIX, HL7, and TLOG.

Ways to create message models

You can create a message model to model your data format.

You can create a message model by using the following methods:

- Importing an application message format that is described by an XML Schema, XML DTD, JSON Schema, C structure, COBOL structure, WSDL definition, or OpenAPI definition.
- By creating an empty message model file, then creating your message by using the editors provided in the IBM App Connect Enterprise Toolkit.
- By using the **Adapter Connection** wizard to import EIS metadata.
- By creating a populated model file from example message data.

Message model schema files

If your message models are to be stored as message model schema files, use the **New Message Model** wizard. If you already have XML schema files, JSON schema files, WSDL files, OpenAPI files, or DFDL schema files, you can import them directly into an application or library.

Message sets

If your message models are to be stored in message sets, use the **New Message Definition File** or **New Message Definition File From** wizards.

Additionally, you can import application message formats by using the **mqsicreatemsgdefs** or **mqsicreatemsgdefsfromwsdl** command-line utilities.

The **mqsicreatemsgdefs** command has a bulk import capability, but **mqsicreatemsgdefsfromwsdl** imports only one WSDL definition at a time.

Importing from other model representations to create message definitions

Importing other model representations is a convenient way to create an IBM App Connect Enterprise message model.

You can import the following message formats to create message sets:

- XML schema files
- XML DTD files
- JSON schema files
- C header files
- COBOL copybooks
- WSDL definitions
- EIS metadata
- Database records
- OpenAPI definitions

When you import one of these formats, a new message model is created to represent your message format. You can choose the name of the message model; if it already exists, the content is deleted and re-created as part of the import operation.

The new message model that is created can consist of both logical and physical information.

To find out which wizards to use to import message formats, see "Ways to create message models" on page 2139.

Tip: The following information is relevant only if you are using a message set to contain your message models.

You can also import C header files, COBOL copybooks, XML DTD files, or XML schema files by using the **mqsicreatemsgdefs** command-line utility. The **mqsicreatemsgdefs** command allows you to import

several middle-format files in a single operation, and allows you to create a message set (based on an existing message set) into which the message definition files are placed.

WSDL definitions can be imported by using the **mqsicreatemsgdefsfromwsdl** command-line utility. This utility imports only one WSDL definition at a time.

Message sets: Importing from XML Schemas to create message definitions

You can populate a message set with message definitions by importing XML Schema files, by using the **New Message Definition File From XML Schema file** wizard, the **Start from WSDL and/or XSD files** quick start wizard or the **mqsicreatemsgdefs** command.

Tip: This topic is relevant only if you are using a message set to contain your message models. If you are using an application or library, you can use one of the following methods to import XML schema files:

- Use the **New Message Model** wizard.
- Drop your XML schema files directly into your project; see "Creating an XML schema file by using the New Message Model wizard" on page 2244.

Each XML Schema file that you import results in a new message definition file within the message set. The root name of the message definition file defaults to the root name of the XML Schema file, but the **New Message Definition File From XML Schema file** wizard allows you to choose a different root file name.

If the message definition file already exists, you must have enabled overwriting to occur for the import to proceed, in which case the existing content is deleted and re-created.

The namespace to which the message definition file created belongs depends on whether namespaces have been enabled for the message set.

- If namespaces have been enabled, the message definition file belongs to the target namespace of the XML Schema file that is imported.
- If namespaces have not been enabled for the message set, the message definition file belongs to the `noTarget` XML namespace irrespective of the target namespace of the imported XML Schema file and therefore is contained in the `(default)` location in your workspace.

A report file is created during the import operation. This is located by default in the `log` folder of the message set. By default it takes the name of the message definition file, with `.report.txt` appended.

Import by using the New Message Definition File From XML Schema file wizard

When you import by using the **New Message Definition File From XML Schema file** wizard, you can specify which of the global elements or global complex types within the imported XML Schema file are to be messages within the message definition file.

You can import only one XML Schema file with each import operation. If your XML Schema file references other XML Schema files, with import or include elements, these XML Schema files must be imported into the same message set by using a separate import operation.

Import by using the command-line

When you import by using the command line you have the option of either creating no messages or creating a message for each global element and global complex type within the imported XML Schema file. The import operation creates a message and corresponding global element in the message definition file for each global element you specify. If you do not specify that messages are to be created, you must create them manually using the message definition editor after the import has completed.

You can import several XML Schema files in each import operation.

Physical information

In addition to creating logical information, the import can also create physical information. If the message set contains any XML wire format physical formats, the physical format properties for *all* XML Wire Format layers is populated. If the message set does not contain any XML physical formats, only logical information is created. Also, if you import from the command line, only logical information is created in

the new message set by default. If you want physical information created as well, see "Message Sets: Importing from the command line" on page 2301 for details.

MRM CWF and TDS physical format properties are *not* populated and so take default values.

If you have one or more CWF or TDS layers, the import can cause entries in the task list, warning you that certain CWF or TDS properties must be set if the XML structures you have imported are to appear in a CWF or TDS message.

If the CWF or TDS physical formats are not applicable to your XML structures, you can ignore these task list entries because they are just warnings, they do not prevent your model being generated in another form; for example, as a message dictionary.

Command-line invocation

The **mqsicreatemsgdefs** command-line utility allows you to import several XML Schema files in a single operation. All the XML Schema files must be in single directory, and the directory location must be passed as a parameter to the utility.

When you import into a message set for which namespaces are not enabled, the action to take for unsupported constructs can be specified by using an XML options file. This must contain an XML element called <XSD_NO_NS> that holds a set of information that applies to all XML Schema files that are imported during an invocation of the utility. A default XML options file, called `mqsicreatemsgdefs.xml`, is supplied. If you want to apply different sets of information to different XML Schema files, you must create multiple XML files and run the utility multiple times.

When you are importing into a message set for which namespaces are not enabled, there are two other options that you can specify in the <XSD_NO_NS> element in the XML options file:

- The prefix to use for the `http://www.w3.org/2001/XMLSchema-instance` namespace; the default is `xsi`.
- Additional namespace URI and prefix pairs.

The **mqsicreatemsgdefs** utility also allows you to create a message set into which the message definition files are placed, as part of the import operation. You can also choose to base the message set created on an existing message set. This facility enables you to prepare an empty message set that contains an XML physical format and pre-populated message set level XML properties, which are then copied into the message set that is created by the import.

Further information about XML Schema

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

Message sets: Importing from IBM supplied messages to create message definitions
You can add messages to a message set by using the **New Message Definition File From IBM supplied messages** wizard to import IBM supplied messages.

Tip: This topic is relevant only if you are using a message set to contain your message models. If you are using an application or library, use the **New Message Model** wizard, and select the data format with which you are working.

Each IBM supplied message that you import results in a new message definition file in the message set. The name of the message definition file defaults to the name of the IBM supplied message, but you can use the **New Message Definition File From IBM supplied messages** wizard to choose a different file name.

For information about what IBM supplied messages can be imported, see "Message Sets: Importing from the command line" on page 2301.

When you import message by using the **New Message Definition File From IBM supplied messages** wizard, you can specify only one IBM supplied message definition for each import operation.

If the message definition file already exists, you must have permitted overwriting to occur for the import to proceed, in which case the existing content is deleted and re-created.

A report file is generated during the import operation that allows you to examine what occurred during the import process and check any errors that resulted.

Message sets: Importing from DTDs to create message definitions
You can populate a message set with message definitions by importing DTD files, by using either the **New Message Definition File From XML DTD file** wizard .

Tip: This topic is relevant only if you are using a message set to contain your message models. If you are using an application or library, use the **New Message Model** wizard, select **Other XML** as the data format that you are working with, then select **Create an XML schema by importing an XML DTD**.

Each XML DTD file that you import results in a new message definition file within the message set. The root name of the message definition file defaults to the root name of the XML DTD file, but the **New Message Definition File From XML DTD file** wizard allows you to choose a different root file name.

If the message definition file exists, you must have permitted overwriting to occur for the import to proceed, in which case the existing content is deleted and re-created.

All message definition files that are created as a result of DTD file import belong to the `noTarget` XML namespace and so are contained in the `(default)` location in your workspace.

A report file is created during the import operation, by default in the `log` folder of the message set. By default, it takes the name of the message definition file, with `.report.txt` appended.

Import by using the New Message Definition File From XML DTD file wizard

When you import by using the **"New Message Definition File From XML DTD file"** wizard, you can specify which of the elements within the imported XML DTD file are to be messages within the message definition file.

You can import only one XML DTD file with each import operation.

Import by using the command line

When you import by using the command line you have the option of either creating no messages or creating a message for each element within the imported XML DTD file. The import operation creates a message and a corresponding element in the message definition file for each element that you specify. If you do not specify that messages are to be created, you must create them manually using the message definition editor after the import has completed.

You can import several XML DTD files in each import operation.

Physical information

In addition to creating logical information, the import can also create physical information. If the message set contains any XML wire format physical formats, the physical format properties for *all* XML Wire Format layers is populated. If the message set does not contain any XML physical formats, only logical information is created. Also, if you import from the command line, only logical information is created in the new message set by default. If you want physical information created as well, see “Message Sets: Importing from the command line” on page 2301 for details.

MRM CWF and TDS physical format properties are *not* populated and therefore take default values.

If you have one or more CWF or TDS layers, the import can cause entries in the task list, warning you that certain CWF or TDS properties must be set if the XML structures that you have imported are to appear in a CWF or TDS message.

If the CWF or TDS physical formats are not applicable to your XML structures, you can ignore these task list entries because they are just warnings; they do not prevent your model being generated in another form, such as a message dictionary.

Command-line invocation

The **mqsicreatemsgdefs** command-line utility allows you to import several XML DTD files in a single operation. All the XML DTD files must be in single directory, and the directory location must be passed as a parameter to the utility.

The **mqsicreatemsgdefs** utility also allows you to create a message set into which the message definition files are placed, as part of the import operation. You can also choose to base the message set created on an existing message set. This facility enables you to prepare an empty message set that contains an XML physical format and pre-populated message set level XML properties, which are then copied into the message set that is created by the import.

Further information about XML DTDs

For details about XML DTDs, see the World Wide Web Consortium (W3C) website.

Message sets: Importing from C header files to create message definitions
Create a message definition file from a C header file for use in the MRM and IDOC domains.

Tip: This topic is relevant only if you are using message definition files. As an alternative, consider the newer **New Message Model** wizard to create a schema for use in the DFDL domain; see Creating a DFDL schema file from a C header file.

You can populate your message set with message definitions by importing C header files, by using either the **New Message Definition File From C header file** wizard or the **mqsicreatemsgdefs** command.

Each C header file that you import results in a new message definition file. The root name of the message definition file defaults to the root name of the C header file, but the **"New Message Definition File From C header file"** wizard allows you to choose a different root file name.

If the message definition file already exists, you must have permitted overwriting to occur for the import to proceed, in which case the existing content is deleted and re-created.

By default, all message definition files that are created as a result of an import from a C header file belong to the `noTarget` XML namespace and therefore reside in the `(default)` location in your workspace. This default namespace can be overridden by specifying a target namespace. See "Namespaces with non-XML messages" on page 2160 for reasons why you might want to do this.

In your C header file there are typically one or more C structures. You can select which of these structures to import. The import operation then imports those structures, plus any others that they require. All imported structures are converted into the equivalent elements, groups, and types in the message definition file.

You can also specify which of the selected structures are to be messages in the message definition file. The import operation creates a message and a corresponding global element in the message definition file for each structure that you specify. If you do not specify that messages are to be created, you must create them manually using the Message Definition editor after the import has completed.

If you import by using the **"New Message Definition File From C header file"** wizard you can import only one C header file with each import operation. But, if you import by using the command-line utility, you can import several C header files in each import operation.

If your C header file needs any other header files for a successful compilation, you must provide these and specify their location, because a compilation of your header file is performed as part of the import operation.

A report file is created during the import operation. This is located by default in the `log` folder of the message set. By default, it takes the name of the message definition file, with `.report.txt` appended.

Physical information

In addition to creating logical information, the import can also create physical information.

If the message set contains any Custom Wire Format (CWF) physical formats, the physical format properties for all CWF layers are populated.

If the message set does not contain any CWF physical formats, only logical information is created. Also, if you import from the command line, only logical information is created in the new message set by default.

XML and TDS physical format properties are *not* populated and so take default values.

If you have one or more TDS layers, the import can cause entries in the task list, warning you that certain TDS properties must be set if the C structures you have imported were to appear in a TDS message.

If the TDS physical format is not applicable to your C structures, you can ignore these task list entries because they are just warnings; they do not prevent your model being generated in another form, such as a message dictionary.

Because physical information is created, the application target environment (platform and compiler) is important because it governs the way that, for example, integers appear in the message. You can specify environment-specific information as part of the import operation, and the necessary properties are set accordingly. There is a range of environments supported; if your environment is not shown, choose the closest match and review the created physical information by using the Message Definition Editor after the import has completed.

Command-line invocation

The **mqsicreatemsgdefs** command-line utility allows you to import several C header files in a single operation. All the C header files must be placed in the same directory and the directory location passed as a parameter to the utility.

You provide the necessary environment-specific information, and include file location information by using an XML file. This must contain an XML element called <C> which holds one set of information that applies to all C header files imported during an invocation of the utility. A default XML file called `mqsicreatemsgdefs.xml` is supplied. If you want to apply different sets of information to different header files, you must create multiple XML files and run the utility multiple times.

The **mqsicreatemsgdefs** utility also allows you to create message set into which the message definition files are placed, as part of the import operation. You can also choose to base this new message set on an existing message set. This facility enables you to prepare an empty message set containing a CWF physical format and message set level CWF properties already populated, which then gets copied into the message set created by the import.

Message sets: Importing from COBOL copybooks to create message definitions
You can populate your message set with message definitions by importing COBOL copybook files, by using the **"New Message Definition File From COBOL file"** wizard or the **mqsicreatemsgdefs** command.

Tip: This topic is relevant only if you are using a message set to contain your message models. If you are using an application or library, use the **New Message Model** wizard, select **COBOL** as the data format that you are working with, then select **Create a DFDL schema by importing a COBOL copybook or program**; see Creating a DFDL schema file by using the New Message Model wizard.

Each COBOL copybook that you import results in a new message definition file. The root name of the message definition file defaults to the root name of the COBOL copybook file, but the **"New Message Definition File From COBOL file"** wizard allows you to choose a different root file name.

If the message definition file already exists, you must have permitted overwriting to occur for the import to proceed, in which case the existing content is deleted and re-created.

By default, all message definition files that are created as a result of COBOL copybook file import belong to the `noTarget` XML namespace and therefore reside in the `(default)` location in your workspace. This default namespace can be overridden by specifying a target namespace. See "Namespaces with non-XML messages" on page 2160 for reasons why you might want to do this.

In your COBOL copybook file there are typically one or more level 01 structures. You can select which of these structures to import. The import operation then imports those structures, plus any others that they require. All imported structures are converted into the equivalent elements, groups, and types in the message definition file.

You can also specify which of the selected level 01 structures are to be messages in the message definition file. The import operation creates a message and corresponding global element in the message definition file for each structure that you specify. If you do not specify that messages are to be created, you must create them manually using the Message Definition Editor after the import has completed.

If you import by using the **"New Message Definition File From COBOL file"** wizard, you can import only one COBOL copybook file with each import operation. If you use the command-line utility, you can import several COBOL copybook files in each import operation.

If your COBOL copybook file needs any other copybooks in order to compile successfully, you must provide these in the same directory, because a compilation of your copybook is performed as part of the import operation.

A report file is created during the import operation. This is located by default in the `log` folder of the message set. By default it takes the name of the message definition file, with `.report.txt` appended.

The copybook must not contain field names that are COBOL reserved keywords.

Physical information

In addition to creating logical information, the import can also create physical information. If the message set contains any Custom Wire Format (CWF) physical formats, the physical format properties for all CWF layers are populated. If the message set does not contain any CWF physical formats, only logical information is created. If you import from the command line, only logical information is created in the new message set by default. If you want physical information created as well, see "Message Sets: Importing from the command line" on page 2301 for details.

XML and TDS physical format properties are *not* populated and therefore take default values.

If you have one or more TDS layers, the import can cause entries in the task list, warning you that certain TDS properties must be set if the COBOL structures that you have imported were to appear in a TDS message.

If the TDS physical format is not applicable to your COBOL structures, you can ignore these task list entries because they are just warnings, they do not prevent your model being generated in another form, such as a message dictionary.

Because physical information is created, the application target environment (platform and compiler) is important because it governs the way that, for example, integers appear in the message. You can specify environment-specific information as part of the import operation, and the necessary properties are set accordingly. There is a range of environments supported; if your environment is not shown, choose the closest match and review the created physical information by using the Message Definition Editor after the import has completed.

Command-line invocation

The **`mqsicreatemsgdefs`** command-line utility allows you to import several COBOL files in a single operation. All the COBOL copybook files must be in single directory, and the directory location passed as a parameter to the utility.

You provide the necessary environment-specific information by using an XML file. This must contain an XML element called <COBOL> that holds one set of environment-specific information that applies to all COBOL copybook files that are imported during an invocation of the utility. A default XML file called `mqsicreatemsgdefs.xml` is supplied. If you want to apply different sets of information to different copybooks, you must create multiple XML files and run the utility multiple times.

The **`mqsicreatemsgdefs`** utility also allows you to create message set into which the message definition files are placed, as part of the import operation. You can also choose to base the message set created on an existing message set. This facility enables you to prepare an empty message set that contains a CWF physical format and pre-populated message set level CWF properties, which are then copied into the message set that is created by the import.

Message sets: Importing WSDL files to create message definitions
Import WSDL files by using the **New Message Definition File From WSDL file** wizard, the **Start from WSDL and/or XSD files** Quick Start wizard, or the **mqsicreatemsgdefsfromwsdl** command.

Tip: This topic is relevant only if you are using a message set to contain your message models. If you are using an application or library, you can import your WSDL files, and any referenced XML schema files, directly into the application or library.

Each WSDL file that you import results in one or more new message definition files within the message set. A new message definition file is created for each namespace that is defined for the message set. The name of the message definition file defaults to the name of the WSDL file, but the **New Message Definition File From WSDL file** wizard allows you to choose a different file name.

If the message definition file exists, you must have permitted overwriting to occur for the import to proceed. The existing content is deleted and re-created.

The message set that you are importing the WSDL file into must be namespace-enabled. If it uses the MRM domain, it must have an XML physical format so that the message set is suitable for the runtime parsing of XML messages such as SOAP.

Use the report generated during the import operation to see what happened and to check any errors.

You specify a single WSDL definition for each import operation. If the WSDL definition consists of a hierarchy of files, you must supply the name of the file that contains the WSDL service or binding definitions. The WSDL definition that is imported must contain one or more WSDL bindings for the import to proceed. You can then select multiple bindings from the WSDL definition to define messages to model in the message set.

Importing by using the New Message Definition File wizard

When you import by using the New Message Definition File wizard, you can specify only one WSDL definition for each import operation. A WSDL definition can be held as one or more WSDL files, which are all imported as a result of importing the definition. The WSDL definition that is imported must contain one or more WSDL bindings for the import to proceed.

Importing by using the command line

The WSDL command-line importer (**mqsicreatemsgdefsfromwsdl**) can create a message set or update an existing one. If the message set project exists, it must be namespace-enabled and have an XML physical format layer. If the project does not exist, a new namespace-enabled project is created. If the import succeeds, new message definition files are added to the message set.

The **mqsicreatemsgdefsfromwsdl** command allows you to import one WSDL definition in a single operation.

The **mqsicreatemsgdefsfromwsdl** command copies the WSDL files it needs into the workspace before the import runs. These files are the top-level WSDL files and any imports are resolved by using an absolute or relative location. The files are copied under the specified message set in a folder called `importFiles`. They are not removed after the import; the user can later update or run validation on them in the IBM App Connect Enterprise Toolkit.

Physical information

An XML physical format layer is required for the MRM domain, and must be added to an existing message set before importing the WSDL definition.

Message domains and parsers

IBM App Connect Enterprise supplies a range of parsers to parse and write messages in different formats.

A parser is called when the bit stream that represents an input message must be converted to the format that is used internally by the integration node; this process is known as parsing. For more information

about the logical message tree structure created by parsing a message, see “Logical tree (message assembly)” on page 501.

A serializer is called when a logical tree structure must be converted into a bit stream; this process is known as serializing.

Each parser is suited to a particular class of messages, known as a message domain. The following list contains some examples of the message domains used in IBM App Connect Enterprise:

- XMLNSC - for XML documents
- DFDL - for general text or binary data streams including industry standards
- JSON - for JSON documents
- DataObject - for data without a stream representation

For more information, including the full list of parsers that are supplied with IBM App Connect Enterprise, see “Parsers” on page 520.

The message model

A message model is used by IBM App Connect Enterprise to model a message format. The message models used by IBM App Connect Enterprise are all based on either the World Wide Web Consortium (W3C) XML Schema 1.0 (XSD) or the JSON Schema, a standard from json-schema.org.

XML Schema is an international standard that defines a language for describing the structure of XML documents. It is suited to describing XML messages that flow between business applications, and it is widely used in the business community for this purpose. IBM App Connect Enterprise uses models that are based on XML Schema to describe the structure of XML messages, as well as messages in a number of other message formats.

JSON Schema defines a language for describing the structure of JSON documents. It is suited to describing JSON messages that flow between business applications, and it is widely used in the business community for this purpose. IBM App Connect Enterprise uses models that are based on JSON Schema to describe the structure of JSON messages. Draft 4 and draft 5 of JSON Schema are supported, including the extensions for OpenAPI V2.0 and V3.0.

Data Format Description Language 1.0 (DFDL) is an open standard modeling language from the Open Grid Forum (OGF) that builds upon the features of XML Schema 1.0 in order to model and validate all kinds of general text and binary data. It uses standard XSD model objects to describe the logical structure of data, together with DFDL annotations that describe the physical text or binary representation of data. IBM App Connect Enterprise uses DFDL schema files to describe text and binary data, including industry standard formats.

WebSphere Adapter Schema is an IBM extension to XML Schema 1.0. It uses standard XSD model objects to express the logical structure of data, together with IBM annotations that are used when exchanging data with EIS systems that use the WebSphere Adapters of the integration node.

Message definition files within message sets also use standard XSD model objects to express the logical structure of data, together with IBM annotations that describe the physical representation.

Tip: A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see “Enabling message set development” on page 2248 .

To understand the different ways that you create and populate message model schema files, see “Ways to create message models” on page 2139.

XML Schema

XML Schema is an international standard from the World Wide Web Consortium (W3C) that defines a language for describing the structure of XML documents.

The XML Schema language is ideally suited to describing XML messages that flow between business applications, and it is widely used in the business community for this purpose.

IBM App Connect Enterprise uses XML Schema 1.0 to describe the logical structure of XML messages. At a simple level, the types and elements in the message are modeled by using XML Schema types and elements. However, when the need arises, all of the advanced modeling features of XML Schema are available for modeling messages.

IBM App Connect Enterprise defines some extensions of XML Schema, documented in "XML Schema extensions" on page 2148 and "Message Sets: XML Schema extensions in message sets" on page 2174. It also defines some restrictions, documented in "Message Sets: XML Schema restrictions in message sets" on page 2174.

Further information about XML Schema

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

XML Schema extensions
IBM App Connect Enterprise provides some additional facilities that are not specified in the XML Schema 1.0 specification.

Messages

A message is a global element that represents an entire message (rather than a structure within a message). Within an XML Schema file, a message is represented by a special global element that carries the extra information required by IBM App Connect Enterprise.

Further information about XML Schema

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

Message model objects
An introduction to the objects that make up a message model. Message model objects are defined by XML Schema 1.0, except for Message which is an IBM App Connect Enterprise extension to XML Schema.

Message
A *message* describes the structure and content of a set of data that is exchanged between applications that send and receive the data. A *message* is a special complex element.

Simple element
A *simple element* describes one or more named data fields in a message. It is based on a *simple type* (for example, string, integer or float). A simple element can repeat, and it can define a default or a fixed value.

Simple type
A *simple type* describes a class of data within a message. It describes the type of data (for example, string, integer or float) and it can have value constraints which place limits on the values of any simple elements based on that simple type.

Complex element
A *complex element* describes a named complex structure within the message. The content of a complex element is defined by a *complex type*. A complex element can repeat.

Complex type
A *complex type* describes a complex structure within a message. It contains *elements* (simple or complex), *attributes* (if the data is XML), and *groups* that are organized into a tree-like hierarchy.

Group
A *group* describes a list of elements with information about how those elements can appear in a message. Groups can be ordered (sequence), unordered (all), or selective (choice). A group can repeat.

Attribute
An `attribute` describes an XML attribute. Attributes are similar to simple elements, but they require special treatment when used with XML messages. In messages that are not XML messages, attributes are not used.

Global and local objects

Most objects in the message model can be either global or local. A global object must have a unique name, which is used to refer to the object from one or more places in the message model. Local objects are defined and used in only one place in the message model.

Make objects local unless they must be used in more than one place. This reduces the probability of name clashes among the global objects in the message model, and makes the message set easier to work with.

Properties of message model objects

All message model objects have properties. The properties fall into three categories:

Logical
The logical properties of an object are defined by XML Schema. They relate to the format-independent description of the object called the 'logical model'. Logical properties describe *what* data the object contains without saying anything about *how* it is written down.

Physical
If the message model is for a data format that is not XML, additional physical properties are provided for an object that describe how the object is written down. These properties control the parsing and writing of the object. If the message model is a DFDL schema, then the properties are defined by the DFDL 1.0 specification. If the message model is in a message set, then the properties are an IBM proprietary set that is understood by the MRM domain and parser.

Documentation
This field is present for all message model objects. It provides a standard place for any description of the object that you might require. Text entered here does not affect the processing of messages in any way.

Message model objects: messages
A *message* describes the structure and content of a set of data that is passed from one application to another.

A message consists of elements that are organized into a logical structure agreed by the sending and receiving applications. This logical structure can be modeled so that message data can be parsed into a logical tree and manipulated easily by the integration node.

In the message model, a message is always based on a global element. The complex type of a global element describes the contents of the global element, and therefore describes all of the content of the message.

Multipart messages

If necessary, a message can contain other messages, and is necessary for modeling certain large and complex messaging standards such as SWIFT and EDIFACT. Such a message is known as a *multipart message*. The contained messages are known as *embedded messages*.

Message identification

Messages are identified by their name. In a message set only, a message can also be identified by an alias. The alias is an optional user-specified string that identifies the (multipart) message. The name and alias of a message must be unique within a message set.

Message model objects: elements

An *element* is a named piece of information (a field) within a message, with a meaning that is agreed by the applications that create and process the message.

An element has a specific meaning that is agreed by the applications that create and process the message. For example, a message might include a string that your applications have agreed is a 'Customer Name'. An element is always based on a type, either simple or complex.

An element:

- Has a business meaning.
- Is an instantiation of a simple or complex type.
- Can be accessed by name from ESQL, Java, or a Map.
- Is further defined by its type; for example, the type defines the range of values that an element can have.
- Can be defined globally or locally.

Simple and complex elements

Elements can be simple or complex. A simple element is a single, named piece of information such as 'Age' or 'Customer Name'. A simple element is based on a *simple type* that defines its content.

A complex element is a named structure that contains other elements. A complex element named 'Customer Details' might contain the simple elements 'Age' and 'Customer Name'. A complex element can also contain other complex elements. A complex element is based on a *complex type* that defines its content and structure.

Global and local elements

Elements can be global or local. A *global element* can be used in several different messages, or even in several places within the same message. It must be given a unique name by which it can be referenced by an *element reference*. A *local element* is defined in one position within one complex type or group, and is not available for reuse elsewhere in the message model.

Optional and repeating elements

Elements can be defined as optional, mandatory, and repeating, by using the properties `Min Occurs` and `Max Occurs`. For further information, see “Cardinality: optional, required, and repeating elements” on page 2157.

Default and fixed values

An element can be given a default value, so that if no value is supplied by the message, the default value is used. Alternatively, a fixed value can be defined, and the element always takes that value. The precise use of default and fixed values is dependent on the message domain.

Value constraints

The value of an element can be constrained by using *value constraints* which define the range of legal values for the element. The value constraints are associated with the simple type on which the element is based. For further information, see “Message model objects: simple types” on page 2152. The XML Schema term for a value constraint is a *facet*.

Defining substitution groups

If you are modeling XML messages, an element can be marked as a valid substitute for another element by using the substitution group property on the element. In this way, groups of elements can be assembled where any of the elements in the group can substitute for one element, the *head* element. For further information, see “Substitution groups in the message model” on page 2158.

Message model objects: types
Types describe the data content of elements.

Simple types describe simple elements with data types such as string, integer, or dateTime.

Complex types describe complex elements - elements that contain a hierarchy of other elements.

For more information, see:

- "Message model objects: simple types" on page 2152
- "Message model objects: complex types" on page 2151
- "Message model objects: type inheritance" on page 2153

Message model objects: complex types
A *complex type* describes the structure of one or more complex elements.

Complex types are an essential part of every message model because they define the logical structure of the messages and elements in the model.

What is a complex type for?

Complex types define the structure of the messages and elements in the message model. By combining elements, attributes, groups, and wildcards, almost any message structure can be modeled.

Contents of a complex type

Elements

Most complex types contain some elements, and some contain a large hierarchy of complex elements. The elements within a complex type are always contained within a group. This group can be local to the complex type, in which case the Message Definition Editor hides it from view.

Alternatively, the group that contains the elements can be a global group, and this group defines the element content, the composition, and the content validation for the complex type.

If a complex type is derived from a simple type, it cannot contain any element content.

Attributes
If you are modeling XML messages, your complex types can contain attributes. The attributes for a complex type can be local or global, and they can be contained within an attribute group.

Groups
Groups enable sets of elements to be included in a complex type. The members of the group are included as peers of the other elements. For more information about their use, see "Message model objects: groups" on page 2155.

Wildcards
If you are modeling XML messages, your complex types can contain wildcard elements. Wildcard elements enable unmodeled elements to be present in the complex type. Any such, elements must be present within the message at the same position as the wildcard. Complex types can also contain wildcard attributes. Wildcard attribute enable unmodeled attributes to be present within any elements that are based on the complex type.

Global and local complex types

Complex types can be global or local. A global complex type can be used as the basis for more than one complex element. It must be given a unique name by which it can be referenced. A local complex type is associated with a single complex element, and is not available for reuse elsewhere in the message model. Local types do not have a name, and are sometimes referred to as anonymous types.

Composition

The composition of a complex type describes how the members of the type are organized. For more information, see "Message model objects: groups" on page 2155.

Substitution settings

A complex type has parameters that control whether other types can be derived from it (final) and whether other types can substitute for it (block). For more information, see "Substitution groups in the message model" on page 2158 and "Message model objects: type inheritance" on page 2153.

Message model objects: simple types
A *simple type* is an abstract definition of an item of data such as a number, a string, or a date.

The purpose of a simple type is to define the content of one or more simple elements. Simple types (and any elements that are based on simple types) cannot contain attributes or child elements. Simple types stand in contrast to complex types, which define the structure of an element, but typically do not define any simple data.

Global and local simple types

Simple types can be global or local. A global simple type can be used as the basis for more than one element. It must be given a unique name by which it can be referenced. A local simple type is associated with a single element, and is not available for reuse elsewhere in the message model. Local types do not have a name and are sometimes referred to as anonymous types.

Variations of simple types

Built-in

XML Schema defines many simple types for you to use, covering all the standard data types such as strings, integers, decimals, and floats.

Restriction

You can define your own simple types by deriving from another simple type (the base type) by restriction. A restriction type can have value constraints applied to it.

A restriction type can derive from a built-in simple type or a restriction simple type.

List

For XML messages only, a list type is a way of rendering a repeating simple value in XML. The notation is more compact than the notation for a repeating element, and offers a way to have multi-valued attributes.

A list type can be based on a union type (introduced later in this section). This can describe a space-separated list of items in which each item can be based on any of the simple types in the union.

A list of lists is not legal. The item type of a list cannot be a list itself, or derived at any level from another list type.

A list type can have the facets of minLength, maxLength, and length applied to it. These facets restrict the number of items in the list. To restrict the values of each item in the list, facets must be applied to the item type and not to the list itself. The message definition editor provides additional support for enumeration and pattern facets directly on a List type, to enable the import of any schema that uses them, but issues a warning that enumeration and pattern facets are ignored by the integration node.

Union

A union type is a union of two or more other simple types.

A union type enables a value to conform to any one of several different simple types. The simple types that comprise a union type are known as its member types. There is no upper limit on how many member types can exist, but there must be at least one. A member type can be defined as a built-in simple type, a user defined simple type, or a local simple type defined anonymously within the union type.

A union type can also include list, union, and restricted simple types, among its members.

Value constraints

Value constraints are known as facets by XML Schema. Any value constraints that are applied to a derived type must further restrict the base type. It is not valid for a derived type to weaken or remove a value constraint that its base type has defined. If no value constraints are applied to the derived type, the derived type is almost identical to its base type, but it is treated as a restriction of the base type in situations where that is relevant (type inheritance and element substitution).

Message model objects: type inheritance
The XML Schema language allows a type definition to be based on another type definition. In this way, a hierarchy of types can be constructed.

This topic outlines the concepts of *type inheritance*, and highlights some important issues relating to substitution.

A full discussion of XML Schema type inheritance can be found on the World Wide Web Consortium (W3C) website, or in numerous books about XML Schema.

Restriction and extension

A type is a *restriction* of its base type, if elements of the derived type have a smaller range of valid values (or valid type members) than elements of the base type.

- For example, a restriction of a complex type might reduce the number of occurrences of one of its type members, or might omit that type member completely.
- Similarly, a restriction of a simple type might lower the `Max Inclusive` facet value, or raise the `Min Inclusive` facet value.

A type is an *extension* of its base type if elements of the derived type have a wider range of valid values (or valid type members) than elements of the base type.

- For example, an extension of a complex type might add type members that were not present in the base type, or might allow a type member to repeat.
- Similarly, an extension of a simple type must *always* be a complex type that is based on the simple type; you cannot extend a simple type by widening its range of valid values.

Special rules apply to the derivation of simple types. A simple type cannot extend another simple type. This ensures that restrictions that are imposed by a simple type cannot be removed by deriving another simple type from it.

However, a complex type can extend a simple type. This does not affect the range of valid values of the simple type, but it does allow attributes to be added. The result of extending a simple type is always a complex type that contains zero or more attributes.

Controlling type inheritance

The `final` attribute on a complex type can take three values, with the following effects:

- restriction: It is not valid to derive another complex type from this type by restriction.
- extension: It is not valid to derive another complex type from this type by extension.
- all: It is not valid to derive another complex type from this type by either extension or restriction

Type inheritance and substitution

XML Schema provides two different substitution mechanisms, both of which use type inheritance information to allow or disallow substitutions.

Element substitution is controlled by substitution groups, and element substitution can be blocked or allowed for extension and restriction by settings on either the element itself or the type of the element.

Type substitution allows the type of the element to be defined within the instance document, using the xsi:type attribute on the element, so that the real type of the element is not known until the element has been partly parsed. This mechanism can also be blocked or allowed based on the derivation method of the types involved.

Message model objects: simple type value constraints

Value constraints, also known as *facets* in XML Schema, refine a simple type by defining limits on the values that it can represent.

It is often useful to be able to constrain the values that an element or attribute can take, perhaps to ensure that messages conform to business rules. This topic describes how to add value constraints to a simple type, in order to constrain the values of all elements or attributes that are based on that simple type.

If the model is deployed to IBM App Connect Enterprise, elements and attributes can be validated against value constraints, so that violations are reported as errors or warnings. The DFDL, SOAP, XMLNSC, and MRM domains all support validation.

Types of value constraint

Length Constraints: `Length`, `Min Length`, `Max Length`

Using length constraints, the length of all elements based on the simple type can be constrained, or even limited to a single value.

Length constraints can be applied to simple types that are derived from xsd:hexBinary, xsd:base64Binary or xsd:string (including built-in schema types such as xsd:normalisedString).

Length constraints are inherited from ancestor types, and any length constraints that are defined for a simple type must not relax the constraints that are imposed by any of its ancestor types. For example, a type 'longString' (`Max Length`=100) cannot be derived from a type 'shortString' (`Max Length`=10).

Range constraints: `Min Inclusive`, `Max Inclusive`, `Min Exclusive`, `Max Exclusive`

Range constraints specify the allowable range of values for all elements that are based on the simple type. Inclusive constraints include the specified endpoints in the permitted range, whereas exclusive constraints do not. Range constraints can be applied to simple types that are numeric, or that relate to calendar and time values. They cannot be applied to strings, because the ordering of string values depends on the character set that is used.

Range constraints are inherited from ancestor types, and any range constraints that are defined for a simple type must not relax the constraints that are imposed by any of its ancestor types. For example, a type 'largeNumber' (`Max Inclusive`=100) cannot be derived from a type 'smallNumber' (`Max Inclusive`=10).

Enumeration constraints

An enumeration constraint specifies a single permitted value for all elements that are based on the simple type. A list of permitted values can be specified by defining more than one enumeration constraint for the same simple type. Enumeration constraints can be applied to all simple types.

Enumeration constraints are inherited from ancestor types, and any set of enumeration constraints that are defined for a simple type must not increase the range of permitted values. For example, a type 'AllColors' (with enumerations for all colors of the rainbow) cannot be derived from a type 'MonoColors' (with enumerations for 'black' and 'white' only).

Precision constraints: Total Digits and Fraction Digits

Precision constraints relate only to decimal and integer values. They limit the number of significant digits (total digits) and, for decimals, the number of decimal places (fraction digits) for all elements that are based on the simple type. Precision constraints can be applied to simple types that are derived from xsd:decimal and xsd:integer.

Precision constraints are inherited from ancestor types, and any precision constraints that are defined for a simple type must not relax the constraints that are imposed by any of its ancestor types. For example, a type 'veryPrecise' (`Fraction Digits`=10) cannot be derived from a type 'notVeryPrecise' (`Fraction Digits`=1).

Pattern constraints

A pattern constraint is a regular expression that specifies a set of permitted values for all elements that are based on the simple type. Multiple patterns can be defined for the same simple type, permitting complex validation rules to be expressed in logically separate parts. Each pattern

constraint on a simple type contributes to the set of permitted values for elements that are based on the simple type; that is, all the patterns are combined by using Boolean OR.

As with all value constraints, a simple type can inherit pattern constraints from the simple type on which it is based. In this case, the set of pattern constraints that are contributed by each ancestor type must be satisfied, in addition to the set that is contributed by the simple type itself; that is, the sets of pattern constraints from each level in the type hierarchy are combined by using Boolean AND.

White space constraints

A white space constraint specifies how a parser treats white space for all elements that are based on the simple type.

Note: For the DFDL and MRM domains, white space constraints are not applied.

Message model objects: groups

A *group* is a list of elements that defines how those elements appear in a message. Groups define the composition and content validation of a complex type.

In XML Schema, groups can be ordered (sequence), unordered (all), or selective (choice).

In DFDL Schema, groups can be ordered (sequence), unordered (sequence but with DFDL property dfdl:sequenceKind="unordered"), or selective (choice).

In message definition files in message sets, groups can be ordered (sequence), unordered (all), or selective (choice). For more information, see "Message Sets: XML Schema extensions in message sets" on page 2174.

What are groups for?

Groups can be used for any of the following purposes:

- To define the entire element content of a complex type.

  A complex type can refer to a global group that completely defines its content. (If it does not, the content of the complex type is defined by an *anonymous local group*, which is hidden within the Message Definition Editor.)
- To represent a common substructure within more than one type.

  Two or more complex types can refer to the same global group, if they both contain the same subset of elements.
- To change the composition midway through a complex type.

  You might have a complex type that is a sequence of three members, but the second member is a choice of two elements. To model this circumstance, a group with `composition` set to choice can be inserted as the second member of the sequence.

Contents of a group

Groups can contain complex elements, simple elements, wildcard elements, and groups.

By combining these components, the structure of any message can be modeled. Wildcard elements can be included to enable the presence of unmodeled elements, thus making the message model robust and flexible.

Global and local groups

Groups can be global or local.

A *global group* can be used in more than one place in the message model. It represents a structure that is present in more than one place in the message model. A global group must be given a unique name by which it can be referenced by a *group reference*.

A *local group* is defined in one position within one group, and is not available for reuse elsewhere in the message model. Local groups do not have a name, and are displayed by using the composition of the group.

Message model objects: attributes
An *attribute* describes an XML attribute. They are used only when the data is XML.

Global and local attributes

Attributes can be global or local.

A *global attribute* can be used in more than one place in the message model. It must be given a unique name by which it can be referenced by an *attribute reference*.

A *local attribute* is defined in one position within one complex type, and cannot be used elsewhere in the message model.

Optional attributes

Attributes can be defined in XML Schema as optional, required, or prohibited. Attributes cannot repeat. For further information, see "Cardinality: optional, required, and repeating elements" on page 2157.

Default and fixed values

An attribute can be given a default value so that, if the attribute is missing from the message, the default is used. Alternatively, a fixed value can be defined, and the attribute always takes that value. The precise use of default and fixed values is dependent on the message domain.

Value constraints

The value of an attribute can be constrained by using *value constraints*, which define the range of legal values for the attribute. Value constraints are associated with the simple type on which the attribute is based. For more details, see "Message model objects: simple types" on page 2152. In XML Schema, the term for *value constraint* is *facet*.

Message model objects: attribute groups
For XML messages, an *attribute group* defines a set of attributes that can be present in a complex type.

An attribute group provides a way to include the same set of attributes in more than one complex type, without duplicating the definitions.

For example, if most of the elements in your message model have the attributes 'amount', 'currency' and 'date', these elements can be contained in a single attribute group, which is referenced by all the complex types that use them.

Message model objects: Wildcard elements
For XML messages, a wildcard element represents an element that is not present in the message model, but which might be present at the position of the wildcard element in a message.

Wildcard elements provide a means of adding flexibility to the message model, so that messages can be parsed even if they do not exactly match the message model.

Wildcard elements can be present only within a complex type or group with `Composition` of sequence.

The `Process Content` and `Namespace` properties control the namespace to which elements that are present at the position of the wildcard element must belong.

Message model objects: Wildcard attributes
For XML messages, a *wildcard attribute* enables unmodeled attributes to be present in a message.

The `Process Content` and `Namespace` properties control the namespace to which attributes that are present in the position of the wildcard must belong.

Message model object identification
Objects in a message model (elements, attributes, types, groups) are identified by their name only.

This means that no two objects in the same scope can have the same name. Name clashes can be avoided more easily if global objects are used only when necessary. Local objects are not visible outside of the scope of their parent object, so their names can be reused without causing a name clash.

Namespaces
Each message model schema can specify a namespace. Namespaces are an XML Schema mechanism for organizing groups of related objects into a named 'module'.

Global objects in different namespaces can share the same name. Therefore, namespaces offer another means of avoiding name clashes among global objects.

Valid names
Since the message model is based on the XML Schema language, the name of every message model object must be a valid XML Schema identifier. For information about what constitutes a valid XML Schema identifier, see XML Schema Part 0: Primer.

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

Cardinality: optional, required, and repeating elements
The number of occurrences of an element can be controlled using the properties `Min Occurs` and `Max Occurs`. Using these properties, an element can be defined as mandatory, optional or repeating.

Elements

A *mandatory*, or required, element has `Min Occurs`>= 1. A mandatory element must occur at least once in the message.

An *optional* element has `Min Occurs` = 0. An optional element can be omitted from the message.

A *repeating* element has `Max Occurs`> 1 to indicate a bounded number of repeats, or `Max Occurs`=unbounded (sometimes displayed as -1), to indicate an unlimited number of repeats. A repeating element occurs more than once in the message, and all the occurrences must appear together without any other elements between them.

If a complex type or a group contains two, or more, members that refer to the same element, the second reference is a *duplicate*. This is different from a repeating element, because the two references are typically separated by other members of the type or group. In the message, the second occurrence typically does not appear immediately after the first occurrence.

Attributes

The number of occurrences of an attribute can be controlled by setting it to *required*, *optional* or *prohibited*.

A *required* attribute is similar to a mandatory element - it must occur in the message.

An *optional* attribute is similar to an optional element - it can be omitted from the message.

A *prohibited* attribute must not appear in the message.

An attribute is not allowed to repeat, and duplicate attribute references are not allowed within an attribute group.

Self-defining elements and messages
An instance element is *predefined* if it is possible for the parser to find a matching element definition in the message model with an appropriate set of properties and in the correct context. Otherwise, it is *self-defining*. Similarly, an entire message is self-defining if no corresponding message is present in the message model.

Self-defining elements can be used only when the format of the message is a self-describing one, such as XML or JSON. For general text or binary formats (for example, comma separated), you must ensure that your message model defines every message and every element that must be parsed.

If you have chosen not to model your messages, or you have a model but have chosen not to deploy it to the integration node, all messages and elements are self-defining. In this situation, you cannot use message definitions to influence the parsing and writing of elements; the self-defining elements are parsed and written according to the default behavior of the parser and writer.

Self-defining elements, and all elements within a self-defining message, are not validated against value constraints, and any missing fields are not assigned default or fixed values, and all data is assumed to be string type unless the parser is able to deduce the type in a reliable manner.

Substitution groups in the message model
Substitution groups are an XML Schema feature that provides a way of substituting one element for another in an XML message.

A substitution group is a list of global elements that can be present in place of another global element, called the *head element*.

A substitution group is defined by setting the `substitution group` property on one global element (the *member* element) to point at another global element (the *head* element). This adds the member element to the substitution group of the head element.

Head elements
A head element is an element that can be substituted. When a message is parsed, one of its member elements can be present in place of the head element without causing a validation error.

Abstract elements
An abstract element is a head element which must be substituted, and is indicated by the 'abstract' attribute on the element. Typically, abstract elements have other elements in their substitution group, otherwise they are of little use. Wherever an abstract element is present in a message definition, a member of its substitution group must be present instead.

The `block` attribute on elements
The `block` attribute on an element limits the set of global elements that can substitute for the element. The `block` attribute can take any subset of the values restriction, extension, substitution, or all.

- If the `block` attribute contains restriction, an element that is based on a restriction of the type of the element cannot be substituted for the element.
- If the `block` attribute contains extension, an element that is based on an extension of the type of the element cannot be substituted for the element.
- If the `block` attribute contains substitution, an element that is a member of the substitution group of the element cannot be substituted for the element.
- If the `block` attribute contains all, all of the above limits apply.

The `final` attribute on elements
The `final` attribute on an element limits the set of global elements that can be a member of the substitution group of the element. The `final` attribute can take any subset of the values restriction, extension, or all.

- If the `final` attribute contains restriction, an element that is based on a restriction of the type of the element cannot be in the substitution group of the element.
- If the `final` attribute contains extension, an element that is based on an extension of the type of the element cannot be in the substitution group of the element.
- If the `final` attribute contains all, both of the above limits apply.

The `block` attribute on complex types
The `block` attribute on a complex type limits the set of other types that can substitute for that type. The `block` attribute can take values restriction, extension, or all. The meanings for these values are the same as the values that are shown for the block attribute on an element. An element that is a member of a substitution group can substitute only for the head element if its type is compatible with the block attribute on the type of the head element.

Default `block` and `final` attributes
A default for the `block` and `final` attributes can be set at the message definition file level. If a default for one or both of these attributes has been set and the relevant `block` or `final` attribute has not been set at the object level, the default setting is used for that object. You can override the default setting at the object level.

Namespaces in the message model
Use namespaces to qualify message model object names.

A single XML instance document can contain elements and attributes that are defined for, and possibly used by, multiple applications. Two different elements or attributes within the same document might require the same name. Individual applications must be able to recognize the elements and attributes that they are designed to process. In circumstances such as this, the definitions can be distinguished from each other by qualifying each element with a different namespace. This avoids problems of name collision and mistaken recognition.

XML Schemas can define a target namespace. Global elements, attributes, groups, and types that are defined within an XML Schema are qualified by the target namespace, if it has been defined. Optionally, local elements and attributes can also be qualified by the target namespace. Therefore, namespaces assist in the development of a library of XML Schemas that can be developed independently. If the namespace name that is used for an XML Schema is unique, you do not have to be concerned about name clashes with objects that are defined within other XML Schemas.

The scope of a namespace extends beyond the scope of its containing document and is identified by a Uniform Resource Identifier (URI). In order to serve its purpose, a URI must be unique. You might be more familiar with the concept of a Universal Resource Locator (URL). URIs often use the same syntax as URLs, but the URI definition is broader than the specification of a URL. This is an example of a URI: `http://mycompany.com/xml_schema`

A namespace prefix is declared as a shorthand for the full URI name and this is used to qualify all elements that belong to that namespace. The prefix to be substituted for a namespace in an XML instance document or XML Schema is specified by using an `xmlns` attribute. A default namespace can also be defined by using an `xmlns` attribute. If a default namespace is defined, any element or attribute with no prefix is qualified with the default namespace. If no default namespace is defined, any element or attribute with no prefix is not qualified by a namespace.

Namespaces and the message model

Message model schema files in applications or libraries, and message definition files in message sets, support namespaces.

A single application, library, or message set can contain a number of different namespaces. Each namespace is represented by a different message model schema file or message definition file. When you create a file, you can choose whether it has an associated namespace, or whether it is in the notarget namespace. If you associate a namespace, you must also choose a prefix.

If the file has an associated namespace, the following global objects are qualified with the namespace:

- Elements
- Attributes
- Simple Types
- Complex Types
- Groups
- Attribute Groups

Optionally, local elements and attributes can be qualified with the namespace.

Objects that are defined in a file can reference objects in other files. To create these references, import or include one file within another file. A message model schema file can import or include another file in the same application or library, or in a separate IBM App Connect Enterprise library. A message definition file can import or include another file only if it is in the same message set.

Message parsing and message flows

IBM App Connect Enterprise parsers for XML data recognize prefixed names in the XML messages that they parse, and internally map these to the correct namespace. The message tree stores the name and the namespace of the element or attribute.

Namespaces can be used even when the data is not XML. DFDL schema, Adapter schema, and message definition files can be created with an associated target namespace. Though the data itself does not contain prefixed names, the namespace is obtained from the corresponding element in the file. Again, the message tree stores the name and the namespace of the element.

You can specify namespaces when writing ESQL or Java. It is not necessary to write ESQL or Java that is namespace aware if you are not using namespaces. However, if you decide to use namespaces it is necessary to write namespace-aware ESQL or Java. The namespace in which an element is contained is stored in the message tree when parsed. This is a logical property and it is held regardless of the physical wire format in which messages are parsed and written. Syntax has been added to ESQL to make it easy to reference namespaces of other elements by using defined prefixes. In Java, XPath expressions are used to reference elements.

Further information about XML

On the World Wide Web Consortium (W3C) website, see:

- Extensible Markup Language (XML)
- XML Schema Part 0: Primer
- Namespaces in XML

Namespaces with non-XML messages
The use of namespaces by IBM App Connect Enterprise is not necessarily limited to XML message models.

There is one scenario where the use of namespaces by non-XML message models can simplify the ESQL or Java code that you write. Before describing this scenario, it is important to understand that the DFDL and MRM parsers, when parsing messages that are defined in a file that has a target namespace, produce a logical message tree that contains both name and namespace information. For non-XML messages, the namespace is obtained from the element declaration in the file, and not from the data.

Consider a transformation scenario where a message from a COBOL application requires to be transformed into namespace-aware XML; for example, a SOAP XML message. The transform must map the logical message tree that was created for the COBOL message to a logical message tree that matches the XML message. If the COBOL message tree does not contain namespace information, each mapping from a COBOL field to an XML element must set the namespace for the XML element. However, if the COBOL message tree already contains the required namespace information, this mapping is much simpler.

To enable the DFDL or MRM parser to create namespace information in a message tree that was created from a non-XML message, you must specify a target namespace for the DFDL schema or message definition file. For MRM, this must be done as part of the file creation process; for DFDL this must be done after the file has been created in the DFDL editor. Make the target namespace of the file the same as the target namespace of the XML message into which the non-XML message is being transformed.

When dealing with both the message tree for the non-XML message and the message tree for the XML message, the ESQL or Java code that you write to perform the transformation must be namespace aware.

Specifying namespaces in the Message property
When using the DFDL or MRM domains, the *Message* property (formerly the *Message Type* property) of a node is used to specify the name of the message.

The format of a simple message is `{namespace-uri}:name` where *name* is the name of the message, and *namespace-uri.* identifies the namespace. The namespace must be the full URI specification and must be enclosed in braces.

If you omit `{namespace-uri}`, the first match for the name that is found in the model is used. You should omit `{namespace-uri}` only if a name is unique within a message model.

For MRM only, the format `{namespace-uri}name` (that is, with no colon) is also valid. This maintains compatibility with previous version.

The following are examples of message property types:

- A simple message property for a message in a real target namespace: `{http://www.ibm.com/space}:myMessage`
- A simple message property for a message in the notarget namespace: `{}:myMessage`
- A simple message property for a message in any namespace: `myMessage`

Reusing message model files
One message model schema file or message definition file can reuse message model objects defined in another file.

There are two mechanisms that XML Schema provides to reuse message definition files: **`import`** and **`include`**. The namespaces of the two files determine which of the **`import`** or **`include`** commands is be used:

	Target file has a target namespace	**Target file has notarget namespace**
Parent file has a target namespace	xsd:import	xsd:include[1]
Parent file has notarget namespace	xsd:import	xsd:include

Note: When a target namespace file includes a notarget namespace file, referencing an object in the target file from the parent file causes the object to be present in the namespace of the parent file.

When **`import`** or **`include`** are used, global objects from the target file can be used in the parent file. For example, an element in the parent file can be given a complex type defined in the target file.

The namespace of objects in the target file is preserved in the parent file, with the exception noted in the previous table of a target namespace file that includes a notarget namespace file. This exception is sometimes called the chameleon namespace effect.

A message model schema file can import or include another file in the same application or library, or in a separate IBM App Connect Enterprise library. A message definition file can import or include another file only if it is in the same message set.

XML Schema provides a variation of xsd:include called xsd:redefine, which is supported when using message model schema files, but not when using message definition files. A Quick Fix is offered to convert occurrences of xsd:redefine into xsd:include when using message definition files.

Namespaces with MRM XML messages
The namespace that is associated with a message definition file is part of the logical layer of the message model.

Therefore, it is not dependent on an XML Wire Format being present. However, if you have an XML Wire Format, the namespace information from the logical layer is used to populate some of the properties of the XML Wire Format. If namespaces are enabled for a Message Set, in the XML Wire Format, a table of namespace URI/prefix pairs is maintained. This table is initially populated with the namespaces of all of the Message Definition Files with their prefixes when they were created.

If your message set has namespaces enabled, the integration node does not store the values of any `xmlns` attributes in the tree when it parses an XML instance document. It also does not store the values of any `Schema Location` and `No Namespace Schema Location` attributes. When an XML document is written out, the integration node regenerates this information from the properties of the XML Wire Format of the message set.

The table of namespace URI/prefix pairs is used by the MRM Domain when it produces an XML message. Elements and attributes that are qualified by a namespace are prefixed with the corresponding prefix from the table. The integration node also manages the output of the corresponding `xmlns` attributes that map the prefixes to namespaces. You can choose whether `xmlns` attributes for all of the entries in the namespace URI/prefix table are written at the start of the document, or whether they are only written in the document when required.

If namespaces are enabled for a Message Set, in the XML Wire Format there is a table of schema locations that map namespace URIs to file names. You can add entries to this table and you can map a file name to the notarget namespace. If you are using IBM App Connect Enterprise, this table is used to produce `schemaLocation` and `No Namespace Schema Location` attributes at the start of the XML document.

JSON Schema

JSON Schema is a standard from json-schema.org that defines a language for describing the structure of JSON documents.

The JSON Schema language is ideally suited to describing JSON messages that flow between business applications, and it is widely used in the business community for this purpose.

IBM App Connect Enterprise uses JSON Schema to describe the structure of JSON messages. Draft 4 and draft 5 of JSON Schema are supported, including the extensions for OpenAPI V2.0 and V3.0.

For details about JSON Schema, see json-schema.org

Data Format Description Language (DFDL)

Data Format Description Language (DFDL) 1.0 is a modeling language from the Open Grid Forum that is used to define the structure of general text and binary formatted data in a way that is independent of the data format. It is based on XML Schema 1.0.

DFDL is a way of describing the data. It is not a data format. DFDL can describe many data formats, including:

- Textual and binary
- Commercial record-oriented
- Scientific and numeric
- Modern and legacy
- Industry standards

DFDL schema files use XML Schema objects, and annotations on those objects to define the data.

- The XML Schema objects define the logical format of the data. You cannot use XML attributes in the data model.
- DFDL schema annotations describe the physical format of the data.
- XPath expressions are used to reference fields within the data.

DFDL is not intended to be used to model XML documents. Use normal XML Schema files to model XML.

For a simple example, see Example DFDL schema.

Support for DFDL

Support for DFDL in this product includes:

- DFDL parser and domain.
- DFDL parser (C and Java).
- DFDL serializer (C and Java).
- DFDL schema file creation wizards. See “Creating a DFDL schema file” on page 2223.
- DFDL schema editor for modeling text and binary data formats. See DFDL schema editor.
- DFDL Test perspective for testing your DFDL schema files. See “Testing a DFDL schema file” on page 2226.
- Developing independent applications that use the IBM DFDL API. See “Developing independent DFDL applications” on page 2239.

Not all features of the DFDL 1.0 specification are supported, and this implementation has some limitations. See the following topics:

- “Unsupported features” on page 2164
- “Implementation-specific limits” on page 2168

Further information about DFDL 1.0

For more information about DFDL, see the Open Grid Forum (OGF) website.

A navigable copy of the DFDL v1.0 Specification is included with this information. The specification is produced by the Open Grid Forum (OGF) DFDL Working Group and is an OGF Grid Recommendation. The master specification documents are hosted at https://github.com/OpenGridForum/DFDL.

The OGF document repository also contains a DFDL tutorial, comprising a number of PDF files. IBM have several DFDL modeling scenarios available on developerWorks.

DFDL extensions
Additional facilities available in this product that are not specified in the DFDL 1.0 specification.

Messages

A message is a global element that represents an entire data stream (rather than a structure within a larger data stream). Within a DFDL schema file, a message is represented by a special IBM annotation on a global element.

Further information about DFDL

For more information about DFDL, see the Open Grid Forum web site. This site has tutorials on DFDL.

DFDL encoding information
When an integration node calls a parser or serializer, the integration node provides the parser or serializer with encoding information that defines the character encoding (CCSID) and numeric encoding (byte order and floating point representation) of the data that is to be parsed or serialized.

When parsing or serializing messages in the DFDL domain, the DFDL parser or DFDL serializer is called. The way that the DFDL parser and DFDL serializer use encoding information is defined by your DFDL message model.

In a DFDL message model, you must set the character encoding (CCSID) and numeric encoding (byte order and floating point representation) by using DFDL properties on each type definition. DFDL predefines a set of external variables, each of which has default values that can be externally overridden. It is these predefined variables that the integration node overrides to pass in encoding information. For more information about DFDL predefined variables, see DFDL predefined variables in.

If you have set the encoding properties in your DFDL message model to specific, static types, the DFDL parser and DFDL serializer interpret message data by using this static encoding information, and ignore the encoding information that is provided by the integration node for each individual message instance. Note that if you set the encoding properties in your DFDL message model to specific, static types, and the message data is not encoded in the format that you specified, you might encounter the following problems:

- Parsing errors due to the message data being interpreted incorrectly
- Incorrect numeric values due to the wrong byte order (endianness) being used

To avoid these problems, set the DFDL encoding properties in your DFDL message model as follows:

- encoding: `{dfdl:encoding}`
- byteOrder: `{dfdl:byteOrder}`
- binaryFloatRep: `{dfdl:binaryFloatRep}`

These settings allow the DFDL parser to correctly interpret your data by using the encoding information that the integration node obtains for an individual message instance, for example from the transport headers in an input message. Similarly, these settings ensure that bit stream data is encoded according

to the values that are defined in the integration node properties, when the data is processed by the DFDL serializer.

DFDL schema version and keywords
When you develop a DFDL schema, you can define key information that you want to associate with it, including the file version.

After you have deployed your DFDL schema in a BAR file, you can view the properties of the DFDL schema file. The properties of the DFDL schema file include the deployment dates and times, the modification dates and times (the default information that is displayed), and any additional keyword information that you have set.

Keywords

You can define keywords anywhere in your DFDL schema by using either XML comments or the XML Schema documentation annotation facility. Keywords must follow certain rules to ensure that the information contained in the file can be parsed. The following examples show the type of information that you can define:

- `$MQSI Version=1.2 MQSI$`
- `$MQSI Author=John Smith MQSI$`

The following table contains the information that is displayed:

DFDL schema name	
Deployment Time	28-Aug-2004 15:04
Modification Time	28-Aug-2004 14:27
Version	1.2
Author	John Smith

DFDL grammar information
IBM App Connect Enterprise has only one compiled DFDL grammar for each Application domain.

A deployed Application has a level of isolation from anything else deployed. The Application sees only the DFDL schemas deployed within that Application.

- Anything outside of the Application cannot see the schemas inside the Application.
- Anything that is deployed just as a flow or message definition exists in its own space as well. Everything that is not explicitly in an Application can be thought of as in an Integration Server level Application domain.

Even though separate flows might use separate message models, each importing separate schema, when they are deployed, the schema/models are merged into a single model.

Unsupported features
The following features of the DFDL 1.0 specification are currently not supported in this implementation.

Property enumerations

The following property enumerations are unsupported.

Feature	**Reference in DFDL specification**
dfdl:textBiDi "yes"	21. Optional DFDL Features
dfdl:occursCountKind "stopValue"	16. Properties for Array Elements and Optional Elements

Feature	Reference in DFDL specification
dfdl:binaryCalendarRep "packed"	13.13 Properties Specific to Calendar with Binary Representation
dfdl:floating "yes"	14.4 Floating Elements
dfdl:lengthKind "endOfParent"	12.3 Properties for Specifying Lengths
dfdl:assert testKind "pattern"	7.3 The dfdl:assert Statement Annotation Element
dfdl:discriminator testKind "pattern"	7.4 The dfdl:discriminator Statement Annotation Element
dfdl:separatorSuppressionPolicy "trailingEmptyStrict"	14.2 Sequence Groups with Separators
dfdl:encodingErrorPolicy "replace"	11.2 Character Encoding and Decoding Errors
dfdl:textZonedSignStyle "asciiTandemModified"	13.6 Properties Specific to Number with Text representation
dfdl:bitOrder "leastSignificantBitFirst"	11. Properties Common to both Content and Framing
dfdl:escapeCharacterPolicy "delimiters"	13.2.1 The dfdl:escapeScheme Properties

Properties

The following properties are unsupported:

Feature	Reference in DFDL specification
dfdl:hiddenGroupRef	14.5 Hidden Groups
dfdl:inputValueCalc dfdl:outputValueCalc	17. Calculated Value Properties.

Functions

The following functions are unsupported in DFDL expressions:

Feature	Reference in DFDL specification
fn:count fn:exactly-one	23.5 Constructors, Functions and Operators
fn:name fn:local-name fn:namespace-uri	
dfdl:contentLength dfdl:valueLength	
dfdl:testBit dfdl:setBits	
dfdl:occursIndex	
dfdl:checkConstraints	

Feature	Reference in DFDL specification
dfdl:timeZoneFromDate dfdl:timeZoneFromDateTime dfdl:timeZoneFromTime	
All dfdl: constructor functions	
dfdl:decodeDFDLentities dfdl:encodeDFDLentities dfdl:containsDFDLentities	

Annotations

The following annotations and annotation placements are unsupported:

Feature	Reference in DFDL specification
dfdl:defineVariable with external=true	7.7 The dfdl:defineVariable Annotation Element
dfdl:newVariableInstance	7.8 The dfdl:newVariableInstance Statement Annotation Element
dfdl:assert on global element and simple type	7.3 The dfdl:assert Statement Annotation Element
dfdl:discriminator on global element and simple type	7.4 The dfdl:discriminator Statement Annotation Element

Other restrictions

The following restrictions also apply:

Feature	Reference in DFDL specification
Use of default values is not supported during parsing.	9.4 Element Defaults
When default values are applied to a missing complex element during serialization and the element is a choice, only the first choice branch is used to supply default values. If an error occurs on the first branch then serialization fails.	9.4 Element Defaults
When dfdl:lengthKind is 'implicit' for a complex element, the element can be prematurely terminated by encountering a higher level terminating delimiter.	12.3.2.1 Non-Delimited Elements within Delimited Constructs
When encoding is 'UTF-8', 'UTF-16' or 'UTF-32' a byte order mark at document start is not automatically processed, and must be modeled explicitly if it is to affect the encoding of the document.	11.1 Unicode Byte Order Marks (BOM)
Schemas must contain only one DFDL xs:appinfo element within each xs:annotation element, as subsequent xs:appinfo elements might not be processed correctly.	6. DFDL Syntax Basics

Feature	Reference in DFDL specification
When dfdl:lengthKind is 'prefixed', the simple type referenced by the dfdl:prefixLengthType property can not also have dfdl:lengthkind 'prefixed'.	12.3.4 dfdl:lengthKind 'prefixed'
Not all instances of inapplicable DFDL property placement are reported.	2.7 Optional Checks and Warnings
All global elements are assumed to be potential document roots and are validated accordingly.	2.7 Optional Checks and Warnings
dfdl:lengthKind 'pattern' can not be used with elements of binary representation.	12.3.5 dfdl:lengthKind 'pattern'
When parsing, the distinction between an element being 'missing', having an 'empty representation' and having an 'absent representation', is not in accordance with the specification.	9.2 DFDL Data Syntax Grammar
When an element has binary representation, a DFDL character entity is not allowed in the definition of a nil value for the element.	13.15 Nil Value Processing
dfdl:textStandardDecimalSeparator is not allowed to be a list of values.	13.6 Properties Specific to Number with Text representation
dfdl:textStandardExponentRep is not allowed to be more than one character, and not allowed to be empty string.	13.6 Properties Specific to Number with Text representation
The '@' (significant digits) symbol is not allowed in dfdl:textNumberPattern.	13.6 Properties Specific to Number with Text representation
The '_' (underscore) character is not allowed in dfdl:calendarLanguage.	13.11 Properties specific to Calendar with Text or Binary Representation
dfdl:calendarTimeZone is not allowed to be empty string or to be an Olson format time zone.	13.11 Properties specific to Calendar with Text or Binary Representation
A binary packed number with dfdl:lengthUnits 'bits' is not checked to see that the length is a multiple of 4 bits.	12.3.7.2.6 Length of Packed Decimal Calendar Elements
A binary packed number with dfdl:alignmentUnits 'bits' is not checked to see that the alignment is a multiple of 4 bits.	12.1.3 Mandatory Alignment for Packed Decimal Data
All elements with text representation are assumed to align on an 8-bit boundary. There is no support for encodings that are not 8-bit aligned.	12.1.2 Mandatory Alignment for Textual Data

Feature	Reference in DFDL specification
dfdl:textStandardDecimalSeparator, dfdl:textStandardGroupingSeparator, dfdl:textStandardExponentRep, dfdl:textStandardInfinityRep, dfdl:textStandardNanRep and dfdl:textStandardZeroRep are not checked to ensure they are all distinct from one another.	13.6 Properties Specific to Number with Text representation
dfdl:calendarLanguage is not allowed to be an expression.	13.11 Properties specific to Calendar with Text or Binary Representation
dfdl:assert message is not allowed to be an expression.	7.3 The dfdl:assert Statement Annotation Element
dfdl:discriminator message is not allowed to be an expression.	7.4 The dfdl:discriminator Statement Annotation Element
Path locations in DFDL expressions are not correctly validated. Specifically, array elements without predicates and references into other choice branches are not flagged as errors. Avoid using such path locations.	23. Expression language
dfdl:initiator and dfdl:textStandardZeroRep incorrectly allow the use of %WSP*; entity class on its own. Use %WSP+; instead.	12.2 Properties for Specifying Delimiters , 13.6 Properties Specific to Number with Text representation
dfdl:terminator and dfdl:separator incorrectly allow the use of %WSP*; entity class on its own when scanning for delimiters. Use %WSP+; instead when scanning for delimiters.	13.6 Properties Specific to Number with Text representation , 14.2 Sequence Groups with Separators
When serializing, the application of an escape scheme takes place after the application of dfdl:emptyValueDelimiterPolicy.	13.2.1 The dfdl:escapeScheme Properties
A value of empty string for dfdl:binaryBooleanTrueRep is not supported.	13.10 Properties Specific to Boolean with Binary Representation
The fn:concat function is limited to four arguments.	23.5.2.3 String Functions

Implementation-specific limits
Some limits in the DFDL specification are implementation-defined.

The following limits apply to this implementation:

- A 1,000 digit limit applies during parsing or serializing of numbers with text representation.
- A maximum precision of 33 digits is supported during parsing or serializing of numbers. If this limit is exceeded, behavior is undefined.
- The maximum number of elements in an array is 2,147,483,647.
- Fractional second digits are supported to millisecond accuracy.

Message Sets: Message sets overview

A message set is the original container for message models used by IBM App Connect Enterprise.

Tip: A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see "Enabling message set development" on page 2248 .

A message set is a folder in a message set project that contains a logical grouping of your messages and the objects that comprise them (elements, types, groups). A message set contains the following files:

- Exactly one message set file
- Zero or more message definition files
- Zero or more WSDL files
- Zero or more message category files

Note: A message set cannot contain JSON Schema.

The message set file provides message model information that is common to all the messages that are defined in the message set. You can create this information by using the Message Set editor.

You can base a new message set on an existing message set. In this case, all the definitions in the existing message set are copied into the new message set.

When you have created your message set, you must specify the following key properties:

Supported message domains
: The message domains that are supported by the message set. The supported domains determine what is generated for deployment to an integration node, and are used when parsing and writing the messages that are defined within the message set.

Default message domain
: The default domain of the message set.

When you have created your message set, you typically import application message formats described by XML DTD, XML Schema, WSDL files, C structures, COBOL structures, EIS systems, or creating and populating message definition files. Using the Message Definition editor, you can then edit the logical structure of your messages, and create and edit the physical formats that describe the precise appearance of your message bit stream during transmission. Alternatively, you can create an empty message definition file and create your messages by using only the editor.

When your message definition files are complete, you can generate the message set in a form that can be used by an integration node, parser, or application. This might be in one of the following forms:

- A message dictionary for deployment to an integration node
- An XML Schema file for use by an application to validate XML messages, or for deployment to an integration node
- A Web Services Description Language (WSDL) file for a web services client, or for deployment to an integration node
- Documentation to give to programmers or business analysts

Optionally, messages can be grouped into message categories for convenience. You can add messages to message categories by using the Message Category editor.

Each time you save a message set file, message definition file, or message category file, the content is validated to ensure that the message model that you are creating follows certain rules. There are rules for both the logical structure and the physical formats. This model validation ensures the integrity of your model, but does not necessarily prevent you from saving a message model file that is not valid.

IBM App Connect Enterprise supplies a range of parsers to parse and write message formats. Each parser is suited to a particular class of messages (for example, fixed-length binary, delimited text, or XML) known

as a message domain. When you create a message set, you specify which domains the message set supports. This property determines which parsers can be used when you parse and write messages that are defined within that message set.

Message Sets: Message set projects
A *message set project* is a specialized container in which you create and maintain all the resources associated with one message set.

Tip: Message set projects are used when working with message sets. A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see "Enabling message set development" on page 2248 .

The content of a message set project is a single message set folder, and additional folders if you are modeling EIS data, CORBA data, or SCA import or export data. The name of the message set project provides the name of the message set. You can create a message set project by using the New Message Set wizard.

The following restrictions apply to message set projects:

- A message set project must contain just one message set.
- A message set project cannot refer to any other message set.

Message Sets: Message set resources
Resources in a message set are created as files, and are displayed under the message set folder in the Application Development view.

- Message set file `messageSet.mset`

  There is always one, and only one, `messageSet.mset` file in a message set. This file contains message model properties that are common to all the content of the message set. It is also where you define the physical formats that you want for this message set. These can be Custom Wire Format (CWF), Tagged Delimited String Format (TDS), and XML Wire Format (XML).

  The file is created for you when a new message set is created, and you manipulate its content with the Message Set Editor.
- Message definition files that have the suffix `.mxsd`

  You can have many message definition files in a message set. Each file contains the logical model and the associated physical model, in XML Schema form, for a group of related messages.
- Deployable WSDL files that have the suffix `.wsdl`

  These files are used by the SOAP domain. You can have many WSDL files in a message set.
- Message category files that have the suffix `.category`

  These files are optional. You can have many message category files in a message set. A message category provides another way of grouping your messages, perhaps for documentation purposes.

When you have completed the resources in your message set, you can generate the content of the message set in a form that can be used by an integration node parser or an application. This might be:

- a message dictionary for deployment to an integration node
- XML Schema for use by an application building XML messages, or for deployment to an integration node
- Web Services Description Language (WSDL) for a web services client, or for deployment to an integration node
- documentation to give to programmers or business analysts

Message Sets: Message set identification
A message set is identified by the name of the message set folder in the message set.

When you must refer to a message set from a message flow (for example, when setting the `Message model` property of an input node), use the message set name.

A message set also has a 13-character identifier that is guaranteed to be unique. You can use this identifier, instead of the message set name, to refer to a message set, but only if you are using the MRM or IDOC domains. Other domains do not recognize the identifier.

A message set also has an alias. An alias can be used only with MRM multipart messages.

Message Sets: Message set limitations
A message set is the original container for message models used by IBM App Connect Enterprise.

Tip: In WebSphere Message Broker Version 8.0, message model schemas in integration projects are the preferred way to model messages for all kinds of data format. Message sets continue to be supported, and are required if you use the MRM or IDOC domains for your formats.

You can have as many message definition files as you want within one message set, but you must limit your message sets to a few related message definition files that share the same physical formats.

There are several reasons for the suggested limitations:

- Generation of a message dictionary and other representations is quicker.
- Generated documentation is more manageable.
- MRM physical formats apply to *all* objects within the message set.

  Therefore, for example, if you are using the MRM domain and have an XML message and an unrelated CWF message modeled in the same message set, CWF physical format properties are present for all objects. But the CWF properties are of no interest to the XML message and therefore take default values in those objects, which can result in unwanted task list warnings.
- You cannot use recursion for MRM CWF and TDS physical formats.

  Therefore, if you are modeling XML messages that have a recursive structure, you must ensure that recursive XML messages do not share a message set with MRM CWF or TDS physical formats.

Message Sets: Message set version and keywords
When you develop a message set, you can define the version of the message set, and other key information that you want to be associated with it.

After you have deployed the message set in a BAR file, you can view the message set properties in the IBM App Connect Enterprise Toolkit and the web user interface. The properties include the deployment and modification dates and times (the default information that is displayed), and the additional version or keyword information that you have set.

Version

You can set the version of the message set in the `Version` property.

You can also define a default message set version in the `Default version tag` of the message set preferences. All message sets that you create after you have set this property have this default applied to the `Version` property at the message set level.

Keywords

You must define keywords in the `Documentation` property of the message set. Keywords follow certain rules to ensure that the information can be parsed. The following example shows the type of information that you can define in the `Documentation` property:

```
$MQSI Author=John Smith MQSI$
```

The following table contains the information that is displayed by the IBM App Connect Enterprise Toolkit and the web user interface:

Message set name	
Deployment Time	28-Aug-2004 15:04

Modification Time	28-Aug-2004 14:27
Version	1.0
Author	John Smith

Message Sets: Message definition files
A *message definition file* contains the messages, elements, types, and groups which make up a message model within a message set.

Tip: Message definition files are used when working with message sets. A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see "Enabling message set development" on page 2248 .

Every message set requires at least one message definition file to describe its messages. Message definition files use the XML Schema language to describe the *logical format* of one or more messages. Extra information in the form of XML Schema annotations is used to describe any *physical formats* that you define for the messages.

Large message sets can contain several message definition files. This keeps the individual files to a manageable size, making them faster and easier to work with.

Message definition files can be created by using the Message Definition editor, or can be imported from a range of different file formats as described in "Importing from other model representations to create message definitions" on page 2139.

A message definition file can be associated with a namespace, so that all message model objects that are declared within the file belong to that namespace. Namespaces provide a means of avoiding name clashes among similarly named global objects. They are described in detail in "Namespaces in the message model" on page 2159.

One message definition file can reuse message model objects that are defined in another message definition file. XML Schema provides two mechanisms to do this: **`import`** and **`include`**. For more information, see "Reusing message model files " on page 2161.

Message Sets: XML Schema restrictions in message sets
Some XML Schema 1.0 features are not supported when message models are contained in message sets.

Unsupported XML Schema features

The following feature is accepted, but not supported, and causes validation errors if it is used in your message model:

- Redefines

A quick fix is provided to convert Redefines into Include.

Further information about XML Schema

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

Message Sets: XML Schema extensions in message sets
IBM App Connect Enterprise provides some additional facilities that are not specified in the XML Schema 1.0 specification. When using a message set, further extensions are provided.

Composition

The message model in a message set adds the following compositions that are beyond the XML Schema 1.0 specification:

message
A refinement of *choice* that can contain only a set of references to messages within the same message set. Groups and complex types with composition of *message* are used when modeling multipart messages.

orderedSet
A set of elements that must be present in the order that they are listed. Groups cannot be used within an *orderedSet*. Elements can repeat, but duplicate elements cannot be used.

unorderedSet
A set of elements that can be present in any order. Groups cannot be used within an *unorderedSet*. Unlike an *all* group, elements within an *unorderedSet* can repeat. However, duplicate elements cannot be used.

Compositions *orderedSet* and *unorderedSet* enable message models that were produced in earlier versions of the product to be supported.

Content validation

The message model in a message set adds a validation control called ‘Content validation' that is used only if the domain is MRM or IDOC, and if validation is selected. It determines how strictly the content of the group is validated. See MRM content validation for more details.

The Content validation property does not affect validation in the XMLNSC or SOAP domains. Validation in these domains follows the rules of XML Schema 1.0.

Physical format information

If one or more physical formats are defined for a message set, the XML Schema objects within the message set can hold extra information about how they must be parsed and serialized.

Further information about XML Schema

For details about XML Schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

Message Sets: Multipart messages
A *multipart message* contains one or more other messages within its structure. The contained message is sometimes referred to as an *embedded message*.

Tip: Multipart messages are used when working with messages that are modeled by using message sets. A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see “Enabling message set development” on page 2248 .

A multipart message must contain a group, or a complex type, with its `Composition` property set to Message. This group or complex type can contain a list of references to messages that can be present at that location in the message structure. If the group or complex type is empty, any message can be present. When a message is parsed, only one embedded message can be present in that location.

Message envelopes

A common use of multipart messages is to define an outer message with a fixed structure. This outer message is called the *message envelope*. Within the message envelope a group or complex type is included, as described earlier in this topic. Examples of message standards that can be modeled by using this technique are EDIFACT, X12, SWIFT, SOAP XML, SAP ALE IDoc, multipart MIME, and RosettaNet.

Identifying the embedded message

When a multipart message is parsed, the parser must be able to identify the embedded message; it might be any of the messages that are referenced by the group or complex type, or it might be a message that

is not referenced by the group or complex type, perhaps from a different message set. This is achieved by using one of four techniques, *Automatic*, *Message Identity*, *Message Path*, or *Manual*.

Automatic
Used when parsing XML messages, such as SOAP. The parser automatically identifies and parses embedded messages by using the tag in the XML document.

Message Identity
Used by the MRM parser. See "Message Sets: Identifying an embedded message by using a Message Identity" on page 2176.

Message Path
Used by the MRM parser. See "Message Sets: Identifying an embedded message by using a Message Path" on page 2178.

Manual
Used by the MIME parser. The parser treats embedded messages as BLOBs. If you want to parse the BLOB by using another parser, you must do so manually by using ESQL, or Java, or a ResetContentDescriptor node.

Restrictions

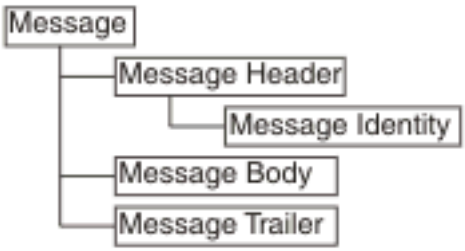
Unless using the *Manual* identification technique, all embedded messages must be of the same physical format as the outermost message, and have the same character set and encoding.

When using the *Automatic* or *Message Path* identification techniques, all embedded messages must be from the same message set as the multipart message.

Message Sets: Identifying an embedded message by using a Message Identity
You can identify an embedded message by using the Message Identity. This technique is used by the MRM domain, and replaces the use of the Message Key.

Tip: Multipart messages are used when working with messages that are modeled by using message sets.

The Message Identity technique for identifying embedded messages is useful when a multipart message has a format such as that shown in the diagram:



In this example, the Message Header and Message Trailer act as an envelope for the message body. They typically have a fixed structure, although the Message Body can be defined with many different structures.

A place holder for an embedded message is created by setting the `Composition` property of the complex type or group of the Message Body element to Message. This enables an embedded message to be added within the outer Message, creating a multipart message.

When using the Message Identity technique to parse such a multipart message, the embedded message must be identified earlier in the Message Header by using a Message Identity element. A Message Identity Element is a string element (or attribute) that precedes the embedded message in the model and whose `Interpret Value As` property is set to Message Identity.

When a multipart message is input to a message flow, the Message Identity element must have a value that corresponds to either the `Name` or the `Message Alias` of the next embedded message in the bit stream. This enables the MRM parser to correctly identify the embedded message in the model.

For cases where the Message Identity element value does not match the `Name` of the message, use the `Message Alias` property to specify this value. The MRM parser tries to match on `Name` first, and if that fails, it tries to match on `Message Alias`.

When the MRM parser has encountered a Message Identity element, its value applies to all embedded messages that are contained immediately within the current message. This does not apply to embedded messages within embedded messages; any embedded message must have its identity provided by a Message Identity element within its immediate parent message.

If a second Message Identity element is encountered within the current message, its value overrides any previously held. This enables different peer embedded messages to exist within a given message.

Message Identity takes priority over Message Path. If both are specified, Message Identity is used. Use only one of these techniques for a given multipart message.

Embedded messages defined in different message sets

By default, an embedded message is assumed to be defined within the same message set as the current message. This can be overridden by using a Message Set Identity, which works in a similar manner to a Message Identity.

An embedded message that is defined within a different message set must have its message set identified earlier in the message, by using a Message Set Identity element. A Message Set Identity Element is a string element (or attribute) that precedes the embedded message in the model and whose `Interpret Value As` property is set to Message Set Identity.

When a multipart message is input to a message flow, the Message Set Identity element must have a value that corresponds to either the `Identifier`, `Name`, or `Message Set Alias` of the message set that defines the next embedded message in the bit stream. This enables the MRM parser to correctly identify the message set to use.

If the Message Set Identity element value does not match the `Identifier` or `Name` of the message set, use the `Message Set Alias` property to specify this value. The MRM parser tries to match on `Identifier` first, then on `Name`, and finally on `Message Set Alias`.

After the MRM parser has encountered a Message Set Identity element, its value applies to all embedded messages that are contained within the current message. It also applies to embedded messages within embedded messages, unless an embedded message also contains a Message Set Identity element.

If a second Message Set Identity element is encountered within the current message, its value overrides any previously held. This enables peer embedded messages to be contained within different message sets.

The following example of an X12 message shows the use of both Message Identity and Message Set Identity. The field that contains `004010X092` within the GS segment on line 0002 holds the Message Set Identity as a `Message Set Alias`. The 207 on line 0003 in the ST segment is the Message Identity held as a `Message Alias`. The embedded message is from line 0004 - 0015 inclusive.

Note: The line numbers and spaces at the beginning of each line are for illustrative purposes only and do not exist in the actual message.

Physical format considerations

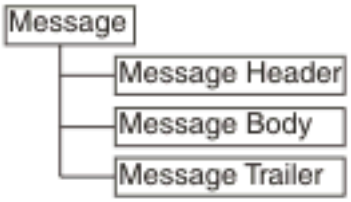
Both Message Identity and Message Set Identity are applicable to all physical formats.

Message Sets: Identifying an embedded message by using a Message Path
The Message Path technique for identifying embedded messages is useful when the multipart message contains no information about the identity of an embedded message.

Tip: Multipart messages are used when working with messages that are modeled by using message sets.

This technique is used by the MRM domain.

In the diagram, the Message Header and Message Trailer act as an envelope for the message body. Typically, they have a fixed structure, but the Message Body can be defined with many different structures.



A place holder for an embedded message is created by setting the `Composition` property of the complex type or group of the Message Body element to Message. This enables an embedded message to be added within the outer message, creating a multipart message.

When using the Message Path technique to parse such a multipart message, the embedded message must be identified by a fixed path to the innermost message from the outermost message. For this example, this would be:

```
Message/Message Body
```

If the path to the innermost message contains intermediate elements, these intermediate elements must also be included in the path. In the following example, these elements are shown in bold:

```
Message/Data1/Data12/Message Body
```

This technique can be used to identify nested embedded messages as well, by extending the path. For example:

```
Message/Data1/Data12/Message Body/Data2/Inner Message
```

The path is specified by using one or both of two properties, the `Message Type` property of an IBM App Connect Enterprise input node (or MQRFH2 header) and the `Message Type Prefix` property of the containing message set. These two properties are combined to produce a final path that is used to locate embedded messages.

Message Identity takes priority over Message Path. If both are specified, Message Identity is used. Use only one of these techniques for a given multipart message.

You cannot use the Message Path technique to identify multiple peer embedded messages.

Embedded messages defined in different message sets

This option is not supported by the Message Path technique.

Physical format considerations

The Message Path technique is applicable to all physical formats.

Message Sets: Message categories
Message category files have the suffix `.category`. These files are optional. You can have many message category files in a message set.

A message category provides another way of grouping your messages, perhaps for documentation or convenience purposes. A message category can also be used for assisting in the generation of Web Services Description Language (WSDL) files, but this use is deprecated. For more information, see "Generation of WSDL files" on page 2206.

A message set category file is created by using the New Message Category File wizard.

When you have created your message category file, you must specify one key property.

Message Category Kind
The Message Category Kind indicates whether the message category is to participate in the generation of WSDL files.

You can then add messages to the message category file. If the message category is to participate in WSDL generation, assign appropriate values to the `Role Name` and `Role Type` properties of each member message.

Message category identification

The name of a message category is provided by the name of the `.category` file. You can change the message category name by renaming the file.

Message Sets: Physical formats in the MRM domain
Each message definition file within a message set describes both the *logical structure* of your messages, and the *physical formats* that describe the precise appearance of your message bit stream during transmission.

Tip: A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see "Enabling message set development" on page 2248 .

If you are using the MRM domain or the IDOC domain, physical format information *must* be provided, as it tells the parser exactly how to parse the message bit stream.

You can think of a message as a packet of data that is sent from one place to another. The sender and receiver of the message will have agreed the structure of the message and what each field in the message means. This is the platform and protocol independent logical structure.

The sender and receiver will have also agreed on the physical representation of the message, how the data is physically laid out on the wire. For example, if you define a message that conveys information about a debit of an individual's bank account, it can be represented in different physical forms (examples are XML, or a fixed structure such as a COBOL copybook). The meaning and data are the same in both cases: only the physical layout has changed.

If you are using the MRM domain, you can model various different physical representations by using named physical formats.

- Use the Custom Wire Format (CWF) physical format to model fixed-format messages from applications that are written in C, COBOL, PL/I and other languages. This support includes the ability to create a message model directly from a C header file or COBOL copybook.
- Use the Tagged Delimited String Format (TDS) physical format to model formatted text messages, perhaps with field content identified by tags or separated by specific delimiters or both. This support is rich enough to model industry standards such as SWIFT, EDIFACT, and X12.
- Use the XML physical format to model XML messages, including those that use XML namespaces. This support includes the ability to create a message model directly from an XML DTD or XML Schema file.

Different physical representations

The following example shows how a simple logical message can have different physical representations.

The logical model defines the structure and order of the message. In the following example, the three fields are simple integers, and C follows B, which follows A:

```
int   A;
int   B;
int   C;
```

- A typical Custom Wire Format representation for this logical message would be 12 bytes of data, with each of A, B and C occupying 4 bytes. Alternatively, perhaps A is 4 bytes long, but B and C are only 2 bytes long. You supply the precise physical information for each field in the message as CWF properties.
- TDS enables several different representations to be modeled. Each integer can be preceded by a tag to identify it and a delimiter to terminate it, as follows:

  ```
  {A_tag:xxxxxxxx;B_tag:xxxxxxxx;C_tag:xxxxxxxx}
  ```

  An alternative might rely on the data being ordered so only the terminating delimiter must be specified, as follows:

  ```
  [xxxxxxxx;xxxxxxxx;xxxxxxxx]
  ```

  You supply the precise identification regime as TDS properties.
- A typical XML representation of this model is as follows:

  ```
  <Msg><A>xxxxxxxx</A><B>xxxxxxxx</B><C>xxxxxxxx</C></Msg>
  ```

  where xxxxxxxx is the value of the integer represented as a string (XML deals only with strings). An alternate representation might be:

  ```
  <Msg A="xxxxxxxx" B="xxxxxxxx" C="xxxxxxxx"/>
  ```

  where the values of the integers are stored as XML attributes rather than XML elements. You supply the precise XML rendering for each field in the message as XML properties.

This shows that the logical model is unchanged. It is constant, regardless of the physical representation that you choose to model on top of it, using the physical format support provided by the MRM domain. The MRM parser is able to transform the message from the input physical representation to any number of output representations, based on the physical format layers that you have defined.

Creating physical formats

When you have created your message set, you can create physical formats. You do this using the Message Set Editor. When you next save the `messageSet.mset` file, any new physical formats are added to all the objects in all the message definition files in that message set.

The next time you edit an object in a message definition file, you see the physical formats in the properties hierarchy pane of the Properties tab. If you click a physical format for an object, you are presented with a property sheet where you can enter the information for that physical format for that object.

Not all objects have properties in all physical formats. For example:

- CWF properties apply only to local elements and attributes, and element and attribute references.
- Complex types and groups have only TDS properties.
- Messages have only XML properties.

These differences occur because of the different nature of each physical format, and are explained in more detail in the section for each physical format.

There is no limit to the number of physical formats you can create in a given message set. However there are some recommendations that apply if you want to mix physical formats of different kinds in the same message set.

Physical formats can be deleted if no longer required.

MRM Custom Wire Format
Custom Wire Format (CWF) is the physical representation of a message that is composed of a number of fixed-format data structures or elements, which are not separated by delimiters.

Tip: In Version 8, when modeling and parsing general text or binary data use message model schema with the DFDL domain, instead of message sets and the MRM domain.

Within a CWF messaging environment, it is not possible to distinguish one element from the next without knowledge of the message structure. To correctly determine the values of individual elements, the following information must be made available to the message parser:

- The order (this is defined in the logical properties)
- The length (can be specified in bytes, characters, or character units)
- The cardinality (that is, the number of repeats)
- The type of data contained in each element (this is partly defined in the logical properties but can be further qualified in the CWF physical format)
- A number of characteristics based upon the logical type of the data

A CWF physical format is typically used to describe messages which are mapped to a C structure, a COBOL copybook, or other programming language data structure definition.

You can add more than one CWF physical format to a message set, but within that message set, each physical format must have a unique name. When parsing a CWF message by using the MRM parser, the physical format name specifies the physical properties that are to be used by the parser.

Adding a CWF physical format to a message set enables you to process input messages and construct output messages in this format. Messages can be transformed between CWF and the other physical representations (for example TDS or XML). While the other physical representations support self-defining elements (that is elements which do not have a definition in the logical model) within the MRM domain, the parsing of a CWF message does not. Consequently, any such self-defining elements are discarded during the output of messages in CWF format.

MRM Custom wire format: Message model integrity
When you save a message definition file, the definitions that it contains are checked to ensure that they make sense and provide sufficient information about the message. This action is called *model validation*.

The CWF physical format depends on fixed-format data structures. Therefore, most tests that are applied to a CWF message confirm that each fragment of a message - and therefore, the message as a whole - has a well-defined length. Therefore, these tests examine properties such as `Length`, `Length Reference` and `Length Units`.

Typically, one or other of `Length` and `Length Reference` must be set. If `Length Reference` is set, it must refer to an element that is of simple type integer and that appears earlier in the message than the current item.

Tests other than these tend to be both simple and obvious so that, for example, the message set property `First Day of Week` must be the name of a day in the week.

The fact that CWF relies on fixed-format data structures also imposes some limitations on the messages that can be represented:

- CWF cannot represent a message that includes the use of XML Schema wild cards; this is a consequence of its inability to handle undefined content.
- CWF cannot represent a message that includes recursive definitions.
- CWF cannot represent a message that includes the use of substitution groups, because there is no way to recognize the substituted element.

MRM Custom wire format: NULL handling
CWF supports the handling of explicit NULL values within messages, if the logical nillable property of the element is set.

An explicit null is identified by a specific value that identifies an element as being null.

The `Boolean Null Value` can be specified at the message set level, and applies to the Boolean elements of all messages that are defined in that message set. The null value of all other element types can be specified individually for each element.

CWF supports the representation of null values by using the `Encoding Null` and `Encoding Null Value` element properties. Together, this information controls how null values are handled by the MRM parser.

The `Encoding Null` property can be set to one of four values:

NullLogicalValue

The `Encoding Null Value` property is interpreted as a logical value. Therefore, if its value is set to 0, for example, both `0` and `0.00` are interpreted as null values.

NullLiteralValue

The `Encoding Null Value` property is interpreted as a string value. Therefore, the value of the element in the bit stream must match exactly the value that is specified to be interpreted as a null value.

NullPadFill

Used for fixed-length elements. On output, any element with a null value is padded to the appropriate length with the specified padding character.

NullLiteralFill

The `Encoding Null Value` property is interpreted as a single character string value. Therefore, each character of the value of the element in the bit stream must match exactly the character value specified to be interpreted as a null value.

MRM Custom wire format: Multipart messages
The Custom Wire Format (CWF) supports both the Message Identity technique and the Message Path technique of identifying embedded messages within a multipart message.

Alternatively, you can resolve an embedded message by using ESQL or Java to identify the message. The first message that you reference in this way is assumed to be the selected message. This technique works in an identical manner to `unresolved choice` handling.

MRM Custom wire format: Data Conversion
The Custom Wire Format supports the conversion of data to a different code page (for string simple types) or encoding (for numeric simple types), or both.

A message set contains properties to enable the character (CCSID) and numeric encoding (`Byte Order` / `Float Format`) information to be specified. If you generate a message dictionary for deployment to an IBM App Connect Enterprise, this information can be overridden by using the appropriate fields of the IBM MQ message header, or other transport header.

MRM Custom wire format: Relationship to the logical model
Some restrictions exist in relation to the logical model for messages that are defined by using the CWF.

Composition

A CWF message is always written with the elements in the sequence that is specified in the logical message model definition. However, you do not always have to specify the ESQL or Java that builds the elements in that sequence. The following rules for coding ESQL are given for each value of the type `Composition` property.

Sequence
You must build the output message to match the sequence of the elements or groups in the message. You can normally do this using ESQL SET statements to assign a value to each element or type. The first SET statement sets the value of the first element or type in the message, the second SET statement sets the value for the second element or type, and so on. You can vary this sequence of statements by using ESQL ATTACH, CREATE, and MOVE statements.

If the elements or types have default values, and you do not build the message in the correct sequence, those elements that are built out of sequence contain their default values, not the values that you set. This is because elements that are built out of sequence are assumed to be self-defining and, for CWF, these are discarded when the message is written to the bit stream.

Ordered Set
You must build the output message to match the sequence of the elements in the message. You can normally do this using ESQL SET statements to assign a value to each element. The first SET statement sets the value of the first element in the message, the next SET statement sets the value for the second element, and so on. You can vary this sequence of statements by using ESQL ATTACH, CREATE, and MOVE statements.

If the elements have default values, and you do not build the message in the correct sequence, those elements that are built out of sequence contain their default values, not the values that you set. This is because elements that are built out of sequence are assumed to be self-defining and, for CWF, these are discarded when the message is written to the bit stream.

Unordered Set
You can build elements of the output message in any sequence. On output, the elements are written in the order that is specified in the logical message model definition.

All
You can build elements of the output message in any sequence. Each element must be present only once (that is, it must not repeat). On output, the elements are written in the order that is specified in the logical message model definition.

Choice
A choice cannot be resolved purely from the data. The receiving program must interpret the data and decide which option of the choice the message instance contains. This process is known as *unresolved choice* handling. The first reference in the application to any one of the choice elements resolves the choice to the option that contains that element.

Message
Mechanisms for the resolution of embedded messages are discussed in the "MRM Custom wire format: Multipart messages" on page 2182 topic.

Content validation

CWF is a fixed format, and all elements must be present in a message. Therefore, content validation is ignored. On output, all elements must be set explicitly (for example, by using ESQL SET), set implicitly (by using a tree copy function), or must have a default value defined.

Default values

On output of a CWF message in the MRM domain, any element, or occurrence of an element for which a value has not been set (either explicitly or implicitly), inherits the specified default value of the element. If no default value has been specified then an exception is thrown.

Min Occurs and Max Occurs

The logical properties `Min Occurs` and `Max Occurs` specify the permitted number of occurrences of an element, or group, in a message. These properties are used when parsing and writing messages, and when validating the content of a message.

In CWF, `Max Occurs` occurrences are expected when parsing, and `Max Occurs` occurrences are produced when writing. Default values are used for missing elements, and any excess elements are discarded.

- A varying number of occurrences (`Min Occurs` <> `Max Occurs`) is ignored, `Max Occurs` is assumed.
- Optional occurrence (`Min Occurs` = 0) is ignored, `Max Occurs` is assumed.
- Always absent (`Max Occurs` = 0) is allowed.
- An unbounded number of occurrences (`Max Occurs` = -1) is allowed if the element or group is the last child in its parent group, and the group is terminated by the end of the message bit stream. On writing, the writer writes all occurrences in the message tree, if this number is less than `Min Occurs`, additional default values are written.

These rules arise because, in a CWF message format, there are no tags or other markup that can be used to determine the end of a variable number of repeats.

However this behavior is overridden if the CWF property `Repeat Reference` is set, which indicates that the number of occurrences is given instead by an integer element that occurs earlier in the message. In this case `Max Occurs` is ignored.

When validating, `Min Occurs` and `Max Occurs` are both used to check that the content of the message tree matches the model.

Simple types - lists and unions

Lists and unions are XML-specific concepts. An element or attribute of a simple type that is a list or a union causes a task list warning if a CWF physical format is present in the message set. The user can choose whether to make this an error, warning, or information by editing the Validation preferences. The dictionary generator omits messages defined to contain such elements or attributes from the CWF section of the dictionary.

MRM TDS format

The Tagged/Delimited String format (TDS) is the physical representation of a message that has a number of data elements separated by tags and delimiters.

Tip: In Version 8, when modeling and parsing general text or binary data, use message model schema with the DFDL domain, instead of message sets and the MRM domain.

The TDS physical format is designed to model messages that consist of text strings, but it can also handle binary data. Examples of TDS messages are those that conform to the ACORD AL3, EDIFACT, HL7, SWIFT, or X12 standards. The TDS physical format allows a high degree of flexibility when defining message formats, and is not restricted to modeling specific industry standards; therefore, you can use the TDS format to model your own messages.

TDS message characteristics

There are a number of features of text string messages that are common to many formats. This is an overview of the main features that are supported by the TDS physical format:

Tags

The text strings in the message can have a *tag* or a label preceding the data value. The tag is a string that uniquely identifies the data value. The TDS format allows you to associate a tag with each element when you define the element.

Delimiters and tagged data separators

The message can contain various special characters or strings in addition to the tags and text string data values. The TDS format supports a number of different types of special characters or strings.

Some messages have a special character or string that separates each data value from the next. In the TDS format this is a known as a *delimiter*.

In formats that have a tag before each data value, the tag can be separated from its data value by a special character or string. In the TDS format this is known as a *tag data separator*.

Group indicators and terminators

A message can be split into a number of substructures in a similar manner to a COBOL or C structure. You can model each of these substructures separately by defining groups, complex types, or elements for each one.

A substructure can have a special character or string that indicates its start within the data. This is known in the TDS format as a *group indicator*.

A substructure can also have a special character or string that indicates its end in the data. In the TDS format, this is known as a *group terminator*.

A group indicator and group terminator can also be defined for the whole message. Group indicators and group terminators are optional for the message and each substructure.

Fixed-length strings
Some text strings within a message can be of fixed length; therefore, a delimiter between each data value is not necessary. This is supported by the TDS format.

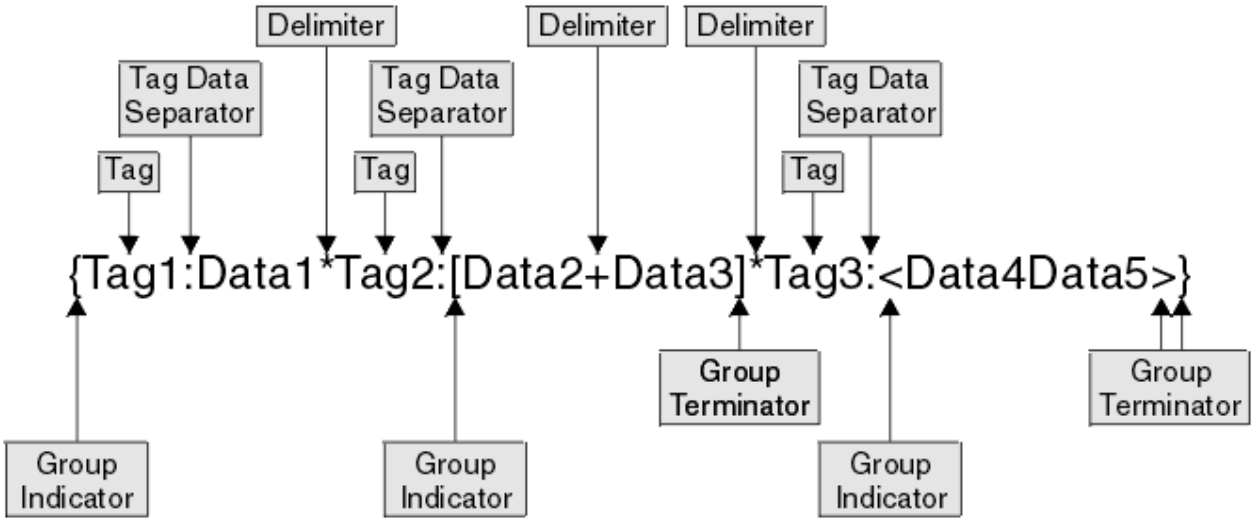
Fixed-length tags
Some tags can be defined as fixed length; therefore, a tag data separator is not necessary.

Separation types
The TDS property that controls the way text strings are separated is `Data Element Separation`. It has several options, for example, whether tags are used, whether strings lengths are fixed or variable, and what types of text strings are permitted.

The substructures within a message can use different types of data element separation and use different special characters. Therefore the TDS format allows you to define different types of data element separation and special characters for each complex type within the message.

Regular Expressions
If you choose the Use data pattern option for `Data Element Separation`, you can use regular expressions to identify parts of the message data to be assigned to sub fields. This is done by setting the regular expression in the `Data Pattern` property.

The following diagram shows an example data message with each of its components labeled.



- At the top level, each data value has a *tag* associated with it, each tag is separated from its data value by using a *tag data separator* of colon (:), and the data values are separated from each other using the asterisk *delimiter* (*).
- The *group indicator* for the message is the left brace ({) and the *group terminator* is the right brace (}).
- The data values `Data2` and `Data3` are in a substructure in which there are no tags, and each data element is separated from the next using the plus delimiter (+). The group indicator for this substructure is the left bracket ([) and the group terminator is the right bracket (]).
- The data values `Data4` and `Data5` are in a substructure in which the values are fixed length, and are therefore not separated by a delimiter. The group indicator for this substructure is the less than symbol (<) and the group terminator is the greater than symbol (>).

MRM TDS format: Determining the length of simple data values
The TDS format supports two categories of simple data types: textual and non-textual.

The Physical Type of an element determines whether it is categorized as textual or non-textual.

Textual data
Physical Type is either Text or TLOG Specific. For textual data, the Data Element Separation of the parent complex type or group determines how the length of the data is determined. See "MRM TDS format: Data element separation" on page 2186 and its subtopics.

Non-textual data
Elements of all other Physical Types are non-textual. The length of non-textual data is determined by the Physical Type of the element. For non-textual data, the Data Element Separation property of the parent complex type or group does not determine the length, unless Data Element Separation is Use Data Pattern. See "MRM TDS format: Data pattern separation types" on page 2195 for more information.

The following table describes how the length of data is determined for each Physical Type.

Physical Type	Determination of Length
Text TLOG Specific	The Data Element Separation of the parent complex type or group determines how the length of the data is determined.
External Decimal Integer Packed Decimal Float Time Seconds Time Milliseconds	Uses the value of the Length property of the element. If Physical Type is Time Seconds, the Length property is set to 4. If Physical Type is Time Milliseconds, the Length property is set to 8. In neither case can this value be changed.
Length Encoded String 1 Length Encoded String 2	Uses the encoded length value in the data.
Null Terminated String	Uses the null terminator at the end of the data.
Binary	Uses the value of the Length Reference or Length property of the element.

MRM TDS format: Data element separation
Data element separation defines how a TDS message is to be parsed.

Data element separation defines which method of identifying data elements is to be used and how the data elements are constructed. The different methods vary from full flexibility to fixed format, depending on how they are defined.

The four main types of data element separation are:

Fixed-length types
Fixed-length types are dependent on each element having a length. See "MRM TDS format: Fixed-length separation types" on page 2187.

Tagged separation types
Tagged separation types are dependent on each element having tag prefix to identify it. See "MRM TDS format: Tagged separation types" on page 2188.

Delimited separation types
Delimited separation types use delimiters to identify the end of one data elements and the beginning of the next. See "MRM TDS format: Delimited separation types" on page 2191.

Data pattern types
Data pattern types use a regular expression to identify each element. See “MRM TDS format: Data pattern separation types” on page 2195.

There is a fifth category, which is different from the four described earlier in this topic:

Undefined separation types
Undefined separation types contain no data elements. They are applicable to embedded messages only. They use none of the TDS type-specific parameters other than `Data Element Separation`. See “Message Sets: Multipart messages” on page 2175.

MRM TDS format: Fixed-length separation types
For fixed-length separation types, each data value is a fixed length.

For fixed-length data element separation types, all textual elements have a length or length reference, and are padded out to their full length in the bit stream. No tags or delimiters are used, and each data value directly follows the preceding data value.

For example:

```
data1data200data30
```

The first element is length 5, the second is length 7, and the third is length 6. The padding character is "`0`".

For non-textual elements, the length is determined by the `Physical Type` of the element. See “MRM TDS format: Determining the length of simple data values” on page 2186.

Fixed-length type

In fixed-length type, all textual elements must have a length or length reference, and must be written out to that full length. The elements must be presented in the correct order, and all elements must be written in the bit stream. This includes all repeats of any repeating element (that is, the `Maximum Occurrences` must be written out for each element).

For non-textual elements, the length is determined by the `Physical Type` of the element. See “MRM TDS format: Determining the length of simple data values” on page 2186.

For example:

```
data10data2data2data2data300
```

The first element is length 6, the second is length 5, and repeats three times, and the third element is length 7. The padding character is "`0`".

Applicable parameters

The main parameters for this format are the `Length` or `Length Reference` of the element. All fields must be padded out to their full length for the bit stream to be correctly specified to the parser.

Tag and delimiter parameters are ignored. Group indicators and terminators are observed, because they are of fixed length.

Default values are required for each field that might not be set, because then every field can be produced as output, even if it is not filled with data from the message.

Fixed-length AL3 type (Deprecated)

This separation type has been deprecated. ACORD AL3 support will be provided by a different method in a future release, at which time this separation type will be removed from service.

Fixed-length AL3 types are similar to fixed-length types, but follow extra rules that are specified by the ACORD AL3 format regarding truncation and missing elements. If elements are missing from the end of an AL3 type, they can be truncated. They cannot be omitted from the middle of a bit stream. If a field is missing from the middle of the bit stream, that field is produced for output as the appropriate length string of the "?" character.

Applicable parameters

The main parameters for this format are the `Length` or `Length Reference` of the element. All fields must be padded out to their full length for the bit stream to be correctly specified to a parser.

Tag and delimiter parameters are ignored. `Group Indicators` and `Terminators` are observed, because they are of fixed length.

MRM TDS format: Tagged separation types

For tagged separation types, each data value is preceded by a tag that is specified as an element property.

The `Tag Data Separator`, or specific `Length of Tag` parameter is used to determine where the tag ends and the data starts. Different methods are used by each separation type to determine the end of the data.

After considering these two parameters, this topic describes the following supported tagged separation types:

- "Tagged Delimited separation" on page 2188
- "Tagged Fixed Length separation" on page 2189
- "Tagged Encoded Length separation" on page 2190

Tagged separation is a flexible format. The elements do not have to occur in a specific order. They do not all need to be present, and can be absent from any point in the message.

`Tag Data Separator` and `Tag Lengths`

Either `Tag Data Separator` and `Length of Tag` are used by all tagged separation types. But only one of these parameters can be set at the same time.

The point at which a tag ends and data starts can be determined by one of two methods. If the `Tag Data Separator` is set, then this character indicates where the data ends. For example, the string might be:

```
tag1:data1
```

where `Tag Data Separator` is :

However if the `Tag Data Separator` is not set and the `Length of Tag` field *is* set, then the tag is the specified length, and is immediately followed by the data. No separating character is required. For example, the string might be:

```
tag1data1
```

where `Length of Tag` is 4

Tagged Delimited separation

Tagged Delimited separation is a flexible format. Elements are separated by a predefined delimiter. The textual elements are not of specific lengths. For non-textual elements, the length is determined by the `Physical Type` of the element. See "MRM TDS format: Determining the length of simple data values" on page 2186.

Applicable parameters

These parameters are used:

- `Group Indicator` indicates the start of a group or complex type.
- `Group Terminator` indicates the end of a group or complex type.
- `Delimiter` separates the data elements within a group or complex type.
- `Tag` for each element, indicates the tag needed to precede the data in that field.
- Either `Tag Data Separator` or `Tag Length` as described earlier in this topic.

Examples

If `Tag Data Separator` is set to :

```
{tag1:data1*tag2222222:data2*tag333:data3}
```

where:

- `Group Indicator` is {.
- `Group Terminator` is }.
- `Delimiter` is *.
- Tag defined for each element, is tag1 (for data1), tag2222222 (for data2), and tag333 (for data3).

or, for example, if `Length of Tag` is set to 5

```
{tag11data1*tag22data2*tag33data3}
```

where parameters are as above, except:

- Tag, defined for each element (fixed at five characters), is tag11 (for data1), tag22 (for data2), and tag33 (for data3).

Tagged Fixed Length separation

Although Tagged Fixed Length separation is a flexible format, the data must be a specific length. This means that a delimiter is not needed to determine the end of each element.

Applicable parameters

These parameters are used:

- `Group Indicator` indicates the start of a group or complex type.
- `Group Terminator` indicates the end of a group or complex type.
- Tag for each element, indicates the tag needed to precede the data in that field.
- For each textual element, `Length` or `Length Reference` indicates the length of the data (this value does *not* include the length of the tag). For non-textual elements, the length is determined by the `Physical Type` of the element. See “MRM TDS format: Determining the length of simple data values” on page 2186.
- Either `Tag Data Separator` or `Tag Length` as described earlier in this topic.

Examples

If `Tag Data Separator` is set to :

```
{tag1:data1tag22222222:data2000tag333:data300}
```

where:

- `Group Indicator` is {.
- `Group Terminator` is }.
- `Delimiter` is *.
- Tag, defined for each element, is tag1 (for data1), tag22222222 (for data2000), and tag333 (for data300).
- `Length`, defined for each element, is 5 (data1), 8 (data2000), and 7 (data300).

or, for example, if `Length of Tag` is set to 5

```
{tag11data1tag22data2000tag33data300}
```

where parameters are as above, except:

- Tag, defined for each element (fixed at five characters), is tag11 (data1), tag22 (data2000), and tag33 (data300).

Tagged Encoded Length separation

This method has both a tag and a length field before the data. The length field indicates to the parser the length of the data following it.

The length of this length field is itself defined in the `Length of Encoded Length` parameter. Extra lengths to be added in this, such as the length of the field itself, is set in the `Extra Chars in Encoded Length` parameter.

Only textual elements and elements with a Binary logical and physical type are supported within a Tagged Encoded Length separation.

These examples show how the values set in these parameters are applied:

- `tagA007dataAAAtagB006dataBBtagC009dataCCCCC`

  If `Length of Tag` is 4, `Length of Encoded Length` is 3, `Extra Chars in Encoded Length` is 0, then in this bit stream, `TagA` is followed by the three character long length field. This indicates that the following data (`dataAAA`) is seven characters long. The next field, `tagB` is then considered, and so on.

- `tagA012dataAAAAAtagB010dataBBBtagC016dataCCCCCCCCC`

  If `Length of Tag` is 4, `Length of Encoded Length` is 3, `Extra Chars in Encoded Length` is 3, then in this bit stream, `TagA` is followed by the three-character length field. This indicates that the following data, plus extra characters, is 12 characters long: length of the length field (3) + length of data (9) = 12. Therefore the length of the actual data is only 12-3 = 9. The next field, `tagB` is then considered, and so on. In each case the length given in the bit stream is 3 greater than the actual length of the data.

Applicable parameters

These parameters are used:

- `Group Indicator` indicates the start of a group or complex type.
- `Group Terminator` indicates the end of a group or complex type.
- `Tag` for each element, indicates the tag needed to precede the data in that field.
- `Length of Encoded Length` indicates the length of the length field in the bit stream.
- `Extra Chars in Encoded Length` indicates how many extra characters should be included in calculating the value for the length field in the bit stream.
- Either `Tag Data Separator` or `Tag Length` as described earlier in this topic.

Examples

If `Tag Data Separator` is set to :

```
{tag1111:008data1tag222222222:010data2AAtag3333:009data3A}
```

where:

- `Group Indicator` is {
- `Group Terminator` is }
- `Length of Encoded Length` is 3
- `Extra Chars in Encoded Length` is 3
- Tag, defined for each element, is tag1111, tag222222222, tag3333, and so on

or, for example, if `Length of Tag` is set to 5

```
{tag11008data1tag22010data2AAtag33009data3A}
```

where parameters are as above, except:

- Tag, defined for each element (fixed at five characters), is tag11, tag22, tag33, and so on

MRM TDS format: Delimited separation types
For delimited separation types, a delimiter is used to separate data fields, but there are no tags present. The data fields must be given in the correct order in the bit stream and elements cannot be omitted from the middle of the bit stream.

The All Elements Delimited separation type means that data fields are delimited by a pre-specified character or string. In this example, four data fields are separated by an asterisk (*) delimiter:

```
data1*data2*data3*data4
```

Delimited separation types are restrictive in the ordering and presence of elements:

- The elements must be given in the order specified.
- No element can be omitted in the middle of a group or complex type, because the parser cannot determine this from the resulting bit stream.
- Elements can sometimes be absent from the end of a complex type or group.

After considering "Delimiter suppression and truncation rules" on page 2191, this topic describes the following delimited separation types:

- "All Elements Delimited" on page 2192
- "Variable Length Elements Delimited" on page 2193

Delimiter suppression and truncation rules

- Elements cannot be omitted from the middle of a group or complex type. An absent element results in the inclusion of a zero-length string.

  For example, with all elements present, the string might be:

  ```
  data1*data2*data3*data4
  ```

  where `Delimiter` is *

  If `data2` is missing, the string would read:

  ```
  data1**data3*data4
  ```

- It is possible to suppress the delimiters at the end of a string for absent elements. The `Suppress Absent Element Delimiter` property determines whether this is done. If this property is set to End of Type, this can be done (with one exception, shown later in this section).

  In this case, for the example with `data3` and `data4` missing, the string would read:

  ```
  data1*data2
  ```

  That is, the delimiters have been suppressed from the end of this group or complex type.

- If the Suppress Absent Element Delimiter property is set to Never, delimiter suppression never takes place. The string would read:

  ```
  data1*data2**
  ```

  That is, the delimiters must be present to indicate absent (zero-length) elements.

  An exception to the above rule occurs in the case where the same delimiters are used at multiple levels in the model.

  For example, you have a complex type or group with delimiter * and this contains an element of another complex type (indicated by the element3 prefix on data fields in the following example), which also has delimiter *. If both types use a delimited separation type, with all elements present, you might have:

  ```
  data1*data2*element3Data1*element3Data2*element3Data3*data4
  ```

  If element3Data2 and element3Data3 are missing, and the delimiters are suppressed, it is not possible for the parser to determine which elements are missing.

  Therefore, in this case, you must override the Suppress Absent Element Delimiter property, and write out all the delimiters to clearly define the message to the parser. Therefore, the string must be:

  ```
  data1*data2*element3Data1***data4
  ```

  This restriction also applies where Group Indicators and Group Terminators use the same character strings as delimiters; otherwise, the bit stream is not clear to the parser.

All Elements Delimited

In an All Elements Delimited separation type, all elements are separated by a delimiter; for example:

```
data1*data2*data3*data4*data5
```

where Delimiter is *.

An All Elements Delimited separation type does not use tags or their associated parameters.

For textual elements, the length is determined by the delimiter, and the Length property is ignored unless the Observe Element Length property is set.

For non-textual elements, the length is determined by the Physical Type of the element. See “MRM TDS format: Determining the length of simple data values” on page 2186.

Applicable properties

These properties are used:

- Group Indicator indicates the start of a group or complex type.
- Group Terminator indicates the end of a group or complex type.
- Delimiter indicates the separator between the data elements within a group or complex type.
- Suppress Absent Element Delimiters indicates whether delimiter suppression is permitted.

For example:

```
{data1*data22222*data3}
```

where:

- Group Indicator is {
- Group Terminator is }
- Delimiter is *

Repeating element rules

If an element must be repeated when the separation type is All Elements Delimited, the `Repeating Element Delimiter` (RED), is used to separate the repeated elements.

For example if `data2` repeats five times:

```
data1*data2:data2:data2:data2:data2*data3*data4
```

where:

- `Delimiter` is *
- `Repeating Element Delimiter` is:

If the `Suppress Absent Element Delimiters` property is set to End of Type, you can use delimiter suppression. Therefore, if only the first `data2` element was present in the previous example, the bit stream reads:

```
data1*data2*data3*data4
```

However, if the `Suppress Absent Element Delimiters` property is set to Never, the bit stream reads:

```
data1*data2::::*data3*data4
```

If `Delimiter` and RED match, two delimiters are output to indicate that the repeat is ending. Therefore, if the delimiter and RED are *, the bit stream reads:

```
data1*data2**data3*data4
```

Variable Length Elements Delimited

In a complex type with Variable Length Elements Delimited separation, some elements are determined by their length, and other elements are delimited. This combination of a delimited and a fixed-length format follows rules that are associated with both formats. Lengths can be given and used, but they are not mandatory.

- If a length is present for a textual element, it is used, and a delimiter is not needed to terminate that element. The element must be padded to the correct length, and cannot exceed that length.
- If no length is given for a textual element, the delimiter is required.
- For non-textual elements, the length is determined by the `Physical Type` of the element. See "MRM TDS format: Determining the length of simple data values" on page 2186.

A complex type with Variable Length Elements Delimited separation that contains only variable length elements resembles a complex type with All Elements Delimited separation. If it contains only fixed-length elements, it resembles a Fixed Length type.

For example:

```
data1*data2*data3*data4000data5
```

where:

- `Delimiter` is *
- `data4` has a length of 8

Applicable properties

The following properties are used:

- `Group Indicator` indicates the start of a group or complex type.
- `Group Terminator` indicates the end of a group or complex type.
- `Delimiter` indicates the separator between the data elements within a group or complex type.

- `Suppress Absent Element Delimiters` indicates whether delimiter suppression is permitted.
- (Optionally) `Length` or `Length Reference` indicates the length of a textual element. If a textual element has a length, this length is used. Because the length of this element is known, it is not necessary to output a delimiter after it. If the length is not known, a delimiter is required. A delimiter is never required for a non-textual element.

In this example, the fourth field (containing `data4`) is of fixed length 8 and its padding character is `0`:

```
{data1*data22222*data3*data4000data5}
```

where:

- `Group Indicator` is {
- `Group Terminator` is }
- `Delimiter` is *

Repeating element rules

The action of a repeating element in a Variable Length Elements Delimited environment is dependent on the minimum and maximum number of repeats and whether the element has a length.

Delimited Element Repeating

If a delimited element (that is, an element with no length) is repeated, a `Repeating Element Delimiter` (RED) is required and the rules for All Elements Delimited are followed. A delimiter is therefore required after the last repeat. Delimiter suppression of this repeat can also occur.

For example, if `data2` is repeating:

```
data1*data2:data2:data2:data2:data2:data2*data3*data4000data5
```

where:

- `Delimiter` is *
- `Repeating Element Delimiter` is :
- `data4` has a fixed length of 8

If the `Suppress Absent Element Delimiters` field is set to End of Type, you can use delimiter suppression.

If in the above example only the first `data2` is present:

```
data1*data2*data3*data4000data5
```

However, if `Suppress Absent Element Delimiters` is set to Never, the bit stream reads:

```
data1*data2:::::*data3*data4000data5
```

If the delimiter and RED match, two delimiters are output to indicate that the repeat is ending. So if the delimiter and RED are both *, the bit stream reads:

```
data1*data2**data3*data4
```

This also applies for a non-fixed length complex type or group inside a Variable Length Elements Delimited environment.

Fixed Length Element Repeating

If an element with a defined length (a fixed-length element) is repeating and the minimum occurrences is not the same as maximum occurrences, an RED is not required, but a delimiter *is* required after the last repeat. Delimiter suppression of this repeat can occur.

For example, if data4 (with a fixed length of 8) is repeating, and its minimum occurrences is 2, maximum occurrences is 4:

```
data1*data2*data3*data400data400data400data400*data5
```

where Delimiter is *

Or, if there are only two occurrences of data4:

```
data1*data2*data3*data4000data4000*data5
```

If an element with a defined length (a fixed-length element) is repeated, and the minimum occurrences is the same as maximum occurrences, an RED is not required. A delimiter is also not required after the last repeat. Truncation of this repeat cannot occur and all elements need to be present.

For example, if data4 (with a fixed length of 8) repeats four times:

```
data1*data2*data3*data4000data4000data4000data4000data5
```

where Delimiter is *

Or, if there are only two occurrences of data4:

```
data1*data2*data3*data4000data4000000000000000000data5
```

This also applies for a non-fixed length complex type or group inside a Variable Length Elements Delimited environment.

If a complex type has Variable Length Elements Delimited separation, a delimiter is always output between an included ('child') complex element and the next element even if the separation of the 'child' complex element is Fixed Length. On input, the parser accepts the bit stream with or without such a delimiter.

MRM TDS format: Data pattern separation types
For a data pattern separation type, each data value is matched with a regular expression that is specified as a property of each element.

The length of both textual and non-textual data is determined by the Data Pattern property of the element. If the Physical Type of the element is Length Encoded String 1 or Length Encoded String 2, the regular expression must match both the encoded length and the following data. The length in the encoded length must be consistent with the length matched by the regular expression. If the Physical Type of the element is Null Terminated String, the regular expression must match both the data and the following null terminator.

The Data Pattern separation type uses a regular expression that is specified for each element to match the data. The parser matches the data with the regular expression in the Data Pattern property for that element. TDS parsing in the MRM parser uses the regular expression in Data Pattern to determine the length of the element, whether it is repeating, and whether it is present in the bit stream.

No delimiters or tags, other than those coded as part of the regular expression pattern, are used in the bit stream. See Message Sets: Using regular expressions to parse data elements for an explanation of pattern matching.

For example, if the first three Data Pattern properties are, respectively:

- [A-Z]{1,3}
- [0-9]+
- [a-z]*

and the message data is:

```
DT31758934information for you
```

Then, in this example:

- First data element = DT
- Second data element = 31758934
- Third data element = information

The first data pattern means "from one to three characters in the range A to Z", the second means "one or more characters in the range 0 to 9", and the third means "zero or more characters in the range a to z". Note how each element's data was terminated by the first character that did not match the element's Data Pattern.

If the TDS message that is being parsed is encoded in a single-byte code page, the Data Pattern property can include hexadecimal values. A hexidecimal value is specified as \xNN, where N is a hexadecimal digit in the range 0 to F. Note, however, that the value \x00 is not valid.

Performance issues

The parsing required in Data Pattern separation type is the slowest of all the different separation types because of its complexity.

Therefore, use Data Pattern separation type only when no other separation type models the message. Do not use it, for example, when you can use Fixed Length separation type.

Applicable parameters

Only one parameter is used:

Data Pattern for each element, indicates the regular expression that is used for string matching.

MRM TDS format: Message model integrity
When you use the TDS wire format, you must conform to a number of rules that apply to the setting of values of properties. This is necessary to avoid any discrepancies when processing a message within the specified model.

Rules of TDS physical format properties

Restrictions to message formats are checked. These restrictions follow the rules specified in Message Sets: TDS message model integrity. Most rules are applied for at least one of these reasons:

Rules for message definition
Some rules are necessary for the message to be defined.

For example, in a Fixed Length separation type all elements must have some length defined, either directly or by using a Length Reference. Without this information, it is impossible to tell in the message bit stream where one data element ends and the next starts.

Rules for nesting
Nesting rules relate to which separation types can be nested inside each other.

Such rules are applied when an element of a complex type is present inside another complex type. An example is that it is not possible to have a Tagged Delimited separation type inside a Fixed Length type. Because a Tagged Delimited separation type is of variable length, the parent Fixed Length type would be unable to tell where that particular element ended, as there would be no length provided. Therefore the message could not be processed.

Rules linking to the logical model
There are also rules linking TDS to the logical model.

These rules occur where a group composition or group content validation cannot be used with a particular separation type. Again this is for message integrity. For example, a separation type of All Elements Delimited cannot have a group composition of Open, as there is no information as to what the extra elements represent and where they are in the bit stream.

MRM TDS format: NULL handling
NULL handling dictates the way in which the MRM parser for TDS messages handles elements that have been set to Null.

Null handling takes place only if the logical Nillable property of the element is set. The rules for whether nulls are permitted are described in Message Sets: TDS Null handling options.

Null properties

The element properties `Encoding Null` and `Encoding Null Value` control how null handling is represented for individual elements.

You can select the `Encoding Null` property from the enumerated values NULLPadFill, NULLLogicalValue, NULLLiteralValue, and NULLLiteralFill. The use of the `Encoding Null Value` property is dependent on the value that you select for the `Encoding Null` property.

NULL values are not defined for schema xsd:hexBinary simple types. The properties `Encoding Null` and `Encoding Null Value` are therefore not set for xsd:hexBinary types.

NULL values for schema `Boolean` simple types are defined at the message set level. The message set property `Boolean Null Representation` specifies the value to be used for Boolean Null representation.

MRM TDS format: Multipart messages
The Tagged/Delimited String Format (TDS) supports both the Message Identity technique and the Message Path technique of identifying embedded messages within a multipart message.

The SWIFT, X12, and EDIFACT messaging standards can all be modeled by using the Message Identity technique.

MRM TDS format: Data conversion
TDS string data is subject only to CCSID conversion.

All TDS message data apart from binary types are handled as strings. All string data is therefore subject to CCSID conversion only. This includes the special characters used as delimiters, data separators, and so on \.

MRM TDS format: Relationship to the logical model
TDS separation types and logical model properties have some restrictions, such as group composition and group content validation.

The rules that govern these options are explained in Message Sets: Restrictions for nesting complex types.

These rules exist to ensure the integrity of the message. A combination of separation type and group composition or group content validation must not lead to a message that is unclear to a TDS parser.

Default values

In TDS, *Default* values are only observed by fixed-length elements:

Separation Type	**Use of `Default` values**
Tagged Delimited Tagged Fixed Length Tagged Encoded Length All Elements Delimited Data Pattern	`Default` values are never observed.
Fixed Length Fixed Length AL3	`Default` values are observed on output by all elements. An absent element that has no `Default` value defined, causes an error on writing.

Separation Type	Use of `Default` values
Variable Length Elements Delimited	`Default` values are only observed by fixed-length elements on output. Absent fixed-length values must have a `Default` value available to them. An absent element that has no `Default` value defined, causes an error on writing.

Simple types - lists and unions

Lists and unions are XML-specific concepts. An element or attribute of a simple type that is a list or a union causes a task list warning if a TDS physical format is present in the message set. The user can choose whether to make this an error, warning, or information by editing the Validation preferences. If a dictionary is generated from the message set, and an attempt is made to parse a TDS message defined to contain such elements or attributes, a runtime error occurs.

`Min Occurs` and `Max Occurs`

The logical properties `Min Occurs` and `Max Occurs` specify the permitted number of occurrences of an element or group in a message. They are used when parsing and writing messages, and when validating the content of a message.

When parsing and writing, the exact interpretation of these properties depends on the `Data Element Separation` property of the parent complex type or group as shown in the following table.

However, this behavior is overridden if the TDS `Repeat Reference` property is set, which indicates that the number of occurrences is given instead by an integer element that occurs earlier in the message. See “Repeat reference” on page 2200 for more information.

When validating, `Min Occurs` and `Max Occurs` are both used to check that the content of the message tree matches the model.

Separation type	Interpretation of `Min Occurs` and `Max Occurs`
Tagged Delimited Tagged Fixed Length Tagged Encoded Length	`Min Occurs` and `Max Occurs` are effectively ignored when parsing and writing. When parsing, the number of occurrences is identified by the tags in the message. When writing, the writer outputs all occurrences in the message tree. • A varying number of occurrences (`Min Occurs` <> `Max Occurs`) is allowed. • Optional occurrence (`Min Occurs` = 0) is allowed. • Always absent (`Max Occurs` = 0) is allowed. • An unbounded number of occurrences (`Max Occurs` = -1) is allowed.

Separation type	Interpretation of Min Occurs and Max Occurs
All Elements Delimited	Max Occurs is used only when parsing and writing, with the element's Repeating Element Delimiter property, and the parent type's Suppress Absent Element Delimiters property. A varying number of occurrences (Min Occurs <> Max Occurs) is allowed if Suppress Absent Element Delimiters is set to End of Type. • If the Delimiter is different from the Repeating Element Delimiter, the Delimiter signifies the end of the occurrences. • If the Delimiter is the same as the Repeating Element Delimiter, an empty repeat signifies the end of the occurrences. • In both these cases, Max Occurs is the maximum number of repeats that are expected. If Suppress Absent Element Delimiters is Never, all occurrences are expected when parsing, and produced when writing, although parsing accepts elements being absent. Optional occurrence (Min Occurs = 0) is ignored and a delimiter is still expected when parsing, and produced when writing. Always absent (Max Occurs = 0) is allowed. No delimiter is expected when parsing, nor output when writing. An unbounded number of occurrences (Max Occurs = -1) is only allowed if the Repeating Element Delimiter is different from the Delimiter. The repeats must be terminated by the delimiter, or a containing group's Group Terminator or Delimiter, or by the end of the message bit stream. On writing, the writer outputs all occurrences in the message tree.
Fixed Length Fixed Length AL3	Max Occurs is used only when parsing and writing. In general, Max Occurs occurrences are expected when parsing, and Max Occurs occurrences are produced when writing; default values are used for missing elements, and any excess elements are discarded. A varying number of occurrences (Min Occurs <> Max Occurs) is ignored, Max Occurs is assumed. Optional occurrence (Min Occurs = 0) is ignored, Max Occurs is assumed. Always absent (Max Occurs = 0) is allowed. Fixed Length only. An unbounded number of occurrences (Max Occurs = -1) is allowed if the element or group is the last child in its parent group, and the group is terminated by a Group Terminator or a containing group's Group Terminator or Delimiter or by the end of the message bit stream. On writing, the writer outputs all occurrences in the message tree, if this number is less than Min Occurs, additional default values are written.
Variable Length Elements Delimited	For fixed length simple elements, the rules for Fixed Length separation above are followed with two differences. 1. A varying number of occurrences (Min Occurs <> Max Occurs) is allowed, the end of the occurrences being signified by an extra delimiter. 2. An unbounded number of occurrences (Max Occurs = -1) is allowed, the end of the occurrences being signified by an extra delimiter. On writing, the writer outputs all occurrences in the message tree, followed by an extra delimiter. For variable length simple elements, all complex elements and groups, the rules for All Elements Delimited above are followed.

Separation type	Interpretation of `Min Occurs` and `Max Occurs`
Data Pattern	`Min Occurs` and `Max Occurs` are effectively ignored when parsing and writing. When parsing, the pattern is matched as many times as possible. When writing, the writer outputs all occurrences in the message tree. Note that on parsing, if the data pattern permits a zero length match, and a zero length match occurs, an element is added to the message tree, and the matching terminates to prevent an infinite loop. A varying number of occurrences (`Min Occurs` <> `Max Occurs`) is allowed. Optional occurrence (`Min Occurs` = 0) is allowed. Always absent (`Max Occurs` = 0) is allowed. An unbounded number of occurrences (`Max Occurs` = -1) is allowed.

`Repeat reference`

The TDS property `Repeat reference` specifies a field that holds the number of repeats of an object (Element or Group) within a message. The field that holds the number of repeats must be within the message before the object that it refers to.

From a parsing perspective, the `Repeat reference` property replaces the role of the `minOccurs` and `maxOccurs` properties.

If a value for the `Repeat reference` property is specified for an object, values that are specified for `minOccurs` and `maxOccurs` are ignored when parsing and writing. However, values that are specified for `minOccurs` and `maxOccurs` are used by logical validation.

When parsing and writing, the exact interpretation of the `Repeat reference` property depends on the `Data Element Separation` property of the parent complex type or group as shown in the following table.

Separation type	Interpretation of `Repeat reference`
Tagged Delimited Tagged Fixed Length Tagged Encoded Length	`Repeat reference` is effectively ignored when parsing and writing. When parsing, the number of occurrences is identified by the tags in the message. When writing, the writer outputs all occurrences in the message tree.
All Elements Delimited	`Repeat reference` is used when parsing and writing, with the element's `Repeating Element Delimiter` property, and the parent type's `Suppress Absent Element Delimiters` property. A `Repeat reference` is allowed only if the parent complex type or group has `Suppress Absent Element Delimiters` set to Never. All `Repeat reference` occurrences are expected when parsing, and produced when writing. However, parsing accepts elements being absent. `Repeat reference` = 0 is allowed. No delimiter is expected when parsing, nor produced when writing.
Fixed Length Fixed Length AL3	`Repeat reference` is used when parsing and writing. `Repeat reference` occurrences are expected when parsing, and are produced when writing, with default values used for missing elements. `Repeat reference` = 0 is allowed.
Variable Length Elements Delimited	For fixed length simple elements, the rules for Fixed Length separation above are followed. For variable length simple elements, all complex elements and groups, the rules for All Elements Delimited that are listed above are followed.

Separation type	Interpretation of `Repeat reference`
Data Pattern	`Repeat reference` is effectively ignored when parsing and writing. When parsing, the pattern is matched as many times as possible. When writing, the writer outputs all occurrences in the message tree. Note that, on parsing, if the data pattern permits a zero length match, and a zero length match occurs, an element is added to the message tree, and the matching terminates to prevent an infinite loop.

MRM XML physical format

The MRM XML physical format describes the physical representation of an XML message for use by the MRM parser.

Tip: In Version 8, when modeling and parsing XML data, use message model schema with the XMLNSC or SOAP domains, instead of message sets and the MRM domain.

An XML wire format describes the physical representation of a message that is written according to the standards given in the W3C Extensible Markup Language (XML) specification. The wire format defines information that is used to parse or write XML messages in a runtime environment such as an integration node. XML versions 1.0 and 1.1 are both supported.

You can add more than one XML physical format to a message set, but within that message set, each physical format must have a unique name. The default name for an XML wire format is XML1. The physical format name identifies the definitions that are to be used by the integration node at run time.

After adding an XML physical format, all XML properties for all existing objects in the message set are set to default values. Therefore, immediately after adding the format and deploying the message set to a runtime environment, you can process XML messages by using MRM features.

You can configure XML properties for the message set, and for objects within the message set. Objects that can have XML properties are messages, elements, and attributes. For example, a message object can be customized to define a specific DTD declaration on output; an element can have a tag name assigned to it which is different from its element name in the model.

Adding an XML wire format to a message set allows you to both process input messages, and to construct output messages in this format. You can also transform messages between XML and either CWF or TDS.

XML messages are, by their nature, self-describing: each piece of data is prefixed by a tag name or an attribute name. Therefore, it is possible for an XML message instance to contain elements that are not in the definition for that message.

- If such an element exists in the message set, the model objects for that element are used in parsing or writing the message.
- If the element does not exist in the message set, it is treated as a self-defining element, and its data type is set to string.

Although it is possible to define an XML message 'by hand', using the Message Definition Editor, IBM App Connect Enterprise also provides importers for both XML Schema and DTD, and these are often quicker and easier than manual definition.

MRM XML physical format: Message model integrity

When you save a message definition file, the definitions that it contains are checked to ensure that they make sense and provide sufficient information about the message. This action is called *model validation*.

For XML, these checks mostly concern the uniqueness and validity of XML names in global elements and attributes, and also for elements and attributes within complex types or groups.

Tests other than these tend to be both simple and obvious so that, for example, the message set property `First Day of Week` must be the name of a day in the week.

MRM XML physical format: NULL handling
The purpose of null handling is to specify how messages deal with null values; that is, the absence of a meaningful value for an element.

Null properties for the MRM XML physical format are set for the message set only, and apply to all the defined objects within the message set, by using the four properties `Encoding Null Num`, `Encoding Null Non-Num`, `Encoding Null Num Val` and `Encoding Null Non-Num Val`.

Null handling takes place only if the logical Nillable property of the element is set.

The purpose of these parameters is to specify how messages deal with null values. In an XML message there are several options. Most obviously an element could omit a value, for example:

```
<element1></element1>
```

Or, the element could include a distinctive value that means that no real value is present, for example.

```
<element1>null</element1>
```

Or, the element could follow XML Schema instance rules:

```
<element1 xsi:nil="true"/>
```

The properties `Encoding Null Num` and `Encoding Null Non-Num` specify the style of null handling, for example, that null is represented by an empty element.

The properties `Encoding Null Num Val` and `Encoding Null Non-Num Val` provide a value (if needed) to represent a null value. For an element of type string, this might be `null` or `unspecified` while for a number it might be `0` or `0.0`.

MRM XML physical format: Multipart messages
Identify embedded messages by using either a Message Identity or a Message Path.

If you are using the MRM XML physical format, an embedded message can be identified in any of the following ways:

- Message Identity

  See “Message Sets: Identifying an embedded message by using a Message Identity” on page 2176.
- Message Path

  See “Message Sets: Identifying an embedded message by using a Message Path” on page 2178.
- Automatic

  The MRM parser identifies the message by matching the next XML tag in the bit stream against the XML Name of a message definition.

If you choose the Message Identity or Message Path technique, the MRM parser still checks that the next XML tag name matches the XML Name of the message that was identified. If the XML Name does not match, an exception is thrown.

Where you have defined the embedded message in a different message set, you must use a Message Set Identity element or attribute value to specify the target message set. Note that the message sets within which the root and subsequent embedded messages are defined must be consistent in their use of the 'Use Namespace' property of the message set. That is, embedded messages that are defined in a namespace-aware message set and that are contained within a parent message that is defined in a message set that is not namespace-aware, are not supported. Similarly, embedded messages that are defined in a message set that is not namespace-aware and that are contained within a parent message that is defined in a namespace-aware message set, are not supported.

If the embedded message definition is a complex type, the message definition contains a complex element based on that complex type. This complex element has its own tag, which appears in the bit stream before the tag for the embedded message. If you want to avoid this extra tag, you can create

the embedded message definition from a group, and insert the group at the appropriate position in the message model.

Tip: Note that the root tag property of an embedded message is not applicable.

MRM XML physical format: Relationship to the logical model
The MRM XML physical format generally respects all the settings in the logical model, but shares certain restrictions in common with the other physical formats.

These restrictions are documented in MRM restrictions.

Default values

The MRM XML physical format ignores default and fixed values on elements and attributes. If validation is enabled in IBM App Connect Enterprise, this can lead to unexpected validation errors for missing elements, even though they have default or fixed values.

Simple types - unions and lists

The XML properties of an element or attribute of a simple type that is a union or list vary depending on the members of the union or the itemType of the list. If the union or list includes a dateTime type (or other date/time related type) the `Date Format` field is displayed. If the union includes a binary type, the `Encoding` field is displayed.

Min Occurs and Max Occurs

The logical properties `Min Occurs` and `Max Occurs` specify the permitted number of occurrences of an element or group in a message. They are used when validating the content of a message.

When parsing and writing, using the MRM XML physical format, `Min Occurs` and `Max Occurs` are effectively ignored. When parsing, the number of occurrences is identified by the tags in the message. When writing, the writer outputs all occurrences in the message tree.

- A varying number of occurrences (`Min Occurs` <> `Max Occurs`) is allowed.
- Optional occurrence (`Min Occurs` = 0) is allowed.
- Always absent (`Max Occurs` = 0) is allowed
- An unbounded number of occurrences (`Max Occurs` = -1) is allowed.

When validating, `Min Occurs` and `Max Occurs` are both used to check that the content of the message tree matches the model.

MRM XML physical format: Handling xsi:type attributes
The prefix "xsi" is the namespace prefix used by convention for the XML Schema instance namespace. XML documents can contain elements that have an xsi:type attribute. This behavior provides an explicit data type for the element.

The MRM XML parser in sensitive to xsi:type attributes in the XML document. It modifies the data type of the element accordingly and adds the xsi:type attribute into the message tree.

The MRM XML writer is sensitive to xsi:type attributes in the message tree. It produces xsi:type attributes according to XML Wire Format message set property **Output policy for xsi:type attributes**. For example, xsi:type attributes can be removed, output on all elements or output according to rules specified in the SOAP standard.

If validation is enabled for an IBM App Connect Enterprise message flow, the validation logic is sensitive to xsi:type attributes and uses them to modify the validation of the element. It also validates the values of xsi:type attributes by using the rules described in XML Schema Part 1: Structures on the World Wide Web Consortium (W3C) website.

There are several important points to remember when parsing and writing XML documents that contain xsi:type attributes.

- In order to detect and use xsi:type attributes, the message set must be namespace-enabled. To make a message set namespace-enabled, check the message set property **Use namespaces**.
- If the value of the xsi:type attribute contains a namespace prefix, the prefix is expanded into a fully qualified URI by the MRM XML parser. If the same xsi:type attribute is produced later by the MRM XML writer, the same prefix is not automatically used for the value. You can control the prefixes used on output by using the **Namespace settings** list in the XML Wire Format message set properties. If no prefix is supplied, the XML writer assigns a default prefix.
- If the xsi:type attribute of an element does not resolve to a type in the model, the behavior depends on whether MRM validation is enabled. If not validating, the MRM assumes that the type of the element is that declared in the model, and continue. If validating, a validation exception occurs.
- If MRM validation is enabled, any required xsi:type attributes must be present in the message tree at the point when validation is performed. An xsi:type attribute is required when its value is different from the data type of the element as defined in the message model (this most commonly occurs when using XML Schema type derivation).
  - If validation is being performed on an input message, the MRM XML parser ensures that xsi:type attributes appear in the message tree, as described above.
  - If validation is being performed on an output message, you must ensure that the correct xsi:type attributes appear in the message tree. Ensure that any required xsi:type attributes are copied from input message tree to output message tree, or are explicitly created in the output message tree.
- If you are using simple types that are xsd:unions, an xsi:type attribute can be used to direct the MRM XML parser when resolving the union.
- If you have migrated from an earlier version of WebSphere Message Broker that was not sensitive to xsi:type attributes, you might notice some changes of behavior. For example, xsi:type attributes are no longer treated as self-defining attributes, so they appear in the message tree with the name ‘type' instead of ‘@type'. If your message flow logic is sensitive to xsi:type attributes in the message tree, change your message flow to comply with the current behavior.

For more information about xsi:type attributes, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) website.

Message Sets: Generate message dictionaries

A *message dictionary* is data structure that describes all of the messages in a message set in a form suitable for deployment to the MRM parser.

Purpose of a message dictionary

A dictionary describes the logical structure and content of a set of messages, and typically contains one or more physical formats that describe how those messages are serialized in a bit stream. The MRM parser within IBM App Connect Enterprise uses this information to parse an incoming message bit stream into a message tree, or to write a message tree into a physical bit stream.

Contents of a message dictionary

A message dictionary contains the same information as the message set from which it was created, but in a compressed form that the MRM parser within IBM App Connect Enterprise can understand and use. A message dictionary contains all the elements in the message set, the structure of the messages, and all the value constraints. A message dictionary also contains any physical formats that were defined in the message set.

Generating a message dictionary

Before a message dictionary can be used, it must be deployed to IBM App Connect Enterprise. To do this, add the message set to a BAR file, then deploy the BAR file to an integration node. The generation of the message dictionary is performed automatically when a message set is added to a BAR file, if the message set supports the MRM domain.

Before adding a message set to a BAR file, the IBM App Connect Enterprise Toolkit performs a full validation of the message set. If this validation finds any errors, the message set is not added to the BAR file, and therefore no message dictionary is generated.

Dictionary generation report files
Whenever a message dictionary is generated, a user log file is also generated and added to the same BAR file. This file contains informational messages and warnings that relate to the use of the generated dictionary. Always check this file after generating a message dictionary.

Message model integrity

When you create your message model, it is important that it is internally consistent.

To assist with this, whenever you save a message model schema file or message definition file, it is validated as follows:

Logical validation
This validation ensures that the logical model is correct. For message definition files, this involves ensuring that the rules of XML Schema have been correctly followed.

Physical validation
This validation ensures that any physical properties that you have specified for your model have been correctly populated and are consistent. There is a set of checks for each of the MRM domain physical formats - CWF, XML, and TDS - and for DFDL.

After model validation has taken place, any errors or warnings are shown in the task list. Double clicking a task list entry opens the file and positions the editor at the object in error. Organize the task list so that errors are shown before warnings. In this way, errors are not hidden. The task list provides a comprehensive filtering capability if you want to hide low priority warnings, or warnings that you are know about and are comfortable with.

The deployment of a message model in a BAR file is prevented if any errors are present. The presence of warnings alone does not prevent deployment, but high priority warnings must be reviewed because a model that generates such warnings might be incomplete.

Where task list warnings or errors occur, these are listed in the Problems view of the Integration Development perspective. While a majority of these require you to manually investigate and resolve them, a number of warnings and errors that meet specific criteria can be repaired by using a quick fix process.

Generation of model representations

You can use your message model to facilitate application development and to parse and validate messages.

After you have created and populated your message model, you can use it in the following ways:

- At development time to speed up message flow application development, by using the models as the source and target of a map in the Map editor, or by enabling ESQL code assist in the ESQL editor.
- At run time for parsing and validating your messages, by deploying them to an integration node.

Additionally, you can generate your message model in a different form for use by other message flows or other external applications. For example:

- W3C XML Schema, for use by an application building or processing equivalent XML messages.
- Web Services Description Language (WSDL), for a web services client or server application.
- Documentation, to give to programmers or business analysts.

Generating your model in a different form is achieved by using the **Generate** menu actions.

Generation of XML schema
You can generate a schema file from a message model.

XML schema is a standard way of describing complex message models.

You can generate an XML schema file for an individual DFDL schema file in an application or library, an individual message definition file in a message set, or for all message definition files in a message set.

Generating from DFDL

A DFDL schema file is a valid XML schema file, so the generation process consists of removing the DFDL annotations from the DFDL schema. The result is a pure W3C XML Schema file.

Generating from message sets

If any XML physical formats have been defined for the message set, you can select which of these XML wire formats are to be applied.

- If an XML format has been selected, the physical format information is also included.
- If no XML format is selected, the generated schema file contains information about only the logical message model.

You can choose whether 'strict' or 'lax' schema generation is to be performed. This is necessary because the logical extensions to the XML schema model provided by the message definition file cannot be represented in XML schema. So you can choose either to generate a schema with more strict or more lax validation than the equivalent validation performed by the message model parser. The affected model extensions are:

- `Content Validation` = open
- `Content Validation` = open defined
- `Composition` = unordered set

Further information about XML schema

For details about XML schema, see XML Schema Part 0: Primer on the World Wide Web Consortium (W3C) Web site.

Generation of WSDL files

A *Web Services Description Language* (WSDL) document specifies the interface to a web service, and enables a web service client to start it. A WSDL document that is generated from a message model defines web service requests and responses in terms of the messages that you have defined in that message model.

Tip: If you need to generate a WSDL document, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see “Enabling message set development” on page 2248.

You can generate a WSDL document for a message model that resides in a message set.

Use message model files with target namespaces when you generate WSDL. If you do not, IBM App Connect Enterprise uses the WSDL target namespace as the default target namespace.

In the main WSDL document, operations are defined in terms of logical messages, which are themselves defined in terms of the elements and types that are defined in these message model files.

WSDL operations are grouped into a logical interface or portType, and are then associated with a binding which defines the physical format of the messages. You can select only one of the following bindings when you generate WSDL:

- SOAP (over JMS)
- SOAP (over HTTP)

A WSDL service definition specifies the endpoint where the service is available. You can elect to have the service, binding, and portType definitions generated as a single file or as separate files. Tools that use WSDL are typically more tolerant of the single-file format. If you select single-file, you can also choose whether the associated XML Schema is generated from the message model as a separate file or in-line.

Considerations for deploying a WSDL file with regular expression definitions

The W3C XML Schema standard specifies how to define regular expressions using the pattern facet of simple type definitions in XML schemas, and WSDL files. Regular expressions can include a quantifier that specifies how many instances of a character, group, or character class must be present in the input, in order for a match to be found.

When the WSDL is deployed to an integration server, it is compiled into a binary file, which the IBM App Connect Enterprise XMLNSC parser uses to validate input messages at run time. The total size of the binary file is the accumulated size of each regular expression, which depends on the quantifier ranges in each expression. A large binary file requires the integration server JVM heap size to be large enough to enable the WSDL file to be successfully deployed.

The following is an example where the quantifier is exceptionally large:

```
<xsd:simpleType name="VeryLargeBoolean">
    <xsd:restriction base="xsd:string">
       <xsd:pattern value="([T|t][R|r][U|u][E|e])|([F|f][A|a][L|l][S|s][E|e]){0,2147483647}" />
    </xsd:restriction>
</xsd:simpleType>
```

The quantifier in this example is {0,2147483647}, which during deployment will generate a binary file that is at least 2 GB in size.

The accumulated size of the regular expressions can cause a very large binary file to be created at deployment time, which might exhaust the integration server JVM heap storage. In the example shown above, the deployment failed with the following sequence of error messages:

```
  BIP4041E: Integration server '<Server name>' received an administration
  request that encountered an exception.

  BIP5044E: A failure occurred while the integration server was preparing
  the XML and DFDL schema files that are contained in the application
  <Application Name>.

  BIP5043E: The XMLNSC compiler ran out of memory during the preprocessing
  of XML Schema files for the XMLNSC domain.
```

If this problem occurs, modify the range of the quantifiers in the regular expressions to generate a smaller number of pattern matching instances, and therefore a smaller binary WSDL file.

Generation of message model documentation

When you have created one or more message models, it can be useful to generate documentation for business analysis and for developers who are involved with the messages.

Message model schema files contain both logical and physical definitions for the message model. The generated documentation describes the logical information only.

The documentation exists as an HTML file.

Modeling different data formats

You can use IBM App Connect Enterprise to create message models for a range of data formats.

About this task

Most message formats are not self-defining, and a parser must have access to a predefined model that describes the message, if it is to parse the message correctly. Even if your messages are self-defining, and do not require modeling, message modeling has advantages. For a full description of the advantages of using message models, see “Why model messages?” on page 2138.

The topics in this section describe how to create a message model for different data formats by using IBM App Connect Enterprise.

Working with web services XML data

You can create a message model for your SOAP XML data by using XML Schema.

About this task

SOAP is an XML message format used in web service interactions. SOAP messages are typically sent over HTTP or JMS, but other transport protocols can be used.

For more information about SOAP, see “What is SOAP?” on page 807

You can create a message model for your web services XML data in IBM App Connect Enterprise by using XML Schema; see:

- “Opening an existing XML schema file” on page 2242
- “Creating an XML schema file” on page 2243
- “Deleting an XML schema file” on page 2244
- “Generating HTML documentation from an XML Schema file” on page 2245
- “Working with XML Schema message model objects” on page 2245

Working with other XML data

You can create a message model for your XML data by using XML Schema.

About this task

XML, or EXtensible Markup Language, is a platform-independent data format. For more information about XML messages, see XML constructs

You can create a message model for your XML data in IBM App Connect Enterprise by using XML Schema; see:

- “Opening an existing XML schema file” on page 2242
- “Creating an XML schema file” on page 2243
- “Deleting an XML schema file” on page 2244
- “Generating HTML documentation from an XML Schema file” on page 2245
- “Working with XML Schema message model objects” on page 2245

Working with CSV data

You can create a message model for Comma Separated Value (CSV) data by using DFDL schema.

About this task

The Comma Separated Value (CSV) format is used to exchange data between database applications or spreadsheet applications. Although the CSV format is widely used, a definitive specification has not been formally documented.

For more information about the CSV format, see CSV messaging standard

You can create a message model for your CSV format data in IBM App Connect Enterprise by using DFDL schema; see:

- “Creating a DFDL schema file by using the New Message Model wizard” on page 2223
- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Working with other delimited text data

You can create a message model for delimited text data by using DFDL schema.

About this task

You can create a message model for your delimited text data in IBM App Connect Enterprise by using DFDL schema; see:

- “Creating a DFDL schema file by using the New Message Model wizard” on page 2223
- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Working with custom text or binary data by using DFDL

Create a message model for custom text or binary format data by using DFDL schema.

About this task

You can create a message model for your custom text or binary format data in IBM App Connect Enterprise by using DFDL schema; see:

- “Creating a DFDL schema file by using the New Message Model wizard” on page 2223
- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221

- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Working with COBOL data

You can create a message model for COBOL data by importing a COBOL copybook to create a DFDL schema.

About this task

You can create a message model for your COBOL data in IBM App Connect Enterprise by using DFDL schema; see:

- “Creating a DFDL schema file by using the New Message Model wizard” on page 2223
- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Working with C data

You can create a message model for C data by importing a C header file to create a DFDL schema.

About this task

You can create a message model for your C data in IBM App Connect Enterprise by using DFDL schema; see:

- “Creating a DFDL schema file by using the New Message Model wizard” on page 2223
- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Working with PL/I data

You can create a message model for PL/I data by using DFDL schema.

About this task

You can create a message model for your PL/I data in IBM App Connect Enterprise by using DFDL schema; see:

- “Creating a DFDL schema file by using the New Message Model wizard” on page 2223
- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223

- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Working with CORBA data

You can create a message model for data from a CORBA system by using XML Schema.

About this task

The Common Object Request Broker Architecture (CORBA) is a standard defined by the Object Management Group (OMG) that enables software components written in multiple computer languages and running on multiple computers to work together.

For more information about CORBA, see “Common Object Request Broker Architecture (CORBA)” on page 1153.

You can create a message model for your CORBA data in IBM App Connect Enterprise by using XML Schema; see:

- “Opening an existing XML schema file” on page 2242
- “Creating an XML schema file” on page 2243
- “Deleting an XML schema file” on page 2244
- “Generating HTML documentation from an XML Schema file” on page 2245
- “Working with XML Schema message model objects” on page 2245

Working with SAP data

You can create a message model for data from an SAP system by using DFDL or by using WebSphere Adapter Schema.

About this task

You can create a message model for your SAP data in IBM App Connect Enterprise by using DFDL; see:

- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230

Alternatively, you can create a message model for your SAP data in IBM App Connect Enterprise by using WebSphere Adapter Schema.

For more information about WebSphere Adapter for SAP Software, see “Overview of WebSphere Adapter for SAP Software” on page 1052.

Working with Siebel data

You can create a message model for data from a Siebel system by using WebSphere Adapter Schema.

About this task

You can create a message model for your Siebel data in IBM App Connect Enterprise by using WebSphere Adapter Schema.

For more information about WebSphere Adapter for Siebel Business Applications, see “Overview of WebSphere Adapter for Siebel Business Applications ” on page 1092.

Working with PeopleSoft data

You can create a message model for data from a PeopleSoft system by using WebSphere Adapter Schema.

About this task

You can create a message model for your PeopleSoft data in IBM App Connect Enterprise by using WebSphere Adapter Schema.

For more information about WebSphere Adapter for PeopleSoft Enterprise, see “Overview of WebSphere Adapter for PeopleSoft Enterprise” on page 1098.

Working with JD Edwards data

You can create a message model for data from a JD Edwards system by using WebSphere Adapter Schema.

About this task

You can create a message model for your JD Edwards data in IBM App Connect Enterprise by using WebSphere Adapter Schema.

For more information about WebSphere Adapter for JD Edwards EnterpriseOne, see “Overview of WebSphere Adapter for JD Edwards EnterpriseOne” on page 1102.

Working with database records

You can create a message model for data from database records by using XML Schema.

About this task

You can create a message model for your database record data in IBM App Connect Enterprise by using XML Schema; see:

- “Opening an existing XML schema file” on page 2242
- “Creating an XML schema file” on page 2243
- “Deleting an XML schema file” on page 2244
- “Generating HTML documentation from an XML Schema file” on page 2245
- “Working with XML Schema message model objects” on page 2245

Working with JSON data

Message modeling for JSON format data is supported by IBM App Connect Enterprise.

About this task

JSON (JavaScript Object Notation) is a simple data-interchange format based on a subset of the JavaScript programming language. A JSON message consists of name-value pairs (objects), and ordered collections of values (arrays). Objects, arrays, or both structures can be nested.

You can create a message model for your JSON data in IBM App Connect Enterprise by using JSON Schema.

For more information about JSON, see the JavaScript Object Notation (JSON) web site.

Working with MIME data

You can create a message model for MIME data by using XML Schema.

About this task

Multipurpose Internet Mail Extensions (MIME) is a message format that specifies message headers, but which leaves the message body as ASCII text.

For more information about MIME, see RFC 1521: MIME Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies.

You can create a message model for your MIME data in IBM App Connect Enterprise by using XML Schema; see:

- “Opening an existing XML schema file” on page 2242
- “Creating an XML schema file” on page 2243
- “Deleting an XML schema file” on page 2244
- “Generating HTML documentation from an XML Schema file” on page 2245
- “Working with XML Schema message model objects” on page 2245

How to model data with DFDL

Analyze data formats for which no model exists. Understand the structure, so that you can create the corresponding DFDL model.

Data modeling with DFDL has a strong analogy with programming. Suppose you want to learn a new programming language and write a program to solve a business problem. Take Java as an example. You buy a Java book and read up on the language theory. You get hold of a good Java editor and learn how to use it. But the hardest part is working out how to structure the program that solves your business problem. To get a head start, you might look at examples that other programmers created.

DFDL data modeling is the same. You can learn the theory about the modeling language and you can learn how to use an editor for that language. But the hardest part is looking at the actual data and working out how to go about creating the best model for it. If you are lucky the problem is solved in whole or in part by already having a model of the data in one format or another (metadata). For DFDL, IBM provides importers to convert certain data formats (for example, COBOL and C metadata) into DFDL schemas. But what do you do when you have no model to reference, just one or more examples of the data format? Formatted text messages, such as comma-separated values (CSV) messages, often have no model. You can learn how to analyze data formats in order to understand the structure and create the corresponding DFDL model.

The task consists of the following stages:

1. “Understanding the logical structure” on page 2214
2. “Configuring the DFDL annotations” on page 2215

3. “Organizing the DFDL model” on page 2219

Understanding the logical structure

The first stage of an approach to modeling data by using DFDL involves examining the logical structure of your data.

Procedure

1. Identify complex structures.

   Complex structures correspond to the complex types in the model. There will be an overall complex type for the entire data itself. If the data contains substructures, each substructure has a complex type. For example, each structure level in a COBOL copy book, or each different row in a CSV message, corresponds to an element of complex type.
2. Identify simple items.

   Simple items occur within each complex type, and each has a logical data type. Simple items correspond to simple elements. For example, each field in a COBOL copy book with a PIC clause, or each comma-separated value in a CSV message, corresponds to an element of simple type.
3. Identify structure ordering.

   Ordering determines whether the group within a complex type is a sequence or a choice. In a choice, only one of the listed items can occur. Examples are C unions and COBOL REDEFINES.
4. Identify structure and item cardinality.

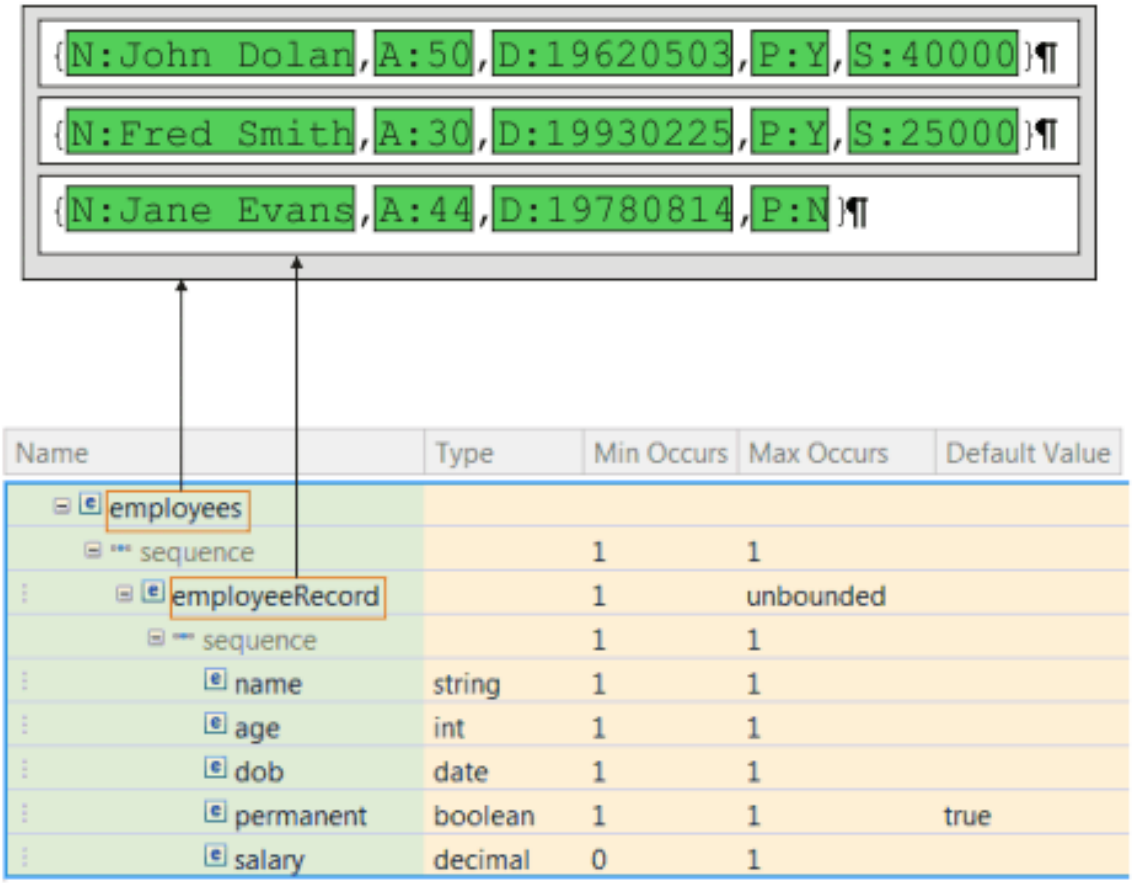
   Cardinality provides the values for the `minOccurs` and `maxOccurs` logical properties of your elements.

   - Is an element required (`minOccurs != 0`) or optional (`minOccurs = 0`)?
   - Is an element an array (`maxOccurs > 1`)?
   - If so are there a fixed number of occurrences (`minOccurs = maxOccurs`) or a variable number of occurrences (`minOccurs != maxOccurs`)?
   - Can the number of occurrences be unlimited (`maxOccurs = unbounded`)?
5. Identify nillable items and default values.

   Some elements might need to carry a special out-of-range value, in which case they must be nillable. For example, a numeric field in a COBOL copy book might sometimes be set to SPACES, which is not legal for a DFDL number. Some required elements might be empty in the data, in which case a default value can be provided.
6. Consider whether any components can be reused.

   If any of the types are common, consider creating global complex or simple types. If any of the elements are common, consider creating global elements.

Example



As an example, the picture shows a file of employee records. This file could be modeled using DFDL as an overall complex element `employees` that contains a complex element `employeeRecord`. The `employeeRecord` element repeats an arbitrary number of times, hence maxOccurs is set to unbounded.

The `employeeRecord` is a sequence of simple elements:

- `name` of type `xs:string`
- `age` of type `xs:int`
- `dob` of type `xs:date`
- `permanent` of type `xs:boolean`
- `salary` of type `xs:decimal`.

The `salary` element is present only when `permanent` is Y, so it is optional and has minOccurs `0`. All the other simple elements are required and have minOccurs `1`.

What to do next

The next stage is to configure the DFDL annotations: “Configuring the DFDL annotations” on page 2215

Configuring the DFDL annotations

The second stage of an approach to modeling data using DFDL involves adding DFDL annotations to the logical structure that you established. The DFDL annotations describe the physical format of the components.

Before you begin

Follow the guidance in “Understanding the logical structure” on page 2214.

About this task

Determine the characteristics of your components.

Procedure

1. All elements (simple and complex)
   a) Does the element have any delimiters, that is, an initiator or a terminator? If so what is the encoding, and are they present when the element is empty or nil?

      This characteristic determines the dfdl:initiator, dfdl:terminator, dfdl:encoding and associated properties.

   b) How is the content of the element established?

      This characteristic determines the dfdl:lengthKind and associated properties:

      - `explicit` for a fixed length.
      - `prefixed` if there is a length prefix.
      - `delimited` if bounded by a delimiter.
      - `pattern` to use a regular expression.
      - `implicit` if the length is determined by its type.
      - `endOfParent`, if bounded by its parent.

   c) If the element is optional or is an array, how is the number of occurrences established?

      This characteristic determines the dfdl:occursCountKind and associated properties.

   d) Are there any alignment rules to apply?

      This characteristic usually occurs only for binary data, and determines the dfdl:alignment, dfdl:fillByte, and associated properties.

   e) How is any nil value described?

      This characteristic determines the dfdl:nilKind, dfdl:nilValue and associated properties.

   f) Is an assert or discriminator needed to establish whether the element exists?
2. Simple elements
   a) Is the element text or binary representation? The representation and simple type determines which other properties must be set.

      - For text, the properties are dfdl:encoding, and the several DFDL text-related properties.
      - For binary, the properties are dfdl:byteOrder, and the several DFDL binary-related properties.

   b) For text formats, is an escape scheme needed?

      This characteristic determines whether a dfdl:defineEscapeScheme annotation is needed, and if so a dfdl:escapeSchemaRef to reference it.

   c) If global simple types are identified, decide whether the simple type can carry some of the properties rather than the element, thus creating reusable physical types.

3. Sequences
   a) Is the sequence ordered or unordered?

      This characteristic determines the dfdl:sequenceKind property.

   b) Does it have a separator that is used to delimit its child elements, and if so is the separator's position `infix`, `prefix` or `postfix`? Are separators sometimes suppressed (for example, when optional elements are missing)?

      These characteristics determine the dfdl:encoding, dfdl:separator, dfdl:separatorPosition, and dfdl:separatorSuppressionPolicy properties.

   c) Do all the child elements of the sequence have unique initiators that can identify that they exist?

      This characteristic determines the dfdl:initiatedContent property.

   d) Does the sequence itself have an initiator or a terminator?

      This characteristic determines the dfdl:initiator, dfdl:terminator, dfdl:encoding, and associated properties.

4. Choices
   a) Is the choice one where all the branches must occupy the same length or not?

      This characteristic determines the dfdl:choiceLengthKind and associated properties.

   b) Do all the branches of the choice have unique initiators that can identify which one appears?

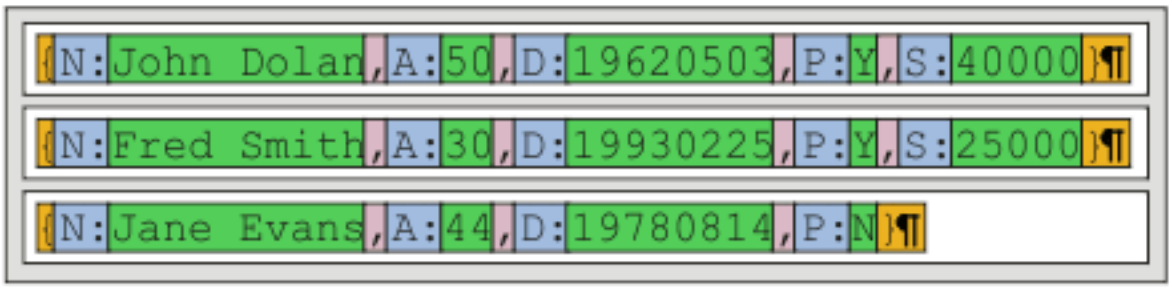
      This characteristic determines the dfdl:initiatedContent property.

   c) Are discriminators needed on the branches to establish which one appears?

   d) Does the choice itself have an initiator or a terminator?

      This characteristic determines the dfdl:initiator, dfdl:terminator, dfdl:encoding, and associated properties.

Example



Name	Type	Min Occurs	Max Occurs
employees			
sequence		1	1
employeeRecord		1	unbounded
sequence		1	1
name	string	1	1
age	int	1	1
dob	date	1	1
permanent	boolean	1	1
salary	decimal	0	1

Property	Value
Comment	
General	
Encoding (code p	US-ASCII
Byte Order	bigEndian
Content	
Length Kind	implicit
Occurrences	
Min Occurs	1
Max Occurs	unbounded
Occurs Count Kind	implicit
Delimiters	
Initiator	{{
Terminator	}%CR;%LF;

To continue with the example of a file of employee records, in which all data is text, with a dfdl:encoding of ASCII.

- The `employees` element does not have an initiator or a terminator so dfdl:initiator and dfdl:terminator are set to empty string ''. Its length is determined by its child elements, so dfdl:lengthKind is `implicit`.
- The sequence for `employees` has dfdl:sequenceKind `ordered`, because its child components always appear in the order specified.
- The `employeeRecords` element starts with `{`, so has a dfdl:initiator `{{`. (Two opening braces (`{{`) are needed to prevent the DFDL initiator from being misinterpreted as a DFDL expression.) The element ends with `}` and CR/LF, and so has dfdl:terminator `}%CR;%LF;`. (An alternative is to model the `}` and CR/LF as the separator of the parent sequence.) Again, its length is determined by its child elements, so dfdl:lengthKind is `implicit`.
- Its sequence has dfdl:sequenceKind `ordered`.
- Each simple element has dfdl:representation `text`. Each has a unique start tag that is used as the dfdl:initiator. Each has a variable length value that is delimited either by ',' or, if the element is last in the record, by `}` and CR/LF. Consequently, dfdl:lengthKind is `delimited`.
- The `','` delimiter is best modeled as the dfdl:separator of the parent sequence, and not as the dfdl:terminator of the element. The dfdl:separatorPosition is `infix` meaning that the `','` occurs only between the child elements in the sequence.
- Because each simple element has an initiator, dfdl:initiatedContent `yes` must be set on the parent sequence. This means the parser uses the initiator to positively identify each element.
- Although the `salary` element is optional, no DFDL discriminator is needed because the DFDL parser deduces that it is missing when it finds the `employeeRecord` terminator. When `salary` is missing,

notice that the `','` before it is suppressed. That is modeled using dfdl:separatorSuppressionPolicy `trailingEmpty` on the parent sequence.

- Several other text-related properties must be set for each simple element. These properties control whether any padding or trimming takes place, and whether an escape scheme is in use to prevent data characters being interpreted as delimiters.
- Several other type-specific properties must be set for each simple element, to control the interpretation of the data value. For example, the `permanent` element is type xs:boolean and so needs dfdl:textBooleanTrueRep Y and dfdl:textBooleanFalseRep N.

What to do next

The next stage is to organize the DFDL model: "Organizing the DFDL model" on page 2219.

Organizing the DFDL model

The third stage of an approach to modeling data by using DFDL involves organizing the DFDL model so that common DFDL property values are declared in a single place and act as defaults for all the components in the schema.

Before you begin

Before you start:

Follow the guidance in "Understanding the logical structure" on page 2214 and "Configuring the DFDL annotations" on page 2215.

About this task

All DFDL schemas that are created by the IBM DFDL wizards and importers follow the practices as described here.

Procedure

- Set up common DFDL property defaults by using a dfdl:format annotation at the top level of the schema.

  A DFDL schema can be set up so that DFDL properties that are common to multiple schema components need be declared only once, by using a dfdl:format annotation at the top level of the schema itself to declare properties. These properties effectively act as defaults for all components in the schema. (DFDL has no built-in property defaults.)
- A further refinement is to place those properties in a separate DFDL schema for reuse in other related DFDL schemas.

  Create a separate DFDL schema to contain these common DFDL properties, and place them inside a dfdl:defineFormat annotation. This schema is then included into the main DFDL schema through an XSD include or import. The dfdl:format annotation at the top level of the main schema instead uses dfdl:ref to refer to the dfdl:defineFormat. Much like a macro expansion, properties are pulled from the dfdl:defineFormat onto the dfdl:format, where they then act as defaults for all components in

the schema in the way described above. In this way, common DFDL properties can be shared across multiple related DFDL schemas.

```
<xs:schema>
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/" >
      <dfdl:defineFormat name="myDefaults" >
         <!- Declare common DFDL property values -->
         <dfdl:format encoding="ASCII" representation="text" ... />
      </dfdl:defineFormat>
    </xs:appinfo>
  </xs:annotation>
</xs:schema>
```

Figure 36. defaults.xsd

- Now, you need only to set a handful of properties directly on each object to complete configuration.

1.
```
<xs:schema>
  <xs:include schemaLocation="defaults.xsd" />

  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/" >
      <!- Apply common DFDL property values as defaults -->
      <dfdl:format ref="myDefaults" />
    </xs:appinfo>
  </xs:annotation>

  <!- Add only DFDL properties that differ from the defaults -->
  <xs:element name="employeeRecord" maxOccurs="unbounded" dfdl:lengthKind="implicit"
                                    dfdl:initiator="{{" dfdl:terminator="}%CR;%LF;" >
    <xs:complexType>
         ...
    </xs:complexType>
  </xs:element>

  ...

</xs:schema>
```

Figure 37. employees.xsd

Working with DFDL schema files

Create, open, modify or delete a DFDL schema file.

About this task

This topic area describes the tasks that are involved in working with a DFDL schema file:

- “Opening an existing DFDL schema file” on page 2221
- “Creating a DFDL schema file” on page 2223
- “Importing a DFDL schema file” on page 2221
- “Editing a DFDL schema file” on page 2225
- “Testing a DFDL schema file” on page 2226
- “Deleting a DFDL schema file” on page 2229
- “Working with DFDL message model objects” on page 2230
- “Developing independent DFDL applications” on page 2239

Opening an existing DFDL schema file

Open an existing DFDL schema file in the DFDL schema editor to view or edit the contents of the file.

About this task

To open an existing DFDL schema file:

Procedure

1. Right-click the DFDL schema file (file extension `*.xsd`) that you want to open, and select **Open**.
   The DFDL schema file opens in the DFDL schema editor.

   Tip: The Eclipse framework lets you open resource files with other editors. However, you are advised to use the DFDL schema editor to work with DFDL schema files. This editor correctly validates any changes that are made to your DFDL schema files. Other editors might not correctly validate files.
2. View or edit the data in your DFDL schema file.
   For more information about using the DFDL schema editor, see DFDL schema editor.

Importing a DFDL schema file

You can import DFDL schema files that were created outside of the IBM App Connect Enterprise Toolkit, and use them in developing message flow applications.

About this task

Note: For information about how to create a DFDL schema file from an existing resource, see "Creating a DFDL schema file by using the New Message Model wizard" on page 2223.

Complete the following tasks to import your DFDL schema files:

- "Importing DFDL schema files into the workspace" on page 2221
- "Adding IBM App Connect Enterprise annotations to imported DFDL schema files" on page 2221

Importing DFDL schema files into the workspace

Before you begin

- You must have created a DFDL schema file that conforms to the DFDL specification.
- You must have the IBM App Connect Enterprise Toolkit open in the Integration Development perspective.

About this task

You can use the drag-and-drop method to import DFDL schema files from your file system into the IBM App Connect Enterprise Toolkit. In the Application Development view, drag the DFDL schema files that you are importing to the application or library. Do not drag them onto a blank area in the Application Development view.

Adding IBM App Connect Enterprise annotations to imported DFDL schema files

If you have imported DFDL schema files that were created outside of the IBM App Connect Enterprise Toolkit, you must add the required DFDL annotations for use with IBM App Connect Enterprise.

Before you begin

Before you start:

Complete the following task:

- "Importing DFDL schema files into the workspace" on page 2221

About this task

If you want to use a DFDL schema file that has been created outside of the IBM App Connect Enterprise Toolkit, you must add the required IBM App Connect Enterprise annotations before you can use the DFDL schema file in the development of your message flow applications. You may encounter errors if you use a DFDL schema file that does not contain the required IBM App Connect Enterprise annotations.

To add the required IBM App Connect Enterprise annotations to your DFDL schema file:

Procedure

1. In the Application Development view, right-click the imported DFDL schema file (file extension `*.xsd`) that you want to open, and select **Open with** > **XML Editor**.

   The DFDL schema file opens in the XML editor.
2. Add the namespace `xmlns:ibmSchExtn="http://www.ibm.com/schema/extensions"` by completing the following steps:
   a) In the XML editor, right-click anywhere within your DFDL schema file and select **Edit Namespaces...**.

      The **Edit Schema Information** window opens.
   b) In the **Edit Schema Information** window, click **Add...**.

      The **Add Namespace Declarations** window opens.
   c) In the **Add Namespace Declarations** window, select **Specify New Namespace**.
   d) In the Prefix field, enter `ibmSchExtn`. In the Namespace Name field, enter `http://www.ibm.com/schema/extensions`, then click **OK**.
   e) In the **Edit Schema Information** window, click **OK**.

   The namespace is added to your DFDL schema file, and the **Edit Schema Information** window closes.
3. Add the annotation, `ibmSchExtn:docRoot="true"` to the top-level element of your message model by completing the following steps:
   a) In the XML editor, locate the top-level element of your message model. Right-click this element and select **Add Attribute** > **Default**.

      An attribute containing default values is added to your message model.
   b) Locate the default attribute that you created in the last step. Right-click this attribute, and select **Edit Attribute...**.

      The **Edit Attribute** window opens.
   c) In the Name field, enter `ibmSchExtn:docRoot`. In the Value field, enter `true`. Click **OK**.

   The annotation is added to your DFDL schema file, and the **Edit Attribute** window closes.
4. In the Navigator view, right-click your DFDL schema file (file extension `*.xsd`), and select **Open with** > **DFDL Editor**.

   The DFDL schema file opens in the DFDL schema editor.

What to do next

Next:

- You can continue to edit your DFDL schema by using the DFDL schema editor.
- You can test your message model, see "Testing a DFDL schema file" on page 2226.

Reimporting IBM supplied message models

If you have modified one or more IBM supplied message models, you can reimport them to overwrite your changes, restoring them to their default state.

About this task

Procedure

1. Click **File** > **New** > **Other**.
   A window opens in which you can select a wizard.
2. Expand **App Connect Enterprise - Application Development**, select **Message Model ...**, click **Next**.
   The **New Message Model** wizard opens.
3. Select **IBM supplied**, then click **Next**.
4. Select **Replace the imported IBM supplied definitions**. Click **Next**,
5. Step through the remainder of the wizard, clicking **Next** to move to a new panel, and then click **Finish** when you have selected the IBM supplied message model that you want to replace.

Results

The IBM supplied message model that you selected is reimported. It is displayed in the **XML and DFDL Schemas** folder of your project and is opened in the DFDL schema editor.

What to do next

Next:

- You can continue to edit your DFDL schema by using the DFDL schema editor.
- You can test your message model, as described in "Testing a DFDL schema file" on page 2226.

Creating a DFDL schema file

You can create DFDL schema files to model your text and binary formatted data.

About this task

You can use DFDL schema to model various data formats, including:

- Comma Separated Value (CSV)
- Record-oriented text
- Custom text or binary
- COBOL data structures
- C data structures

Creating a DFDL schema file by using the New Message Model wizard

Use the **New Message Model** wizard to create DFDL schema files.

About this task

You can use DFDL schema to model various data formats, including:

- Comma Separated Value (CSV).
- Record-oriented.
- COBOL data structures. For an overview of how to use the COBOL importer, go to the Rational Application Developer for WebSphere Version 8.5.5 product documentation online and search for *COBOL Importer overview*.

- C Header files. Some restrictions apply; see Importing from C (DFDL): restrictions.
- Custom text or binary.

Procedure

1. Open the New Message Model wizard by using one of the following methods:
   - In the navigator, click **New**, then click **Message Model ...**.
   - Right-click the white space of the navigator, then click **New** > **Message Model ...**.
2. Step through the wizard, clicking **Next** to move to a new panel, and clicking **Finish** when you have entered the information required to create your DFDL schema.

   Your new DFDL schema is created, and is displayed in your application or library.

What to do next

Next:

The schema file is opened in the DFDL editor, and you can edit it immediately.

Creating a DFDL schema file from a C header file
Create a DFDL schema file from a C header file.

About this task

Using the wizard, you can create a DFDL schema file by:

- Importing a single C header file. Some restrictions apply; see Importing from C (DFDL): restrictions.
- Importing or replacing the IBM-supplied DFDL C format schema.

Tip: If you want to import many header files at once from the command line, see Message sets: Importing from C header files to create message definitions. This procedure produces message definitions for use in the MRM domain, not the DFDL domain.

Procedure

1. Click **File** > **New** > **Other** > **Message Model**, and select **C header file**.
2. Step through the wizard to create the DFDL schema file.

Creating a DFDL schema file from a COBOL resource
Create a DFDL schema file from an existing COBOL resource.

Before you begin

Linux The COBOL importer requires 32-bit versions of the Linux operating system libraries. Some of these libraries are not installed by default on the following distributions:

Red Hat Enterprise Linux V6 64-bit
Ubuntu 10.4 or later, 32-bit and 64-bit

For details of which libraries to install, see https://www.ibm.com/support/docview.wss?uid=swg21512074

About this task

Using the wizard, you can create a DFDL schema file by:

- Importing a COBOL copybook or program.

  Note: The copybook must not contain field names that are COBOL reserved keywords. Also, the COBOL importer can only import files that have file names of 60 characters long or less. If you attempt to

import a COBOL file with a name longer than 60 characters, the COBOL importer fails with the message `IWAA0652E: File name cannot be longer than 60 characters`.

- Importing or replacing the IBM-supplied DFDL COBOL format schema.

Procedure

1. Click **File** > **New** > **Other** > **Message Model**, and select **COBOL**.
2. Step through the wizard to create the DFDL schema file.

Editing a DFDL schema file

Use the DFDL schema file editor to change an existing file.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. Click in the Outline view to select the category that you want to work with.
   For example, to edit message elements, select a child of the **Messages** item.

   The selected item is displayed in a table in the main editing area. Click **Show all sections** on the main toolbar of the editor to display all sections, including empty ones.
2. Use the buttons immediately above the table to modify items in the selected category, for example, deleting or adding elements.

   Different buttons are available, depending on the category that you are working with.
3. Use the **Representation Properties** tab on the right of the editor to modify properties.

   Tip:

   - You can select multiple objects in the Editor, but you see properties for only the first item that you selected.
   - Use **Filter** to find the property that you want to change.
   - Click **Show Only Basic Properties** to filter properties. If only basic properties are displayed, click **Show All Properties** to display all properties
   - To unset a property value, use the **Clear local property value** and **Clear all local properties** buttons to the right of the filter bar and filter actions. Using the **Delete** key can result in the property being set to an empty string, rather than being unset.
   - The value that is entered in the Sample Value column in the main editor view, or the Sample value text field in the properties, is the lexical representation of the corresponding XML Schema type. This value is what will appear in the logical instance that is generated. Information on the lexical representation of the different XML Schema types can be obtained from XML Schema Part 2: Datatypes Second Edition.
4. Save your file.

   Errors or warnings are displayed in the Problems view.

What to do next

Next:

Test your DFDL schema file.

Testing a DFDL schema file

When you have defined your DFDL schemas, test them in the editor before they are used on a production system.

Before you begin

Create or open a DFDL schema file.

About this task

You can use the DFDL Test Perspective to test-parse and test-serialize sample data against your DFDL schemas.

You can test a DFDL schema in one or all of the following ways:

- Generate a logical instance document from your DFDL schema; see "Testing a DFDL schema by creating a logical instance" on page 2226.
- Test-parse sample data against your DFDL schema; see "Testing a DFDL schema by parsing test input data" on page 2227.
- You can test-serialize from a logical instance using data from your DFDL schema; see "Testing a DFDL schema by serializing test output data" on page 2228.

What to do next

Next:

- You can continue to edit your DFDL schema by using the DFDL schema editor.

Testing a DFDL schema by creating a logical instance

You can create a logical instance of messages that are modeled by your DFDL schemas by using the DFDL Test Perspective.

Before you begin

Create or open a DFDL schema file.

About this task

You can use the DFDL Test Perspective to generate a logical instance from your selected DFDL schema. The data used to create the logical instance comes from the "Sample Test Data" values in the schema.

Procedure

1. Open the DFDL schema that you want to test.
2. Right-click the document root that you want to test, and click **Create a logical instance for the DFDL schema**.

   A dialog is displayed that asks you whether you want to open the DFDL Test Perspective.
3. Click **Yes**.

   The DFDL Test Perspective opens, and your generated sample message is displayed in the **DFDL Test - Logical Instance** view.
4. View your sample message as a logical tree by clicking the **Tree View** tab, or view your sample message as XML by clicking the **XML view** tab.

What to do next

Next:

- You can test-serialize the logical instance data that you have created; see "Testing a DFDL schema by serializing test output data" on page 2228.

- You can continue to edit your DFDL schema by using the DFDL schema editor.
- You can test-parse sample data against your DFDL schemas; see "Testing a DFDL schema by parsing test input data" on page 2227.
- If the DFDL schema is complete, you can add it to a BAR file for deployment; see Creating a BAR file.

Testing a DFDL schema by parsing test input data

You can test-parse sample data against your DFDL message model by using the DFDL Test Perspective.

Before you begin

Create or open a DFDL schema file.

About this task

You can use the DFDL Test Perspective to test-parse sample data against your selected DFDL message, to verify that the DFDL schema is correct.

Procedure

1. Open the DFDL schema that you want to test.
2. In the DFDL schema editor, expand the **Messages** section.
3. Select the message that you want to test.
4. Click **Test parse model**, or right-click the message that you want to test and click **Test parse model**.
   The **Test Parse Model** window opens.
5. In the **Parser Input** section, select the location of the input data that you want to test-parse:
   - If you have not previously serialized a test message:
     a. Select **Content from the file...**
     b. In the **Input file name** field, enter the location of your input data file, or click **Browse** to locate it.
   - If you have previously serialized a test message, select from the following options:
     – Select **Content from the file...** to test-parse the contents of an input file, as described in the previous step.
     – Select **Content from 'DFDL Test - Serialize' view** to test-parse the data that is displayed in the **DFDL Test - Serialize** view.
6. Enter **Runtime encoding options** as required.
7. Optional: Select **Validate data against schema** to check for validation errors.
8. Click **OK**, and confirm that you want to open the DFDL Test Perspective.

Results

- The DFDL Test Perspective opens, and the results of your test-parse are displayed in the **DFDL Test - Parse** view.
- You can view a log of parser actions in the **DFDL Test - Trace** view.
- You can view the logical instance in the **DFDL Test - Logical Instance** view, as a tree, or as XML.

What to do next

Next:

- You can continue to edit your DFDL schema by using the DFDL schema editor.
- You can generate a structural preview of a message from your DFDL schema; see "Testing a DFDL schema by creating a logical instance" on page 2226.
- You can test-serialize data from your DFDL schema, see "Testing a DFDL schema by serializing test output data" on page 2228.

- You can change the following settings, and then test-parse again by clicking the **Run Parser** button in the **DFDL Test - Parse** view.
  - In the **DFDL Test - Parse** view, you can change the input data and encoding.
  - In the Editor, you can select a different message to be test-parsed.

  All other settings from the last test-parse are retained.
- If the DFDL schema is complete, you can add it to a BAR file for deployment; see Creating a BAR file.

Debugging

About this task

If an error occurs during parsing, the following resources are available to help correct the model:

- An error message is displayed. The message summarizes the problem, and contains links to view the trace and partial logical instance that was created.
- The **DFDL Test - Parse** view shows the location of the error in the data. At the top of this view is a hyperlink that opens the **DFDL Test - Trace** view.
- The object in error is marked in the Editor with the following marker:  . The error marker has hover help that provides information about the error. To clear the error marker, correct the model and then parse the data again. The error marker is also removed when you close the DFDL editor.
- The **DFDL Test - Logical Instance** view shows the infoset parsed up to the error.

Testing a DFDL schema by serializing test output data

You can produce serialized test data from your DFDL schemas by using the DFDL Test Perspective.

Before you begin

Create or open a DFDL schema file.

About this task

You can use the DFDL Test Perspective to test-serialize sample data against your selected DFDL message to verify that the DFDL schema is correct.

Procedure

1. Open the DFDL schema that you want to test.
2. In the DFDL schema editor, expand the **Messages** section.
3. Select the message that you want to test.
4. Click **Test serialize model**, or right-click the message that you want to test and click **Test serialize model**.

   The **Test Serialize Model** window opens.
5. In the **Serializer Input** section, select the location of the logical instance data that you want to test-serialize:
   - If you have a populated 'DFDL Test - Logical Instance' view, select **Content from 'DFDL Test - Logical Instance'** to test-serialize the data that is displayed there.
   - If you do not have a populated 'DFDL Test - Logical Instance' view:
     a. Select **Content from a logical instance file**.
     b. In the **Input file name** field, enter the location of your file of logical instance data, or click **Browse** to locate it.
6. Enter **Runtime encoding options** as required.
7. Optional: Select **Validate data against schema** to check for validation errors.
8. If prompted, confirm that you want to open the DFDL Test Perspective.

Results

- The DFDL Test Perspective opens, and the results of your test-serialize are displayed in the **DFDL Test - Serialize** view.
- You can view a log of parser actions in the **DFDL Test - Trace** view.
- You can view the logical instance in the **DFDL Test - Logical Instance** view, as a tree, or as XML.
- You can change the following settings, and then test-serialize again by clicking the **Run Serializer** button in the **DFDL Test - Serialize** view.
  - In the **DFDL Test - Serialize** view, you can change the logical instance and encoding.

  All other settings from the last test-serialize are retained.

What to do next

Next:

- You can continue to edit your DFDL schema by using the DFDL schema editor.
- You can generate a structural preview of a message from your DFDL schema; see "Testing a DFDL schema by creating a logical instance" on page 2226.
- You can test-parse sample data against your DFDL schemas, see "Testing a DFDL schema by parsing test input data" on page 2227.
- You can change the following settings, and then test-serialize again by clicking the **Run Serializer** button in the **DFDL Test - Serialize** view.
  - In the **DFDL Test - Serialize** view, you can change the logical instance and encoding.

  All other settings from the last test-serialize are retained.
- If the DFDL schema is complete, you can add it to a BAR file for deployment; see Creating a BAR file.

Debugging

About this task

If an error occurs during parsing, the following resources are available to help correct the model:

- An error message is displayed. The message summarizes the problem, and contains links to view the trace output.
- The **DFDL Test - Serialize** view shows the location of the error in the data. At the top of this view is a hyperlink that opens the **DFDL Test - Trace** view.

Deleting a DFDL schema file

You can delete a DFDL schema file.

Before you begin

Create a DFDL schema file.

Procedure

1. Right-click the DFDL schema file (file extension `.xsd`) that you want to delete, then click **Delete**.

   Alternatively, select the DFDL schema file that you want to delete, then, from the menu bar, click **Edit** > **Delete**, or press the Delete key.
2. In the **Confirm Resource Delete** window, click **Yes** to delete the DFDL schema file.

   Important: this action cannot be undone.

Results

Important: All files and objects that are associated with the DFDL schema file are deleted.

Working with DFDL message model objects

Add, configure, and delete objects.

About this task

The following tasks are described:

- "Adding DFDL message model objects" on page 2230
- "Configuring DFDL message model objects" on page 2235
- "Deleting objects" on page 2238
- "Linking from one DFDL schema file to another" on page 2238

Adding DFDL message model objects

Use the DFDL schema editor to add DFDL message model objects.

About this task

The following tasks are described:

- "Adding DFDL format annotations" on page 2230
- "Adding DFDL escape schemes" on page 2231
- "Adding a message" on page 2231
- "Adding a global element" on page 2232

Adding DFDL format annotations

Data formats are collections of DFDL properties that can be referenced by objects in the DFDL schema such as elements and sequences.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, right-click **DFDL** and then click **Add a Definition Format** to add an existing format. If a format does not already exist, click **Add a default format**.
2. Configure the scheme in the **Representation Properties** .

What to do next

Next:

To apply the format to an object in the schema, select the format in the **Data Format Reference** property.

Adding DFDL escape schemes
An escape scheme tells DFDL to treat characters literally, rather than as a separator or terminator. For example, you might need to escape commas in a CSV file.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

About this task
Add an escape scheme, and then refer to it using the "Escape Scheme Reference" property on the relevant elements.

Procedure
1. In the Outline view, expand **DFDL** > **Escape Schemes**.
2. In the DFDL schema editor, click the icon to add an escape scheme to the schema, and type a name when prompted.
3. Configure the scheme in the **Representation Properties** :
   a) `Escape Kind` :
      Possible values:
      - `escapeCharacter`: A single escape character that causes only the next character to be interpreted literally. The escape character itself is escaped by the `Escape Escape` character.
      - `escapeBlock`: A pair of escape strings that causes the enclosed group of characters to be interpreted literally. The ending escape string is escaped by the `Escape Escape` character.
   b) **Escape Character**: if the escape kind is `escapeCharacter`, type a single character that escapes the following character.
   c) **Escape Block Start**: type the string of characters that mark the beginning of the escape block.
   d) **Escape Block End**: type the string of characters that mark the end of the escape block.
   e) **Escape Escape**: specify the character that escapes the escape character or string.
   f) **Extra Escaped Character**: optionally, specify any other characters that must be escaped when serializing.
   g) **Generate Escape Block**: if the escape kind is `escapeBlock`, define when escaping is used during serialization.

Adding a message
Add a global element that represents an entire message.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure
1. In the Outline view, right-click **Messages**, and then select **Add**.
2. Type a name for the message.
3. Specify whether the content of the message is a sequence or a choice.

Adding elements
Define global and local elements.

About this task

By using an *element reference*, a *global* element can be reused across messages, types, groups, and other elements.

A *local* element is available only where it is declared and cannot be reused.

Adding a global element
Use the outline view of the DFDL schema editor to create a global element.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, right-click **Elements**, and then select **Add a Global Element**.
2. Type a name for the element.

What to do next

Next:

Configure the global element; see "Editing a DFDL schema file" on page 2225.

Adding a local element
Use the outline view of the DFDL schema editor to add a local element.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. If necessary, in the Outline view, select the appropriate part of the schema.

   This action displays the selected area in the main editing area.
2. In the main editing area, right-click the parent element and select either **Add a Local Element** or **Add Complex local element**. If you are adding a complex local element, specify whether it is a `sequence` or a `choice` element.

   The new element is created as the last child of the parent element.
3. Optional: Use the **Up** and **Down** arrows above the table that you are working in to reposition the new element.

Adding an element reference
Reuse a global element that you have defined.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

About this task

After you have defined a global element, you can include a reference to it in a sequence or choice. You define the element only once, and can then easily reuse it. Any changes that you make to the element are automatically reflected in other objects that contain a reference to the element.

Procedure

1. In the Outline, select the message, element, type, or group that you want to add an element reference to.
2. Right-click the selected object in the Editor area of the screen and select **Add Element Reference**.
3. Select the appropriate element from the list.

   A reference to the element is inserted. An arrow on the icon next to the element name denotes that it is a reference to another element.

Adding a simple type
Create a global simple type.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, right-click **Simple Types**, and then select **Add**.
2. Type a name and select an existing that the new type inherits its properties from.
3. Edit the properties of the new type as appropriate.

Adding a global complex type
Create a complex type.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, right-click **Complex Types**, and then select **Add**.
2. Type a name for the new type.
3. In the Editor area, add elements to the new type as appropriate.

Adding groups
Define a group of elements that can be used in complex type definitions.

About this task
A group can be either of the following compositions:

Sequence
All objects in the group can appear in the data.

Choice
Only one of the objects in the group can ever appear in the data.

Both compositions of group can be either global or local.

A *global* group has a name. Using a group reference, it can be reused across messages, elements, types, and other groups.

A *local* group has no name. In the editor, it is shown as either *sequence* or *choice*. It is available only where it is declared and cannot be reused.

Adding a global group
Create a named group of elements that you can reuse in complex definitions.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, right-click **Groups** > **Add a Group**, and then type the group name.
   The group is displayed in the editor area of the window.
2. Add and configure elements as appropriate.

Adding a local sequence
Add an unnamed sequence.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, select the object that you want to add a group to.
2. In the editor area, right-click the element that you want to add a group to, and select **Add Sequence**.
   The new group is placed as the last item. You can reorder it, and add elements to it.

Adding a local choice
Add an unnamed choice.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, select the object that you want to add a group to.
2. In the editor area, right-click the element that you want to add a group to, and select **Add Choice**.
   The new group is placed as the last item. You can reorder it, and add elements to it.

Adding a group reference
Reuse a global group that you have defined.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

About this task
After you have defined a group, you can include a reference to it in other objects. You define the group only once, and can then easily reuse it. Any changes that you make to the group are automatically reflected in other objects that contain a reference to the group.

Procedure

1. In the Outline, select the message, element, type, or group that you want to add a group reference to.
2. Right-click in the Editor area of the screen and select **Add Group Reference**.
3. Select the appropriate group from the list.
   A reference to the group is inserted. An arrow by the group name denotes that it is a reference to another group.

Adding a user-defined variable
You can use a user-defined variable to specify a value in your DFDL schema that is used in parsing your message, but varies between messages. Variables are defined as top-level annotations in a schema. A

variable holds a value that can be set once, and then accessed from DFDL expressions in property values, asserts, and discriminators.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, right-click **Variables**, then select **Add a Variable Definition**.
2. Type a name and select a data type for your user-defined variable.
3. Edit the default value of your new variable.
4. Save your message model.

Results

Your user-defined variable is added to the DFDL schema.

What to do next

Add your user-defined variable to a DFDL schema object. See "Setting variables on a schema object" on page 2237.

Configuring DFDL message model objects

Use the DFDL schema editor to configure DFDL message model objects.

About this task

The following tasks are described:

Renaming objects

Rename an existing object, such as a message or complex or simple type.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. Locate the object in the editor area.
2. Click the name of the object, and type a new name.

Reordering objects

Move a local element, sequence, or choice up or down the schema.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. Locate the object in the editor area.
2. Right-click the object, and select **Move Up** or **Move Down**.
   You can also use the icons that are below the main toolbar, in the editor area of the screen.

Changing the type of an element
Change the type of an element, for example from `integer` to `float`.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, select the parent of the element that you want to change.
   For example, to change a local element in a message, select the parent message.
2. In the editor area, click the **Type** property of the object, and select the appropriate type from the list.

   Tip:

   - Click **Anonymous** to define a new local complex type.
   - Click **Browse** to open a **Type Selection** window. From here, if the type that you require is not found, you can add a reference to another schema.

Configuring object properties
Configure DFDL, validation, and documentation properties.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

About this task

You can set properties for message, elements, types, groups, escape schemes, and formats. Different properties are displayed, depending on the object selected. The value of a property can be either inherited, or set locally. If the value is inherited, the following icon is shown to the left of the property value:  . For more information, see sections 10 - 17 of the DFDL v1.0 Specification.

Procedure

1. In the Outline view, select the appropriate message, element, type, group, escape scheme, or format.
   The selected object is displayed in the Editor area.
2. In the Editor area, select the element to configure.
   If properties can be configured for that element, they are displayed in the DFDL Properties area.
3. To change the type of an element, click the **Type** field in the Editor area.
   Other properties that are displayed in the Editor area can be set there.

4. Otherwise, find the property that you want to configure on the Representation Properties tab of the DFDL Properties area.

   These tools are available:

   - **Filter**, near the top of the Properties area.
   - The **Show Only Basic Properties** button at the top of the properties area will cause only basic properties to be displayed. If only basic properties are displayed, click **Show All Properties** to display all the properties.
   - The **Show Only Basic Properties** button at the top of the properties area hides properties that are inherited. If only local properties are displayed, click **Show Inherited Properties** to display all properties that this object possesses.
   - Hover over a property to see more information. If the property is inherited, information about the inheritance is displayed, and a link to the source is provided.

   Tip:

   - Use the property wizard  where available.
   - Use the **Validation** section to specify permissible values for the object. You can then check the data during test parsing.
   - Use the **Comment** property to add a brief note about an object.

Setting variables on a schema object
Set the value of a variable within a DFDL schema. You can use a variable to specify a value in your message model that is used later in parsing your message.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure
1. In the **Editor** view, select the DFDL schema object on which you want to set a variable.
2. On the **Variables** tab of the DFDL Properties area, in the **Set Variables** section, click **Add variable reference**.

   A list of available variables is displayed.
3. Select the variable from the list, and enter the required value for the variable in the **Value** field.
4. Save your message model.

Results
Your variable is used when the message model is run.

Adding an assert to a schema object
Add asserts to a DFDL schema object to define tests to ensure that data in the message are well-formed.

Before you begin
Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure
1. In the **Editor** view, select the DFDL schema object on which you want to add an assert.
2. On the **Asserts and Discriminators** tab of the DFDL Properties area, select **Asserts**, then click **Add assert**. If a discriminator is already applied to the object, the **Asserts** option is disabled, as an object cannot have both an assert and a discriminator applied to it.

3. Enter your test expression in the **Test Condition** field, and a human-readable failure message in the **Message** field.

   Content assistance is available for the **Test Condition** field; press Ctrl+Space to open the **XPath Expression Builder**.

Results

Your assert is used when the message model is run.

Adding a discriminator to a schema object

You can add a discriminator to a DFDL schema object to enable the DFDL parser to resolve a point of uncertainty.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the **Editor** view, select the DFDL schema object on which you want to add a discriminator.
2. On the **Asserts and Discriminators** tab of the DFDL Properties area, select **Discriminators**, then click **Add discriminator**. If an assert is already applied to the object, the **Discriminators** option is disabled, as an object cannot have both an assert and a discriminator applied to it.

   A new entry in the table is created.
3. Enter your test expression in the **Test Condition** field, and a human-readable failure message in the **Message** field.

   Content assistance is available for the **Test Condition** field; press Ctrl+Space to open the **XPath Expression Builder**.
4. Save your message model.

Results

Your discriminator is used when the message model is run.

Deleting objects

Delete an object that you have defined.

Before you begin

Create or open a DFDL schema file. See DFDL schema editor for a description of the DFDL schema editor.

Procedure

1. In the Outline view, select the object that you want to delete. If you do not see the object in the Outline view, click its parent object.
   For example, to rename a local element in a message, select the parent message.
2. In the editor area, click the object, and then click the **Delete** button.

Linking from one DFDL schema file to another

Add a link to a different schema.

Before you begin

1. Create two DFDL schema files.
2. Open the schema file that you want to add a link to.

About this task

Linking is needed when you have DFDL objects in one schema file, and you want to refer to them in a different schema file. For example, the first file contains a simple type, which an element in the second file wants to use.

Procedure

1. In the Outline area, right-click Schema and select **Add an import or include**.
2. Within the Add Schema Reference dialog that opens, browse to the schema that you want to include or import.

   The namespaces of the two schema files determine whether to use the `import` or `include` option.

	Target file has a target namespace	**Target file has notarget namespace**
Parent file has a target namespace	xsd:import	xsd:include[1]
Parent file has notarget namespace	xsd:import	xsd:include

[1] When a target namespace file includes a notarget namespace file, referencing an object in the target file from the parent file causes the object to be present in the namespace of the parent file.

Developing independent DFDL applications

Develop independent Java application programs that use the IBM DFDL API to parse a text or binary data stream into the equivalent logical information, or to serialize logical information into an equivalent text or binary data stream.

Before you begin

Before you start:

- Read about the IBM DFDL Java classes. Documentation for the IBM DFDL Java classes is provided in the following `.zip` file:

  install_dir`\server\tools\ibm-dfdl-java.zip`

  install_dir is the directory that you specified as the installation directory for IBM App Connect Enterprise.

About this task

A sample is provided to demonstrate how to use the IBM DFDL API. Run and explore the sample to learn what you can do with the IBM DFDL API. The IBM DFDL API sample is in the *install_dir*`\server\sample\dfdl` directory. For information about how to use the IBM DFDL API to develop independent programs, see “Configuring an environment for independent DFDL applications” on page 2240.

What to do next

- When you have written and tested your programs, you can distribute them to the systems that you want to run those programs. If a system that you want to run your IBM DFDL API independent programs does not have the IBM App Connect Enterprise runtime component installed, you must complete additional configuration steps, as described in “Configuring environments without the IBM App Connect Enterprise runtime component installed” on page 2241.

Configuring an environment for independent DFDL applications

Prepare the system environment in which you want to develop and run your independent applications that use the IBM DFDL API.

Before you begin

Before you start:

Before you can develop and run Java application programs that use the IBM DFDL API, you must install the following prerequisite software on your local computer environment:

- An IBM Java Development Kit (JDK) at a supported Java level.

  A JDK is not supplied with IBM App Connect Enterprise; you must acquire and install a suitable product yourself. You must use an IBM JDK to develop IBM DFDL independent programs and an IBM Java Runtime Environment (JRE) to run these programs. For information about supported Java levels, see IBM App Connect Enterprise system requirements.

About this task

To set up your computer in preparation for building and running IBM DFDL independent programs, you must configure your class path environment variable so that it includes all the JAR files needed for IBM DFDL. The instructions use the Windows path separator; but apply equally to other operating systems, if you change the separator.

Procedure

Update the class path environment variable:

1. Add all of the JAR files that are required for IBM DFDL.
   For example:

   ```
   set CLASSPATH=%CLASSPATH%;install_dir\server\dfdl\lib\ibm-dfdl.jar
   ```

   Repeat this step for each JAR file in your *install_dir*`\server\dfdl\lib` directory, where *install_dir* is the directory that you specified as the installation directory for IBM App Connect Enterprise. Alternatively, to add all of the required JAR files, run the `dfdlprofile` utility that is provided in your *install_dir*`\server\dfdl\bin` directory.
2. If you want to run and explore the IBM DFDL sample, add the `dfdlsample_java.jar` JAR file that is provided in your *install_dir*`\server\sample\dfdl` directory.
   For example:

   ```
   set CLASSPATH=%CLASSPATH%;install_dir\server\sample\dfdl\dfdlsample_java.jar
   ```
3. Add your Java development directory.
4. Add any other JAR files and directories that you require.

What to do next

Next:

- Use the tools that are provided by your JDK to build and run your IBM DFDL independent programs.
- If a system that you want to run your IBM DFDL API independent programs does not have the IBM App Connect Enterprise runtime component installed, you must complete additional configuration steps.

Configuring environments without the IBM App Connect Enterprise runtime component installed

Install and run Java independent programs that use the IBM DFDL API on systems that do not have the IBM App Connect Enterprise runtime component installed.

About this task

You can run Java programs that use the IBM DFDL API on systems where you have not installed the IBM App Connect Enterprise runtime component, but you must ensure that you have purchased a IBM App Connect Enterprise license for each computer on which you intend to run Java programs that use the IBM DFDL API.

The following instructions use the Windows path separator; but apply equally to other operating systems, if you change the separator.

Procedure

To install and run IBM DFDL independent programs in an environment that does not have the IBM App Connect Enterprise runtime component installed, complete the following steps:

1. Ensure that the target system has a compatible Java Runtime Environment (JRE) installed.

   Because you are not installing the IBM App Connect Enterprise runtime component, which includes a JRE, you must use an alternative option. For more information about Java support, see IBM App Connect Enterprise system requirements.
2. Copy the following files from a system that has the IBM App Connect Enterprise runtime component installed, to the target system:
   a) `ibm-dfdl-java.zip` from *`install_dir`*`\server\tools`, where *install_dir* is the directory that you specified as the installation directory for IBM App Connect Enterprise.
   b) Your Java independent program that uses the IBM DFDL API.
3. On the target system, extract the contents of `ibm-dfdl-java.zip` to a location of your choice; for example, `C:\dfdl`.

   Important: Extracting the contents of `ibm-dfdl-java.zip` installs license and entitlement files onto the target computer for use by IBM License Metric Tool (ILMT). You can use ILMT to monitor the usage of IBM (and other) software products.

   The extracted contents of `ibm-dfdl-java.zip` include a Software Identification (SWID) tag for `advanced` mode and a SWID tag for DFDL. The following SWID tags are detected by ILMT:

   - `ibm.com_IBM_App_Connect_Enterprise-12.0.3.swidtag`
   - `ibm.com_IBM_Data_Format_Description_Language_-_FREE-1.1.3.swidtag`

   If your IBM App Connect Enterprise installation is in `advanced` mode, no further action is needed. However, you must update the SWID tag in the directory where `ibm-dfdl-java.zip` is extracted so that ILMT reflects the correct license for the edition of IBM App Connect Enterprise that you have purchased if either of the following is true:

   - You have purchased a different edition of IBM App Connect Enterprise.
   - You change the operation mode to one of the following modes:
     - `standard`
     - `nonproduction`

   You can update the SWID tag by performing the following steps:

   a. On a machine on which you have installed IBM App Connect Enterprise, change to the `swidtag` directory to view the SWID tag files. The SWID tag file has the suffix `swidtag` if the operation mode is active or the suffix `deactivated` if the operation mode is inactive. If you are intending to change

the operation mode, see "Operation modes" on page 3 prior to changing the operation mode to ensure that the correct SWID tag is activated.

b. Copy the active SWID tag file from the `swidtag` directory to the directory where `ibm-dfdl-java.zip` is extracted:

- `ibm.com_IBM_App_Connect_Standard-12.0.3.swidtag` (`standard` mode)
- `ibm.com_IBM_App_Connect_Enterprise_for_NON-PRODUCTION-12.0.3.swidtag` (`nonproduction` mode)

c. Delete the `advanced` mode SWID tag, `ibm.com_IBM_App_Connect_Enterprise-12.0.3.swidtag`, from the directory where `ibm-dfdl-java.zip` is extracted.

For more information about ILMT, see the IBM License Metric Tool website

Update the class path environment variable:

4. Add all of the JAR files that are required for IBM DFDL.
   For example:

```
set CLASSPATH = %CLASSPATH%;C:\dfdl\lib\ibm-dfdl.jar
```

   Repeat this step for each JAR file in your *extract_dir*`\lib` directory, where *extract_dir* is the directory to which you extracted `ibm-dfdl-java.zip`. Alternatively, to add all of the required JAR files, run the `dfdlprofile` utility that is provided in your *extract_dir*`\bin` directory.
5. If you want to run and explore the IBM DFDL sample, add the `dfdlsample_java.jar` JAR file in your *extract_dir*`\samples` directory.
   For example:

```
set CLASSPATH = %CLASSPATH%;C:\dfdl\samples\dfdlsample_java.jar
```

6. Add your DFDL independent program JAR file.
7. Add any other JAR files and directories that you require.

Results

Next: You can now run your DFDL independent programs on the target computer.

Working with XML schema files

Create, open, modify, or delete an XML schema file.

About this task

This topic area describes the tasks that are involved in working with an XML schema file:

- "Opening an existing XML schema file" on page 2242
- "Creating an XML schema file" on page 2243
- "Deleting an XML schema file" on page 2244
- "Generating HTML documentation from an XML Schema file" on page 2245
- "Working with XML Schema message model objects" on page 2245

Opening an existing XML schema file

Open an existing XML schema file in the XML Schema editor to view or edit the contents of the file.

About this task

To open an existing XML schema file:

Procedure

1. Right-click the XML schema file (file extension `*.xsd`) that you want to open, and select **Open**.
   The XML Schema file opens in the XML Schema editor.

   Tip: The Eclipse framework lets you open resource files with other editors. However, you are advised to use the XML Schema editor to work with XML schema files. This editor correctly validates any changes that are made to your XML schema files. Other editors might not correctly validate files.
2. View or edit the data in your XML schema file.

Creating an XML schema file

You can create XML schema files to model your XML format messages

About this task

You can use XML schema to model various message formats, including:

- SOAP XML
- Other XML
- CORBA IDL
- SCA
- Database record

After you create an XML schema file, define the XML Schema elements needed to model your data.

You can create an XML schema file in the following ways:

- "Creating an XML schema file from scratch" on page 2243
- "Creating an XML schema file by using the New Message Model wizard" on page 2244

Creating an XML schema file from scratch

Create an XML schema file to model your XML format data.

Before you begin

Ensure that you have an application, library, or integration project in which to create your XML schema file. If the XML schema file will be used by multiple solutions, consider creating it in a shared library for ease of reuse.

About this task

You can also use a shared library to map between different versions of an XML schema file. Both versions might declare the same elements and types, which cannot coexist in one application. You can build one shared library that contains version 1 of an XML schema file, and another shared library that contains version 2. You can then build a map that references the XML schema files in the shared libraries and maps between the two versions. At deployment time, separate models are built for each of the shared libraries. Therefore, no clash results from the duplicated elements and types.

Procedure

To create an XML schema file, complete the following steps.

1. Click **File** > **New** > **Other**.
   A window opens in which you can select a wizard.
2. Expand **XML**, select **XML Schema File**, click **Next**.
   The **Create XML Schema** wizard opens.
3. Select a parent folder and enter a file name for your XML schema file.
4. Click **Finish**.

Results

Your XML schema file is displayed under the appropriate application, library, or integration project in the Application Development view, and is opened in the XML Schema editor.

What to do next

- Continue to edit your XML schema file by using the XML Schema editor.

Creating an XML schema file by using the New Message Model wizard

Use the **New Message Model** wizard to create XML schema files.

About this task

You can use the **New Message Model** wizard to create an XML schema file by any of the following methods:

- Create an empty XML schema file
- Create an XML schema file by importing an XML DTD file
- Create an XML schema file by using an XML document as an example
- Create an XML schema file by importing an existing schema file

To create an XML schema file:

Procedure

1. Click **File** > **New** > **Message Model ...**.
   The **New Message Model** wizard opens.
2. Select the message format that you want to model.
3. Step through the wizard, clicking **Next** to move to a new panel, then click **Finish** when you have entered the information that is required to create your XML schema file.

Results

Your new XML schema file is created, and is displayed in the **XML and DFDL Schemas** folder of your project.

What to do next

You can continue to edit your XML schema file by using the XML Schema editor.

Deleting an XML schema file

You can delete an XML schema file.

Before you begin

Create a file; see “Creating an XML schema file” on page 2243.

Procedure

1. Switch to the Integration Development perspective.
2. Right-click the XML schema file (file extension `.xsd`) that you want to delete, then click **Delete**.
   Alternatively, select the XML schema file that you want to delete, then, from the menu bar, click **Edit** > **Delete**, or press the Delete key.
3. In the **Confirm Resource Delete** window, click **Yes** to delete the XML schema file.
   Important: this action cannot be undone.

Results

Important: All files and objects that are associated with the XML schema file are deleted.

Generating HTML documentation from an XML Schema file

You can generate HTML documentation from an XML Schema file. The HTML documentation contains various information about the message model that is included in the XML Schema file. This documentation can be useful for providing a summary of the contents of your XML Schema file.

About this task

To generate HTML documentation from an XML Schema file:

Procedure

1. In the Navigator view, right-click the XML Schema file that you want to use to generate HTML documentation.
2. Click **Generate** > **HTML**. The **XSD Documentation Generation Options** dialog opens.
3. Select the style of HTML documentation that you want:
   - Select **Generate XSD Documentation with frames** to generate HTML files in a style that is similar to Javadoc files.
   - Select **Generate XSD Documentation without frames** to generate one HTML file per schema.
4. Specify a location for your HTML documentation. Click **Finish**.

Results

The HTML documentation is created in the location that you specified, and is visible in the Application Development view.

Working with XML Schema message model objects

Add, configure, and delete objects.

About this task

For information about how to add, configure, and delete XML Schema message model objects by using the XML Schema editor, see *Editing XML Schema properties* in the Rational Software Architect product documentation online.

Working with JSON schema files

Create, open, modify, or delete a JSON schema file.

About this task

This topic area describes the tasks that are involved in working with a JSON schema file:

- "Opening an existing JSON schema file" on page 2246
- "Creating a JSON schema file" on page 2246
- "Deleting a JSON schema file" on page 2247

Opening an existing JSON schema file

Open an existing JSON schema file in the JSON editor to view or edit the contents of the file.

About this task

A JSON schema file must either contain schema in the name (for example, `.schema.json`) or the first line of the file must indicate that it is a schema by including a `$schema` property. To open an existing JSON schema file:

Procedure

1. Right-click the JSON schema file that you want to open, and select **Open**.
   The JSON schema file opens in the JSON editor.

   Tip: The Eclipse framework lets you open resource files with other editors.
2. View or edit the data in your JSON schema file.

Creating a JSON schema file

Create a JSON schema file to model your JSON format data.

Before you begin

Ensure that you have an application, library, or integration project in which to create your JSON schema file. If the JSON schema file will be used by multiple solutions, consider creating it in a shared library for ease of reuse.

About this task

You can create a JSON schema file either from scratch in your IBM App Connect Enterprise Toolkit or by importing an existing JSON schema file into your IBM App Connect Enterprise Toolkit.

Procedure

- Create a JSON schema file from scratch:
  a) Click **File** > **New** > **Other**.
     A window opens in which you can select a wizard.
  b) Expand **General**, select **File**, click **Next**.
     The **Create New File** window opens.
  c) Select a parent folder and enter a file name for your JSON schema file.
     Give the file an extension of `.schema.json` or ensure that the file contains the `$schema` property.
  d) Click **Finish**.
- Import an existing JSON schema file from your file system.
  For information about importing files into the IBM App Connect Enterprise Toolkit from your file system, see “Importing files from the file system into the IBM App Connect Enterprise Toolkit” on page 2319.

Results

Your JSON schema file is displayed under the appropriate application, library, or integration project in the Application Development view, and is opened in the JSON editor.

What to do next

- Continue to edit your JSON schema file by using the JSON editor.

Deleting a JSON schema file

You can delete a JSON schema file.

Before you begin

Create a JSON schema file; see “Creating a JSON schema file” on page 2246.

Procedure

1. Right-click the JSON schema file that you want to delete. JSON schema files have the file extension `schema.json` or contain a `$schema` property at the root. Then click **Delete**.

   Alternatively, select the JSON schema file that you want to delete, then, from the menu bar, click **Edit** > **Delete**, or press the Delete key.
2. In the **Confirm Resource Delete** window, click **Yes** to delete the JSON schema file.

   Important: this action cannot be undone.

Results

Important: All files and objects that are associated with the JSON schema file are deleted.

Message Sets: Working with message sets

Use a message set to create a model for a particular message format.

About this task

Tip: In IBM App Connect Enterprise, *message model schema* files contained in applications, integration services, and libraries are the preferred way to model messages for most data formats. Message sets are required if you use the MRM or IDOC domains. For more information about message modeling, see “Message modeling concepts” on page 2134.

The topics in this section describe how to use message sets and message definitions.

Enabling message set development

This task provides instructions for enabling message set creation and editing functionality in IBM App Connect Enterprise.

About this task

In IBM App Connect Enterprise, *message model schema* files contained in applications, integration services, and libraries are the preferred way to model messages for most data formats. Message sets are required if you use the MRM or IDOC domains. For more information about message modeling, see “Message modeling concepts” on page 2134.

You can import message flows containing message sets from previous versions, and they can be viewed, modified, and deployed in the usual way. However, by default, the menu options for creating new message sets or message definition files are hidden. To perform these tasks, you must first enable message set development in the IBM App Connect Enterprise Toolkit.

To enable message set development in IBM App Connect Enterprise, complete the following steps.

Procedure

1. From any perspective in the IBM App Connect Enterprise Toolkit, click **Window** > **Preferences**.
   The **Preferences** window opens.
2. Expand Integration Development, and select **Message sets**.
3. Under Message Set Development, select **Enable menus for Message Set development**.
4. Click **Apply**, then click **OK**.

Results

The **Preferences** window closes, and options for message set development are enabled in the IBM App Connect Enterprise Toolkit.

Message Sets: Working with a message set project

Creating and deleting a message set.

About this task

Tip: In IBM App Connect Enterprise, *message model schema* files contained in applications, integration services, and libraries are the preferred way to model messages for most data formats. Message sets are required if you use the MRM or IDOC domains. For more information about message modeling, see “Message modeling concepts” on page 2134.

Before you begin to develop your message model, you must create a message set. A message set project is automatically created when you create a message set.

This topic area describes the tasks that are involved in working with a message set.

- “Message Sets: Creating a message set” on page 2250
- “Message Sets: Deleting a message set project” on page 2248

Message Sets: Deleting a message set project

Delete a message set project and, optionally, the contents of the associated project directory.

Before you begin

You must have completed the following task:

- “Message Sets: Creating a message set” on page 2250

Tip: Close all open windows within the IBM App Connect Enterprise Toolkit that relate to the message set project or associated files that you want to delete. If you do not do this, errors might occur when you try to process objects that no longer exist your workspace.

About this task

This task topic describes how to delete a message set project and, optionally, the contents of the associated project directory.

To delete a message set project:

Procedure

1. Switch to the Integration Development perspective.
2. In the Application Development view, right-click the message set project that you want to delete, then click **Delete** on the pop-up menu.

   The **Confirm Project Delete** window opens.
3. Choose whether to delete or retain the contents of the project directory.

   By default, project directory contents are not deleted. To delete the contents of the project directory, click **Also delete contents**; all files and directories that are associated with the project are deleted.
4. Click **Yes** to delete the message set project. Alternatively, click **No** or press **Esc** to cancel the deletion.

Results

Message Sets: Working with a message set

Complete a variety of tasks that are involved in working with a message set.

About this task

Tip: A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see "Enabling message set development" on page 2248 .

Message Sets: Configuring message set preferences

This task topic explains how to make changes to preferences that relate to message set processing. These preferences are for message set editors, message set model validation, and importing XML Schema.

About this task

To configure message set preferences:

Procedure

1. Open the **Preferences** window by clicking **Window** > **Preferences** > **Integration Development** > **Message Sets**.

   This displays the following options:

   - Editors
   - Validation
   - XML Schema Importer
2. View or make any necessary changes to the preferences for message set processing.

   These preferences are shown in the right hand area of the window.
3. When you have finished, click **Apply**. Alternatively, click **Restore Defaults** to return to the default settings for the displayed fields.
4. Close the **Preferences** window by clicking **OK**.

Results

Message Sets: Opening an existing message set

Open an existing message set in the Message Set editor so that you can view or edit its contents.

Before you begin

Create a message set by following the instructions in "Message Sets: Creating a message set" on page 2250.

Tip: Although you can open resource files with other editors you are advised to only use the IBM App Connect Enterprise Toolkit Message Set editor to work with message set files because this editor correctly validates changes made to the `messageSet.mset` files when they are saved. Other editors might not do this.

About this task

To open a message set so that you can view or edit its contents:

Procedure

1. Switch to the Integration Development perspective.
2. In the Application Development view, right-click the `messageSet.mset` file of the message set that you are opening then click **Open** on the pop-up menu.

   This opens the Message Set editor for the selected file.

Results

You can now view or edit the file as required.

Message Sets: Creating a message set

Use the New Message Set wizard to create a message set.

About this task

Tip: A *message set* is the original container for message models used by IBM App Connect Enterprise. In IBM App Connect Enterprise, *message model schema* files contained in applications and libraries are the preferred way to model messages for most data formats. Message sets continue to be supported, and are required if you use the MRM or IDOC domains. If you need to model data formats for use in the MRM or IDOC domains, you must first enable message set development in the IBM App Connect Enterprise Toolkit. For more information, see "Enabling message set development" on page 2248 .

The New Message Set wizard also creates a new message set project.

Note: You can also use a Quick Start wizard to create a message set, a message set project, and other resource files that you need to create a new application.

The New Message Set wizard allows you to select what kinds of message format you want to model in your message set. The message domain and the physical format created is inferred from the selection that you make. Note, however, that you can change the inferred domain using the message set editor.

The options are:

- XML documents (general)
- Web services (SOAP)
- Binary data (for example, C or COBOL structures)
- Text data (for example, CSV, SWIFT, or HL7)
- MIME documents other than web services
- Data for WebSphere Adapters
- Database records

The default value is `XML documents (general)`.

Below the list of message formats there are check boxes corresponding to each of the message formats. The check box corresponding to the message format that you selected is not available, but you can select any of the other check boxes to add other message formats to your message set.

If you later select a different default message domain, the checked state for the domain that you originally selected as the default does not change, but the check box is enabled.

As you can now select more than one message domain you can, for example, use the default value of **XML documents (general)** together with **Binary data (for example, C or COBOL structures)** and **Text data (for example, CSV, SWIFT or HL7)**. This results in the selection of the XMLNSC and MRM domains (to handle non-XML documents) within the same message set if you require this functionality.

The mapping between the selection, the domain, and the wire format created is described in the following table:

Selection	Inferred message domain	Physical format created
XML documents (general)	XMLNSC	XML
Web services (SOAP)	SOAP and XMLNSC	XML
Binary data (for example, C or COBOL structures)	MRM	CWF
Text data (for example, CSV, SWIFT, or HL7)	MRM	TDS
MIME documents other than web services	MIME	None
Data for WebSphere Adapters	DataObject	None
Data for CORBA	DataObject	None
Database records	DataObject	None

Depending on your selection, an appropriate IBM supplied message will be imported into the message set.

Note: The XML physical format is created only in case the user switches to MRM XML.

If you click **Finish** on the second page of the New Message Set wizard, the message set that is created has the following default property values:

Property	Default value
Message Domain	XML documents (general)
Physical Format	XML Wire Format (XML1)
Namespace support	Enabled

To create a new message set:

Procedure

1. Switch to the Integration Development perspective.
2. Click **New** > **Other** > **Message Set** to open the New Message Set wizard.
3. In the **Message set name** field, type the name for the message set that you are creating.

   The name that you type is also displayed in the **Message set project name** field.
4. Optional: You can choose a different message set project name; to do this, type this name into the **Message set project name** field.
5. Optional: You can specify a directory in which you want to store the project contents.

   If you do not specify a directory, the default workspace is used. To specify a directory, first clear the **Use default** check box, then either type into the **Directory** field the location of the directory, or click **Browse** to see a list of the folders that you can choose from for the location of the directory.
6. Optional: If you want to create a new message set whose definition is based on existing message set, click **Message Set** in the **Copy message set contents from another message set** pane and choose from the list of message set definitions that are shown; then click **Finish**.

   The new message set (and the message set project that contains it) is created immediately and the New Message Set wizard automatically closes.
7. Optional: If you want to create a message set whose definition is not based on an existing message set, click **Next**.

   You are presented with the next pane which allows you to choose the type of message data that you want to process.

   a) Expand the list shown under **Select the type of message data that you will be working with most often** and choose a value from the list shown. The value that you choose determines the default message domain of the message set. If you choose `XML Documents (general)`, the default message domain XMLNSC is used.

   b) Optional: You can now select additional types of message data. Under **Select any other types of message data that you will be working with** there are check boxes for each of the following message data types:

   - XML documents (general)
   - Web services SOAP
   - Binary data (for example, C or COBOL structures)
   - Text data (for example, CSV, SWIFT or HL7)
   - MIME documents other than web services
   - Data for WebSphere Adapters

   Note: These check boxes correspond to the list of data types from which you chose the data type that you will be working with most often, but the check box that corresponds to the data type that you chose from that list is not available.

   By default, all these check boxes are cleared. You can select any, or all of these check boxes, to add the corresponding data types to your message set.

   If you select the check box for text data, either for the type of message data that you will be working with most often or as another type of message data that you will be working with, you can additionally choose from the displayed list of text messaging standards. This list is the same as

that given in the description of the `Messaging Standard` property in Message Sets: TDS Format message set properties.

c) Click **Next**.

A new panel is displayed that summarizes some information about the message set that you have created. Specifically, it lists:

Supported message domains
Physical formats to be created
IBM supplied messages to be imported

8. Click **Finish** on this page to create the message set, and the message set project that contains it.

The New Message Set wizard closes.

Results

After the New Message Set wizard finishes, the message set editor is opened.

What to do next

You can now create some message definitions in the new message set. You can either create new message definitions from scratch, or create them based on existing artifacts such as WSDL, XSD, DTD, C, COBOL files, or EIS metadata. Use the Message Definition File wizard and the Message Definition File From wizard to help you with this.

Message Sets: Configuring logical properties: Message sets

Configure the logical properties of a message set using the Message Set editor.

Before you begin

You must have completed the following task:

- "Message Sets: Creating a message set" on page 2250

If the `messageSet.mset` file for the appropriate message set is not already open in the Message Set editor, you must first open it as described in "Message Sets: Opening an existing message set" on page 2250.

About this task

This task topic describes how to configure the logical properties of a message set using the Message Set editor.

To configure the logical properties of a message set:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, in the Properties Hierarchy, click **Message Set**.

   This displays the logical properties of the selected message set in the Details view.
3. Configure to your requirements the logical properties that are shown in the Details view.

   Note: Property fields that are disabled cannot be altered. For example, the **Message Set ID** field is disabled because the message set ID is generated automatically when the message set is created; the **Message Set ID** must not then be altered.
4. Save your changes by clicking **File> Save** or by pressing Ctrl+S. Alternatively click **File> Save All** or press Ctrl+Shift+S.

Results

Message Sets: Working with physical formats

If you are using the MRM domain to parse and write your messages, when you are developing your message model you might want to add one or more physical format layers to a message set, then configure the properties of these physical formats.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250

About this task

This topic area covers the following tasks that relate to working with the physical properties of a message set:

- "Message Sets: Adding a Custom Wire Format (CWF)" on page 2254
- "Message Sets: Configuring Custom Wire Format (CWF) properties: Message sets" on page 2255
- "Message Sets: Adding a TDS physical format" on page 2255
- "Message Sets: Configuring TDS properties: Message sets" on page 2256
- "Message Sets: Adding an XML wire format" on page 2256
- "Message Sets: Configuring XML Wire Format properties: Message sets" on page 2257
- "Message Sets: Renaming a physical format" on page 2258
- "Message Sets: Applying default physical format settings: Message sets" on page 2258
- "Message Sets: Removing a physical format" on page 2259
- "Message Sets: Observing 2007 U.S. changes to daylight saving time" on page 2259

Message Sets: Adding a Custom Wire Format (CWF)

You can add a Custom Wire Format (CWF) physical format layer to a message set by using the Message Set editor.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250

About this task

To add a CWF physical format layer to a message set:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, in the Properties Hierarchy, open the **Add Custom Wire Format** window by right-clicking **Custom Wire Formats**, then clicking **Add Custom Wire Format**.
3. On the **Add Custom Wire Format** window, specify the name that you want to use for the new CWF physical format. The default name is 'Binary1'.

   Tip: Physical format names must be unique across a message set. You are recommended to start the name of your new CWF physical format with 'CWF' or 'Binary', because this clearly identifies the type of the physical format that you are adding in relation to any of the other types.

4. Click **OK** to add the physical format layer to the message set. Alternatively, if you decide to cancel the process, click **Cancel** or press Esc on the keyboard.

   Tip: The new physical format layer is added with the relevant default property values. You can configure the message set properties according to your requirements, using the appropriate editor.
5. Save your changes either by clicking **File> Save** or by pressing Ctrl+S.

Message Sets: Configuring Custom Wire Format (CWF) properties: Message sets
Configure the Custom Wire Format (CWF) properties of a message set using the Message Set editor.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250
- "Message Sets: Adding a Custom Wire Format (CWF)" on page 2254

About this task

To configure the CWF properties of a message set:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, the **Custom Wire Formats** node of the Properties Hierarchy shows the name of each of the CWF physical formats that have been added to the message set. If the physical format names are not in view, expand **Custom Wire Formats** by clicking **+**.
3. Click the chosen CWF physical format so that the properties of this format appear in the Details view of the Message Set editor.
4. Configure the CWF properties shown in the Details view according to your requirements.
5. Save your changes either by clicking **File> Save** or by pressing Ctrl+S. Alternatively click **File> Save All** or press Ctrl+Shift+S.

Results

Message Sets: Adding a TDS physical format
Add a Tagged/Delimited String (TDS) physical format layer to a message set using the Message Set editor.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250

About this task

This task topic describes how to add a Tagged/Delimited String (TDS) physical format layer to a message set using the Message Set editor.

To add a TDS physical format layer to a message set:

Procedure

1. Switch to the Integration Development perspective.

2. In the Message Set editor, in the Properties Hierarchy, open the Add **Tagged/Delimited String Format** window by right-clicking **Tagged/Delimited String Formats** then clicking **Add Tagged/Delimited String Format** on the pop-up menu.
3. In the **Add Tagged/Delimited String Format** window, specify the name that you want to use for the new TDS format. The default name is 'Text1'.

   Tip: Physical format names must be unique across a message set. You are recommended to start the name of your new TDS physical format with 'TDS' or 'Text', because this clearly identifies the type of the physical format that you are adding in relation to any of the other types.
4. Click **OK** to add the physical format to the message set. Alternatively, if you decide to cancel the process, click **Cancel** or press **Esc** on the keyboard.

   Tip: The new physical format layer is added with the relevant default property values. You can configure the message set properties according to your requirements, using the Message Set editor.
5. Save your changes either by clicking **File> Save** or by pressing Ctrl+S.

Message Sets: Configuring TDS properties: Message sets
Configure the Tagged/Delimited String (TDS) format properties of a message set using the Message Set editor.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250
- "Message Sets: Adding a TDS physical format" on page 2255

About this task

To configure the *TDS* physical format properties of a message set, take the following steps:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, the **Tagged/Delimited String Formats** node of the Properties Hierarchy shows the name of each of the TDS physical formats that have been added to the message set. If the physical format names are not in view, expand **Tagged/Delimited String Formats** by clicking **+**.
3. Click the chosen TDS physical format so that the properties of this format appear in the Details view of the Message Set editor.
4. Configure the TDS properties shown in the Details view according to your requirements.
5. Save your changes either by clicking **File> Save** or by pressing Ctrl+S. Alternatively click **File> Save All** or press Ctrl+Shift+S.

Results

Message Sets: Adding an XML wire format
You can add an XML wire format physical format layer to a message set by using the Message Set editor.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250

About this task

This task topic describes how to add an XML wire format physical format layer to a message set using the Message Set editor.

To add an XML physical format layer to a message set:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, in the Properties Hierarchy, open the **Add XML Wire Format** window by right-clicking **XML Wire Formats**, then clicking **Add XML Wire Format** on the pop-up menu.
3. On the **Add XML Wire Format** window, specify the name that you want to use for the new XML wire format. The default name is 'XML1'.

   Tip: Physical format names must be unique across a message set. You are recommended to start the name of your new XML physical format with 'XML', because this clearly identifies the type of the physical format that you are adding in relation to any of the other types.
4. Click **OK** to add the physical format layer. Alternatively, if you decide to cancel the process, click **Cancel** or press Esc on the keyboard.

   Tip: The new physical format layer is added with the relevant default property values. You can configure the message set properties according to your requirements, using the appropriate editor.
5. Save your changes either by clicking **File> Save** or by pressing Ctrl+S.

Message Sets: Configuring XML Wire Format properties: Message sets
Configure the XML Wire Format properties of a message set using the Message Set editor.

Before you begin

You must have completed the following tasks:

- “Message Sets: Creating a message set” on page 2250
- “Message Sets: Opening an existing message set” on page 2250
- “Message Sets: Adding an XML wire format” on page 2256

About this task

To configure the XML wire format properties of a message set:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, the **XML Wire Formats** node of the Properties Hierarchy shows the name of each of the XML physical formats that have been added to the message set. If the physical format names are not in view, expand **XML Wire Formats** by clicking **+**.
3. Click the chosen XML physical format so that the properties of this format appear in the Details view of the Message Set editor.
4. Configure the XML wire format properties shown in the Details view according to your requirements.
5. Save your changes either by clicking **File> Save** or by pressing Ctrl+S. Alternatively click **File> Save All** or press Ctrl+Shift+S.

Results

Message Sets: Renaming a physical format
Rename a physical format using the Message Set editor.

Before you begin

You must have completed the following tasks:

- “Message Sets: Creating a message set” on page 2250
- “Message Sets: Opening an existing message set” on page 2250

This task assumes that you have added one or more physical formats to the message set that you are working with. For further information see “Message Sets: Adding a Custom Wire Format (CWF)” on page 2254 or “Message Sets: Adding an XML wire format” on page 2256 or “Message Sets: Adding a TDS physical format” on page 2255.

About this task

This task topic describes how to rename a physical format using the Message Set editor.

To rename a physical format previously added to the message model:

Procedure

1. Close all message definition (`.mxsd`) files that are currently open in the Message Definition editor, otherwise you will not be able to rename the physical format.
2. Switch to the Integration Development perspective.
3. In the Message Set editor, the Properties Hierarchy shows the name of each of the physical formats that have been added to the message set. If the physical format names are not in view, expand **XML Wire Formats**, **Custom Wire Formats**, or **Tagged/Delimited String Formats** by clicking **+**.
4. Right-click the physical format that you want to rename then click **Rename** on the pop-up menu to open the "**Rename wire format**" window.
5. In the "**Rename wire format**" window, type the new name for the physical format.

   The renaming operation modifies all of the message definition files in the message set and saves the amended message set file.
6. Click **Finish** to rename the physical format and save the message set file.

Results

Message Sets: Applying default physical format settings: Message sets
Apply the default settings to a physical format layer that has previously been added to a message set.

Before you begin

You must have completed the following tasks:

- “Message Sets: Creating a message set” on page 2250
- “Message Sets: Opening an existing message set” on page 2250

The tasks in this topic area assume that you have added one or more physical formats to the relevant message set. For further information see “Message Sets: Adding a Custom Wire Format (CWF)” on page 2254 or “Message Sets: Adding an XML wire format” on page 2256 or “Message Sets: Adding a TDS physical format” on page 2255.

About this task

To apply the default settings to a physical format that has previously been added to a message set:

Procedure

1. Switch to the Integration Development perspective.
2. In the Message Set editor, in the Properties Hierarchy, right-click the physical format to which you want to apply the default settings then click **Apply default physical format settings** on the pop-up menu.

Results

The default settings are applied to the physical format that you have selected. No warning appears beforehand.

Message Sets: Removing a physical format
You can remove a physical format layer from your message set.

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250

The tasks in this topic area assume that you have added one or more physical formats to a message set. For further information see "Message Sets: Adding a Custom Wire Format (CWF)" on page 2254 or "Message Sets: Adding an XML wire format" on page 2256 or "Message Sets: Adding a TDS physical format" on page 2255.

About this task

To remove a physical format layer from your message set:

Procedure

1. Close any message definition files that are currently open in the Message Definition editor, otherwise you will not be able to remove the physical format.
2. Switch to the Integration Development perspective.
3. In the Message Set editor, the Properties Hierarchy shows the name of each of the physical formats that have been added to the message set. If the physical format names are not in view, expand **XML Wire Formats**, **Custom Wire Formats**, or **Tagged/Delimited Wire Formats**, by clicking **+**.
4. Right-click the physical format that you want to remove, then click **Delete** on the pop-up menu.

   Tip: If you decide to proceed with deleting the physical format, all of the message definition files under the current message set are modified and the amended message set file is saved.
5. Click **Finish** to remove the physical format, or click **Cancel** to return to the Integration Development perspective without making any changes. Pressing Esc also returns you to the Integration Development perspective without making any changes.

Message Sets: Observing 2007 U.S. changes to daylight saving time

Before you begin

You must have completed the following tasks:

- "Message Sets: Creating a message set" on page 2250
- "Message Sets: Opening an existing message set" on page 2250

This task assumes that you have added and configured one or more physical formats to existing message sets. For further information see: “Message Sets: Working with physical formats” on page 2254.
