     For example, if you use this command to create an identity called `myNodeMQCreds`, you can configure the MQ node to use the credentials associated with this identity by specifying the name `myNodeMQCreds` in the **Security identity** property of the MQ node or policy.
   - Configure a user name and password to be used for all MQ connections to a named queue manager (local or client connections), when no security identity name has been specified in the MQ node or policy:

     ```
     mqsisetdbparms -w workDir -n mq::QMGR::QMName  -u username -p password
     ```

     For example, if you know that all connections to a queue manager called `mySecureQM` will require a user name and password, you can specify that all connections to that queue manager will use the user name and password specified by the **mqsisetdbparms** command:

     ```
     mqsisetdbparms -w workDir -n mq::QMGR::mySecureQM  -u myUsername -p myPassword
     ```
   - Configure a user name and password for all MQ connections (local or client connections) where no security identity name has been set on the MQ node or policy, and where the queue manager that

is being connected to does not match any queue manager names that have been specified using `mq::QMGR::QMName`:

```
mqsisetdbparms -w workDir -n mq::MQ  -u username -p password
```

If no security identity has been specified, no credentials have been set for the queue manager (`mq::QMGR`), and no default credentials set for MQ (`mq::MQ`), no user name and password are passed to the queue manager, and the connection to the secured queue manager fails as a result.

Do not include the `mq::` prefix when setting the security identity on the MQ node or in the policy.

You can use the **mqsireportdbparms** to find out which security credentials have been set for the MQ connection. For example:

```
mqsireportdbparms -w workDir -n mq::*
```

2. If you are using SSL for any MQ connections, specify the location of the key repository by using the **mqsichangeproperties** command.

   This value is specified as the full file path of the SSL key repository minus the `.kdb` file extension. For example, if the SSL key repository is `C:\SSL\key.kdb`, set the location of the key repository by using the following command:

   ```
   mqsichangeproperties ACE11NODE -o BrokerRegistry -n mqKeyRepository -v C:\SSL\key
   ```

   a) Ensure that the SSL key repository password stash file *key repository file name*`.sth` is located in same folder as the key repository.

   This stash file is created using IBM MQ GSKit.

   b) Use the MQSC `REFRESH SECURITY` command to enable the changes to the SSL key repository to take effect.

Follow these steps to complete the required connection configuration in the MQ node or policy:

3. Configure either a local or client connection to the queue manager, as described in one of the following topics:

   - "Configuring a local connection to IBM MQ" on page 744
   - "Configuring a client connection to IBM MQ" on page 745

4. Use the `Security identity` property to provide the user name and password on a specific connection to the secured queue manager, through the security identity that you created by using the **mqsisetdbparms** command.

   The value that you set in this property is the name of the security identity that you defined by using the **mqsisetdbparms** command in step 1.

   If you do not specify the `Security identity` property, the security credentials that have been set for all MQ connections (`mq::MQ`) or for all connections to a specified queue manager (`mq::QMGR::QMName`), will be used, if appropriate.

   You can use the `Security identity` property to provide the security credentials on local and client connections. This property is not available for client connections that use a client channel definition table (CCDT); for these connections, specify the required information in the CCDT.

5. If you are configuring a client connection to a remote queue manager, you can choose whether to use the SSL protocol when a client connection is made to a remote queue manager.
   a) Select the `Use SSL` property on the MQ node to provide confidentiality on the client connection, by using SSL.

      This property is available for client connections that are configured using either the `MQ client connection properties` or a client channel definition table (CCDT).
   b) Specify the `SSL peer name` property, which specifies the name that is passed to the remote queue manager when making the client connection. There must be a positive match for the connection to succeed.

      This property is available only if the client connection details are specified through the `MQ client connection properties`; if the client connection uses a client channel definition table (CCDT), you can specify this information in the CCDT.
   c) Specify the `SSL cipher specification` property, which specifies the name of the symmetric key cryptography algorithm through which the remote queue manager is secured.

      This property is available only if the client connection details are specified through the `MQ client connection properties`; if the client connection uses a client channel definition table (CCDT), you can specify this information in the CCDT.

What to do next

The MQInput node attempts to connect to the queue manager when the flow is deployed and started. The MQOutput, MQGet, and MQReply nodes attempt to connect when the first message is sent or received. If any connection problems occur, see the IBM MQ product documentation for information about any `mqrc` return code values that are reported in the IBM App Connect Enterprise BIP messages.

If you later decide that you want to control connection properties by using an MQEndpoint policy, you can attach a policy to the message flow node. Property values that are set on the MQ Connection tab are ignored when a policy is attached to the message flow node.

Using a remote default queue manager
You can configure an independent integration server to connect to a default queue manager on a remote machine that is running IBM MQ.

Several IBM App Connect Enterprise capabilities use IBM MQ, such as the MQ nodes (MQInput, MQOutput, and MQGet), statistics and monitoring events, and internal state storage for such things as event-driven processing nodes (aggregation, sequencing, collection, and timer nodes). In App Connect Enterprise, interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting.

By using a remote default queue manager, you can configure independent integration servers to direct all MQ traffic to a remote MQ server, without configuring policy settings on each message flow node. You can also configure independent integration servers to share queue managers, which simplifies IBM MQ administration. The MQ topology does not need to be adjusted to allow a local queue manager for App Connect Enterprise integration servers, and App Connect Enterprise integration servers can be provisioned independently of the MQ queue managers.

As the default queue manager can be used to store state for the integration server itself, App Connect Enterprise shuts down if the queue manager becomes unavailable; this applies to remote default queue managers and local default queue managers. In a container-based environment with remote queue managers provisioned separately, the container management infrastructure is responsible for restarting the App Connect Enterprise integration server if the queue manager becomes unavailable, and for providing the new instance of the integration server with a working queue manager connection. The integration server will not start if the remote default queue manager is unavailable.

The remote default queue manager is used only if no local default queue manager has been configured for the integration server. If a message flow interacts directly with MQ, the remote default queue manager is used only if there is no explicit MQ configuration and no policy associated with the message flow nodes.

Properties that are set on the message flow node take precedence over properties set in a remote default queue manager policy.

For statistics and monitoring functions of the integration server, explicit configuration takes precedence over the default queue manager settings. For internal state storage, the remote default queue manager is used if there is no local default queue manager, and you can use the replacement queue prefix setting to maintain separate state stores for different servers using the same queue manager. The internal queues are typically created in advance for the local default queue manager (using sample scripts provided with the product), but they are created automatically if permissions allow this for both local and remote default queue managers. You can also create queues in advance with a different prefix by modifying the sample scripts and running them on a shared queue manager. From an MQ queue manager perspective, the App Connect Enterprise integration server appears as a standard client application, and all the standard client configuration options are supported. As with other MQ client applications, the queue manager does not provide XA transactional coordination. However, security and performance tuning parameters are supported, as described in the IBM MQ product documentation online.

Only independent integration servers can be configured to use a remote default queue manager; for interactions between integration nodes (or integration servers that are managed by an integration node) and IBM MQ, you must install IBM MQ on the same machine as the integration node, and use a local default queue manager to access the MQ queues.

For information about how to configure a connection to a remote default queue manager, see "Configuring an integration server to use a remote default queue manager" on page 751.

For more information about using IBM App Connect Enterprise with IBM MQ, see the following topics:

- "Processing IBM MQ messages" on page 738
- "IBM MQ topologies" on page 739
- "Configuring connections to IBM MQ" on page 743
- "Configuring a client connection to IBM MQ" on page 745
- "Connecting to a secured IBM MQ queue manager" on page 747

Configuring an integration server to use a remote default queue manager
You can configure an independent integration server to connect to a default queue manager on a remote machine that is running IBM MQ.

Before you begin

Read the following topics:

- "Processing IBM MQ messages" on page 738
- "IBM MQ topologies" on page 739
- "Configuring connections to IBM MQ" on page 743

About this task

In IBM App Connect Enterprise, interactions between an independent integration server and IBM MQ can use a client connection to a remote queue manager, by using a default policy setting.

You can configure an independent integration server to use a remote default queue manager by setting the **`remoteDefaultQueueManager`** property in the `server.conf.yaml` file. This property enables an MQEndpoint policy to be used to specify an MQ client connection, which is then used by default when a connection to IBM MQ is made. You can use the **`replacementQueuePrefix`** property in the `server.conf.yaml` file to configure the integration server to use the specified prefix instead of the usual `SYSTEM.BROKER.` queue prefix for MQ queues.

For more information about using a remote default queue manager, see "Using a remote default queue manager" on page 750. For more information about IBM MQ, see the IBM MQ product documentation online.

Procedure

Configure an independent integration server to use a remote default queue manager, by completing the following steps:

1. Create an MQEndpoint policy, as described in "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327. Set the **Connection** property to `Client`, and specify values for the **Queue manager name**, **Queue manager host name**, **Listener port number**, and **Channel name** properties.

   For more information about the properties that you can set in an MQEndpoint policy, see policy.
2. Deploy the policy project to the work directory for the integration server, either by using the command to deploy the BAR file that contains the policy project, or by copying the `.policyxml` file into the run sub-directory of the integration server work directory, in a sub-directory that has the name of the policy project.
3. Set up any security credentials that are required for the remote queue manager connection, as described in "Connecting to a secured IBM MQ queue manager" on page 747.
4. Configure the integration server to use the remote default queue manager, by modifying the integration server's `server.conf.yaml` file:
   a) Open the `server.conf.yaml` configuration file for your integration server, by using a YAML editor.

      If you do not have access to a YAML editor, you can edit the file by using a plain text editor; however, you must ensure that you do not include any tab characters, which are not valid in YAML and would cause your configuration to fail. If you are using a plain text editor, ensure that you use a YAML validation tool to validate the content of your file.

      The `server.conf.yaml` file for an independent integration server is located in the root of the integration server's work directory (`<work directory>/server.conf.yaml`).
   b) Specify the remote default queue manager to be used for the integration server, by setting the **remoteDefaultQueueManager** property to the policy name and project of the MQEndpoint policy that you created in step 1, in the format `{policyProjectName}:policyName`; for example:

      ```
      remoteDefaultQueueManager: '{myPolicyProject}:policy1'
      ```
   c) Optional: If the queue manager is shared by multiple integration servers, you can use the **replacementQueuePrefix** property to specify a unique queue prefix for each integration server, to prevent them from sharing the same queues. Specify this property in the format `replacementQueuePrefix: 'MYPREFIX1'`. This prefix then replaces the `SYSTEM.BROKER.` section of each queue name.

      If the required App Connect Enterprise queues have not already been created on the remote queue manager, and if security restrictions prevent the integration server from creating those queues, you can create them by running the **iib_createqueues** command, as described in "Creating the default system queues on an IBM MQ queue manager" on page 99. If you are using non-default queue names (by specifying a replacement queue prefix), you must modify the queue names in the sample MQSC script `iib_queues_create.mqsc`, which is used by the **iib_createqueues** command to define the queues.
   d) Save the modified `server.conf.yaml` file.

   For more information about configuring an integration server by setting properties in the `server.conf.yaml` file, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.
5. Restart the integration server for the changes to take effect.

Working with IBM MQ

You can use the IBM App Connect Enterprise MQ nodes to handle messages that are received from or sent to IBM MQ applications, enabling you to perform various tasks.

About this task

IBM MQ is available as a separate installation package, and your IBM App Connect Enterprise license entitles you to install and use IBM MQ with IBM App Connect Enterprise. For more information, see "Installing IBM MQ" on page 96.

The following topics provide step-by-step information about how to complete a set of common tasks that involve IBM MQ messages:

- "Receive an MQ datagram message, transform the message, and pass it to an MQ queue" on page 753
- "Receive an MQ request message, pass the message to MQ, and then pass the response from MQ to the requesting client" on page 755

Receive an MQ datagram message, transform the message, and pass it to an MQ queue

Transform IBM MQ messages in IBM App Connect Enterprise in a one-way message pattern.

Before you begin

For this scenario, server bindings are used on the MQ nodes to connect to IBM MQ. IBM MQ therefore must be installed on the same computer as the integration node. Alternatively, you can configure the MQ nodes for remote connections, but these steps are not described within the scenario. For more information, see "Configuring connections to IBM MQ" on page 743.

About this task

This scenario is used to create a one-way messaging pattern.

Scenario:

In an existing IBM MQ messaging topology, you can use IBM App Connect Enterprise to transform an IBM MQ message, and pass it back to a different queue. No reply confirmation is sent; the message is processed and immediately passed to the specified queue. If a reply is required, follow the steps in "Receive an MQ request message, pass the message to MQ, and then pass the response from MQ to the requesting client" on page 755.

For this scenario, there is no message content checking or error handling configured for the message flow nodes, because suitable actions depend on the overall messaging system architecture.

Instructions:

The following steps show how to create a message flow so that a message from IBM MQ can be transformed, and then put to another queue.

Procedure

1. Create a message flow that is named MQ_Task1_One_Way with the following nodes:
   - An MQInput node.
   - A Compute node.
   - An MQOutput node.

   For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the Compute node.

3. Connect the Out terminal of the Compute node to the In terminal of the MQOutput node.

You must now configure the message flow nodes.

4. Set the following properties of the MQInput node:
   a) On the **Basic** tab, set the `Queue name` property to `MQ.TASK1.IN1`.
   b) On the **MQ Connection** tab, set the `Connection` property to `Local queue manager`, and then the `Destination queue manager` property to `TASK1_QUEUE_MANAGER`.
   c) On the **Input Message Parsing** tab:
      - Set the `Message domain` property to `XMLNSC`.
5. Set the following properties of the Compute node:
   a) An ESQL module, `MQ_Task1_One_Way_Compute`, is automatically created. In the Application Development view, open **ESQLs**, and then the `MQ_Task1_One_Way_Compute` module.
   b) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task1_One_Way_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputRoot = InputRoot;
  SET OutputRoot.XMLNSC.Order.TimeStamp = CURRENT_GMTTIMESTAMP;
  RETURN TRUE;
 END;
END MODULE;
```

   The Compute node represents the solution transformation in this scenario.

   The Compute node adds a time stamp value to the message, which shows the time that it was processed.
6. Set the following properties of the MQOutput node:
   a) On the **Basic** tab, set the `Queue name` property to `MQ.TASK1.OUT1`.
   b) On the **MQ Connection** tab, set the `Connection` property to `Local queue manager`, and then the `Destination queue manager` property to `TASK1_QUEUE_MANAGER`.
7. Save the message flow.

You can now test the message flow. Create an IBM MQ message, send the message to the input queue, and observe the changes to the message on the output queue.

8. Create an IBM MQ message with a Payload that contains XML for the input queue in the following format:

```
<SaleEnvelope>
 <OrderNum>123</OrderNum>
 <CustomerNum>456</CustomerNum>
 <ProductCode>789</ProductCode>
 <Qty>20</Qty>
</SaleEnvelope>
```

9. Run the message flow.

Results

When the message flow is run, the following actions occur:

1. The MQInput reads an IBM MQ message in from an application.
2. The Compute node transforms the message.

3. The MQOutput node puts the transformed message onto the specified output queue.

Receive an MQ request message, pass the message to MQ, and then pass the response from MQ to the requesting client
Receive an IBM MQ request message, pass the message to IBM MQ, and then send the IBM MQ response to the requesting client.

Before you begin

For this scenario, server bindings are used on the MQ nodes to connect to IBM MQ. IBM MQ therefore must be installed on the same computer as the integration node. Alternatively, you can configure the MQ nodes for remote connections, but these steps are not described within the scenario. For more information, see "Configuring connections to IBM MQ" on page 743.

About this task

A request-response message flow is a specialized form of a point-to-point application. For a general description of these applications, see "Nodes for connectivity" on page 487.

This scenario is used for connecting client applications.

Scenario:

Two applications with different message formats communicate with each other by using IBM MQ in a request-reply message processing solution. For the applications to communicate successfully, the message formats must be transformed in IBM App Connect Enterprise on both the request and reply messages. The backend application is represented in this scenario by a third message flow, to demonstrate the successful processing of a message.

Two message flows are required for request-reply, because IBM MQ processes messages asynchronously. Messages that are processed asynchronously in IBM App Connect Enterprise do not wait for a response, and IBM MQ does not send a reply message. To process a reply, a store queue takes the original message's `ReplyToQ` property so that a second message flow can process a reply from an application.

This scenario demonstrates how to create Request and Reply message flows, and how to store message state information by using a store queue. The message flow that represents the backend application modifies a "Completion Time" value in the message.

Instructions:

The following steps show how to create the message flows and a store state queue so that a reply message from IBM MQ can be processed.

Procedure

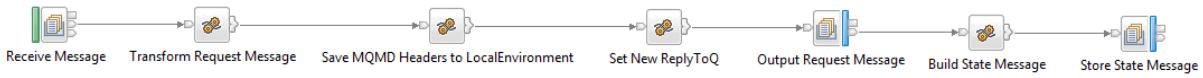
1. Create a message flow that is named MQ_Task2_Request with the following nodes, and name them on the **Description** tab `Node name` property:
   - An MQInput node, named `Receive Message`.
   - Four Compute nodes, named `Transform Request Message`, `Save MQMD Headers to LocalEnvironment`, `Set New ReplyToQ`, and `Build State Message`.
   - Two MQOutput nodes, named `Output Request Message` and `Store State Message`.

   For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the `Receive Message` MQInput node to the In terminal of the `Transform Request Message` Compute node.
3. Connect the Out terminal of the `Transform Request Message` Compute node to the In terminal of the `Save MQMD Headers to LocalEnvironment` Compute node.

   Note: You can add your own transformation node, or a subflow, for the message processing that you require between the `Receive Message` MQInput node and `Save MQMD Headers to`

LocalEnvironment Compute node. The Transform Request Message Compute node is a placeholder in this scenario that does not transform the message.

4. Connect the Out terminal of the Save MQMD Headers to LocalEnvironment Compute node to the In terminal of the Set New ReplyToQ Compute node.
5. Connect the Out terminal of the Set New ReplyToQ Compute node to the In terminal of the Output Request Message MQOutput node.
6. Connect the Out terminal of the Output Request Message MQOutput node to the In terminal of the Build State Message Compute node.
7. Connect the Out terminal of the Build State Message Compute node to the In terminal of the Store State Message MQOutput node.



You must now configure the message flow nodes for the Request behavior of the message flow.

8. Set the following properties of the Receive Message MQInput node:
   a) On the **Basic** tab, set the Queue name property to MQ.TASK2.IN1.
   b) On the **MQ Connection** tab, set the Connection property to Local queue manager, and then the Destination queue manager property to TASK2_QUEUE_MANAGER.
   c) On the **Input Message Parsing** tab, set the Message domain property to XMLNSC.
9. Set the following properties of the Transform Request Message Compute node:
   a) An ESQL module, MQ_Task2_Request_Transform_Reply_Message, is automatically created. In the Application Development view, open **ESQLs**, and then the MQ_Task2_Request_Transform_Reply_Message module.
   b) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task2_Request_Transform_Reply_Message
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputRoot = InputRoot;
  RETURN TRUE;
 END;
END MODULE;
```

   The Transform Request Message Compute does not transform the message, and acts as a placeholder for this scenario.
10. Set the following properties of the Save MQMD Headers to LocalEnvironment Compute node:
    a) On the **Basic** tab, set the Compute mode property to LocalEnvironment.
    b) An ESQL module, MQ_Task2_Request_Save_MQMD_Headers_to_LocalEnvironment, is automatically created. In the Application Development view, open **ESQLs**, and then the MQ_Task2_Request_Save_MQMD_Headers_to_LocalEnvironment module.
    c) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task2_Request_Save_MQMD_Headers_to_LocalEnvironment
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputLocalEnvironment.Variables.OriginalMQMD = InputRoot.MQMD;
  RETURN TRUE;
 END;
END MODULE;
```

    The Save MQMD Headers to LocalEnvironment Compute node saves the MQMD of the original message to a local environment variable, which is then retrieved later in the message flow by the Build State Message Compute node.

11. Set the following properties of the Set New ReplyToQ Compute node:
    a) An ESQL module, MQ_Task2_Request_Set_New_ReplyToQ, is automatically created. In the Application Development view, open **ESQLs**, and then the MQ_Task2_Request_Set_New_ReplyToQ module.
    b) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task2_Request_Set_New_ReplyToQ
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputRoot = InputRoot;
  SET OutputRoot.MQMD.ReplyToQ = 'MQ.TASK2.BACKEND.RESP1';
  SET OutputRoot.MQMD.ReplyToQMgr = 'TASK2_QUEUE_MANAGER';
  RETURN TRUE;
 END;
END MODULE;
```

    The Set New ReplyToQ Compute node sets a new value for ReplytoQ so that the Reply message flow queue is used.
12. Set the following properties of the Output Request Message MQOutput node:
    a) On the **Basic** tab, set the Queue name property to MQ.TASK2.BACKEND.REQ1.
    b) On the **Advanced** tab, select the New message ID property.
13. Set the following properties of the Build State Message Compute node:
    a) An ESQL module, MQ_Task2_Request_Build_State_Message, is automatically created. In the Application Development view, open **ESQLs**, and then the MQ_Task2_Request_Build_State_Message module.
    b) Copy the following ESQL into the module:

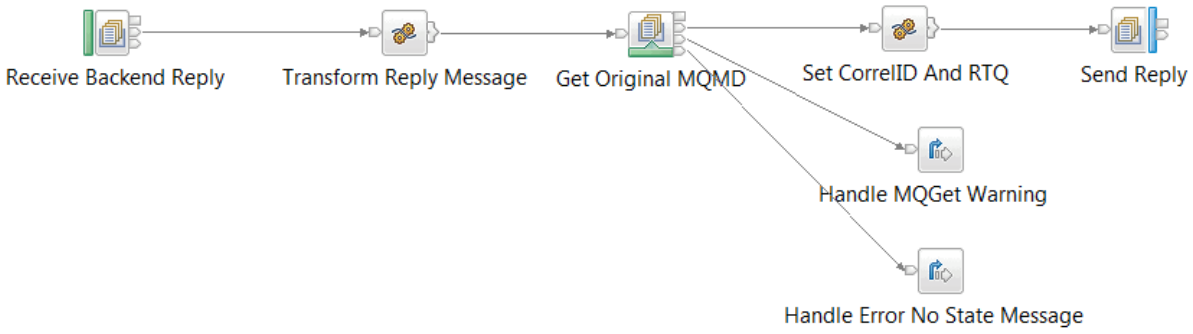
```
CREATE COMPUTE MODULE MQ_Task2_Request_Build_State_Message
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  CALL CopyMessageHeaders();
  SET OutputRoot.MQMD.CorrelId =
 InputLocalEnvironment.WrittenDestination.MQ.DestinationData.msgId;
  SET OutputRoot.MQMD.ReplyToQ = InputLocalEnvironment.Variables.OriginalMQMD.ReplyToQ;
  SET OutputRoot.MQMD.ReplyToQMgr =
 InputLocalEnvironment.Variables.OriginalMQMD.ReplyToQMgr;
  SET OutputRoot.BLOB.BLOB = InputLocalEnvironment.Variables.OriginalMQMD.MsgId;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;
END MODULE;
```

    The Build State Message Compute node:
    i) Extracts the Message ID of the message that is written to MQ.TASK2.BACKEND.REQ1.
    ii) Extracts the original ReplyToQ and ReplyToQMgr values from the LocalEnvironment, and these values are saved in the state message MQMD.
    iii) Extracts the original MessageId value from the LocalEnvironment, and saves this value to the body of the state message.
    iv) Uses the BLOB parser to read and write the body of the state message, because the MessageId is binary data.
14. Set the following properties of the Store State Queue MQOutput node:
    a) On the **Basic** tab, set the Queue name property to MQ.TASK2.STATE1.
    b) On the **Advanced** tab, select the New message ID property.

You must now create the Reply message flow.

15. Create a message flow that is named MQ_Task2_Reply with the following nodes, and name them on the **Description** tab `Node name` property:
    - An MQInput node, named `Receive Backend Application Reply`.
    - An MQGet node, named `Get Original MQMD`.
    - An MQOutput node, named `Send Reply`.
    - Two Compute nodes, named `Transform Reply Message` and `Set CorrelID And RTQ`.
    - Two Throw nodes, named `Handle MQGet Warning` and `Handle Error No Store Message`.
16. Connect the Out terminal of the `Receive Backend Application Reply` MQInput node to the In terminal of the `Transform Reply Message` Compute node.
17. Connect the Out terminal of the `Transform Reply Message` Compute node to the In terminal of the `Get Original MQMD` MQGet node.
18. Connect the Warning terminal of the `Get Original MQMD` MQGet node to the `Handle MQGet Warning` Throw node.
19. Connect the Failure terminal of the `Get Original MQMD` MQGet node to the `Handle Error Not Stored Message` Throw node.
20. Connect the Out terminal of the `Get Original MQMD` MQGet node to the `Set CorrelID And RTQ` Compute node.
21. Connect the Out terminal of the `Set CorrelID And RTQ` Compute node to the `Send Reply` MQOutput node.



You must now configure the message flow nodes for the Reply behavior of the message flow.

22. Set the following properties of the `Receive Backend Application Reply` MQInput node:
    a) On the **Basic** tab, set the `Queue name` property to `MQ.TASK2.BACKEND.RESP1`.
    b) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
23. Set the following properties of the `Transform Reply Message` Compute node:
    a) An ESQL module, `MQ_Task2_Reply_Transform_Reply_Message`, is automatically created. In the Application Development view, open **ESQLs**, and then the `MQ_Task2_Reply_Transform_Reply_Message` module.
    b) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task2_Reply_Transform_Reply_Message
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputRoot = InputRoot;
  RETURN TRUE;
 END;
END MODULE;
```

    The Compute does not transform the message. The Compute node is a placeholder for the solution transformation in this scenario.

24. Set the following properties of the Get Original MQMD MQGet node:
    a) On the **Basic** tab, set the Queue name property to MQ.TASK2.STATE1.
    b) On the **MQ Connection** tab, set the Connection property to Local queue manager, and then the Destination queue manager property to TASK2_QUEUE_MANAGER.
    c) On the **Input Message Parsing** tab, set the Message domain property to BLOB.
    d) On the **Advanced** tab:
        - Set the Copy message property to **Copy Entire Message**.
        - Set the Copy local environment property to **Copy Entire LocalEnvironment**.
    e) On the **Request** tab:
        - Set the Input MQMD location property to InputRoot.MQMD.
        - Select the Get by correlation ID property.
    f) On the **Result** tab:
        - Set the Output data location property to OutputLocalEnvironment.ResultRoot,
        - Set the Result data location to ResultRoot.
25. Set the following properties of the Set CorrelId And RTQ Compute node:
    a) On the **Basic** tab, set the Compute mode property to MQ.TASK2.STATE1.
    b) An ESQL module, MQ_Task2_Reply_Set_CorrelId_And_RTQ, is automatically created. In the Application Development view, open **ESQLs**, and then the MQ_Task2_Reply_Set_CorrelId_And_RTQ module.
    c) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task2_Reply_Set_CorrelId_And_RTQ
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputRoot = InputRoot;
  SET OutputRoot.MQMD.CorrelId = InputLocalEnvironment.Variables.ResultRoot.BLOB.BLOB;
  SET OutputLocalEnvironment.Destination.MQ.DestinationData[1].queueName =
 InputLocalEnvironment.Variables.ResultRoot.MQMD.ReplyToQ;
  SET OutputLocalEnvironment.Destination.MQ.DestinationData[1].queueManagername =
 InputLocalEnvironment.Variables.REResultRoot.MQMD.ReplyToQMgr;
  RETURN TRUE;
 END;
END MODULE;
```

    The Set CorrelId And RTQ Compute node:
        i) Extracts the ReplyToQ and ReplyToQMgr from the MQMD of the state message.
        ii) Sets a CorrelId that is the value of the MessageId in the body of the original state message. The CorrelId is used for the Reply message flow.
26. Set the following properties of the Send Reply MQOutput node:
    a) On the **Advanced** tab, set the Destination mode property to Destination list

    By setting the MQOutput node in Destination List mode, the output queue can be set dynamically.
27. Set the following properties of the Handle MQGet Warning Throw node:
    a) On the **Basic** tab, enter error message text into the Message text field. For example, "MQGet returned a warning."

    If a warning occurs in the message from the MQGet node, the Handle_MQGet_Warning Throw node returns an error message about this warning. The message tree contains the MQMD and any message content that was received.

28. Set the following properties of the Handle Error Not Stored Message Throw node:
    a) On the **Basic** tab, enter error message text into the Message text field.
    For example, "MQGet error, no store message queue received."

    If an error occurs because the MQGet node failed to get the message from the store queue, the Handle_Error_Not_Stored_Message Compute node returns an error message. The message is not processed.

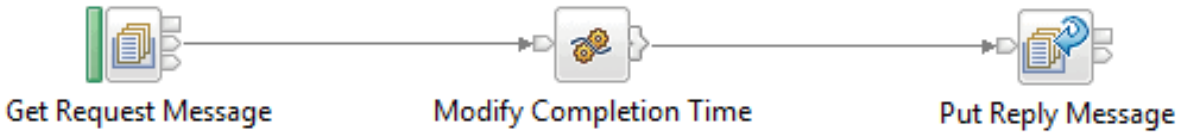
    You cannot return the message from the Reply message flow back to the Request message flow. Therefore, you must consider error handling at a higher level in your messaging architecture than the error handling options that are provided by message flow nodes.

The message flow can now communicate with a backend application. For this scenario, create a third message flow to represent this application.

A backend application, by default, copies the MessageId of the message to its CorrelId, and this value is then sent in the reply message. However, as a real application is not used in this scenario, this action was taken by the Save MQMD Headers to LocalEnvironment Compute node in step "10" on page 756 for the Request message flow.

To demonstrate that the backend application is successfully processed in the Reply message flow, a Compute node modifies the Completion Time value that is in the message.

29. Create a message flow that is named MQ_Task2_BackendApp with the following nodes, and name them on the **Description** tab Node name property:
    - An MQInput node, named Get Request Message.
    - A Compute node, named Modify Completion Time.
    - An MQReply node, named Put Reply Message.
30. Connect the Out terminal of the Get Request Message MQInput node to the In terminal of the Modify Completion Time Compute node.
31. Connect the Out terminal of the Modify Completion Time Compute node to the In terminal of the Put Reply Message MQReply node.



32. Set the following properties of the Get Request Message MQInput node:
    a) On the **Basic** tab, set the Queue name property to MQ.TASK2.BACKEND.REQ1.
    b) On the **MQ Connection** tab, set the Connection property to Local queue manager, and then the Destination queue manager property to TASK2_QUEUE_MANAGER.
    c) On the **Input Message Parsing** tab, set the Message domain property to XMLNSC.
33. Set the following properties of the Modify Completion Time Compute node:
    a) An ESQL module, MQ_Task2_BackendApp_Modify_Completion_Time, is automatically created. In the Application Development view, open **ESQLs**, and then the MQ_Task2_BackendApp_Modify_Completion_Time module.
    b) Copy the following ESQL into the module:

```
CREATE COMPUTE MODULE MQ_Task2_BackendApp_Modify_Completion_Time
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  SET OutputRoot = InputRoot;
  SET OutputRoot.XMLNSC.SaleEnvelope.TimeStamp = CURRENT_GMTTIMESTAMP;
  RETURN TRUE;
 END;
```

```
END MODULE;
```

The `Modify Completion Time` Compute node represents the solution transformation in this scenario. The Compute node adds a time stamp value to the message, which shows the time that it was processed.

34. Set the following properties of the `Get Request Message` MQReply node:
    a) On the **Basic** tab, set the `Queue name` property to `MQ.TASK2.BACKEND.REQ1`.
    b) On the **MQ Connection** tab, set the `Connection` property to `Local queue manager`, and then the `Destination queue manager` property to `TASK2_QUEUE_MANAGER`.
35. Save the message flow.

Results

- When the Request message flow is run, the following actions occur:
  1. The MQInput node reads an IBM MQ request message.
  2. The original message is transformed into an equivalent format for the backend application.
  3. The `ReplyToQ` and `ReplyToQMgr` details are set for the input message to the Reply message flow.
  4. An IBM MQ message is created that contains the transformed message. This message is sent to the backend message flow.
  5. The original `MessageId`, `ReplyToQ`, `ReplyToQMgr` details are saved in a separate IBM MQ message for subsequent retrieval by the Reply message flow.
- When the Reply message flow is run, the following actions occur:
  1. The MQInput reads the IBM MQ message that contains a message in the data format from the backend application.
  2. The message is transformed into the equivalent format for the requester application.
  3. The MQGet node obtains the `CorrelId`, `ReplyToQ`, and `ReplyToQMgr` details of the original request message, by reading theIBM MQ message that was used to store this information in the Request message flow.
  4. An IBM MQ message that contains the transformed message and the retrieved `CorrelId`, `ReplyToQ`, and `ReplyToQMgr` values is created.

How the MQGet node processes messages
The MQGet node processes each message that it receives.

This topic contains the following sections:

Propagating the message

1. If an MQ Message Descriptor header (MQMD) is present in the input tree, the MQGet node uses it. If not, the node creates a default MQMD.
2. The node also creates a default MQ Get Message Options (MQGMO) structure based on the values that you have set for the node properties. If an MQGMO is present in the input tree, the node uses its content to modify the default one.

   When you include an MQGMO to override the default one, you must specify all the options that you are replacing. For example, if you set the option field to MQGMO_CONVERT, that value overrides all options

that you set with the IBM App Connect Enterprise Toolkit. If you do not use an overriding MQGMO, IBM App Connect Enterprise uses the following values:

- If `Wait interval` is not zero, MQGMO_WAIT is set; otherwise, MQGMO_NOWAIT is used.
- If `Transaction mode` is set to `Yes`, MQGMO_SYNCPOINT is used.
- If `Transaction mode` is set to `No`, MQGMO_NOSYNCPOINT is used.
- If `Transaction mode` is set to `Automatic`, MQGMO_SYNCPOINT_IF_PERSISTENT is used.
- The only other option that is used by default in the node properties is MQGMO_COMPLETE_MSG, which is set if `Transaction mode` is set to `Yes` or `No`. This option is not set when your integration node is running on z/OS.
- No other options are used by default.

3. The node makes the `MQGet` call to IBM MQ.
4. The node analyzes the completion code (CC), and propagates the message to the appropriate terminal:

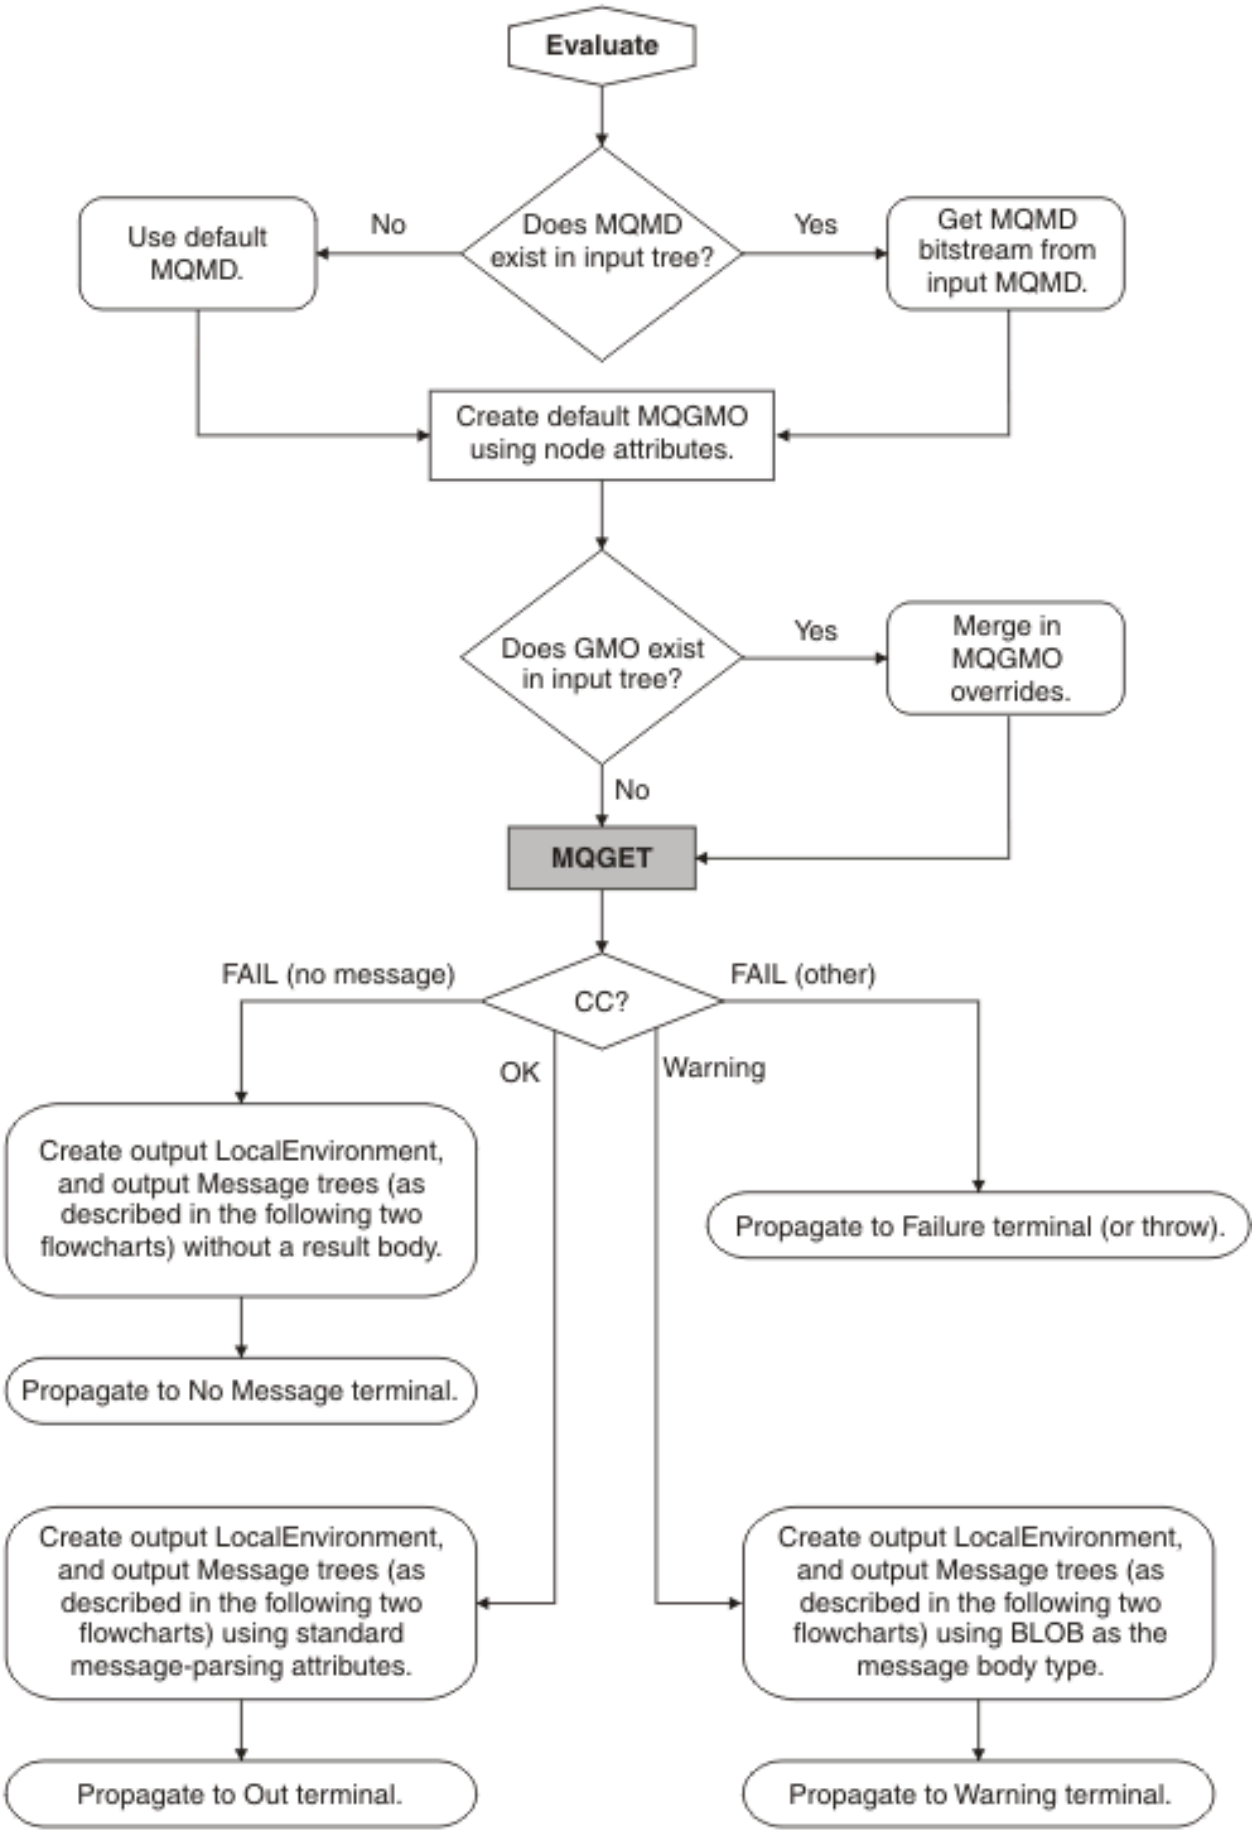
   OK
   The node creates the output LocalEnvironment and the output message trees using standard message-parsing techniques, then propagates the message to the Out terminal.

   Warning
   The node creates the output LocalEnvironment and the output message trees using BLOB as the message body type, then propagates the message to the Warning terminal, if it is connected. If the Warning terminal is not connected, no propagation occurs, and the flow ends.

   Fail (no message)
   The node creates the output LocalEnvironment and the output message trees by copying the input trees, then propagates the message to the No Message terminal, if it is connected. If the No Message terminal is not connected, no propagation occurs. The output message that is propagated to the No Message terminal is constructed from the input message only, according to the values of the `Generate Mode` property, and the `Copy Message` or `Copy Local Environment` properties.

   Fail (other)
   The node propagates the message to the Failure terminal. If the Failure terminal is not connected, the integration node throws an exception and returns control to the closest upstream node that can process it. For more information, see “Handling errors in message flows” on page 1883.

The following diagram shows this processing:



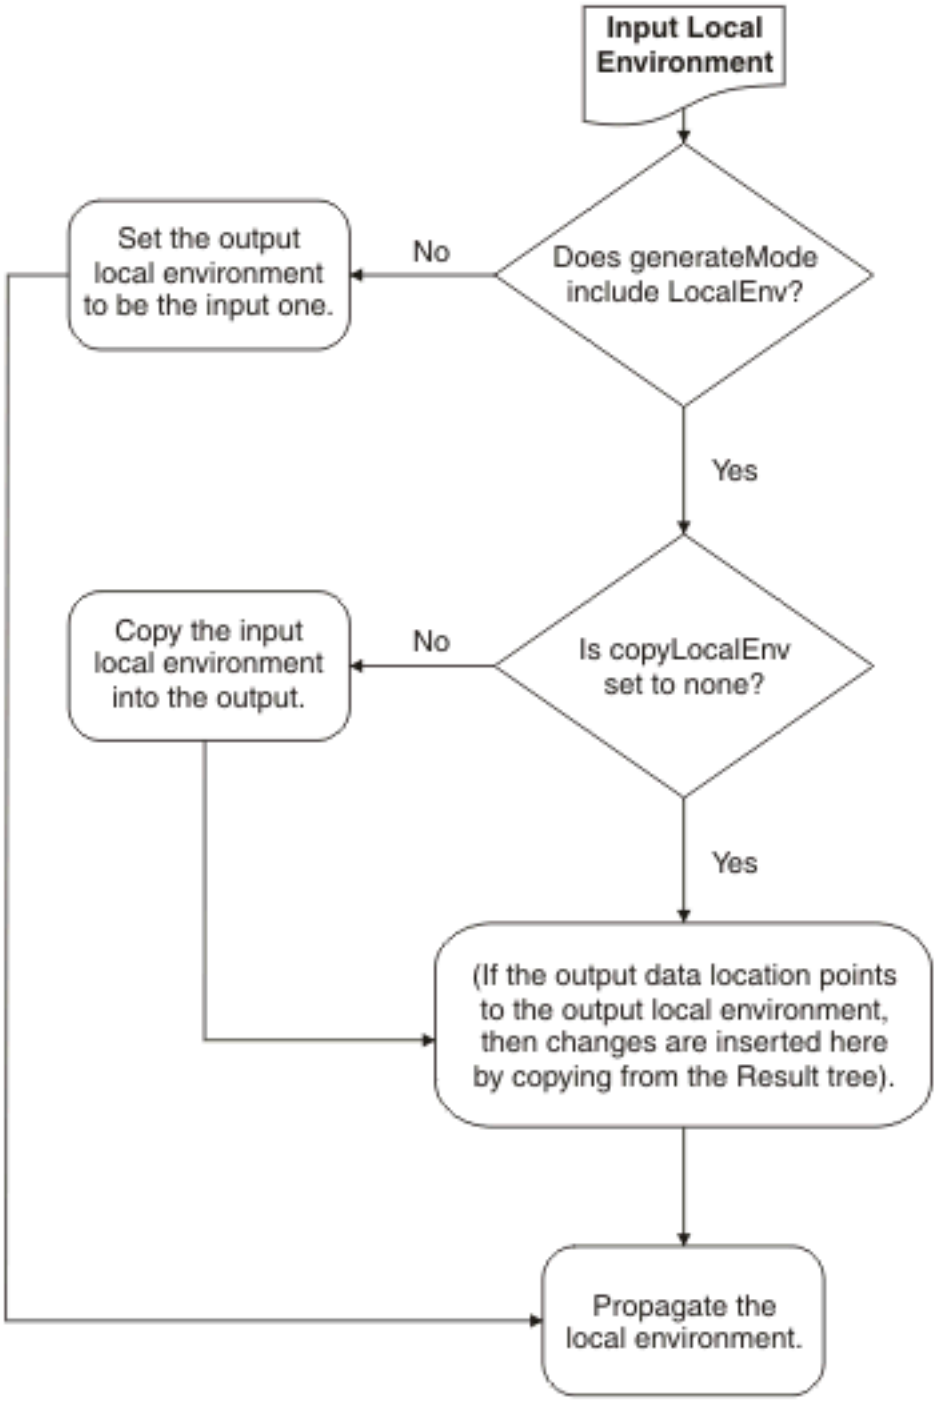
Evaluate
Does MQMD exist in input tree?
No
Use default MQMD.
Yes
Get MQMD bitstream from input MQMD.
Create default MQGMO using node attributes.
Does GMO exist in input tree?
Yes
Merge in MQGMO overrides.
No
MQGET
CC?
FAIL (no message)
FAIL (other)
OK
Warning
Create output LocalEnvironment, and output Message trees (as described in the following two flowcharts) without a result body.
Propagate to Failure terminal (or throw).
Propagate to No Message terminal.
Create output LocalEnvironment, and output Message trees (as described in the following two flowcharts) using standard message-parsing attributes.
Create output LocalEnvironment, and output Message trees (as described in the following two flowcharts) using BLOB as the message body type.
Propagate to Out terminal.
Propagate to Warning terminal.

Constructing OutputLocalEnvironment

1. If the `Generate Mode` property on the MQGet node is set to an option that does not include `LocalEnvironment`, the node copies the input local environment tree to the output local environment tree.

   If this copy is made, any updates that are made in this node to the output local environment tree are not propagated downstream.
2. If the `Copy Local Environment` property is set to an option other than `None`, the node copies the input local environment tree to the output local environment tree.
3. If the output data location points to the output local environment tree, the node applies changes in that tree by copying from the result tree.
4. The local environment tree is propagated.

The following diagram shows this processing:

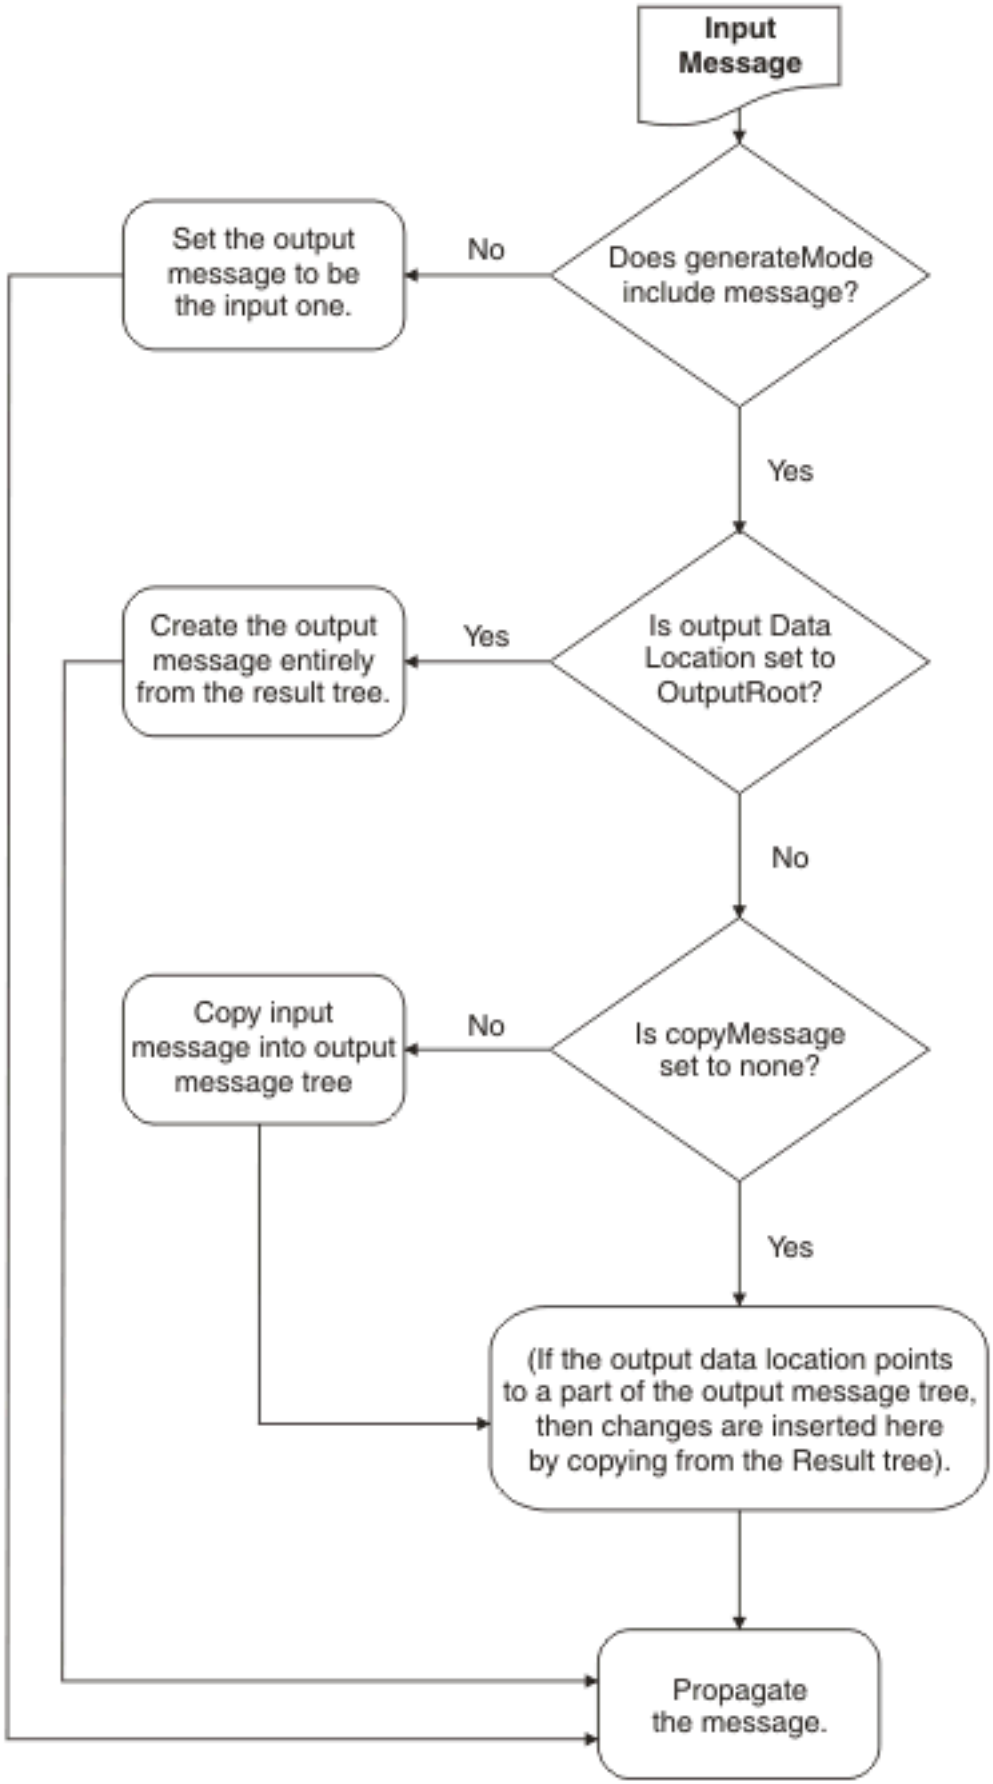


Constructing the Output message

1. If the `Generate Mode` property on the MQGet node is set to an option that does not include `Message`, the node copies the input message tree to the output message tree. Go to step 5.
2. If the `Output Data Location` property is set to `OutputRoot`, the node creates the output message tree entirely from the result tree. Go to step 5.
3. If the `Copy Message` property is set to a value other than `None`, the node copies the input message tree to the output message tree.

4. If the `Output Data Location` property points to a part of the output message tree, the node applies changes in that tree by copying from the result tree at the point that is defined by the `Result Data Location` property.
5. The message tree is propagated.

The following diagram shows this processing:



Input Message
Does generateMode include message?
No
Set the output message to be the input one.
Yes
Is output Data Location set to OutputRoot?
Yes
Create the output message entirely from the result tree.
No
Is copyMessage set to none?
No
Copy input message into output message tree
Yes
(If the output data location points to a part of the output message tree, then changes are inserted here by copying from the Result tree).
Propagate the message.

For an example of how this processing is implemented in a message flow, see "How the MQGet node implements IBM MQ MQGet API calls" on page 768.

How the MQGet node implements IBM MQ MQGet API calls

Review how the MQGet node processes the input messages to construct the output messages, based on both the content of the local environment tree and the input parameters that you set.

You can include an MQGet node anywhere in a message flow, including a flow that implements a request-response scenario. The MQGet node receives an input message on its input terminal from the preceding node in the message flow, issues an MQGET call to retrieve a message from the IBM MQ queue that you have configured in its properties, and builds a result message tree. Finally, it uses the input tree and the result tree to create an output tree that is then propagated to its Output, Warning, or Failure terminal, depending on the configuration of the node and the result of the MQGET operation.

How the MQGet node handles the local environment

The MQGet node examines the local environment tree that is propagated from the preceding node, uses the content that is related to the MQGMO (MQ Get Message Options) and the MQMD (MQ Message Descriptor header), and updates the local environment:

- The node reads the MQGMO structure from `${inputMQParmsLocation}.MQGMO.*`.
- The node copies the IBM MQ completion and reason codes to `${outputMQParmsLocation}.CC` and `${outputMQParmsLocation}.RC`.
- The node writes the complete MQGMO that is used for the MQGET call into `${outputMQParmsLocation}.MQGMO` if `${inputMQParmsLocation}.MQGMO` exists in the input tree.
- The node writes the MQMD that is passed to the MQGET call (that contains the values that are specified in the input message or are generated by the node) into `${inputMQParmsLocation}.MQMD`, deleting any existing content.

Set the value to `${inputMQParmsLocation}` in the MQGet node property Input MQ Parameters Location on the **Request Properties** tab.

Set the value to `${outputMQParmsLocation}` in the MQGet node property Output MQ Parameters Location on the **Result Properties** tab.

For more information about these properties, see node.

In summary:

${inputMQParmsLocation}

- *QueueName*: Optional override for MQGet node *Queue Name* property
- *InitialBufferSize*: Optional override for MQGet node *Initial Buffer Size* property
- *MQGMO.**: Optional MQGET message options that are used by the MQGet node

${outputMQParmsLocation}

- *CC*: MQGET call completion code
- *RC*: MQGET call result code
- *MQGMO.**: MQGET message options that are used if present in `${inputMQParmsLocation}`
- *MQMD*: unparsed MQ Message Descriptor for received messages[1]
- *Browsed*: Set to true if the message is browsed. Not present if the message is removed from the queue

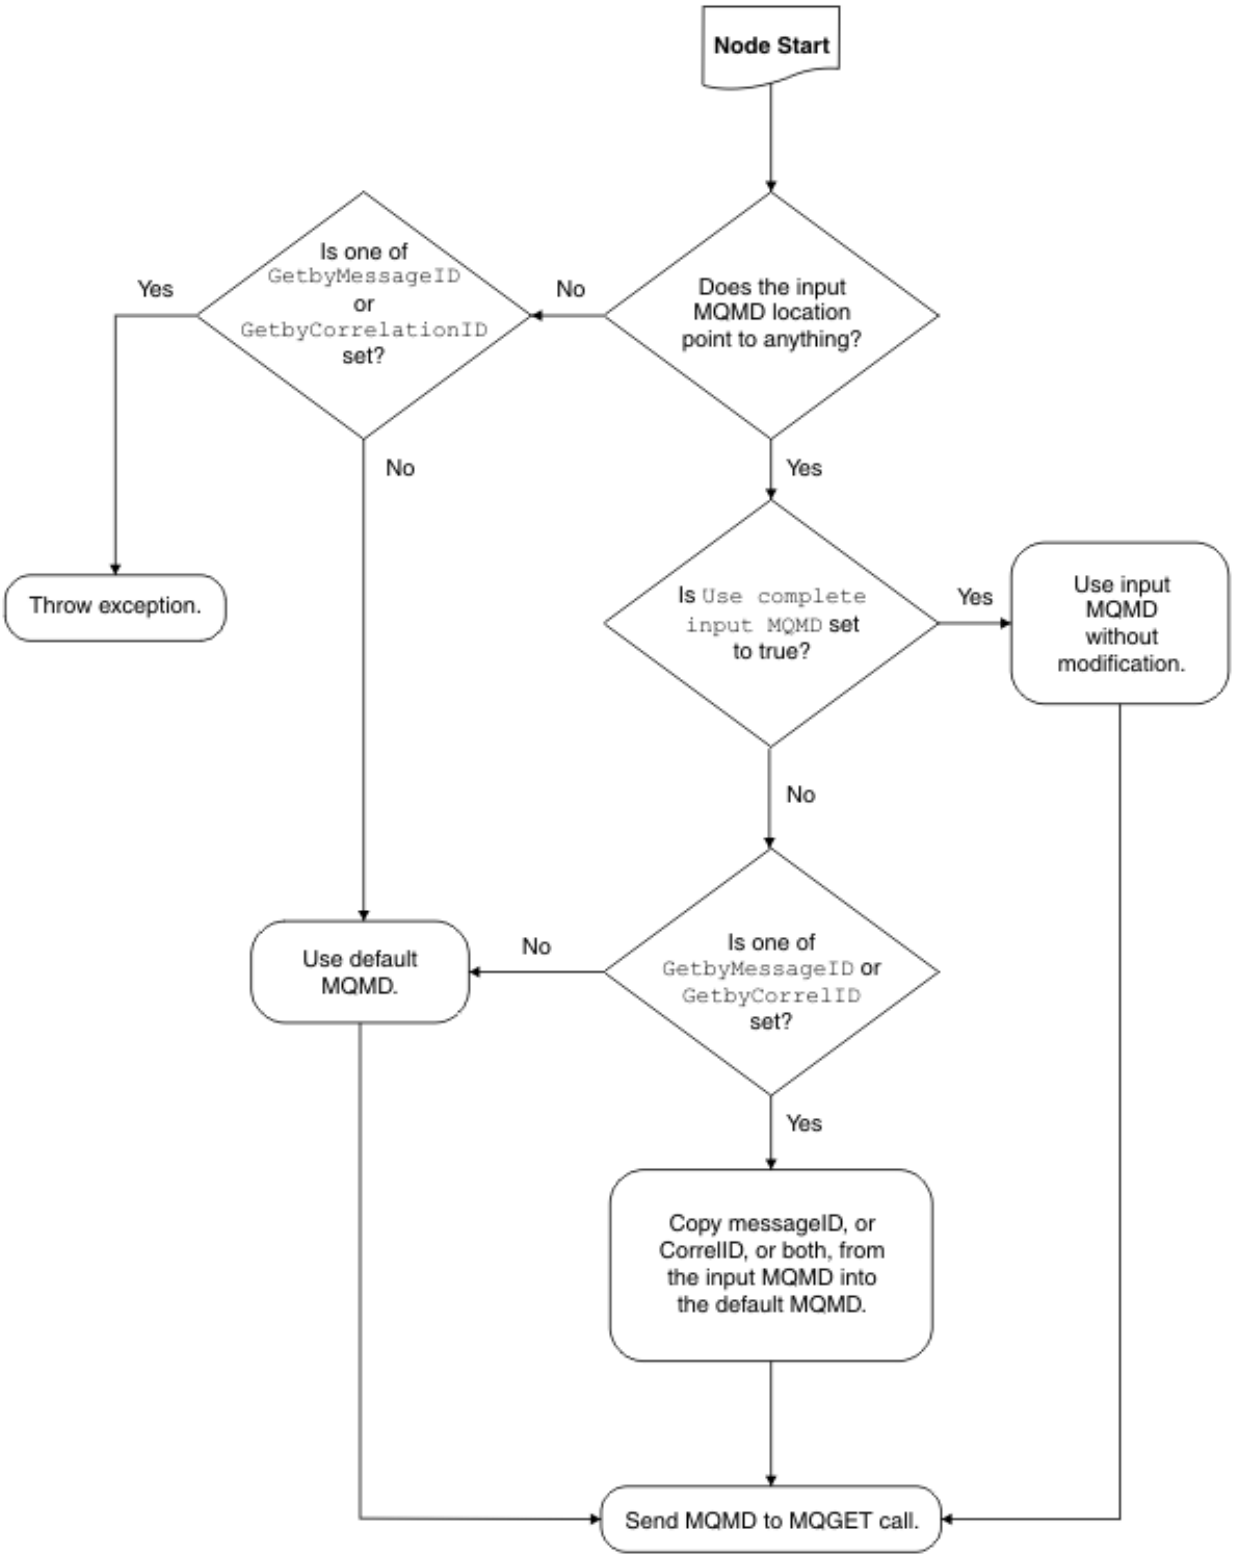
You can parse the MQMD (for example, by using ESQL), where `${outputMQParmsLocation}` is LocalEnvironment.MQ.GET:

```
DECLARE ptr REFERENCE TO OutputLocalEnvironment.MyMQParms;
CREATE FIRSTCHILD OF ptr DOMAIN('MQMD') PARSE(InputLocalEnvironment.MQ.GET.MQMD)
```

How the MQMD for the MQGET call is constructed

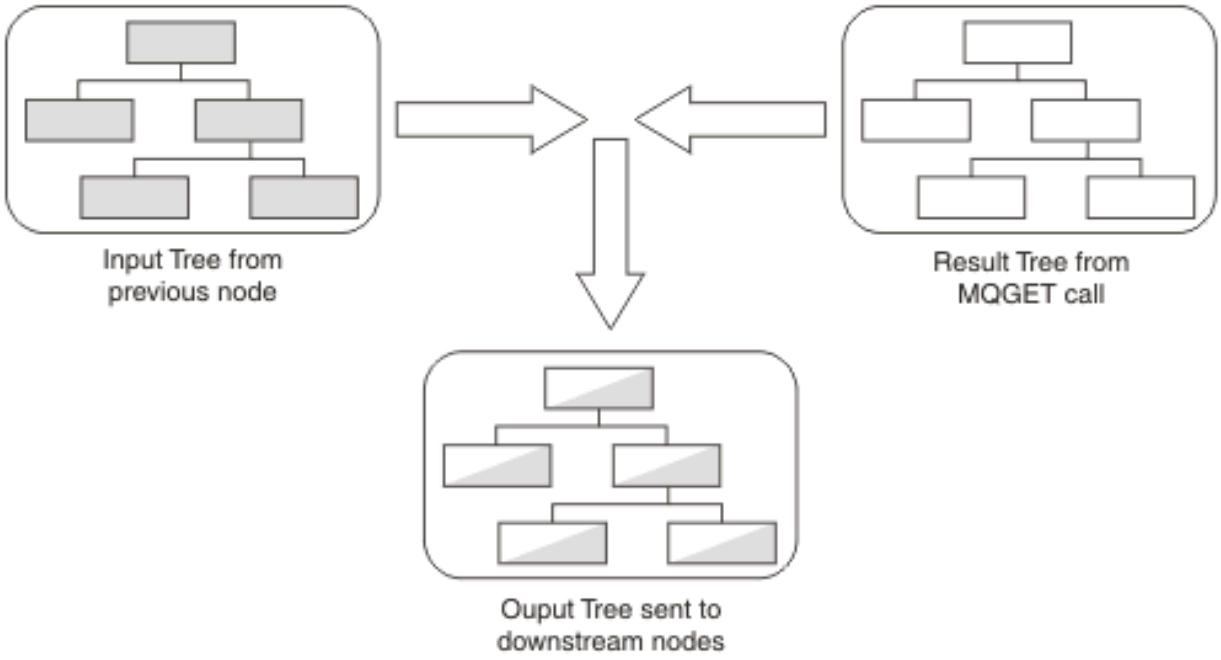
- A default MQMD is prepared. For further information about the MQMD, see the *Application Programming Reference* section of the IBM MQ product documentation online.
- If you do not supply an input MQMD, the default MQMD is used.
- If you do supply an input MQMD, the default MQMD is used after the following modifications:
  - If the property `Use all input MQMD fields` is set, all MQMD fields supplied are copied into the default MQMD from the input MQMD.
  - If the property `Use all input MQMD fields` is not set and the properties `Get by Message ID` or `Get by Correlation ID` are selected, the respective IDs are copied into the default MQMD from the input MQMD.

The following diagram shows how the MQGet node constructs the MQMD that is used on the call to IBM MQ:



How the output message tree is constructed

The following diagram outlines how the MQGet node constructs the output message tree, combining the input tree from the previous node with the result tree from the MQGET call:



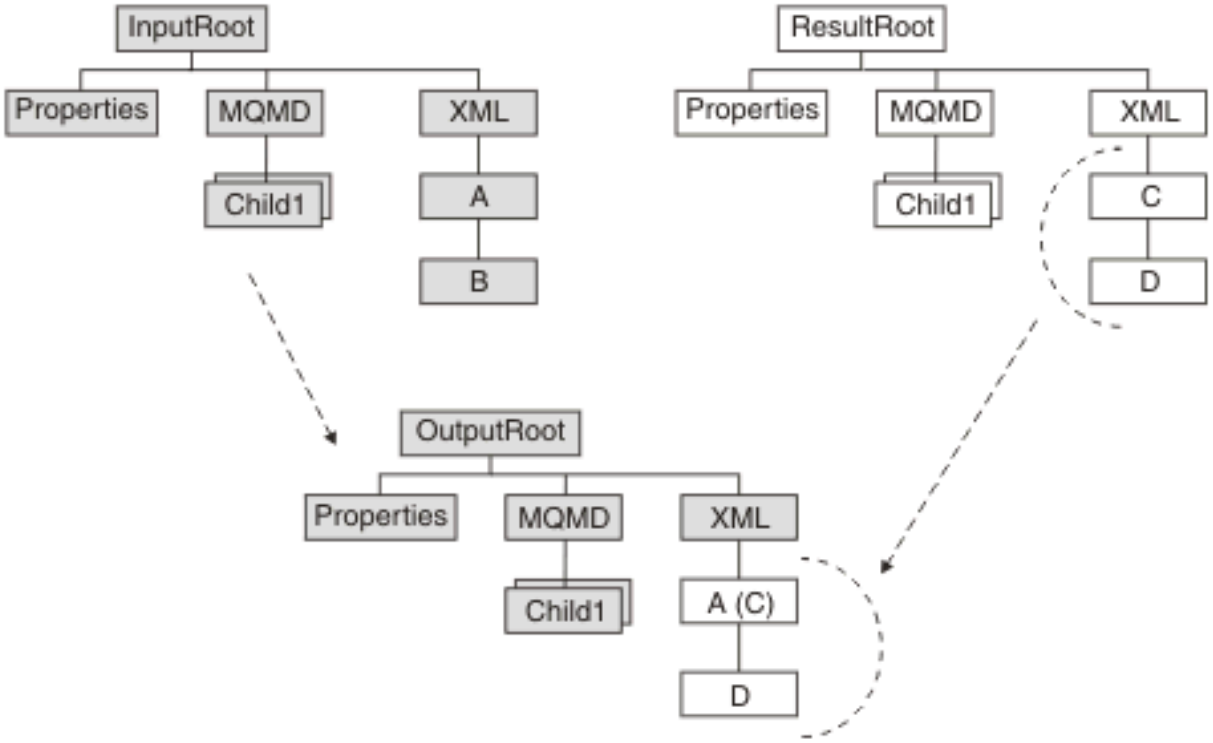
In this example, the MQGet node properties are configured as shown in the following table.

Property	**Action**
Copy Message	Copy Entire Message
Generate Mode	Message
Output Data Location	`OutputRoot.XMLNS.A`
Result Data Location	`ResultRoot.XMLNS.C`

The MQGet node constructs the output tree according to the following sequence:

1. The whole of the input tree is copied to the output tree, including the XML branch with child A, and A's child B.
2. From the result tree, the XML branch's child C, and C's child D, are put into the output tree at position `OutputRoot.XMLNS.A`. Any previous content of A (values and children) is lost, and replaced with C's content, including all values and children it has, in this case child D.
3. The position in the output tree retains the name A.

The following diagram shows this behavior:



For some examples of message trees that are constructed by the MQGet node according to the rules described above, see “MQGet node message tree examples” on page 772.

MQGet node message tree examples

The MQGet node generates message trees based on the input message assembly that it receives, and the options that you have set on the node properties.

The message trees, shown in the following table, are generated according to the rules described in “How the MQGet node implements IBM MQ MQGet API calls” on page 768.

With a message assembly like this:	The message that the MQGet node returns is:
InputRoot **MQMD** {input message MQMD} **MQRFH2** {input message MQRFH2} **XMLNS** {input message body} **InputLocalEnvironment** **MQ** **GET** **MQGMO** MatchOptions = MQMO_MATCH_CORREL_ID **MQMD (with no children)** **Variables** **MQMD** {input MQMD} (with CorrelID = {correct Correlation ID as binary})	**ResultRoot** **MQMD** {result message MQMD} **MQRFH2** {result message MQRFH2} **XML** {result message body}

With the following node property settings:	The resulting output message assembly is:
Input MQMD Location InputLocalEnvironment.Variables.MQMD **Copy Message** Copy Entire Message **Copy Local Environment** Copy Entire LocalEnvironment **Generate Mode** Message and LocalEnvironment **Output Data Location** InputLocalEnvironment.Variables.ReturnedMessage	**OutputRoot** **MQMD** {input message MQMD} **MQRFH2** {input message MQRFH2} **XMLNS** {input message body} **OutputLocalEnvironment** **MQ** **GET** **MQGMO** {MQGMO used for MQGET} **MQMD** {MQMD used for MQGET} **CC = 0** **RC = 0** **Variables** **MQMD** {input MQMD} (with CorrelID = {correct Correlation ID as binary}) **ReturnedMessage** **MQMD** {result message MQMD} **MQRFH2** {result message MQRFH2} **XML** {result message body}

With the following node property settings:	The resulting output message assembly is:
Result Data Location ResultRoot.XML	**OutputRoot** **MQMD** {input message MQMD} **MQRFH2** {input message MQRFH2} **XMLNS** {input message body} **OutputLocalEnvironment** **MQ** **GET** **MQGMO** {MQGMO used for MQGET} **MQMD** {MQMD used for MQGET} **CC = 0** **RC = 0** **Variables** **MQMD** {input MQMD} (with CorrelID = {correct Correlation ID as binary}) **ReturnedMessage (with any attributes and value from ResultRoot.XML)** {result message body} This tree is effectively the result of doing an assignment from `${resultDataLocation}` to `${outputDataLocation}`. The value of the source element is copied, as are all children including attributes.

With the following node property settings:	The resulting output message assembly is:
Copy Local Environment None	**OutputRoot** **MQMD** {input message MQMD} **MQRFH2** {input message MQRFH2} **XMLNS** {input message body} **OutputLocalEnvironment** **MQ** **GET** **MQGMO** {MQGMO used for MQGET} **MQMD** {MQMD used for MQGET} **CC = 0** **RC = 0** **Variables** **ReturnedMessage (with any attributes and value from ResultRoot.XML)** {result message body} This tree has the MQMD that is used for the MQGET call in the OutputLocalEnvironment, because the input MQ parameters location had an MQMD element under it. Even though the input tree is not copied, the presence of the MQMD element causes the MQMD that is used for the MQGET call to be placed in the output tree.

With the following node property settings:	The resulting output message assembly is:
Output Data Location <blank> **Copy Local Environment** Copy Entire Local Environment	**OutputRoot** **MQMD** {result message MQMD} **MQRFH2** {result message MQRFH2} **XMLNS** {result message body} **OutputLocalEnvironment** **MQ** **GET** **MQGMO** {MQGMO used for MQGET} **MQMD** {MQMD used for MQGET} **CC = 0** **RC = 0** **Variables** **MQMD** {input MQMD} (with CorrelID = {correct Correlation ID as binary}) The value that you set for the Copy Message property makes no difference to the eventual output tree in this case.

Enabling IBM MQ applications

If you want to connect IBM MQ applications to the integration node, you must define and secure the required resources.

About this task

- "Defining IBM MQ resources" on page 777
- "Securing IBM MQ resources" on page 778

Defining IBM MQ resources

An application client can run on a computer anywhere in the IBM MQ network. If your applications use IBM MQ facilities to connect to the integration node, and to interact with it (by using the MQI and AMI), you must set up the IBM MQ resources that they require.

About this task

The way that you set up applications is identical to the setup for clients for an IBM MQ server. To support client connections to an integration node:

Procedure

1. If the application runs on the same computer as the integration node, it can establish a local connection with the integration node queue manager by using MQCONN, and you do not have to define any IBM MQ resources to support it.

2. If the application runs on the same computer as another queue manager in the IBM MQ network, it can establish a local connection to that queue manager. In this scenario, you must define the appropriate resource to support communications between the queue manager to which the client has connected and the queue manager that hosts the integration node that provides the required service.
3. If the application runs on a computer that does not support a queue manager, it must make a client connection to a queue manager on another computer:
   - The integration node queue manager

     You must set up the appropriate client connection and server connection definitions to support this option.
   - Another queue manager in the network

     You must set up the appropriate client connection and server connection definitions to support this option, and ensure that definitions are in place to support communications between the queue manager to which the client has connected, and the queue manager that hosts the integration node that provides the required service.

Results

An application can get messages only from queues that are owned by the queue manager to which it is connected (this restriction is true for all IBM MQ applications). Therefore, if an application expects to receive messages from a queue populated by a service within a particular integration node and owned by that integration node queue manager, it must connect to that integration node queue manager (by using a local or IBM MQ client connection).

An application that puts messages, however, can be connected to any queue manager in the IBM MQ network, if the queue manager can resolve the target destination in some way. In all cases, the queue manager to which the client application is connected must know the location of the queue or queues to which the application puts messages (for example, by using remote queue definitions).

When you define an IBM MQ queue for a node in a message flow, you must not give it a name that starts with SYSTEM_BROKER. Names that include these characters are reserved for queues that are defined for internal use by IBM App Connect Enterprise components.

If your application is a subscriber that receives messages published by other applications, it can specify a temporary dynamic queue as its subscriber queue. If it does so, the integration node automatically deregisters the subscription when the queue is deleted.

For more details about applications, putting and getting messages, and the use of IBM MQ clients, see the *Clients* and *Application Programming Guide* sections of the IBM MQ product documentation online.

Securing IBM MQ resources
Secure the IBM MQ resources that your integration solution requires.

About this task

This information does not apply to z/OS.

Integration servers depend on a number of IBM MQ resources to operate successfully. You must control access to these resources to ensure that the integration servers can access the resources on which they depend, and that these same resources are protected from other users.

You can configure a connection to a secured IBM MQ queue manager, by setting properties on an MQ node or in an policy. If you are connecting to a local queue manager, you can optionally configure the connection to use a security identity for authentication. If you are configuring a client connection to a remote queue manager, you can configure the connection to use a security identity for authentication, SSL for confidentiality, or both. For more information, see “Connecting to a secured IBM MQ queue manager” on page 747.

Some authorizations are granted on your behalf when commands are issued. Others depend on the configuration of your integration server network.

- When you start the IBM App Connect Enterprise Toolkit, it connects to an integration server by using an IBM MQ local or client connection. For more information about IBM MQ channel security, see Setting up IBM MQ MQI client security in the IBM MQ product documentation online.
- When you create and deploy a message flow that includes nodes which reference IBM MQ queues, grant get, inq, and put authority to the user ID under which the integration server is running.

Application programming interfaces

IBM App Connect Enterprise supports programming interfaces that are in use by IBM MQ applications; it does not provide any unique programming interfaces.

For example, you can use the Message Queue Interface (MQI). The MQI provides a few calls that allow an application to interact with other applications in a network of IBM MQ queue managers. The calls support a large range of parameters that allow a rich choice of processing options for each message.

Client applications that use the MQI can run on any supported IBM MQ operating system, and therefore any limitations that are enforced for language or function are defined by the relevant product for that operating system.

The MQI is described in the *Application Programming Reference* and *Application Programming Guide* sections in the IBM MQ product documentation online. Details are also provided of the programming language and operating system support available for clients that use this interface.

If you have existing user applications that are written for an IBM MQ interface, the application can typically run unchanged in an integration node environment. You must create the message flows to interact with these applications from the supported protocols, by using the appropriate input and output nodes. IBM App Connect Enterprise provides built-in input and output nodes for its supported protocols and you can create your own user-defined nodes to support additional protocols.

You can also create new user applications to interact with the integration node.

Message headers

IBM App Connect Enterprise provides parsers for many IBM MQ headers, and can therefore accept messages that contain these headers from the IBM MQ Enterprise Transport protocol.

Messages must include an IBM MQ Message Descriptor (MQMD) as the first header, which must precede user or application data in every message. The MQMD contains basic control information that must travel with the message, including:

- The message identifier
- The destination of the reply, if one is to be sent
- Reply and report options (for example, confirm on delivery report)
- The format of any following data in the message

When a message is processed by an IBM App Connect Enterprise integration node, it typically (but not necessarily) has one or more additional headers. The header that follows the MQMD is always identified in the format field within the MQMD, and itself contains another format field to identify either the header that follows, or the format of the user data.

The additional headers can include:

MQRFH
The Rules and Formatting header is used by IBM MQ Publish/Subscribe.

MQRFH2
The MQRFH2 is an updated version of MQRFH and allows Unicode strings to be transported without translation, and it can carry numeric data types. The MQRFH2 header carries a description of the message contents, so that IBM App Connect Enterprise can select the correct message parser when content-based processing is carried out on the message. In addition, this header contains publish/subscribe command messages.

Use the MQRFH2 header in all new applications that are written for the IBM App Connect Enterprise environment that use a supported protocol that is based on IBM MQ technology. The MQRFH2 header must be immediately before the body of the message (that is, the last header).

If an MQRFH2 header is not included (which is normally the case of the application uses a supported protocol that is not based on IBM MQ technology), you must configure the message flow that processes its messages to specify the message characteristics (by setting the input node properties).

Using IBM MQ cluster queues for input and output

Design your integration node network to use IBM MQ queues, if appropriate for your business needs.

About this task

The use of queue manager clusters has the following significant benefits:

1. Reduced system administration

   Clusters need fewer definitions to establish a network; you can set up and change your network more quickly and easily.

2. Increased availability and workload balancing

   You can benefit by defining instances of the same queue to more than one queue manager, therefore distributing the workload through the cluster.

If you use clusters with IBM App Connect Enterprise, consider the following queues:

For SYSTEM.BROKER queues:
The SYSTEM.BROKER queues are defined for you when you create IBM App Connect Enterprise components, and are not defined as cluster queues. Do not change this attribute.

For message flow input queues:
If you define an input queue as a cluster queue, consider the implications for the order of messages or the segments of a segmented message. The implications are the same as for any IBM MQ cluster queue. In particular, the application must ensure that, if it is sending segmented messages, all segments are processed by the same target queue, and therefore by the same instance of the message flow at the same integration node.

For message flow output queues:

- IBM App Connect Enterprise always specifies MQOO_BIND_AS_Q_DEF when it opens a queue for output. If you expect segmented messages to be put to an output queue, or want a series of messages to be handled by the same process, you must specify DEFBIND(OPEN) when you define that queue. This option ensures that all segments of a single message, or all messages in a sequence, are put to the same target queue and are processed by the same instance of the receiving application.
- If you create your own output nodes, specify MQOO_BIND_AS_Q_DEF when you open the output queue, and DEFBIND(OPEN) when you define the queue, if you need to ensure message order, or to ensure a single target for segmented messages.

For publish/subscribe applications:

- If the target queue for a publication is a cluster queue, you must deploy the publish/subscribe message flow to all the integration nodes on queue managers in the cluster. However, the cluster does not provide any of the failover function to the integration node network and function. If an integration node to which a message is published, or a subscriber registers, is unavailable, the distribution of the publication or registration is not taken over by another integration node.
- When a client registers a subscription with an integration node that is running on a queue manager that is a member of a cluster, the integration node forwards a proxy registration to its neighbors in the integration node domain; the registration details are not advertised to other members of the cluster.
- A client might choose to become a clustered subscriber, so that its subscriber queue is one of a set of clustered queues that receive a particular publication. In this case, when registering a

subscription, use the name of an "imaginary" queue manager that is associated with the cluster; this queue manager is not the one to which the publication is sent, but an alias for the integration node to use. As an administrative activity, a blank queue manager alias definition is made for this queue manager on the integration node that satisfies this subscription for all clustered subscribers. When the integration node publishes to a subscriber queue that names this queue manager, resolution of the queue manager name results in the publication being sent to any queue manager that hosts the subscriber cluster queue, and only one clustered subscriber receives the publication.

For example, if the clustered subscriber queue was SUBS_QUEUE and the "imaginary" subscriber queue manager was CLUSTER_QM, the integration node definition is:

```
DEFINE QREMOTE(CLUSTER_QM) RQMNAME(' ') RNAME(' ')
```

This configuration sends integration node publications for SUBS_QUEUE on CLUSTER_QM to one instance of the cluster queue named SUBS_QUEUE anywhere in the cluster.

To understand more about clusters, and the implications of using cluster queues, see Queue manager clusters in the IBM MQ product documentation online.

You can also configure IBM App Connect Enterprise to use queues on an IBM MQ uniform cluster. A uniform cluster is a specific pattern of an IBM MQ cluster that provides a highly available and horizontally scaled small collection of queue managers. In scenarios in which one-way messaging is required, it can be useful to use queues that are defined on an IBM MQ uniform cluster. For more information, see “Using queues on an IBM MQ uniform cluster” on page 781.

Using queues on an IBM MQ uniform cluster

You can configure IBM App Connect Enterprise to use queues on an IBM MQ uniform cluster.

About this task

A uniform cluster is a specific type of IBM MQ cluster that provides a highly available and horizontally scaled small collection of queue managers. These queue managers are configured almost identically, so that an application can interact with them as a single group. This approach makes it easier to ensure that each queue manager in the cluster is being used, by automatically ensuring that application instances are spread evenly across the queue managers.

Uniform clusters differ from other IBM MQ clusters in several respects. For example, a uniform cluster typically has a smaller number of queue managers in the cluster and is used by a single application or a group of related applications. In a uniform cluster, client connections are grouped together based on the application name. Applications that connect to any member of the uniform cluster using the same application name are considered to be equivalent to any other applications using the same application name. All connections from an App Connect Enterprise integration server currently use the same MQ application name.

By using uniform clusters, applications can be designed for scale and availability, and can connect to any of the queue managers within the uniform cluster. As a result, there is no dependency on a specific queue manager, which improves availability and workload balancing of messaging traffic. For more information, see Uniform clusters in the IBM MQ product documentation online.

In some scenarios, it is important that the connection that is made between an IBM App Connect Enterprise integration node or server and an IBM MQ queue manager is maintained with that same queue manager, and not changed to an alternative queue manager. In these circumstances, uniform clusters are not appropriate. For example, in some MQ request/reply scenarios, reply messages must be returned to the same App Connect Enterprise integration server, which can be problematic if the connection is moved to a different queue manager. Another situation in which it is necessary to maintain access to a specific queue manager is when a flow contains nodes that require access to information about the state of in-flight messages, such as Aggregation, Sequence, Resequence, Collector, and Timeout nodes. Information about the state of in-flight messages is held on storage queues that are owned by the queue manager that is associated with the integration server. If the connection is moved to a different queue manager, the required information will no longer be accessible. Uniform clusters are also unsuitable for connections that are made from locally-bound applications; uniform clusters cannot achieve even

workload distribution with locally bound applications, because they cannot connect to any other member of the cluster. For more information, see Limitations and considerations for uniform clusters.

In scenarios where one-way messaging is required, it can be beneficial to use queues that are defined on an IBM MQ uniform cluster. For information about configuring App Connect Enterprise to use uniform clusters, see "Configuring App Connect Enterprise to use IBM MQ uniform clusters" on page 782.

Configuring App Connect Enterprise to use IBM MQ uniform clusters
You can configure IBM App Connect Enterprise to use queues on an IBM MQ uniform cluster.

About this task

A uniform cluster is a specific pattern of an IBM MQ cluster that provides a highly available and horizontally scaled small collection of queue managers. In scenarios in which one-way messaging is required, it can be useful to use queues that are defined on an IBM MQ uniform cluster. For more information about IBM MQ uniform clusters, see "Using queues on an IBM MQ uniform cluster" on page 781.

When messages are running through a non-transactional message flow, if the connection is moved part of the way through the flow to another queue manager in the uniform cluster, the flow continues to operate. Messages that are sent before and after the reconnection might be delivered to different queue managers. This can occur even for separate message flow node instances in the same flow.

In a transactional message flow, if the connection is moved part of the way through the flow to another queue manager in the uniform cluster, the transaction is rolled back and an exception is thrown from the next MQ call, and the backed out message is still on the original queue manager. When the connection has been re-established, the backed out message is available to be processed again, typically in another instance of the application. Optionally, you can catch and ignore the exception, at which point your message flow can continue to do more work on the re-established connection, committing only the work after the connection was re-established.

If a connection is moved to another queue manager in the uniform cluster when a message flow is idle (polling on MQGET without receiving a message), the integration server reconnects to the new queue manager and then continues to poll.

The following sections explain how you can configure IBM MQ to connect App Connect Enterprise to a uniform cluster, and how you can configure App Connect Enterprise to use a connection to an IBM MQ uniform cluster, by using an MQEndpoint policy:

- "Configuring IBM MQ to connect App Connect Enterprise to a uniform cluster" on page 782
- "Configuring IBM App Connect Enterprise to connect to a uniform cluster" on page 782

Configuring IBM MQ to connect App Connect Enterprise to a uniform cluster

About this task

You can connect IBM App Connect Enterprise to an IBM MQ uniform cluster by configuring the connection in IBM MQ. To configure the connection in IBM MQ, configure Client Channel Definition Table (CCDT), and then set either the MQCLNTCF environment variable or configure the `mqclient.ini` file to control the MQ Client code. For more information, see the IBM MQ product documentation online.

Configuring IBM App Connect Enterprise to connect to a uniform cluster

About this task

You can configure App Connect Enterprise to use a connection to an IBM MQ uniform cluster by using the `Reconnect option` property on the MQEndpoint policy. This property enables you to control whether the IBM MQ client automatically attempts to reconnect to the queue manager if the connection is lost. By default, the IBM MQ client's default reconnection strategy is used, modified by using the IBM MQ client configuration described in "Configuring IBM MQ to connect App Connect Enterprise to a uniform cluster" on page 782.

The Reconnect option property is used only for client connections and is ignored for server connections. The property takes the following possible values:

- default - This value corresponds to the IBM MQ option MQCNO_RECONNECT_AS_DEF. This is the default value for the property.
- enabled - This value corresponds to the IBM MQ option MQCNO_RECONNECT.
- disabled - This value corresponds to the IBM MQ option MQCNO_RECONNECT_DISABLED.
- queueManager - This value corresponds to the IBM MQ option MQCNO_RECONNECT_Q_MGR.

These values are passed to the IBM MQ client in the MQCONNX call, which is made by an MQInput node at the start of a message flow. This type of configuration enables you to use different reconnection settings for different deployments to the same integration server, which can be configured to use different MQEndpoint policies. For more information, see policy.

As a result of the mappings between the App Connect Enterprise reconnect settings and the MQCNO options, you must ensure that the options that you select on the MQ nodes do not conflict with your chosen MQCNO option. For example, you cannot use the **Logical order** property on the MQInput node (which is set by default) in conjunction with setting the **Reconnect option** property in the MQEndpoint policy to enabled (which corresponds to the IBM MQ option MQCNO_RECONNECT).

Configuring flows to handle IBM MQ message groups

IBM MQ allows multiple messages to be treated as a group, or as segments of one larger message. IBM App Connect Enterprise provides support for IBM MQ message grouping and partial support for message segmenting.

You can use the MQInput and MQOutput nodes to receive and send messages that are part of an IBM MQ message group. You can use the MQOutput node to send messages that are segments of a larger message.

For guidance about configuring the MQInput and MQOutput nodes to receive and send messages that are part of an IBM MQ message group, see:

- “Receiving messages in an IBM MQ message group” on page 783
- “Sending messages in an IBM MQ message group” on page 785
- “Sending message segments in an IBM MQ message” on page 786

For more information about IBM MQ message groups, see Message groups in the IBM MQ product documentation online.

Receiving messages in an IBM MQ message group

You can configure the MQInput node to receive messages that are in an IBM MQ message group.

About this task

The following properties on the MQInput node control the processing of messages in an IBM MQ message group:

- Logical order
- Order mode
- All messages available
- Commit by message group

To ensure that your message flow receives group messages in the order that has been assigned by the sending application, select Logical order. If you do not select this option, messages that are sent as part of a group are not received in a predetermined order. This property maps to the MQGMO_LOGICAL_ORDER option of the MQGMO of the MQI. More information about the options to which this property maps is available in the *Application Programming Reference* section of the IBM MQ product documentation online.

If you specify a value of By Queue Order on the Order mode property, the message flow processes the messages in the group in the order that is defined by the queue attributes; this order is guaranteed to be

preserved when the messages are processed. This behavior is identical to the behavior that is exhibited if the `Additional instances` property is set to zero. The message flow processes the messages on a single thread of execution, and a message is processed to completion before the next message is retrieved from the queue. If you do not specify this value, it is possible that multiple threads within a single message flow are processing multiple messages, and the final message in a group, which prompts the commit or roll back action, is not guaranteed to be processed to completion after all other messages in the group.

To ensure that only a single instance of the message flow processes the group messages in the order that has been assigned by the sending application, select `Logical order` **and** specify a value of `By Queue Order` on the `Order mode` property.

If you select `All messages available`, message retrieval and processing is performed only when all messages in a single group are available. This means that messages in a group are not received until all the messages in the group are present on the input queue. It is good practice to select this check box when your message flow needs to process group messages. If you do not select this check box, the message flow receives the messages as they arrive on the input queue; if a message in the group fails to arrive on the input queue, the message flow waits for it and cannot process any further messages until this message arrives. This property maps to the MQGMO_ALL_MESSAGES_AVAILABLE option of the MQGMO of the MQI. More information about the options to which this property maps is available in the *Application Programming Reference* section of the IBM MQ product documentation online.

If you select `Commit by message group`, message processing is committed only after the final message of a group has been received and processed. If you leave this check box cleared, a commit is performed after each message has been propagated completely through the message flow. This property is relevant only if you have selected `Logical order`. It is good practice to select this check box together with the `All messages available` check box because this ensures that the complete message group is retrieved and processed in the same unit of work without risk of the message flow waiting indefinitely for messages in the group to arrive on the input queue.

To ensure that the message flow that processes group messages does not wait for unavailable messages:

- Avoid having multiple message flows reading from the same input queue when group messages are being retrieved.
- Avoid deploying additional instances of a flow that retrieves group messages.
- Avoid using expired messages in message groups.
- When expired messages are to be used, ensure either that all messages have the same expiry time or that the first message in the group is set to expire before the rest of the group. If the first message in a group cannot be retrieved, the group can never be started in logical order.

If a message flow waits for a group message that does not arrive within the wait interval, a BIP2675 warning message is issued. From that point on, the message flow always attempts to retrieve the next group message and does not process any other input messages until the next group message is received.

Therefore, if the expected group message does not arrive, or has expired, the message flow must be stopped manually, and any incomplete message group cleared from the input queue.

A message flow cannot receive all the messages in a group in one operation.

If you specify a value of `Yes` or `No` on the `Transaction mode` property, all the segments in a message are received in the message flow as a single message. As a result, the message flow might receive very large messages which might lead to storage problems in the integration node. If you specify a value of `Automatic` on the `Transaction mode` property, message segments are received as individual messages.

Sending messages in an IBM MQ message group
The MQOutput node can send multiple messages that form an IBM MQ message group. Configure a Compute or JavaCompute node to set the MQMD fields to specify message group options.

About this task

The message flow must set the following MQMD fields:

- **GroupId**
- **MsgSeqNumber**
- **MsgFlags**

You can use the following example of ESQL code in a Compute node, which shows how to set these fields:

```
DECLARE MSGNUM INT 0;
  DECLARE MSGTOTAL INT 5;
  WHILE MSGNUM < MSGTOTAL DO
    SET MSGNUM = MSGNUM + 1;
    CALL CopyMessageHeaders();
    -- Manually set the groupId since we cant ask the queue manager to generate one.
    -- the UUIDASBLOB function could be used here to generate one, but this must be done
    -- outside the loop to keep the same groupId throughout!
    SET OutputRoot.MQMD.GroupId = X'000000000000000000000000000000000000000000000001';
    SET OutputRoot.MQMD.MsgSeqNumber = MSGNUM;
    SET OutputRoot.MQMD.MsgFlags = MQMF_MSG_IN_GROUP;
    IF (MSGNUM = MSGTOTAL) THEN
      SET OutputRoot.MQMD.MsgFlags = MQMF_LAST_MSG_IN_GROUP;
    END IF;
    SET OutputRoot.XML.TestCase = MSGNUM;
    PROPAGATE;
  END WHILE;
  RETURN FALSE;
```

You can use the following example of Java code in a JavaCompute node, which shows how to set these fields:

```
public class mq_group_java_JavaCompute extends MbJavaComputeNode {
      public void evaluate(MbMessageAssembly assembly) throws MbException {
        MbOutputTerminal out = getOutputTerminal("out");
        int MSGTOTAL = 5;
        for(int MSGNUM = 1 ; MSGNUM <= MSGTOTAL;MSGNUM++){
           MbMessage newMessage = new MbMessage();
           MbElement root = newMessage.getRootElement();
           MbElement mqmd = root.createElementAsFirstChild("MQMD");
           mqmd.createElementAsLastChild(MbElement.TYPE_NAME_VALUE,
           "GroupId", new byte[]{0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,1});
           mqmd.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "MsgSeqNumber", MSGNUM);
           if (MSGNUM == MSGTOTAL){
               mqmd.createElementAsLastChild(MbElement.TYPE_NAME_VALUE,
               "MsgFlags", 16); // MQMF_LAST_MSG_IN_GROUP 0x00000010
           }
           else{
               mqmd.createElementAsLastChild(MbElement.TYPE_NAME_VALUE,
               "MsgFlags", 8);  // MQMF_MSG_IN_GROUP      0x00000008
           }
           MbElement xmlnsc = root.createElementAsLastChild("XMLNSC");
           MbElement body =
 xmlnsc.createElementAsLastChild(MbElement.TYPE_NAME,"TestCase",null);
           body.setValue(MSGNUM);
           MbMessageAssembly newAssembly = new MbMessageAssembly(assembly,newMessage);
           out.propagate(newAssembly);
        }
    }
}
```

If the message flow is sending multiple messages from one input message, it can create a **GroupId** value, increment the **MsgSeqNumber** value, and set the **MsgFlags** field. The examples of ESQL and Java code show how you can set these values. However, if the message flow is sending multiple messages from more than one input message, it must store the **GroupId** and **MsgSeqNumber** values between flow instances, which is achieved by using shared variables.

For more information about message grouping, see Message groups in the IBM MQ product documentation online. For more information about IBM MQ fields, see MQMD - Message descriptor of the IBM MQ product documentation online.

Sending message segments in an IBM MQ message
The MQOutput node can send multiple message segments that form an IBM MQ message. Configure a Compute node to set the MQMD fields to specify message segment options.

About this task

You can either select `Segmentation allowed` on the node, or set the required fields in the MQMD in the message flow:

- GroupId
- MsgFlags
- Offset

Use the example ESQL code in "Sending messages in an IBM MQ message group" on page 785 and change the code to set these fields.

For more information about message grouping and segmentation, see Message groups of the IBM MQ product documentation online.

Ensuring that messages are not lost

Messages that flow through your integration node domain represent business data that you want to safeguard. Configure the messages, your environment, or both, to ensure that you do not lose messages.

About this task

Messages that are generated by your applications and by runtime components for inter-component communication are important to the operation of your integration nodes.

For messages traveling across IBM MQ, two techniques can protect against message loss:

- Message persistence

  If a message is persistent, IBM MQ ensures that it is not lost when a failure occurs, by copying it to disk.
- Sync point control

  An application can request that a message is processed in a synchronized unit-of-work (UOW)

For more information about how to use these options, refer to the *System Administration Guide* section of the IBM MQ product documentation online.

If delivery of application messages is critical, you must design application programs and the message flows that they use to ensure that messages are not lost. The techniques used depend on the protocol used by the applications.

IBM MQ Enterprise Transport

If you are using the built-in input nodes that accept messages across the IBM MQ protocol, you can use the following guidelines and recommendations:

- Using persistent messages

  IBM MQ messaging products provide *message persistence*, which defines the longevity of the message in the system and guarantees message integrity. Nonpersistent messages are lost in the

event of system or queue manager failure. Persistent messages are always recovered if a failure occurs.

You can control message persistence in the following ways:

- Program your applications that put messages to a queue using the MQI or AMI to indicate that the messages are persistent.
- Define the input queue with message persistence as the default setting.
- Configure the output node to handle persistent messages.
- Program your subscriber applications to request message persistence.

When an input node reads a message from an input queue, the default action is to use the persistence defined in the IBM MQ message header (MQMD), that has been set either by the application creating the message, or by the default persistence of the input queue. The message retains this persistence throughout the message flow, unless it is changed in a subsequent message processing node.

You can override the persistence value of each message when the message flow terminates at an output node. This node has a property that allows you to specify the message persistence of each message when it is put to the output queue, either as the required value, or as a default value. If you specify the default, the message takes the persistence value defined for the queues to which the messages are written.

If a message passes through a Publication node, the persistence of messages sent to subscribers is determined by the registration options of the subscribers. If a subscriber has requested persistent message delivery, and is authorized to do so by explicit or implicit (inherited) ACL, the message is delivered persistently regardless of its existing persistence property. Also, if the user has requested nonpersistent message delivery, the message is delivered nonpersistent regardless of its existing persistence property.

If a message flow creates a message (for example, in a Compute node), the persistence in the MQMD of the new message is copied from the persistence in the MQMD of the incoming message.

- Processing messages under sync point control

  The default action of a message flow is to process incoming messages under sync point in a transaction that is controlled by the integration node. This means that a message that fails to be processed for any reason is backed out by the integration node. Because it was received under sync point, the failing message is reinstated on the input queue and can be processed again. If the processing fails, the error handling procedures that are in place for this message flow (defined either by how you have configured the message flow, or by the integration node) are executed.

IBM MQ Web Services Transport
If you are using the HTTPInput, HTTPRequest, SOAPInput, SOAPRequest nodes, or a SOAPAsyncRequest and SOAPAsyncResponse node pair that accept messages from web services applications, no facilities are available to protect against message loss. You can, however, provide recovery procedures by configuring the message flow to handle its own errors.

Other transports and protocols
If you have created your own user-defined input nodes that receive messages from another transport protocol, you must rely on the support provided by that transport protocol, or provide your own recovery procedures.

Processing HTTP messages

Hypertext Transfer Protocol (HTTP) is an Internet protocol that is used to transfer and display hypertext and XML documents on the Web.

You can configure message flows that include the HTTP or SOAP nodes to access the HTTP transport to work with the following resources:

- SOAP-based web services
- Other web services standards, such as REST or XML-RPC

- General HTTP messaging, where the payload might be XML

HTTP nodes can process non-secure (HTTP) messages and secure (HTTPS or HTTP over SSL) messages.

For SOAP-based web services, several advantages exist if you use the SOAP nodes and the SOAP message domain instead of the HTTP transport nodes and XMLNSC message domain.

- Support for WS-Addressing, WS-Security and SOAP headers.
- A common SOAP logical tree format, independent of the bitstream format.
- Runtime checking against WSDL.
- Automatic processing of SOAP with Attachments (SwA).
- Automatic processing of Message Transmission Optimization Mechanism (MTOM).

Although the HTTP nodes can process SwA messages, you must use the MIME message domain and design your flow to handle the attachments explicitly, and use custom logic to extract and parse the SOAP.

For more information about using SOAP messages and message flow nodes, see "What is SOAP?" on page 807

You can choose how your HTTP and SOAP nodes interact with the TCP/IP network:

- You can use the integration node listener, which receives HTTP messages on one port, and HTTPS messages on a second port.

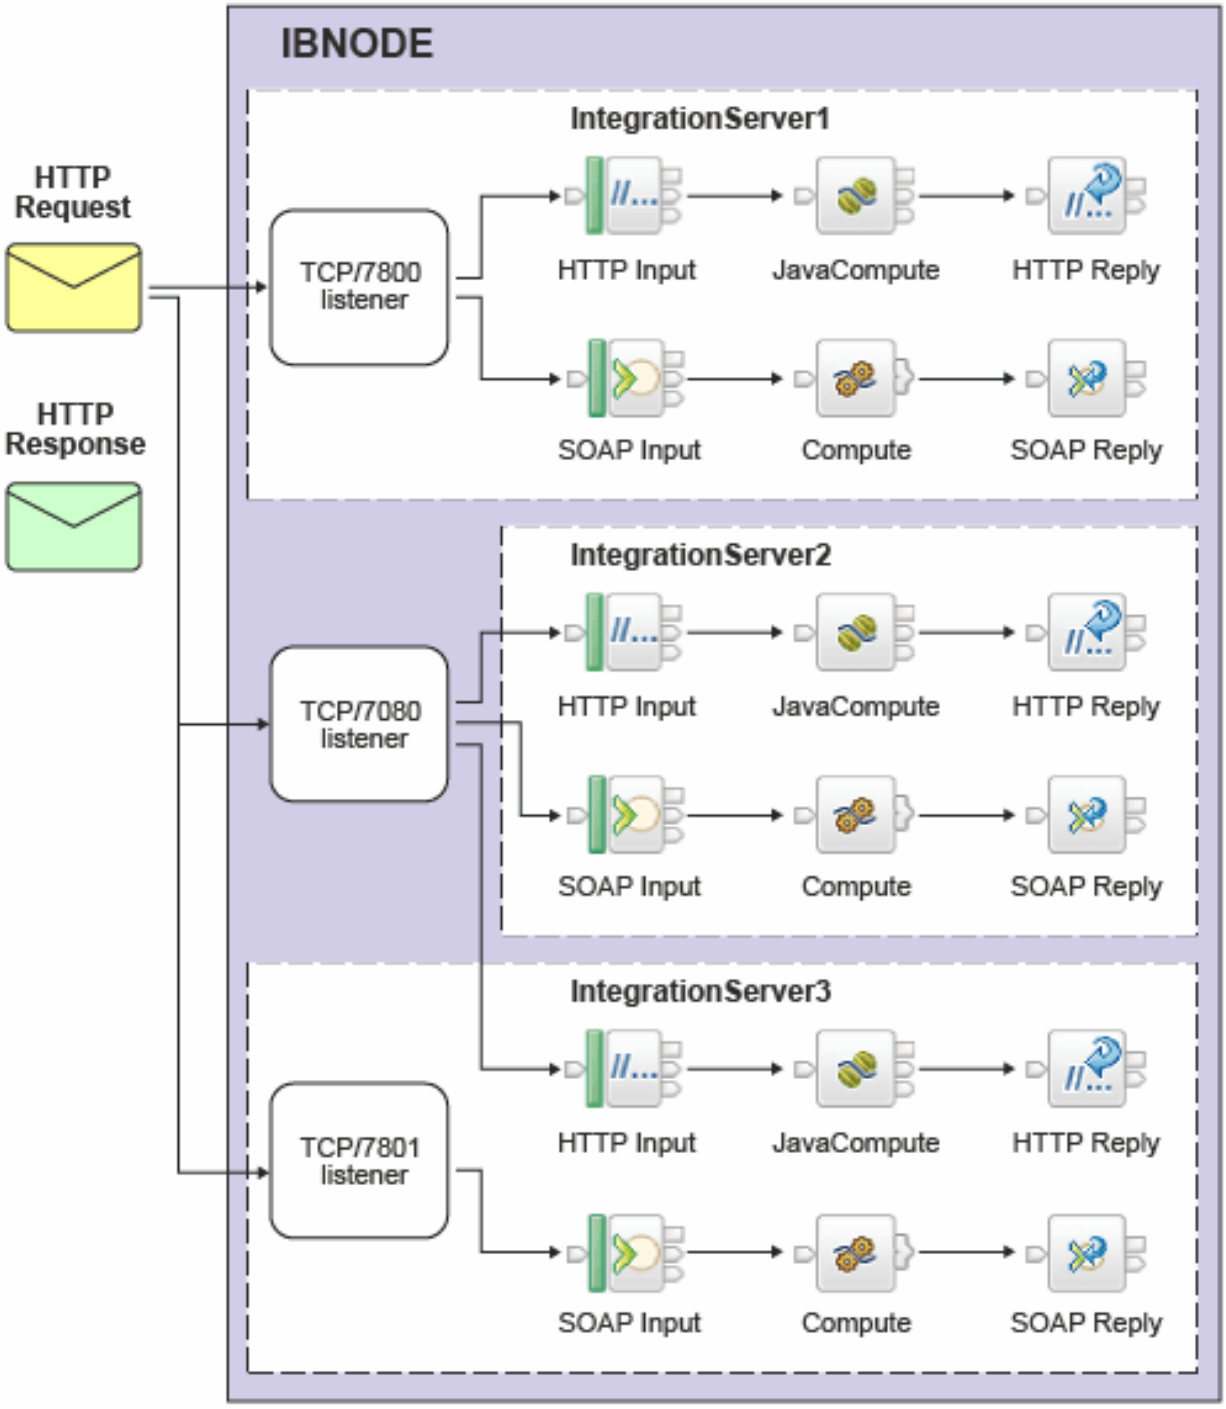
  This option is set as the default configuration for HTTP nodes for both existing and new integration nodes.
- You can use the listener that is embedded within each integration server, which also has two ports for HTTP and HTTPS messages.

  This option is set as the default configuration for SOAP nodes for both existing and new integration nodes.
- You can use a mixture of integration nodes and integration server listeners by keeping or making the integration node listener active, and configuring a subset of integration servers to use the embedded listener. Message flow nodes of the same type within one integration server must use the same type of listener. For example, you cannot have SOAP nodes that use the embedded listener and SOAP nodes that use the integration node listener within the same integration server.

The integration node listener requires access to system queues on the queue manager specified on the integration node, so you must install IBM MQ Server if you want to use an integration node listener. However, if you use HTTP nodes or SOAP nodes with the integration server embedded listener, IBM MQ is not required.

For more information about why you might choose each option, and how to configure them, see "HTTP listeners" on page 795.

The following diagram shows the use of both types of listener, configured on default ports, for HTTP



messages.

You must always use the correct reply node that matches your input node; you cannot combine an HTTPReply node with a SOAPInput, or a SOAPReply node with an HTTPInput node. An exception is generated when the reply is attempted.

You can include the reply node in the same message flow, or in a different message flow:

- If you have configured the HTTPInput node or SOAPInput node to use the integration server listener, you must deploy the second message flow to the same integration server.
- If you have configured the HTTPInput node to use the integration node listener, you can deploy the second message flow to any other integration server defined to the integration node. This is not the case for the SOAPInput node.

- You must pass the correct reply identifier from the input message flow to the reply node.

If you are using SOAP nodes and HTTP nodes in message flows on a single integration node, you can choose to handle HTTP messages by using either the integration node listener or embedded integration server listeners. If a listener in your configuration receives messages that both SOAPInput and HTTPInput nodes might get, you must carefully check the URL specifications in these nodes. If both URL specifications match an incoming message, the wrong type of node might get the message, and processing might fail or produce unexpected results. This situation occurs if you specify identical values for the Path suffix for URL properties of the HTTPInput node and the SOAPInput node. It can also occur if you use wildcards in either or both specifications, and an incoming message matches both properties.

For more information about using the WebSphere Broker HTTP Transport, see the following topics:

- "Working with HTTP flows" on page 792
- "HTTP listeners" on page 795
- "HTTP message format" on page 790
- "HTTP headers" on page 791
- "Web services example messages" on page 804

For information about using HTTPS, see "Implementing SSL authentication" on page 2635.

You can also use the HTTP proxy servlet in an external Web servlet container to provide listener support for a larger number of concurrent HTTP sessions. For more information about the servlet and its uses, see "HTTP proxy servlet overview" on page 141.

Web services: when to use SOAP or HTTP nodes

HTTP and SOAP nodes can both be used to interact with web services. Typically you use SOAP nodes when working with SOAP-based web services.

For SOAP-based web services, several advantages exist if you use the SOAP nodes and the SOAP message domain instead of the HTTP transport nodes and XMLNSC message domain.

- Support for WS-Addressing, WS-Security and SOAP headers.
- A common SOAP logical tree format, independent of the bitstream format.
- Runtime checking against WSDL.
- Automatic processing of SOAP with Attachments (SwA).
- Automatic processing of Message Transmission Optimization Mechanism (MTOM).

Although the HTTP nodes can process SwA messages, you must use the MIME message domain and design your flow to handle the attachments explicitly, and use custom logic to extract and parse the SOAP.

Cases where it might be better to use HTTP nodes include:

- Message flows that interact with web services that use different standards, such as REST or XML-RPC.
- Message flows that never use WS-Addressing, WS-Security, SwA, or MTOM.

HTTP message format

An HTTP message contains components that are appropriate to its type.

The bit stream containing headers and body is parsed and represented within the message tree when an input request is received by an HTTPInput node, or when a response from a web service is received by the HTTPRequest node. A bit stream is created by parsers from the appropriate parts of the message tree when a reply is sent to the client by the HTTPReply node, or when a message is sent by the HTTPRequest node. For further details about these actions, see the individual node descriptions.

HTTP headers

When an HTTPInput or HTTPRequest node receives a message, it parses the HTTP headers to create elements in the message tree. When an HTTPReply or HTTPRequest node sends a message, it parses the HTTP headers from the message tree into a bit stream.

The HTTP headers in a message depend on the type of message that is processed. There are four message types recognized in a message flow, and a parser is associated with each of these.

1. Input. An input message is received by the HTTPInput node from a client. The HTTP headers in the input message (data up to and including the CRLFCRLF) are parsed by the HTTPInput parser and are included in the message tree under the correlation name HTTPInput. The headers shown in the following table are expected in an input message; others might also be present.

Header	Content	Example
Host	The host name to which the client issued the message.	localhost
Content-Length	The length of the body of the input message in decimal (that follows the CRLFCRLF after the last header).	520
Content-Type	The type of the body data.	text/xml; charset=utf-8
SOAPAction		"" (empty string)

   The headers in the following table might also be automatically generated by the HTTPInput node depending on the request.

Header	Content	Example
X-Original-HTTP-Command	An expanded version of the original inbound request	POST http://localhost:7800/Wss001/services/Wss001 HTTP/1.1
X-Remote-Addr	The IP address of the client (or proxy if the client is connecting through a proxy)	127.0.0.1
X-Remote-Host	The host name or address of the client (or proxy if the client is connecting through a proxy)	localhost
X-Server-Name	The integration node's machine name	localhost
X-Server-Port	The integration node's port	7800
X-Query-String	The query string if present in the inbound URL (optional)	a=b&x=y
X-Scheme	The scheme through which the client is connected, either http or https	http

2. Reply. A reply message is sent by the HTTPReply node to the client that sent the corresponding input message. The headers in the reply message are created in the message tree under the correlation name HTTPReply, which is also the name of the parser used to parse that part of the message tree to a bit stream. You can create your own HTTPReply header in a Compute node, or you can configure

the HTTPReply node to create it by using default values, or values taken from the HTTPReply or HTTPResponse trees in the input message, or both.

You can set the HTTPReply Status Code in the local environment; for more information, see the instructions for setting the HTTP Status Code for a reply in “Working with HTTP flows” on page 792.

If the HTTPReply node creates a default HTTPReply header, it contains the headers and values shown in the following table.

Header	Value
Content-Length (if present in the input message)	The calculated length of the reply message body in decimal.
Content-Type	text/xml; charset=*ccsid of the message body*

3. Request. A request message is sent by the HTTPRequest node. The HTTP headers in this message must be created in the message tree under the correlation name HTTPRequest, and are parsed by the HTTPRequest parser when the message tree is parsed to a bit stream. You can create your own HTTPRequest header in a Compute node, or you can configure the HTTPRequest node to create it using default values, or values taken from the HTTPInput or HTTPRequest trees in the input message, or both. If the HTTPRequest node creates a default HTTPRequest header, it contains the headers and values shown in the following table.

Header	Value
Host	Value set in the *`Default Web Service URL`* property.
Content-Length	The calculated length of the request message body in decimal.
Content-Type	text/xml; charset=*ccsid of the message body*
SOAPAction	"" (empty string)
Content-Encoding	"gzip" or "deflate" if the `Use compression` property is set to `gzip`, `zlib` (`deflate`), or `deflate`.
Accept-Encoding	"gzip, deflate" if the `Accept compressed responses by default` property is selected.

4. Response. A response message is received by the HTTPRequest node from the application to which the corresponding request message was sent. The HTTP headers in the response message (data up to and including the CRLFCRLF) are parsed by the HTTPResponse parser and are included in the message tree under the correlation name HTTPResponse. The header shown in the following table is expected in a response message (though not required); others might also be present.

Header	Content	Example
Content-Length	The length of the response message body in decimal.	1585

“Web services example messages” on page 804 provides example messages that include these headers.

Working with HTTP flows

Read this information if you are using HTTP message flows to interact with HTTP applications, including web services and RESTful services.

About this task

- Using secure connections with HTTPS
- Using HTTP asynchronous request-response

- Setting the HTTP Status Code for a reply
- Using LocalEnvironment.Destination.HTTP.RequestIdentifier
- Setting the HTTPRequest node URL dynamically
- Setting `Generate default HTTP headers from reply or response` for the HTTPReply node
- Setting `Generate default HTTP headers from input` for the HTTPRequest node

You must decide which listener you want the HTTP nodes to use:

- The integration node listener (the httplistener component) has an HTTPConnector for handling HTTP messages, and an HTTPSConnector for handling HTTPS (HTTP over SSL) messages. Each connector has its own assigned port.

  The integration node listener requires access to system queues on the queue manager specified on the integration node, so you must install IBM MQ Server if you want to use an integration node listener.
- An embedded listener is part of each integration server. The embedded listener has an HTTPConnector and an HTTPSConnector, and each connector has its own assigned port.

  You can configure one or more integration servers so that all HTTPInput and HTTPReply that you deploy to that integration server use the embedded listener.

  The integration server embedded listener does not require access to IBM MQ.

For a discussion of the advantages of each listener, see "HTTP listeners" on page 795.

You can use `ProxyConnectHeaders` only with HTTPS (SSL) connections; these headers do not work with HTTP connections.

Using secure connections with HTTPS

If you are using an HTTPS connection when the server certificate is replaced, you can use the App Connect Enterprise administration REST API to reload the server certificate from the keystore and apply it dynamically to the running integration server. This means that if an HTTPS connection is in use when a security certificate is replaced, you can apply the new certificate without having to restart the integration server. For more information, see "Updating the HTTPS Connector resource manager by using the administration REST API" on page 440.

For information about setting up HTTPS connections, see "Implementing SSL authentication" on page 2635.

Using HTTP asynchronous request-response

To make an HTTP request and receive a response asynchronously, use the HTTPAsyncRequest and HTTPAsyncResponse nodes in your message flow. The HTTPAsyncRequest node processes the next message without waiting for the response, which is received by the HTTPAsyncResponse node on a different thread and in a new transaction. This means that many more requests can be processed using fewer threads.

For more information, see "Using HTTP asynchronous request-response" on page 803.

Setting the HTTP Status Code for a reply

The default HTTP Status Code is 200, which indicates success. If you want a different status code to be returned, take one of the following actions:

- Set your status code in the field Destination.HTTP.ReplyStatusCode in the local environment tree (correlation name OutputLocalEnvironment). This field overrides any status code that is set in an HTTPResponseHeader header. This action is the preferred option, because it provides the greatest flexibility.
- Set your status code in the field X-Original-HTTP-Status-Code in the HTTPReplyHeader header.
- Set your status code in the field X-Original-HTTP-Status-Code in the HTTPResponseHeader header. This option is useful if you include an HTTPRequest node before the HTTPReply node in your flow, because the HTTPResponseHeader header is created for you. In this scenario, an HTTPResponseHeader header has been created in the logical tree, representing the HTTP headers in the response from another web service. If you have selected the `Generate default HTTP`

`headers from reply or response` property on the HTTPReply node, values for the response header are set as default values when the reply message is created.

Using LocalEnvironment.Destination.HTTP.RequestIdentifier

When the HTTPInput node receives an input request message, it sets the local environment field Destination.HTTP.RequestIdentifier to a unique value that identifies the web service client that sent the request. You can refer to this value, and you can save it to another location if appropriate.

For example, if you design a pair of message flows that interact with an existing IBM MQ application you can save the identifier value in the request flow, and restore it in the reply flow, to ensure that the correct client receives the reply. If you use this technique, you must not change the data, and you must retain the data as a BLOB.

The HTTPReply node extracts the identifier value from the local environment tree and sets up the reply so that it is sent to the specific client. However, if you are using an HTTPReply node in a flow that does not have an HTTPInput node, and this field has been deleted or set incorrectly, message BIP3143S is issued.

If you design a message flow that includes both an HTTPInput and an HTTPReply node, the identifier value is set into the local environment by the HTTPInput node, but the HTTPReply node does not use it. Therefore, if your message flow includes both HTTP nodes and a Compute node in the same flow, you do not have to include the local environment tree when you specify which components of the message tree are copied from input message to output message by the Compute node (the `Compute mode` property).

Setting the HTTP request URL dynamically

You can set the property `Default web service URL` on the HTTPRequest or HTTPAsyncRequest node to determine the destination URL for a web service request. You can configure a Compute node before the HTTPRequest or HTTPAsyncRequest node within the message flow to override the value set in the property. Code ESQL that stores a URL string in LocalEnvironment.Destination.HTTP.RequestURL; the node retrieves and uses the URL string in place of the node property value.

Although you can also set the request URL in the special header X-Original-HTTP-URL in the HTTPRequestHeader header section of the request message (which overrides all other settings) in a Compute node, use the local environment tree content for this purpose for greater flexibility.

Setting `Generate default HTTP headers from reply or response` for the HTTPReply node

If you select `Generate default HTTP headers from reply or response` in the HTTPReply node properties, the node includes a minimum set of headers in the response that is sent to the web service client.

To set headers explicitly, create them in an HTTPReplyHeader header. For example, a Compute node propagates a message in the XMLNSC domain and modifies the Content-Type as follows:

```
CALL CopyMessageHeaders();
SET OutputRoot.HTTPReplyHeader."Content-Type" = 'text/xml';
SET OutputRoot.XMLNSC = InputRoot.XMLNSC;
```

Do not use the ContentType property to set the Content-Type unless you are working in the MIME domain. The ContentType property is intended to set the value of Content-Type used in MIME.

The full set of HTTP headers used in the reply is built by selecting the headers using the algorithm defined in the following steps:

1. Select one or more headers in an HTTPReplyHeader header.
2. If no Content-Type header is yet defined, create one by using a non-empty value in the ContentType property.
3. Select one or more headers in an HTTPResponseHeader header (an HTTPResponseHeader header is propagated on return from an HTTPRequest node).
4. If no Content-Type header is yet defined, create one with the default value `text/xml; charset=`*`ccsid of the message body`*.

5. Create or overwrite the Content-Length header.

Attention: The HTTPReply node always rewrites the Content-Length header, even if you have cleared `Generate default HTTP headers from reply or response`. This action ensures that the content is correct.

If an HTTPReplyHeader header section existed in the message received by the HTTPReply node, and the Output terminal of the HTTPReply node is connected, the HTTPReplyHeader header section is updated with all changed or added values.

Setting `Generate default HTTP headers from input` for the HTTPRequest or HTTPAsyncRequest node

If you select `Generate default HTTP headers from input` in the HTTPRequest or HTTPAsyncRequest node properties, the node includes a minimum set of headers in the request that is sent to the server.

To explicitly set headers, create them in an HTTPRequestHeader header. For example, a Compute node propagating a message in the XMLNSC domain can modify the Content-Type as follows:

```
CALL CopyMessageHeaders();
SET OutputRoot.HTTPRequestHeader."Content-Type" = 'text/xml';
SET OutputRoot.XMLNSC = InputRoot.XMLNSC;
```

Do not use the ContentType property to set the Content-Type unless you are working in the MIME domain. The ContentType property is intended to set the value of Content-Type used in MIME.

The full set of HTTP headers used in the request is built by selecting the headers using the algorithm defined in the following steps:

1. Set the Host header, based on either the request URL or the incoming HTTPRequestHeader header section of the message.
2. Select one or more headers in an HTTPRequestHeader header.
3. If no Content-Type header is yet defined, create one by using a non-empty value in the ContentType property.
4. Select one or more headers in an HTTPInputHeader header (an HTTPInputHeader header is created automatically by an HTTPInput node).
5. If no Content-Type header is yet defined, create one with the default value `text/xml; charset=`*`ccsid of the message body`*
6. If no SOAPAction header is yet defined, create one with the default value `''`.
7. Create or overwrite the Content-Length header.

Attention: The HTTPRequest or HTTPAsyncRequest node always rewrites the Content-Length header, even if you have cleared `Generate default HTTP headers from input or request`. This action ensures that the content is correct.

If an HTTPRequestHeader header exists in the received message, the HTTPRequestHeader header is updated with all changed or added values.

HTTP listeners

You can choose between integration node listeners and integration server (embedded) listeners to manage HTTP messages in your HTTP or SOAP flows. Learn about the two types of listener, how ports are assigned to them, and how you can switch from one to the other for individual integration servers.

Your choice of listener affects message flows that handle inbound web service requests and synchronous replies by using the following nodes:

- SOAPInput with SOAPReply
- HTTPInput with HTTPReply

Message flows that do not handle inbound requests but that instigate outbound requests or asynchronous responses by using the following nodes are not affected:

- SOAPRequest
- SOAPAsyncRequest
- SOAPAsyncResponse
- HTTPRequest
- HTTPAsyncRequest
- HTTPAsyncResponse

The choice of listener also affects integration services and REST APIs. Integration services use a SOAPInput node, so they use the listener that is specified for the SOAPInput node. REST APIs use an HTTPInput node, so they use the listener that is specified for the HTTPInput node.

The integration node listener requires access to system queues on the queue manager specified on the integration node, so you must install IBM MQ Server if you want to use an integration node listener. However, if you use HTTP nodes or SOAP nodes with the integration server embedded listener, IBM MQ is not required.

- "Integration server (embedded) listeners" on page 796
- "Integration node listeners" on page 797
- "Using both integration node and embedded listeners" on page 798

Integration server (embedded) listeners

Each integration server can run an embedded listener. You can configure the listener for HTTP or HTTPS configurations by setting values in the integration server's `server.conf.yaml` file:

```
HTTPConnector:
    #ListenerPort: 0                       # Set non-zero to set a specific port, defaults to
 7800.
    #ListenerAddress: '0.0.0.0'            # Set the IP address for the listener to listen on.
 Default is to listen on all addresses.
    #AutoRespondToHTTPHEADRequests: false   # Automatically respond to HTTP HEAD requests
 without invoking the message flow. Set to true or false, default is false.
    #ServerName: ''                        # Set the value to be returned in the 'Server' HTTP
 header.
    #CORSEnabled: false                    # Set the value to true to make the listener respond
 to valid HTTP CORS requests.
    #CORSAllowOrigins: '*'
    #CORSAllowCredentials: false
    #CORSExposeHeaders: 'Content-Type'
    #CORSMaxAge: -1
    #CORSAllowMethods: 'GET,HEAD,POST,PUT,PATCH,DELETE,OPTIONS'
    #CORSAllowHeaders: 'Accept,Accept-Language,Content-Language,Content-Type'
HTTPSConnector:
    HTTPSConnector:
    #ListenerPort: 0                       # Set non-zero to set a specific port, defaults to
 7843.
    #ListenerAddress: '0.0.0.0'            # Set the IP address for the listener to listen on.
 Default is to listen on all addresses
    #ReqClientAuth: true
    #KeyAlias: ''
    #KeyPassword: 'myPassword'             # Set the password or alias to the password of the
 key
    #KeystoreFile: '/path/to/keystore.jks'
    #KeystorePassword: 'myPassword'        # Set the password or alias to the password of the
 keystore
    #KeystoreType: 'JKS'                   # Set the keystore type, can be 'JKS' or 'p12'.
 Default is JKS.
    #TruststoreFile: /path/tp/truststore.jks
    #TruststorePassword: 'myPassword'      # Set the password or alias to the password of the
 keystore
    #TruststoreType: 'JKS'                 # Set the truststore type, can be 'JKS' or 'p12'.
 Default is JKS.
    #CORSEnabled: false                    # Set the value to true to make the listener respond
 to valid HTTP CORS requests
    #CORSAllowOrigins: '*'
    #CORSAllowCredentials: false
    #CORSExposeHeaders: 'Content-Type'
    #CORSMaxAge: -1
    #CORSAllowMethods: 'GET,HEAD,POST,PUT,PATCH,DELETE,OPTIONS'
    #CORSAllowHeaders: 'Accept,Accept-Language,Content-Language,Content-Type'
```

```
    #EnableTLSTrace: false                  # Enables tracing of TLS handshake messages to the
 console
```

For more information about these parameters, see Integration server HTTP listener parameters (SOAP and HTTP nodes).

The following examples assume that an integration server is associated with an integration node.

Run the following command to display the HTTPConnector properties for an integration server called *default* on integration node *integrationNodeName*:

```
mqsireportproperties integrationNodeName -e default -o HTTPConnector -r
```

Run the following command to display the HTTPSConnector properties for an integration server called *default* on integration node *integrationNodeName*:

```
mqsireportproperties integrationNodeName -e default -o HTTPSConnector -r
```

By default, SOAPInput, SOAPReply, SOAPAsyncResponse, HTTPInput, HTTPReply, and HTTPAsyncResponse nodes use the integration server listener. They also use the integration server listener if the integration node listener is not available, even if you do not explicitly reconfigure them to use the integration server listener. If integration server *default* on integration node *integrationNodeName* is using the embedded listener for SOAP nodes or HTTP nodes, the following commands return a value of `true`:

```
mqsireportproperties integrationNodeName -e default -o ExecutionGroup -n
 soapNodesUseEmbeddedListener
```

```
mqsireportproperties integrationNodeName -e default -o ExecutionGroup -n
 httpNodesUseEmbeddedListener
```

If you configure any of the SOAP nodes or HTTP nodes to use the integration node listener, the previous commands return a value of `false`.

Integration node listeners

You can configure the integration node listener for HTTP and HTTPS configurations by setting values in the integration node's `node.conf.yaml` file:

```
HTTPConnector:
   ListenerPort:  7080
HTTPSConnector:
   ListenerPort:  7083
```

Run the following two commands to display the currently active settings for the integration node listener:

```
mqsireportproperties integrationNodeName -b NodeHttpListener -o HTTPConnector -r
```

```
mqsireportproperties integrationNodeName -b NodeHttpListener -o HTTPSConnector -r
```

Each connector has its own assigned port; default values are `7080` for HTTP and `7083` for HTTPS. You can change these port numbers by using the **mqsichangeproperties** command. For example, run the following command to change the port on which the integration node listener for integration node *integrationNodeName* listens for HTTP messages:

```
mqsichangeproperties integrationNodeName -b NodeHttpListener -o HTTPConnector
   -n ListenerPort -v 8085
```

Run the following command to change the port on which the integration node listener for integration node *integrationNodeName* listens for HTTPS messages:

```
mqsichangeproperties integrationNodeName -b NodeHttpListener -o HTTPSConnector
   -n ListenerPort -v 8086
```

You can configure one or more integration servers so that HTTP nodes that you deploy to those integration servers use the embedded listener, or so that SOAP nodes that you deploy to those integration servers use the integration node listener.

Using both integration node and embedded listeners

Because the option to use the embedded listener is at the integration server level, you can change your configuration such that some integration servers that are associated with an integration node use the integration node listener for HTTP nodes, SOAP nodes, or both, and other integration servers use the embedded listener for HTTP nodes, SOAP nodes, or both.

However, if you disable the integration node listener, the integration server listeners are used for all HTTP and SOAP nodes, even if you do not explicitly enable support for them.

The HTTPRequest node always communicates directly through the HTTP transport, and is therefore unaffected by your choice.

If you change the listener and port that are processing your HTTP or HTTPS messages, you must ensure that you also update your applications to use the updated configuration.

Switching from embedded listeners to an integration node listener
Configure your integration node and integration servers that are associated with an integration node to use the integration node listener for HTTP or SOAP nodes in one or more integration servers.

Before you begin

The integration node listener requires access to system queues on the queue manager specified on the integration node, so you must install

IBM MQ Server and ensure that a queue manager is specified.

About this task

You can change the configuration for integration servers that are associated with an integration node so that HTTP or SOAP nodes use the integration node listener. HTTP nodes and SOAP nodes use the integration server (embedded) listener by default, but you might want to switch to using the integration node listener.

The commands that are shown in the examples here are split across multiple lines for ease of reading. When you enter the command, you must use a single line.

Procedure

1. Check that the integration node is running.
2. If you disabled the integration node listener, run the **mqsichangeproperties** command to restart it.
   For example:

   ```
   mqsichangeproperties integrationNodeName  -b NodeHttpListener -o HTTPListener
    -n startListener -v true
   ```

3. To switch to using the integration node listener for a specific integration server that is associated with the integration node, use the **mqsichangeproperties** command to change the integration server configuration.
   - The integration node must be stopped for the switch to work. If the node is running, stop it by using the following command

     mqsistop *integrationNodeName*
   - To use the **mqsichangeproperties** command, adapt one of the following examples:

     ```
     mqsichangeproperties integrationNodeName -f -e server_name -o ExecutionGroup
     ```

```
 -n httpNodesUseEmbeddedListener -v false
```

```
mqsichangeproperties integrationNodeName -f -e server_name -o ExecutionGroup
 -n soapNodesUseEmbeddedListener -v false
```

4. Optional: If you want to use HTTP applications on multiple integration servers, you need to change the HTTP/HTTPS ports to be unique for each integration server. By default the HTTP port is set to 7800 and the HTTPS port is set to 7843. Configure your integration servers by setting properties in the `server.conf.yaml` file, as described in "Configuring an integration server by modifying the server.conf.yaml file" on page 172
5. Restart the integration node to ensure that your changes take effect.

Example

For more information about this command, and examples of changing other properties that are associated with an integration node or integration server, see the description of the **mqsichangeproperties** command.

Switching from an integration node listener to embedded listeners
Configure your integration nodes and associated integration servers so that some or all of the HTTP or SOAP nodes use an integration server (embedded) listener. SOAP nodes use an embedded listener by default. You might have changed them to use the integration node listener, but now want to return to using embedded listeners.

About this task

You can change the configuration for one or more integration servers that are associated with an integration node so that HTTP or SOAP nodes that are deployed in these integration servers use the embedded listener.

Procedure

1. Check that the integration node is running.
2. If you want all HTTP and SOAP nodes in all integration servers on the integration node to use the embedded listener, you can change the integration node configuration to disable the integration node listener.

   Run the **mqsichangeproperties** command to change the integration node configuration. Do not run this command if you want to keep the integration node listener active for at least one of your associated integration servers.

   ```
   mqsichangeproperties INODE  -b NodeHttpListener -o HTTPListener
    -n startListener -v false
   ```

   All integration servers on the specified integration node detect this change of status, and use the embedded listener when they are restarted, regardless of their own specific configuration. Therefore, you can switch to using embedded listeners for all associated integration servers by running this single command.

   If you disable the integration node listener in this way, you can configure an associated integration server to use the same port or ports that the integration node listener was using for HTTP, HTTPS, or both. Reusing the port numbers means that you do not have to change your client applications to send messages to a different port number.

3. To switch to using the embedded listener for a specific integration server on an integration node, use the **mqsichangeproperties** command to change the integration server configuration.
   - The integration node must be stopped for the switch to work. If the node is running, stop it by using the following command

     mqsistop *integrationNodeName*
   - To use the **mqsichangeproperties** command, adapt one of the following examples:

     ```
     mqsichangeproperties INODE -f -e exgroup1 -o ExecutionGroup
      -n soapNodesUseEmbeddedListener -v true
     ```

     ```
     mqsichangeproperties INODE -f -e exgroup1 -o ExecutionGroup
      -n httpNodesUseEmbeddedListener -v true
     ```

     INODE is the name of your integration node; *exgroup1* is the name of your integration server.
4. Restart the integration node to implement your changes.

Example

For more information about this command, and examples of changing other properties associated with integration nodes or integration servers, see the description of the **mqsichangeproperties** command.

Configuring message flows to process timeouts
Connect the HTTP Timeout terminal of the HTTPInput or SOAPInput nodes to further nodes to process timeouts.

Before you begin

- Read the message flows overview.
- Read about the options that you have for processing web service messages, and learn more about SOAP and HTTP.

About this task

You can configure message flows that start with an HTTPInput or SOAPInput node by connecting the HTTP Timeout terminal to further nodes for processing timeouts:

- On HTTPInput nodes, messages are propagated through this terminal only when you have configured your integration servers such that the HTTP nodes are using the embedded integration server listener.
- On SOAPInput nodes, messages are propagated through this terminal only when you are using an HTTP binding, and you have configured your integration servers such that the SOAP nodes are using the embedded integration server listener.

If these conditions are not met when you deploy the BAR file for the message flow that includes one of these nodes, a warning is generated, and the path of the message flow that you have connected to the HTTP Timeout terminal is ignored. No further warnings are generated until the next restart.

To set a static timeout value in an input node:

1. Create a message flow, or open an existing flow.
2. In the Message Flow editor, select the input node for this message flow. The node properties are displayed in the Properties view (below the editor pane).
3. Set an appropriate time for the timeout interval in the property `Maximum client wait time`. The default interval is 180 seconds.

   If this time expires, and you have not connected one or more nodes to the HTTP Timeout terminal, the listener that received the client request message responds with a SOAP Fault message indicating that a timeout has occurred.

4. If you want to provide customized timeout processing, connect one or more nodes to the HTTP Timeout terminal. You must include in this sequence the reply node that matches the input node. Therefore, if your message flow starts with an HTTPInput node, you must include an HTTPReply; if your message flow starts with a SOAPInput node, you must include a SOAPReply node.

To set a dynamic timeout value in an input node:

- Override the timeout value set on the input node by using the Java plug-in API to update it in a JavaCompute node using the `MbUtilities.changeIdentifierTimeout()` method. The following code shows an example of the `changeIdentifierTimeout` method:

```
MbMessage localEnv = assembly.getLocalEnvironment();
MbElement rootElem = localEnv.getRootElement();
MbElement repIdElement = rootElem.getFirstElementByPath(
   "/Destination/SOAP/Reply/ReplyIdentifier");
Object repId = repIdElement.getValue();
boolean success = changeIdentifierTimeout((byte[])repId, timeout);
```

- Override the timeout value set on the input node by using the CHANGEIDENTIFIERTIMEOUT function.

You can derive the value that you use to replace the existing value by several means; for example:

- Read a record from a database.
- Use a value from a field within the message body.

By propagating from the HTTP Timeout terminal you can then change the contents of the responses that your message flow sends to the client. The processing on the sequence of nodes that you connect to the HTTP Timeout terminal is also subject to a further timeout, so that the client always gets a response within a known timeout interval.

When a message is propagated from the HTTP Timeout terminal the message tree contains the input headers of the original input message and a message body that is the fault timeout message. The original message body along with other information relating to the timeout can be accessed in the LocalEnvironment message tree. For example, the following record can be found in the LocalEnvironment:

```
(0x01000000:Name):HTTP = (
  (0x01000000:Name):Input = (
    (0x01000000:Name):Timeout = (
      (0x03000000:NameValue):OriginalClientLastWaitTime = 10 (INTEGER)
      (0x03000000:NameValue):OriginalClientWaitTime     = 15 (INTEGER)
      (0x03000000:NameValue):OriginalMessageMadeTheFlow = TRUE (BOOLEAN)
      (0x03000000:NameValue):OriginalRequestIdentifier  =
         X'485454500000000000000000000000c00c000000000000' (BLOB)
      (0x03000000:NameValue):OriginalInboundMessage     = X'3c3e' (BLOB)
    )
  )
)
```

For SOAPInput nodes the SOAPReply node connected on the HTTP Timeout terminal path must send a SOAP fault response message and the reply status code of 500 cannot be altered. For HTTPInput nodes any response message can be sent from the HTTP Timeout terminal and the reply status code can be changed by updating the `LocalEnvironment.Destination.HTTP.ReplyStatusCode` message tree field.

Using compression with HTTP and SOAP nodes
You can configure HTTP and SOAP nodes to use HTTP compression and decompression when sending and receiving messages.

The nodes can be configured to compress request messages, accept and decompress responses, and decompress input messages.

Background information

The HTTP transport supports the sending of compressed data. Specific HTTP header fields are used to indicate that the data is compressed, and which compression technique was used for the compression. When an HTTP client makes an HTTP request, it can specify that it accepts a compressed response, and

also which types of compressed data it accepts. The three compression techniques supported by the HTTP transport are GZIP, deflate, and compress.

The Accept-Encoding field is used in an HTTP request to indicate which encodings are accepted in a response message to the request. This field is used to specify the values of `gzip`, `deflate`, `compress` and `identity`, which are not case-sensitive. A value of `identity` indicates that the data must not be compressed. A wildcard of `*` indicates that any encoding is accepted. The Accept-Encoding field can also be empty, indicating that no encoding is accepted.

The Content-Encoding header field indicates the encoding that is applied to the data and it can contain the tokens of `gzip`, `deflate`, and `compress`, but not `identity`. When data is compressed for an HTTP message, the Content-Encoding field contains the name of the compression technique that was used, enabling the recipient to identify the compression scheme and correctly decompress the message data.

The TE header field is used in a request header to indicate which extension transfer encodings it will accept in the response. This is similar to the Accept-Encoding field.

The Transfer-Encoding field is similar to the Content-Encoding field, except that it is a property of the message and not of the entity. The Transfer-Encoding field is primarily used to indicate that a response message is chunked. It is possible to receive a Transfer-Encoding header that indicates other transfer encodings such as "chunked, gzip". In this case the gzip applies to the transfer of the data, not the actual data itself.

HTTP compression in IBM App Connect Enterprise

IBM App Connect Enterprise supports compression and decompression with the HTTP and SOAP nodes using the Accept-Encoding and Content-Encoding fields as follows:

- In a request node, such as an HTTPRequest or SOAPRequest node, if you select the property to allow compressed responses, the integration node sets the Accept-Encoding field on the outbound request.
- When compressing a request, the request nodes set the Content-Encoding header field to indicate that the data is compressed. When receiving a response, the request nodes check the Content-Encoding field to determine if the response is compressed. Multiple values in the header field indicate that the data has been compressed more than once using multiple compression functions.
- When receiving a request, the input nodes check the contents of the Content-Encoding field to determine if the contents of the message are compressed. In response and input nodes, a Content-Encoding value of `x-gzip` is treated as `gzip`.
- IBM App Connect Enterprise supports only the `gzip` and `deflate` compression encodings; the `compress` encoding is not supported.
- Compression and decompression is handled only through the Accept-Encoding and Content-Encoding header fields; the TE and Transfer-Encoding header fields are not supported.

When compressing a request HTTP message, the node checks the Content-Encoding field to determine if the message data is already compressed. If the data is already compressed in the specified scheme then no further compression is needed. However, if the existing data is already compressed in an encoding that is not specified in the node properties, the node further compresses the compressed bit stream using the encoding specified in the node properties. The value of the Content-Encoding field is updated to indicate the additional encoding applied to the data. For example, a Content-Encoding value of `deflate,gzip` indicates that the message should be first decompressed using deflate and then further decompressed using gzip.

The HTTP and SOAP nodes do not support quality values in the Accept-Encoding field, which allow a user to specify a preferred weighting of compression types for responses. Any quality values in the Accept-Encoding field are ignored.

Using HTTP compression with the HTTP and SOAP nodes

The request nodes can request and process compressed responses. You can configure the request nodes to indicate that compression in responses is allowed, and the node automatically decompresses a

compressed response. The Accepts-Encoding header is set to indicate that GZIP and deflate compression techniques are accepted. If the Accept-Encoding header is already set, the node does not override it.

If the request or the AsyncResponse nodes receive a GZIP or deflate compressed response, it is decompressed and any header indication that the message is compressed is removed. If the nodes receive an invalid compressed response or an unrecognized compression function, an exception is raised indicating that the data could not be decompressed.

The request nodes can also send compressed requests. You can configure the node to specify which compression technique is used for the compressed requests that it sends. The value of the Content-Encoding header is set to indicate the compression that is used. You can override this value in the local environment for an individual message. If you override the local environment with a value that is not recognized by the node, the existing node value for Use compression is used.

The input nodes can decompress input data that is compressed using the GZIP and deflate compression scheme. If the input node receives a message that is not compressed validly, a fault message is returned to the client and the input message is not propagated to the message flow. This can occur if:

- The Content-Encoding header is set to an unrecognized compression function
- The message body is not compressed correctly using the named Content-Encoding value.

Using HTTP asynchronous request-response
You can make HTTP requests and receive a response asynchronously using the HTTPAsyncRequest and HTTPAsyncResponse nodes, or the SOAPAsyncRequest and SOAPAsyncResponse nodes, in your message flow.

The SOAPAsyncRequest node supports two methods of asynchronous requests when using HTTP transport:

1. Using WS-Addressing to direct the response to the paired SOAPAsyncResponse node. The SOAPAsyncRequest node waits for the HTTP 202 acknowledgment before continuing with the message flow, and the SOAPAsyncRequest node blocks if the acknowledgment is not received. A new HTTP connection is made by the backend server to reply to the SOAPAsyncResponse node. This is the default behavior.
2. Using HTTP asynchronous request-response. When the SOAPAsyncRequest property **Use HTTP asynchronous request-response** is selected, the SOAPAsyncRequest node passes the HTTP socket to the paired SOAPAsyncResponse node to allow the backend server to reply using the same socket. When this option is selected, WS-Addressing headers are sent, but are not required to be understood by the backend server. The WS-Addressing headers are not marked as mustUnderstand, and the replyTo header is set to anonymous. The node therefore uses asynchronous HTTP socket handling instead of WS-Addressing to make HTTP requests and receive an asynchronous response.

The HTTPAsyncRequest node always uses asynchronous HTTP socket handling to make asynchronous requests and responses.

The asynchronous request nodes return control to the flow without waiting for a response. This action frees the request thread to handle further requests, while the response is handled by the paired response node on a different thread and in a new transaction. The response node can be in a separate message flow, but it must be in the same integration server as its paired request node.

The HTTP asynchronous request-response behavior is asynchronous only because IBM App Connect Enterprise treats the request and the response as such, enabling the message flow to retrieve the next message without waiting for the response from the asynchronous request. The backend server sees the request-response as a typical synchronous HTTP request.

Scenarios

You might want to use HTTP asynchronous request-response in the following situations:

- When interacting with a backend server that has a high latency, using synchronous HTTP requests might result in many outstanding requests which require large numbers of threads to make enough

simultaneous connections to the backend server. Using asynchronous HTTP socket handling instead allows the response to be decoupled from the request.

- Using HTTP asynchronous request-response in the SOAPAsyncRequest is an alternative to using WS-Addressing with a non-anonymous replyTo header.

For information about using HTTP asynchronous request-response with the SOAPAsyncRequest node, see "Choosing asynchronous behavior for the SOAPAsyncRequest node" on page 814.

Limitations

When using the HTTPAsyncRequest node, or the SOAPAsyncRequest node with HTTP asynchronous request-response, the following limitations apply:

- Redirection is not supported. Messages with a redirection status code (3xx) are treated as an error, and the response is routed to the Error terminal of the response node while following the properties specified on the Error tab.
- WS-RM is not compatible with using HTTP asynchronous request-response.

Web services example messages

Examples of complete HTTP messages show typical content in specific scenarios.

The following examples show complete HTTP messages. The first message is a request sent by an HTTPRequest node to a web service that provides a lookup service:

```
POST /greenpages/servlet/rpcrouter HTTP/1.0
Host: localhost
Content-Type: text/xml; charset=utf-8
Content-Length: 520
SOAP Action: ""
Cookie: JSESSIONID=0000B5OSLFIUDMQZFAUXKHD5ZDQ:-1

<?xml version='1.0' encoding='UTF-8'?>
<SOAP-ENV:Envelope xmlns:SOAP-ENV="http://schema.xmlsoap.org.soap/envelope/"
                   xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
                   xmlns:xsd="http://www.w3.org/2001/XMLSchema">
<SOAP-ENV:Body>
<ns1:getUserByName xmlns:ns1="http://tempuri.org/imb.GreenPages"
                   SOAP-ENV:encodingStyle="http:/schemas.xmlsoap.org/soap/encoding/">
<nameField xsl:type="xsd:string">bloggs, joe</nameField>
</ns1:getUserByName>
</SOAP-ENV:Body>
</SOAP-ENV:Envelope>
```

The `Cookie` is an example of a value that can be retrieved from the HTTPRequest tree.

The second message is the corresponding web service response returned to the HTTPRequest node:

```
HTTP/1.0 200 OK
Server: WebSphere Application Server/4.0
Content-Type: text/xml; charset=utf-8
Content-Length: 1585
Content-Language: en
Connection: close

<?xml version='1.0' encoding='UTF-8'?>
<SOAP-ENV:Envelope xmlns:SOAP-ENV="http://schema.xmlsoap.org.soap/envelope/"
                   xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
                   xmlns:xsd="http://www.w3.org/2001/XMLSchema">
<SOAP-ENV:Body>
<ns1:getUserByNameResponse xmlns:ns1="http://tempuri.org/imb.GreenPages"
                   SOAP-ENV:encodingStyle="http:/schemas.xmlsoap.org/soap/encoding/">
<return xmlns:ns2="http://www.greenpages.com/schemas/GreenPagesRemoteInterface"
        xsi:type="ns2:imb.UserRecord">
<fullName xsi:type="xsd:string">Joseph Bloggs</fullName>
<empNum xsi:type="xsd:int">65874</empNum>
<deskPhone xsi:type="xsd:string">(718)545-3623</deskPhone>
</return>
</ns1:getUserByNameResponse>
</SOAP-ENV:Body>
</SOAP-ENV:Envelope>
```

For more information about HTTP return codes, see HTTP Response codes.

Processing web service messages

Use IBM App Connect Enterprise nodes and services to connect to other web services providers and consumers.

About this task

A web service is a software system designed to support interoperable computer-to-computer interaction over a network. It has an interface described by an XML-based specification; specifically, the Web Service Definition Language, or WSDL.

Web services fulfill a specific task or a set of tasks. A web service is described using a standard, formal XML notation, called its service description, that provides all the details necessary to interact with the service, including message formats (that detail the operations), transport protocols, and location.

The nature of the interface hides the implementation details of the service, so that it can be used independently of the hardware or software platform on which it is implemented. The interface is also independent of the programming language in which it is written. This interface handles web service-based applications as loosely coupled, component-oriented, cross-technology implementations. Web services can be used alone, or with other web services, to carry out a complex aggregation or a business transaction.

The IBM App Connect Enterprise environment provides two different development styles for developing web services:

- For an assisted development environment to provide web services, where you can focus on implementing service operations instead of directly handling the transport-level interaction, consider using Services. For more information, see “Developing integration solutions by using integration services” on page 1984.
- For more fine-grained control over developing a web service, consider creating your own message flows which use SOAPInput nodes directly. For more information, see “Message flows for web services” on page 820. You might want to do this in the following situations:
  - You are providing a web service over JMS.
  - You want to provide a gateway for multiple services.
  - You want more operational control over how web services are grouped.

To call a web service as part of your message flow, include SOAPRequest nodes in the message flow appropriately. For more information, see “Message flows for web services” on page 820.

For more information about how IBM App Connect Enterprise acts as a web service provider or consumer, and how it complies with external web service standards, see “IBM App Connect Enterprise and web services” on page 806.

When you have developed an IBM App Connect Enterprise solution, the IBM App Connect Enterprise administrator can apply policies to affect how messages are secured or when messages are retransmitted. The administrator also controls how the listener behaves, and can work with an external listener for HTTP traffic. For more information, see the following topics:

- “Web Services Reliable Messaging” on page 818
- “WS-Security” on page 2650
- “HTTP proxy servlet overview” on page 141

The following topics describe how to work with web services:

- “IBM App Connect Enterprise and web services” on page 806
- “What is SOAP?” on page 807
- “What is WSDL?” on page 815
- “What is SOAP MTOM?” on page 816

- "What is WS-Addressing?" on page 816
- "WebSphere Service Registry and Repository" on page 1005
- "Message flows for web services" on page 820

IBM App Connect Enterprise supplies a Java servlet that you can use in an external Web servlet container such as IBM WebSphere Application Server or Apache Tomcat, to receive HTTP requests from web services client applications. The HTTP proxy servlet is described in "HTTP proxy servlet overview" on page 141.

IBM App Connect Enterprise and web services

an IBM App Connect Enterprise application can participate in a web services environment as a service requester, as a service provider, or both.

The SOAP domain supports these formats:

- Common web services message formats SOAP 1.1, SOAP 1.2, SOAP with Attachments (SwA), and MTOM.
- Consistent SOAP logical tree format, which is independent of the exact message format.
- WS-Addressing, WS-Security, and WS-RM standards.

The following nodes are provided for use in the SOAP domain:

- node
- node
- node
- node
- node
- node
- node

Use the SOAP nodes and SOAP domain where possible; see "Web services: when to use SOAP or HTTP nodes" on page 790.

Web services support conforms to the following open standards:

- SOAP 1.1 and 1.2
- SOAP Messages with Attachments
- MTOM
- HTTP 1.1
- WSDL 1.1
- WS-Addressing (new SOAP domain only)
- WS-Security (new SOAP domain only)
- WS-RM
- WS-MakeConnection

WSDL is also validated against the WS-I Basic Profile Version 1.1. Conformance to the guidelines in this specification improves interoperability with other applications.

For more information about how an IBM App Connect Enterprise application can participate in a web services environment, see the IBM App Connect Enterprise web page on developerWorks®.

What is a web service?

A web service is defined by the World Wide Web Consortium (W3C) as a software system designed to support interoperable machine-to-machine interaction over a network.

A web service fulfills a specific task or a set of tasks, and is described by a service description in a standard XML notation called Web Services Description Language (WSDL). The service description

provides all of the details necessary to interact with the service, including message formats (that detail the operations), transport protocols, and location.

Other systems use SOAP messages to interact with the web service, typically by using HTTP with an XML serialization in conjunction with other Web-related standards.

The WSDL interface hides the details of how the service is implemented, and the service can be used independently of the hardware or software platform on which it is implemented, and independently of the programming language in which it is written.

Applications that are based on web services are loosely-coupled, component-oriented, cross-technology implementations. Web services can be used alone, or in conjunction with other web services to carry out a complex aggregation or a business transaction.

What is SOAP?
SOAP is an XML message format used in web service interactions. SOAP messages are typically sent over HTTP or JMS, but other transport protocols can be used. The use of SOAP in a specific web service is described by a WSDL definition.

There are two versions of SOAP in common use: SOAP 1.1 and SOAP 1.2. Both are supported in IBM App Connect Enterprise. SOAP is defined in the following documents issued by World Wide Web Consortium (W3C):

- Simple Object Access Protocol (SOAP) 1.1 (W3C note).
- SOAP Version 1.2 Part 0: Primer (W3C recommendation).
- SOAP Version 1.2 Part 1: Messaging Framework (W3C recommendation).
- SOAP Version 1.2 Part 2: Adjuncts (W3C recommendation).

Support for SOAP in IBM App Connect Enterprise includes:

- SOAP parser and domain. See "SOAP parser and domain" on page 526.
- SOAP nodes to send and receive messages in SOAP format.
- IBM supplied message definitions for SOAP 1.1 and SOAP 1.2. These message definitions support validation, ESQL content assist, and the creation of message maps for use with SOAP messages, in the SOAP and other XML domains. See Message Sets: IBM supplied messages that you can import.
- HTTP and JMS transport to send SOAP messages. See the W3C SOAP over JMS specification: http://www.w3.org/TR/soapjms/

WSDL validation in IBM App Connect Enterprise refers to the WS-I Basic Profile. For more information, see the WS-I, and in particular the WS-I Basic Profile document:

- http://www.ws-i.org/
- http://www.ws-i.org/deliverables

The structure of a SOAP message
A SOAP message is encoded as an XML document, consisting of an <Envelope> element, which contains an optional <Header> element, and a mandatory <Body> element. The <Fault> element, contained in <Body>, is used for reporting errors.

The SOAP envelope
<Envelope> is the root element in every SOAP message, and contains two child elements, an optional <Header> element, and a mandatory <Body> element.

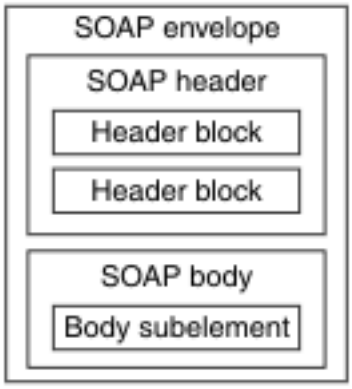
The SOAP header
<Header> is an optional subelement of the SOAP envelope, and is used to pass application-related information that is to be processed by SOAP nodes along the message path; see "The SOAP header" on page 808.

The SOAP body
<Body> is a mandatory subelement of the SOAP envelope, which contains information intended for the ultimate recipient of the message; see "The SOAP body" on page 810.

The SOAP fault

<Fault> is a subelement of the SOAP body, which is used for reporting errors; see "The SOAP fault" on page 810.

XML elements in <Header> and <Body> are defined by the applications that make use of them, although the SOAP specification imposes some constraints on their structure. The following diagram shows the structure of a SOAP message.



The following code is an example of a SOAP message that contains header blocks (the <m:reservation> and <n:passenger> elements) and a body (containing the <p:itinterary> element).

```
<?xml version='1.0' Encoding='UTF-8' ?>
<env:Envelope xmlns:env="http://www.w3.org/2003/05/soap-envelope">
 <env:Header>
  <m:reservation xmlns:m="http://travelcompany.example.org/reservation"
  env:role="http://www.w3.org/2003/05/soap-envelope/role/next">
   <m:reference>uuid:093a2da1-q345-739r-ba5d-pqff98fe8j7d</m:reference>
   <m:dateAndTime>2007-11-29T13:20:00.000-05:00</m:dateAndTime>
  </m:reservation>
  <n:passenger xmlns:n="http://mycompany.example.com/employees"
  env:role="http://www.w3.org/2003/05/soap-envelope/role/next">
   <n:name>Fred Bloggs</n:name>
  </n:passenger>
 </env:Header>
 <env:Body>
  <p:itinerary xmlns:p="http://travelcompany.example.org/reservation/travel">
   <p:departure>
     <p:departing>New York</p:departing>
     <p:arriving>Los Angeles</p:arriving>
     <p:departureDate>2007-12-14</p:departureDate>
     <p:departureTime>late afternoon</p:departureTime>
     <p:seatPreference>aisle</p:seatPreference>
   </p:departure>
   <p:return>
     <p:departing>Los Angeles</p:departing>
     <p:arriving>New York</p:arriving>
     <p:departureDate>2007-12-20</p:departureDate>
     <p:departureTime>mid-morning</p:departureTime>
     <p:seatPreference></p:seatPreference>
   </p:return>
  </p:itinerary>
 </env:Body>
</env:Envelope>
```

The SOAP header

The SOAP header (the <Header> element) is an optional sub-element of the SOAP envelope, and is used to pass application-related information that is processed by SOAP nodes along the message flow.

The immediate child elements of the header are called *header blocks*. A header block is an application-defined XML element, and represents a logical grouping of data which can be targeted at SOAP nodes that might be encountered in the path of a message from a sender to an ultimate receiver.

SOAP header blocks can be processed by SOAP intermediary nodes, and by the ultimate SOAP receiver node. However, in a real application, not every node processes every header block. Each node is typically designed to process particular header blocks, and each header block is processed by particular nodes.

The SOAP header enables you to add features to a SOAP message in a decentralized manner without prior agreement between the communicating parties. SOAP defines some attributes that can be used to indicate what can deal with a feature and whether it is optional or mandatory. Such control information includes, for example, passing directives or contextual information related to the processing of the message. This control information enables a SOAP message to be extended in an application-specific manner.

Although the header blocks are application-defined, SOAP-defined attributes on the header blocks indicate how the header blocks must be processed by the SOAP nodes. SOAP-defined attributes include:

encodingStyle
Indicates the rules used to encode the parts of a SOAP message. SOAP defines a narrower set of rules for encoding data than the flexible encoding that XML enables.

actor (SOAP 1.1) or role (SOAP 1.2)
In SOAP 1.2, the role attribute specifies whether a particular node will operate on a message. If the role specified for the node matches the role attribute of the header block, the node processes the header. If the roles do not match, the node does not process the header block. In SOAP 1.1, the actor attribute performs the same function.

Roles can be defined by the application, and are designated by a URI. For example, `http://example.com/Log` might designate the role of a node which performs logging. Header blocks that are processed by this node specify `env:role="http://example.com/Log"` (where the namespace prefix `env` is associated with the SOAP namespace name of `http://www.w3.org/2003/05/soap-envelope`).

The SOAP 1.2 specification defines three standard roles in addition to those which are defined by the application:

`http://www.w3.org/2003/05/soap-envelope/none`
None of the SOAP nodes on the message path should process the header block directly. Header blocks with this role can be used to carry data that is required for processing of other SOAP header blocks.

`http://www.w3.org/2003/05/soap-envelope/next`
All SOAP nodes on the message path are expected to examine the header block (provided that the header has not been removed by a node earlier in the message path).

`http://www.w3.org/2003/05/soap-envelope/ultimateReceiver`
Only the ultimate receiver node is expected to examine the header block.

mustUnderstand
This attribute is used to ensure that SOAP nodes do not ignore header blocks which are important to the overall purpose of the application. If a SOAP node determines, by using the **role** or **actor** attribute, that it should process a header block, the action taken depends on the value of the **mustUnderstand** attribute.

- 1 (SOAP 1.1) or `true` (SOAP 1.2): The node must either process the header block in a manner consistent with its specification, or not at all (and throw a fault).
- `0` (SOAP 1.1) or `false` (SOAP 1.2): The node is not obliged to process the header block.

In effect, the **mustUnderstand** attribute indicates whether processing of the header block is mandatory or optional.

relay (SOAP 1.2 only)
When a SOAP intermediary node processes a header block, the SOAP intermediary node removes the header block from the SOAP message. By default, the SOAP intermediary node also removes all header blocks that it ignored (because the **mustUnderstand** attribute had a value of `false`). However, when the relay attribute is specified with a value of `true`, the SOAP intermediary node retains the unprocessed header block in the message.

The SOAP body
The SOAP body (the <Body> element) is a mandatory sub-element of the SOAP envelope, which contains information intended for the ultimate recipient of the message.

The body element and its associated child elements are used to exchange information between the initial SOAP sender and the ultimate SOAP receiver. SOAP defines one child element for the body: the <Fault> element, which is used for reporting errors. Other elements in the body are defined by the web service that uses them.

The SOAP fault
The SOAP fault (the <Fault> element) is a sub-element of the SOAP body, which is used for reporting errors.

If present, the SOAP fault element must appear as a body entry and must not appear more than once in a body element. The sub-elements of the SOAP fault element are different in SOAP 1.1 and SOAP 1.2.

SOAP 1.1

In SOAP 1.1, the SOAP fault contains the following sub-elements:

<faultcode>
The<faultcode> element is a mandatory element in the <Fault> element. It provides information about the fault in a form that can be processed by software. SOAP defines a small set of SOAP fault codes covering basic SOAP faults, and this set can be extended by applications.

<faultstring>
The <faultstring> element is a mandatory element in the <Fault> element. It provides information about the fault in a form intended for a human reader.

<faultactor>
The <faultactor> element contains the URI of the SOAP node that generated the fault. A SOAP node that is not the ultimate SOAP receiver must include the <faultactor> element when it creates a fault; an ultimate SOAP receiver is not obliged to include this element, but might do so.

<detail>
The <detail> element carries application-specific error information related to the <Body> element. It must be present if the contents of the <Body> element were not successfully processed. The <detail> element must not be used to carry information about error information belonging to header entries. Detailed error information belonging to header entries must be carried in header entries.

SOAP 1.2

In SOAP 1.2, the SOAP fault contains the following sub-elements:

<Code>
The <Code> element is a mandatory element in the <Fault> element. It provides information about the fault in a form that can be processed by software. It contains a <Value> element and an optional <Subcode> element.

<Reason>
The <Reason> element is a mandatory element in the <Fault> element. It provides information about the fault in a form intended for a human reader. The <Reason> element contains one or more <Text> elements, each of which contains information about the fault in a different language.

<Node>
The <Node> element contains the URI of the SOAP node that generated the fault. A SOAP node that is not the ultimate SOAP receiver must include the <Node> element when it creates a fault; an ultimate SOAP receiver is not obliged to include this element, but might do so.

<Role>
The <Role> element contains a URI that identifies the role in which the node was operating at the point the fault occurred.

<Detail>

The <Detail> element is an optional element, which contains application-specific error information related to the SOAP fault codes describing the fault. The presence of the <Detail> element has no significance as to which parts of the faulty SOAP message were processed.

SOAP nodes

The SOAP nodes act as points in the flow where web service processing is configured and applied. Properties on the SOAP nodes control the processing carried out and can be configured by supplying a WSDL definition, or by manually configuring properties, or both.

SOAP nodes

- The SOAPInput and SOAPReply nodes are used in a message flow which implements a web service. These SOAP nodes are used to construct a message flow that implements a web service provider. The SOAPInput node listens for incoming web service requests, and the SOAPReply sends responses back to the client; see node and node.
- A client can send an HTTP GET request to the endpoint exposed by the flow, suffixed with a query string ?wsdl, and receive a response with the WSDL definition used to configure the flow. For a full description, see “Message flow configuration with a WSDL file” on page 839.
- The SOAPRequest node is used in a message flow to call a web service provider synchronously. Calling a web service synchronously means that the node sends a web service request and waits, blocking the message flow, for the associated web service response to be received before the message flow continues; see node.
- The SOAPAsyncRequest and SOAPAsyncResponse nodes are used to construct a message flow (or pair of flows) which calls a web service asynchronously. Calling a web service asynchronously means that the SOAPAsyncRequest node sends a web service request, but the request does not block the message flow by waiting for the associated web service response to be received because the web service response is received at the SOAPAsyncResponse node, which is in a separate flow. The Node Correlator identifies the logical pairing of the responses against the original requests. Multiple requests can, therefore, be handled in parallel; see node and node.
- You can work on the payload of the SOAP body using the SOAPExtract and SOAPEnvelope nodes. The SOAPExtract node can interoperate with the SOAP domain. The SOAP nodes do not require the SOAPEnvelope node, because they can directly handle non-SOAP messages, but the SOAPEnvelope node is still required for the HTTP nodes. See node and node.
- You can change the Operation mode of the SOAP nodes so that they act in gateway mode. In gateway mode, a WSDL is not required to configure the nodes since they handle generic request/response and one-way SOAP messages that are not tied to a specific WSDL. For more details, see “Gateway operation mode for SOAP nodes” on page 827.

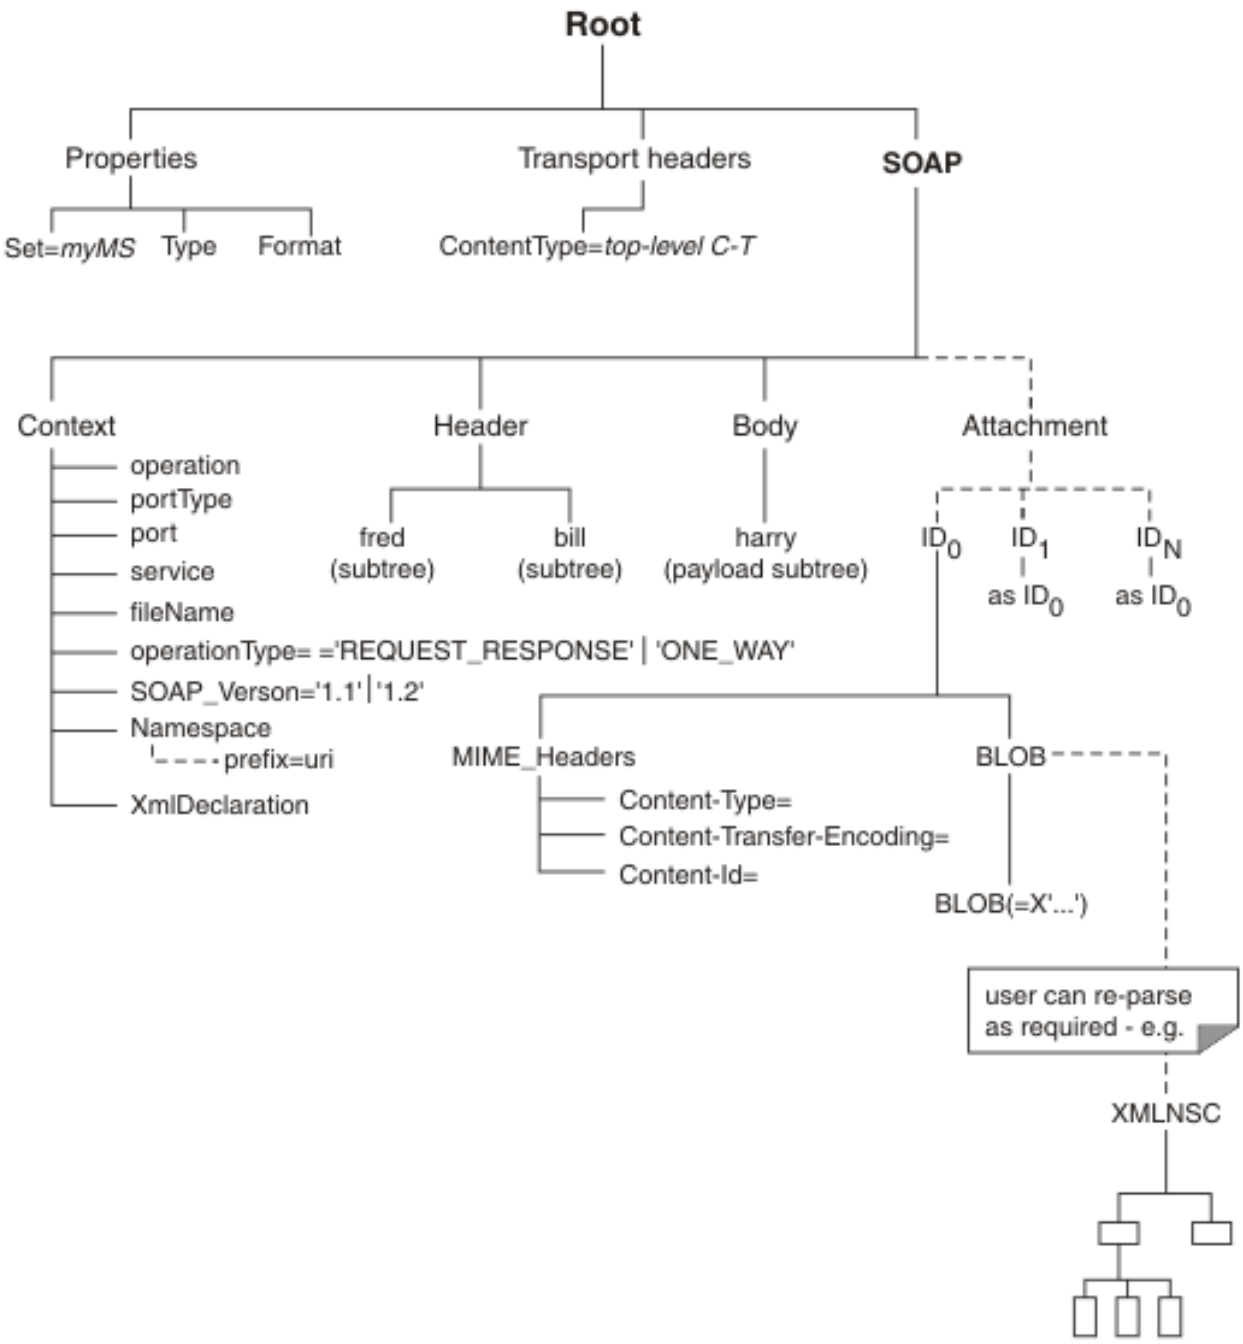
The W3C SOAP specification refers to "SOAP nodes" meaning a unit of application logic (see Web Services Glossary). Typically, references to "SOAP nodes" in the IBM App Connect Enterprise Information Center are referring to IBM App Connect Enterprise SOAP nodes.

If you are using SOAP nodes and HTTP nodes in message flows on a single integration node, you can choose to handle HTTP messages by using either the integration node listener or embedded integration server listeners. If a listener in your configuration receives messages that both SOAPInput and HTTPInput nodes might get, you must carefully check the URL specifications in these nodes. If both URL specifications match an incoming message, the wrong type of node might get the message, and processing might fail or produce unexpected results. This situation occurs if you specify identical values for the Path suffix for URL properties of the HTTPInput node and the SOAPInput node. It can also occur if you use wildcards in either or both specifications, and an incoming message matches both properties.

SOAP tree overview

This tree format allows you to access the key parts of the SOAP message in a convenient way.

This is a diagrammatic representation of the SOAP domain tree:



The SOAP tree contains the following elements:

SOAP.Header
Contains the SOAP header blocks (children of `Envelope.Header`)

SOAP.Body
Contains the SOAP payload (children of `Envelope.Body`)

The content of the Body subtree depends on the WSDL style.

SOAP.Attachment
Contains attachments for an SwA message in their non encoded format.

Note that attachments for an MTOM message are represented inline as part of the SOAP content in a base 64 representation.

SOAP.Context
Contains the following information:

- Input; populated by the SOAPInput node:
  - `operation` - the WSDL operation name. In Gateway mode, the operation is assumed to be the name of the element that is the first child of the SOAP Body element, if present, otherwise it is the constant name 'ComIbmBrokerGenericGatewayOperation'.
  - `portType` - the WSDL port type name. In Gateway mode, this item is empty.
  - `port` - the WSDL port name (if known). In Gateway mode, this item is empty.
  - `service` - the WSDL service name (if known). In Gateway mode, the service has the constant name 'ComIbmBrokerGenericGatewayService'.
  - `fileName` - the original WSDL file name. In Gateway mode, this item is empty.
  - `operationType` - one of 'REQUEST_RESPONSE', 'ONE_WAY', 'SOLICIT_RESPONSE', 'NOTIFICATION'. In Gateway mode, without WSDL, this field contains 'GATEWAY'. This means 'REQUEST_RESPONSE' or 'GATEWAY_ONE_WAY', which means that the node has detected the operation type to be one-way.
  - `SOAP_Version` - one of '1.1' or '1.2'.
  - `Namespace` - Contains `nameValue` child elements; the `name` is the Namespace prefix, and the `value` is the Namespace URI as it appears in the bit stream.
  - `XmlDeclaration` - represents the standard XML declaration.
- Output; the following fields can be placed in `SOAP.Context` to provide override information when SOAPRequest or SOAPAsyncRequest nodes serialize a SOAP message:
  - `SOAP_Version` - one of '1.1' or '1.2'
  - `Namespace` - Contains `nameValue` child elements that define the namespace prefix (the `name`) to be used for a specified namespace URI (the `value`).

    An output message uses the namespace prefixes defined here to qualify any elements in the corresponding namespaces.

    If the `SOAP.Context` was originally created at an input node, it might already contain all the namespace prefix definitions that you need.

    If `SOAP.Context` does not exist, or the outgoing message uses additional namespaces, the SOAP parser generates any required namespace prefixes automatically.

    Alternatively, you can specify your own namespace prefix; the specific name of a namespace prefix does not usually affect the meaning of a message, with one important exception. If the message content contains a `qualified name`, the message must contain a matching namespace prefix definition.

    For example, if the output message is a SOAP Fault containing a `<faultcode>` element with the value `soapenv:Server`, a namespace prefix (which is case sensitive) for `soapenv` must be defined in the logical tree:

```
-- Build SOAP Fault message. Note that as well as defining the correct
-- namespace for the Fault element, it is also necessary to bind the
-- namespace prefix used in the faultcode element (this is set up under
-- SOAP.Context.Namespace)

-- Send back a new user defined SOAP 1.2 fault message
DECLARE soapenv NAMESPACE 'http://www.w3.org/2003/05/soap-envelope';
DECLARE xml     NAMESPACE 'http://www.w3.org/XML/1998/namespace';
DECLARE myNS    NAMESPACE 'http://myNS';

SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soapenv = soapenv;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:myNS = myNS;

SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Code.soapenv:Value = 'soapenv:Receiver';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Code.soapenv:Subcode.soapenv:Value = 'my:subcode value';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Reason.soapenv:Text = 'my Reason string';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Reason.soapenv:Text.(SOAP.Attribute)xml:lang = 'en';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Node = 'my Node string';
```

```
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Role = 'my Role string';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Detail.my:Text = 'my detail string';
```

```
-- Send back a new user defined SOAP 1.1 fault message
DECLARE soapenv NAMESPACE 'http://schemas.xmlsoap.org/soap/envelope/';
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soapenv = soapenv;

SET OutputRoot.SOAP.Body.soapenv:Fault.faultcode = 'soapenv:Receiver';
SET OutputRoot.SOAP.Body.soapenv:Fault.faultstring = 'my fault string';
SET OutputRoot.SOAP.Body.soapenv:Fault.faultactor = 'my fault actor';
SET OutputRoot.SOAP.Body.soapenv:Fault.detail.Text = 'my detail string';
```

Only `Namespace`, `SOAP_Version`, and `XmlDeclaration` influence the bit stream generated for a SOAP tree; the other fields are for information only.

To build a graphical data map for the SOAP domain, use the supplied IBM message for the SOAP domain tree as the input for the map, the output, or both. Use the Cast or Submap features of the Graphical Data Mapper to define the specific content of the SOAP body. See Using message maps for more information about mapping functions.

Web services: when to use SOAP or HTTP nodes
HTTP and SOAP nodes can both be used to interact with web services. Typically you use SOAP nodes when working with SOAP-based web services.

For SOAP-based web services, several advantages exist if you use the SOAP nodes and the SOAP message domain instead of the HTTP transport nodes and XMLNSC message domain.

- Support for WS-Addressing, WS-Security and SOAP headers.
- A common SOAP logical tree format, independent of the bitstream format.
- Runtime checking against WSDL.
- Automatic processing of SOAP with Attachments (SwA).
- Automatic processing of Message Transmission Optimization Mechanism (MTOM).

Although the HTTP nodes can process SwA messages, you must use the MIME message domain and design your flow to handle the attachments explicitly, and use custom logic to extract and parse the SOAP.

Cases where it might be better to use HTTP nodes include:

- Message flows that interact with web services that use different standards, such as REST or XML-RPC.
- Message flows that never use WS-Addressing, WS-Security, SwA, or MTOM.

Choosing asynchronous behavior for the SOAPAsyncRequest node
Choose between WS-Addressing and HTTP asynchronous request-response to make asynchronous requests using the SOAPAsyncRequest node with HTTP transport.

Before you begin

Read the concept information about “Using HTTP asynchronous request-response” on page 803.

About this task

The SOAPAsyncRequest node can use HTTP or JMS transport. It is linked as a pair with a SOAPAsyncResponse node using a unique identifier to correlate response messages with the original request.

The SOAPAsyncRequest node sends a web service request, but the node does not wait for the associated web service response to be received. This asynchronous functionality enables multiple outbound requests to be made almost in parallel because the outbound request is not blocked waiting for the response. The web service response is received by the SOAPAsyncResponse node, which can be in a separate message flow.

The SOAPAsyncRequest node supports two methods of asynchronous requests when using HTTP transport:

1. Using WS-Addressing to direct the response to the paired SOAPAsyncResponse node. The SOAPAsyncRequest node waits for the HTTP 202 acknowledgment before continuing with the message flow, and the SOAPAsyncRequest node blocks if the acknowledgment is not received. A new HTTP connection is made by the backend server to reply to the SOAPAsyncResponse node. This is the default behavior.
2. Using HTTP asynchronous request-response. When the SOAPAsyncRequest property **Use HTTP asynchronous request-response** is selected, the SOAPAsyncRequest node passes the HTTP socket to the paired SOAPAsyncResponse node to allow the backend server to reply using the same socket. When this option is selected, WS-Addressing headers are sent, but are not required to be understood by the backend server. The WS-Addressing headers are not marked as mustUnderstand, and the replyTo header is set to anonymous. The node therefore uses asynchronous HTTP socket handling instead of WS-Addressing to make HTTP requests and receive an asynchronous response.

Typically you should choose the HTTP asynchronous request-response method to make asynchronous requests using the SOAPAsyncRequest node with HTTP transport. To use this behavior, ensure that the SOAPAsyncRequest node property **Use HTTP asynchronous request-response** is selected.

However, you might want to use WS-Addressing instead to make asynchronous requests using the SOAPAsyncRequest node in the following cases:

- If you want to use WS-Addressing to explicitly set the replyTo header for the response message
- If the backend server has a high latency, you might want to use WS-Addressing instead of HTTP asynchronous request-response so that the HTTP socket is not left open for a long time.

To use WS-Addressing instead of HTTP asynchronous request-response behavior when you are using HTTP transport, ensure that the SOAPAsyncRequest node property **Use HTTP asynchronous request-response** is cleared. This is the default behavior of the SOAPAsyncRequest node.

What is WSDL?
WSDL is an XML notation for describing a web service. A WSDL definition tells a client how to compose a web service request and describes the interface that is provided by the web service provider.

IBM App Connect Enterprise supports WSDL 1.1, as defined in the following document issued by the World Wide Web Consortium (W3C): Web Services Description Language (WSDL) 1.1. IBM App Connect Enterprise support for WSDL also adheres to the Web Services Interoperability Organization (WS-I) Basic profile 1.1; see Web Services Interoperability Organization (WS-I).

A WSDL definition is divided into separate sections that specify the logical interface and the physical details of a web service. The physical details include both endpoint information, such as HTTP port number, and binding information, which specifies how the SOAP payload is represented and which transport is used.

Support for WSDL in IBM App Connect Enterprise includes:

- Import of WSDL to create message roots in an application or library; see "Importing from WSDL" on page 2305.
- Generation of WSDL from a message set; see Message Sets: WSDL generation.
- WSDL editor with text and graphical design views.
- Use of WSDL to configure nodes in the SOAP domain; for example, you can drag WSDL onto a node, and a client can request the WSDL that was used to configure a SOAPInput node. For more details, see "Message flow configuration with a WSDL file" on page 839

When you import or generate WSDL, the WSDL is validated against the WS-I Basic Profile. You must fix validation errors before the application, library, or message set can be deployed. Validation warnings do not prevent deployment, but can indicate potential interoperability problems. The validated WSDL becomes an integral part of the application, library, or message set.

The WSDL editor supports a graphical design view so that you can navigate from the WSDL to its associated message roots. The application or library contains all the message roots (or the message set contains all the message definitions) required by message flows that are working with the web service described by the WSDL. At development time, the message roots or definitions support ESQL

Content Assist and the creation of mappings. At run time, the deployed application, library, or message set supports schema validation in the SOAP, XMLNSC, and MRM domains. In the SOAP domain, runtime checks are also made against the WSDL itself, and WSDL information is included in the SOAP logical tree.

What is SOAP MTOM?
SOAP Message Transmission Optimization Mechanism (MTOM) is the use of MIME to optimize the bitstream transmission of SOAP messages that contain significantly large base64Binary elements.

The MTOM message format allows bitstream compression of binary data. Data that would otherwise have to be encoded in the SOAP message is instead transmitted as raw binary data in a separate MIME part. A large chunk of binary data takes up less space than its encoded representation, so MTOM can reduce transmission time, although it can increase processor usage. Candidate elements to be transmitted in this way are defined as base64Binary in the WSDL (XML Schema).

An MTOM message is identified by a Content-Type with a type of `application/xop+xml`.

The SOAP domain handles inbound MTOM messages automatically, and MTOM parts are reincorporated automatically into the SOAP Body.

The use of outbound MTOM messages can be configured on the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes; for details, see "SOAP MTOM and the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes" on page 849.

For details of the external specification published by the World Wide Web Consortium (W3C), see SOAP MTOM.

What is WS-Addressing?
Web Services Addressing (WS-Addressing) is a World Wide Web Consortium (W3C) specification that aids interoperability between web services by defining a standard way to address web services and provide addressing information in messages.

Start here to find out how IBM App Connect Enterprise supports WS-Addressing.

The WS-Addressing specification introduces two primary concepts: endpoint references, and message addressing properties. This topic contains an overview of each concept. For further details, select the following links to access the WS-Addressing specifications:

- W3C WS-Addressing specifications
- W3C submission WS-Addressing specification

Endpoint references (EPRs)

EPRs provide a standard mechanism to encapsulate information about specific endpoints. EPRs can be propagated to other parties and then used to target the web service endpoint that they represent. The following table summarizes the information model for EPRs.

Abstract Property name	Property type	Multiplicity	Description
[address]	xs:anyURI	1..1	The absolute URI that specifies the address of the endpoint.
[reference parameters]*	xs:any	0..unbounded	Namespace qualified element information items that are required to interact with the endpoint.
[metadata]	xs:any	0..unbounded	Description of the behavior, policies and capabilities of the endpoint.

The following prefix and corresponding namespace is used in the previous table.

Prefix	Namespace
xs	http://www.w3.org/2001/XMLSchema

The following XML fragment illustrates an endpoint reference. This element references the endpoint at the URI http://example.com/fabrikam/acct, has metadata specifying the interface to which the endpoint reference refers, and has application-defined reference parameters of the http://example.com/fabrikam namespace.

```
<wsa:EndpointReference xmlns:wsa="http://www.w3.org/2005/08/addressing"
                       xmlns:wsaw="http://www.w3.org/2006/05/addressing/wsdl"
                       xmlns:fabrikam="http://example.com/fabrikam"
                       xmlns:wsdli="http://www.w3.org/2005/08/wsdl-instance"
                       wsdli:wsdlLocation="http://example.com/fabrikam
                       http://example.com/fabrikam/fabrikam.wsdl">
    <wsa:Address>http://example.com/fabrikam/acct</wsa:Address>
    <wsa:Metadata>
        <wsaw:InterfaceName>fabrikam:Inventory</wsaw:InterfaceName>
    </wsa:Metadata>
    <wsa:ReferenceParameters>
        <fabrikam:CustomerKey>123456789</fabrikam:CustomerKey>
        <fabrikam:ShoppingCart>ABCDEFG</fabrikam:ShoppingCart>
    </wsa:ReferenceParameters>
</wsa:EndpointReference>
```

Message addressing properties (MAPs)

MAPs are a set of well defined WS-Addressing properties that can be represented as elements in SOAP headers. MAPs can provide either a standard way of conveying information, such as the endpoint to which message replies should be directed, or information about the relationship that the message has with other messages. The MAPs that are defined by the WS-Addressing specification are summarized in the following table.

Abstract WS-Addressing MAP name	MAP content type	Multiplicity	Description
[action]	xs:anyURI	1..1	An absolute URI that uniquely identifies the semantics of the message. This proprety corresponds to the [address] property of the endpoint reference to which the message is addressed. This value is required.
[destination]	xs:anyURI	1..1	The absolute URI that specifies the address of the intended receiver of this message. This value is optional because, if not present, it defaults to the anonymous URI that is defined in the specification, indicating that the address is defined by the underpinning protocol.
[reference parameters]*	xs:any	0..unbounded	Correspond to the [reference parameters] property of the endpoint reference to which the message is addressed. This value is optional.
[source endpoint]	EndpointReference	0..1	A reference to the endpoint from which the message originated. This value is optional.
[reply endpoint]	EndpointReference	0..1	An endpoint reference for the intended receiver of replies to this message. This value is optional.
[fault endpoint]	EndpointReference	0..1	An endpoint reference for the intended receiver of faults relating to this message. This value is optional.

Abstract WS-Addressing MAP name	MAP content type	Multiplicity	Description
[relationship]*	xs:anyURI plus optional attribute of type xs:anyURI	0..unbounded	A pair of values that indicate how this message relates to another message. The content of this element conveys the [message id] of the related message. An optional attribute conveys the relationship type. This value is optional.
[message id]	xs:anyURI		An absolute URI that uniquely identifies the message. This value is optional.

The abstract names in the previous tables are used to refer to the MAPs throughout this documentation.

The following example of a SOAP message contains WS-Addressing MAPs:

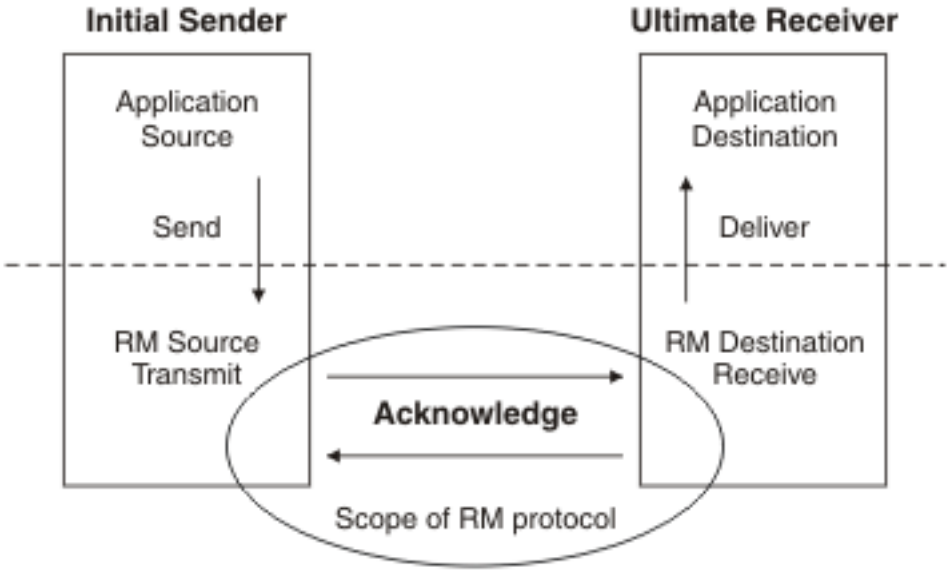
```
<S:Envelope xmlns:S="http://www.w3.org/2003/05/soap-envelope"
            xmlns:wsa="http://www.w3.org/2005/08/addressing"
            xmlns:fabrikam="http://example.com/fabrikam">
    <S:Header>
        ...
     <wsa:To>http://example.com/fabrikam/acct</wsa:To>
              <wsa:ReplyTo>
        <wsa:Address> http://example.com/fabrikam/acct</wsa:address>
              </wsa:ReplyTo>
            <wsa:Action>...</wsa:Action>
              <fabrikam:CustomerKey wsa:IsReferenceParameter='true'>123456789
              </fabrikam:CustomerKey>
             <fabrikam:ShoppingCart wsa:IsReferenceParameter='true'>ABCDEFG
             </fabrikam:ShoppingCart>
              ...
    </S:Header>
        <S:Body>
          ...
        </S:Body>
</S:Envelope>
```

Web Services Reliable Messaging
IBM App Connect Enterprise supports WS-RM (Web Services Reliable Messaging), which allows two systems to reliably exchange messages with each other.

Web Services Reliable Messaging (WS-RM) is an OASIS standard that allows two systems to reliably exchange SOAP messages with each other. The purpose of WS-RM is to ensure delivery of messages in situations such as the destination endpoint being temporarily unavailable (for example, in the case of a server restart) or the message path crossing multiple transport connections, any of which might fail (for example, across a firewall). WS-RM offers greater reliability when using HTTP transport, but has a performance impact.

WS-RM is applicable only to HTTP transport. If you configure WS-RM on a message flow that uses JMS transport, the WS-RM settings are not used when the flow is deployed.

Systems that implement WS-RM retransmit messages that have not been successfully delivered and acknowledged, and prevent duplicate messages from being delivered to the application destination. WS-RM is a web services protocol and can be used with WS-Security and WS-Addressing.



Reliable messaging takes place between two endpoints known as the *reliable messaging source* and the *reliable messaging destination*. Before the messages are sent, the reliable source and reliable destination perform a message exchange to establish a *Sequence*. A Sequence is identified by a unique identifier and comprises a sequence of messages which are numbered starting from one. Sending a group of messages in a Sequence ensures the reliability of all the messages in that Sequence.

The reliable messaging source sends each message one or more times to the reliable messaging destination. The destination sends back acknowledgment for each message it receives to show that the message has been successfully received. If the reliable messaging source does not receive an acknowledgment that a message has been received by the destination, it sends the message again until an acknowledgment is received.

When all messages in a sequence have been successfully received by the destination and acknowledgment received by the source, the source sends a TerminateSequence message to instruct the destination that the message sequence is complete.

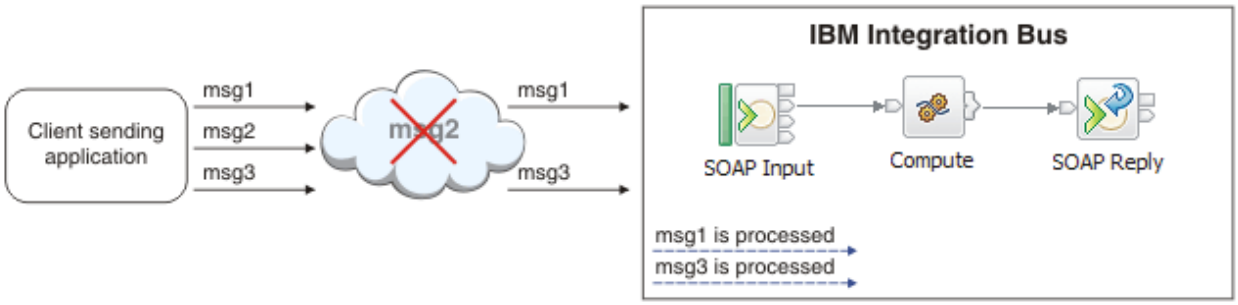
If the client is waiting for messages that have not been delivered, it can initiate a WS-MakeConnection request. WS-MakeConnection is a specification that describes how messages can be exchanged between a server and a client using a transport-specific back-channel. The client's MakeConnection request allows the server to respond with any queued messages that have not been received by the client.

IBM App Connect Enterprise does not support using HTTP compression or SSL with WS-RM.

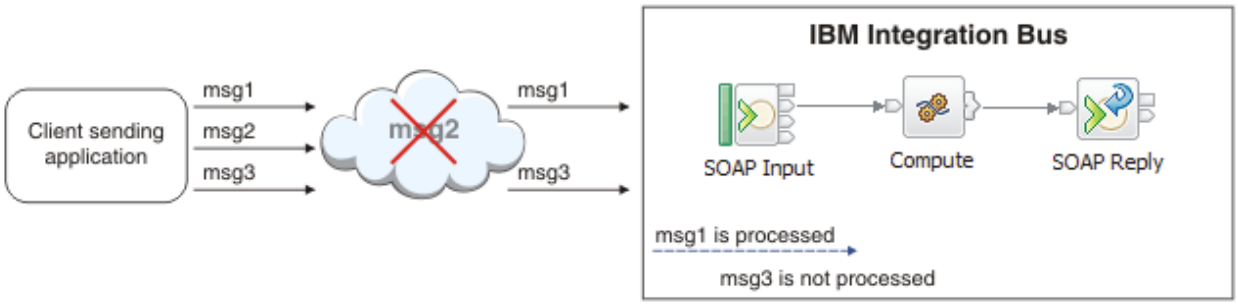
Message order

WS-RM specifies a number of delivery assurances to be supported by the provider. The InOrder assurance asserts that messages are delivered to the application destination by the RM Destination in the order in which they were sent, according to their sequence numbers. For example, if the RM Destination receives messages in the order m1, m3, m2, it first delivers m1, then retains m3 until it receives m2, and then delivers m2 and m3 to the application destination. Messages are not persisted in the event of an integration node restart.

The following diagram shows an example scenario where InOrder is not used, and messages need not be delivered in the order in which they were sent. The second message in the sequence is lost, but the third message is processed even though the second message has not been delivered.



In the following scenario the option is selected, and messages must be delivered in the order in which they are sent. The second message in the sequence is lost, and so the third message is not processed until msg2 can be delivered.



The InOrder assurance affects only inbound message processing, for example, when the policy set that asks for InOrder delivery is associated with a SOAPInput node or an inbound message flow. When InOrder delivery is enabled for inbound SOAP message processing, the messages are processed by the flow according to their message number as assigned by the RM Source.

The InOrder assurance does not apply to outbound message processing. If InOrder delivery is selected for outbound SOAP message processing, for example, with a SOAPRequest node, messages are not necessarily delivered to the application destination in the same order in which they are sent from the message flow.

Message flows for web services

Message flows that need to work with web services can use either the SOAP domain or one of the XML domains.

The following topics describe both types of flow.

- “SOAP domain message flows” on page 820
- “XML domain message flows” on page 826

The following topics describe web services tasks.

- “WS-Addressing overview” on page 830
- “WSDL overview” on page 837
- “Configuring message flows to process timeouts” on page 800
- “SOAP MTOM and the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes” on page 849

SOAP domain message flows

SOAP domain message flows typically use SOAP nodes, WSDL, and a common logical tree format that is independent of the exact format of the web service message.

The following nodes are provided for use in the SOAP domain:

- node
- node

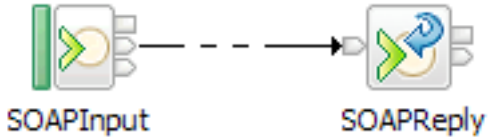
- node
- node
- node

The following nodes can also be used to simplify SOAP payload processing in a message flow; these nodes are not specific to the SOAP domain.

- node
- node

The SOAP nodes are used together in the following basic patterns:

- As a web service provider, for example:



- As a web service consumer, for example:

Or:

- As a web service facade, for example, by combining the provider and consumer scenarios:

You can use the SOAPExtract node in conjunction with these patterns to extract the SOAP payload. If you are working with the HTTP nodes, you can use the SOAPEnvelope node to rebuild a SOAP envelope.

The main SOAP domain nodes are typically configured by WSDL, and in this mode, a prerequisite for a SOAP domain message flow is a deployable WSDL. You can either import a WSDL file into an application or library, or generate a WSDL file from an existing message set. For more information about importing a WSDL file, see “Importing from WSDL” on page 2305. For more information about generating WSDL from an existing message set, see Message Sets: WSDL generation.

Deployable WSDL can then be used to configure SOAP nodes. You can do this by dragging the WSDL resource onto the node or by selecting the required WSDL resource from the node properties.

The WSDL is deployed with your completed message flow, enabling exceptions to be raised if a web service message does not correspond to the specified WSDL description.

You can change the operation mode of the SOAP domain nodes so that they act in gateway mode. In gateway mode, a WSDL is not required to configure the nodes because they handle generic request/

response and one-way SOAP messages that are not tied to a specific WSDL. For more details, see “Gateway operation mode for SOAP nodes” on page 827.

A client can send an HTTP GET request to the endpoint exposed by a SOAPInput node, suffixed with a query string `?wsdl`, and receive a response with the WSDL definition used to configure the flow; see “Message flow configuration with a WSDL file” on page 839.

The SOAP domain uses a common logical tree format that is independent of the exact format of the web service message. For details of the SOAP tree format, see “SOAP tree overview” on page 811. Useful WSDL information is included in the logical tree under `SOAP.Context`.

Example usage of WS-Addressing
Set up a sample message flow by using WS-Addressing, and test the flow.

About this task

Complete the steps in the following set of topics.

1. Build the main message flow that includes SOAP nodes, a Filter node, and a Mapping node by following the instructions in “Building the main message flow” on page 822.
2. Build a logging message flow, so that you can send a reply to an address different from the originating client, by following the instructions in “Building the logger message flow” on page 824.
3. Deploy the message flows by following the instructions in “Deploying the message flows” on page 825.
4. Test the message flows, by using a tool that uses HTTP. This task illustrates that the contents of the SOAP message determine where the replies are routed. Follow the instructions in “Testing the message flows” on page 825.

Building the main message flow
You can construct a sample main message flow to use with WS-Addressing.

About this task

These steps are the first in a set of instructions on setting up your system to use WS-Addressing with IBM App Connect Enterprise; they explain how to set up a message flow to use this feature. This topic describes how to construct a sample main message flow when using WS-Addressing.

Procedure

1. Switch to the Integration Development perspective.
2. Create message flow and message set projects using the **Start from WSDL and/or XSD files** wizard.
3. Select the **Web Services** folder on the message flow palette to display the contents, and drag a SOAPInput node onto the canvas.
4. Add a SOAPExtract node to the message flow to remove the SOAP envelope from the incoming message, followed by a SOAPReply node. Wire the Out terminal of the SOAPInput node to the In terminal of the SOAPExtract node, and wire the Out terminal of the SOAPExtract node to the In terminal of the SOAPReply node.
5. Select the WSDL file that you need under **Deployable WSDL** from the Active Working Set, and drag it onto the SOAPInput node.

   The SOAPInput node is configured with the WSDL.
6. Select the **Construction** folder on the message flow palette to display the contents.

7. Select a Trace node and move the mouse to the right of the SOAPExtract node.
   a) Click the left mouse button to add the node to the message flow.
      The name is selected automatically.
   b) Press **Enter** to accept the default name.
   c) Wire the submitPORequest terminal of the SOAPExtract node to the In terminal of the Trace node.
8. Select the Trace node to display the properties.
   a) Use the menu to set **Destination** to `File`
   b) Set the **File path** that you require.
   c) Enter the **Pattern** that you require.
9. Expand the **Routing** folder on the palette and select **Filter**.
10. Add the Filter node to the right of the Trace node.
    a) Type the name for the node that you require and press **Enter**.
    b) Wire the Out terminal of the Trace node to the In terminal of the Filter node.
11. Select the Filter node to display the properties.
    a) Enter the **Data source** name that you require.
    b) Change the name of **Filter expression** to the name that you selected for the Filter node.
    c) Clear the **Throw exception on database error** check box.
12. Double-click the Filter node to open the ESQL editor.
    Create or change the ESQL for the node; for more information, see "Creating ESQL for a node" on page 1618 and "Modifying ESQL for a node" on page 1620.
13. Expand the **Transformation** folder on the palette and select a Mapping node.
14. Add the Mapping node to the right of the Filter node.
    a) Type the name for the node that you require and press **Enter**.
    b) Wire the True terminal of the Filter node to the In terminal of the Mapping node.
    c) Wire the Out terminal of the Mapping node to the In terminal of the Reply node.
15. Select the Mapping node to display the properties, and change the name of the Mapping routine if required.
16. Double-click the Mapping node to open the mapping editor.
    a) Select **submitPORequest** as the map input.
    b) Select **SOAP_Domain_msg** as the map output.
    c) Click **OK**
    For more information, see Creating a message map from a Mapping node.
    The created map provides the default mapping for the Message Assembly Properties.
17. Expand the **SOAP_Domain_Msg** then **Body** in the output pane.
18. Right-click **Wildcard Message** in the output pane, then select **submitPORequest** on the input, and drag it to an element in the output below the body.
19. Set the transform type to **Submap** and then, in the list of properties, click **New..** to create the new submap.
20. In the New Map wizard for the submap, select **submitPORequest** as the input, and select **submitPOResponse** as the output.
21. Click **OK** to create the submap and enter the Graphical Data Mapping editor.
22. Expand the **submitPORequest** input tree and the **submitPOResponse** output tree and wire the required transforms from the input elements to the output.
23. Save the main map and the submap.

Building the logger message flow
This is the second of a set of instructions on setting up your system to use WS-Addressing with IBM App Connect Enterprise, and illustrates the use of a reply being sent to an address other than the originating client.

About this task

This topic describes the construction of a sample logger message flow when using WS-Addressing. This flow echoes back the input while creating a trace entry in a file to indicate that the flow has been invoked.

Procedure

1. Switch to the Integration Development perspective.
2. Select the message flow name that you used in "Building the main message flow" on page 822
3. Press the right mouse button and select **New->MessageFlow**.
   a) Enter the name that you require for this message flow; for example, `Logger`.
   b) Press **Finish** to create the flow.
4. Select the **HTTP** folder on the message flow palette to display the contents.
5. Select an **HTTPInput** node and move the mouse to the left side of the canvas.
   a) Click the left mouse button to add the node to the message flow and enter the name `Logger`.
   b) Press **Enter** to finish.
6. Select the **HTTPReply** node from the palette and move the mouse to the right of the HTTPInput node, leaving room for a node in between.
   a) Click the left mouse button to add the node to the message flow and enter the name that you require; for example, `Logger`.
   b) Press **Enter** to finish.
7. Select the **Construction** folder on the message flow palette to display the contents.
8. Select a **Trace** node and move the mouse to the right of the HTTPInput node.
   a) Click the left mouse button to add the node to the message flow and enter the name that you require; for example `Trace`.
   b) Press **Enter**.
   c) Wire the `out` terminal of the HTTPInput node to the `In` terminal of the Trace node.
   d) Wire the `out` terminal of the Trace node to the `In` terminal of the HTTPReply node.
9. Select the HTTPInput node to display the properties.
   In the **Basic** tab:
   a) Enter the **Data source** name that you require.
   b) Change the name of the input node `Logger` as the **Path suffix for URL**.
10. Select the **Input Message Parsing** tab and select `XMLNSC` as the **Message domain**.
11. Select the Trace node to display the properties.
    a) Set **Destination** to `File`
    b) Set the **File path** that you require.
    c) Enter the **Pattern** that you require.
12. Save the message flow.

Deploying the message flows
This is the third of a set of instructions on setting up your system to use WS-Addressing with IBM App Connect Enterprise, and illustrates the deployment of the message flows.

About this task

This topic describes the deployment of the message flows that you have already constructed.

Procedure

1. Select the **LocalProject** project under **BARs** in the navigator pane.
   a) Right-click in the Application Development view, then click **New** > **BAR file**.
   b) Set the location to `LocalProject`.
   c) In the Name field, enter the name that you selected for the main message flow described in "Building the main message flow" on page 822.
   d) Click **Finish** to open the BAR Editor.
2. In the BAR Editor, complete the following steps.
   a) Select **Message flows, libraries, and other message flow dependencies**, and select the main message flow and logger message flow, and the main message set.
   b) Click **Build and Save** and confirm that the build operation was successful.
3. To deploy the message flows to the default integration servers, right-click the BAR file that you have just built, then click **Deploy**.
4. Select the default integration server and click **Finish** to start the deployment.
   Ensure that you receive a successful response message, and press **OK** to dismiss the information dialog.
5. Use the **Deployment Log** to confirm that the deploy operation was successful:

Testing the message flows
This is the fourth of a set of instructions about how to set up your system to use WS-Addressing with IBM App Connect Enterprise; these instructions illustrate how to test the message flows.

About this task

This topic describes how to test the message flows that you have already constructed. In this scenario, you use a tool that uses HTTP protocol rather than IBM MQ protocol. You can use any tool that has the facilities that are described in the following procedure.

Procedure

1. Start the tool and select `http://localhost:nnnn/`, where *nnnn* is the address of the port that you are using.
2. Set the URL to the host, port, and selection for the deployed flow.
   The SOAPInput nodes listen on a different port from the HTTP nodes, and the listener is built into the integration server rather than using a different process.
3. The SOAPInput node expects a SOAPAction entry in the HTTP headers, therefore you must add one.
   a) Click **Add New Header**.
   b) Enter the **Value** part of the header.
      The value must match the `SOAPAction` attribute of the `SOAP:operation` element in your code.
   c) Select **New Header** in the **Name** pane.
   d) Change the name from **New Header** to `SOAPAction` and click **Enter**.
4. Select **Load File** and go to the directory that contains the XML file you want to use.

5. Select the file and click **Open**.

   Note the following conditions:

   - If the message does not include any WS-Addressing entries, the `ReplyTo` and `FaultTo` locations default to `anonymous`. This means that the results are returned on the original client connection.
   - If the message includes a WS-Addressing header (`ReplyTo`) with a value of `anonymous`, the reply is returned to the original client by using the original TCP/IP connection.
   - If the message includes a WS-Addressing header with a value of `FaultTo` explicitly included, the reply is returned to that address rather than the default of using the location that was specified in the `ReplyTo` header.

6. Click **Send** to test the flow.

   The result appears in the right pane.

XML domain message flows

If you are not using the SOAP domain, your message flow must take account of the bitstream format of the web service messages with which you are working. A different logical tree format is used by each domain.

If the messages are SOAP, you can use either the XMLNSC domain or the MRM XML domain. Both domains offer validation. The XMLNSC domain is more efficient, while the MRM XML domain can be useful if you have specific message transformation requirements (for example, if your message flow also uses binary data formats).

If the messages use MIME (for example, SOAP with Attachments or MTOM), you can use the MIME domain. In this case, your message flow typically needs to identify at least the MIME part that corresponds to the SOAP payload, then explicitly parse this part by using the XMLNSC or MRM domain.

In the SOAP domain, WSDL is used to configure your nodes automatically with the appropriate endpoint information. If you are not using the SOAP domain, select and configure the transport nodes manually. Typical WSDL bindings are:

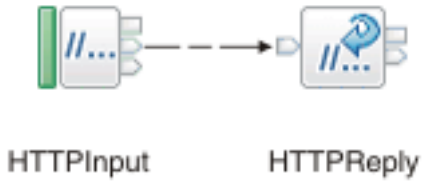
- SOAP/HTTP; in which case, implement a flow by using HTTP nodes. Use the HTTPInput and HTTPReply nodes if a flow implements a web service, or use the HTTPRequest node if a flow calls a web service.
- SOAP/JMS; where you implement a flow by using JMS or MQ nodes.

You can configure message flows that receive input messages from clients by using one transport, and interact with a web service or legacy application by using another.

You can propagate a message to more than one location. For example, the web service response to be returned to a client by an HTTPReply node might first be sent to an auditing application by using an MQOutput node, after making any required adjustments to the message headers.

Nodes are used together in the following basic patterns, by using HTTP nodes as example transports:

- As a web service provider, for example:



- As a web service consumer, for example:

- As a web service facade, for example:

If required, you can use the SOAPExtract and SOAPEnvelope nodes in conjunction with these patterns to respectively extract the SOAP payload and rebuild a SOAP Envelope.

To enable your message flow to validate messages, deploy an appropriate application, library, or message set with the flow. The application, library, or message set must contain a WSDL file. You can import a WSDL file into an application or library, or you can generate a WSDL from an existing message set. For details about importing existing WSDL, see "Importing from WSDL" on page 2305. For details about generating WSDL from an existing message set, see Message Sets: WSDL generation.

If you have generated a WSDL file from a message set, the generated message set contains message definitions for the relevant SOAP Envelope version and for the XML payload data defined by the WSDL. If you have imported a WSDL file into an application or library, message roots are created instead of message definitions. In the XMLNSC domain, messages can be validated against the message set, application, or library. In the MRM domain, messages can be validated against a message set only. For more details, see "Validating messages" on page 610.

Gateway operation mode for SOAP nodes
The SOAPInput, SOAPRequest, and SOAPAsyncRequest nodes have two operation modes: WSDL mode, and Gateway mode.

If the node is configured to be in WSDL mode, which is the default, the web service operations performed by the node are specified by a WSDL that configures the node. In Gateway mode, SOAP nodes in a message flow handle generic SOAP request messages in the following scenarios.

Provider scenario
In a provider scenario, IBM App Connect Enterprise receives generic SOAP/HTTP or SOAP/JMS requests by using a SOAPInput node, and sends a reply to the originating client by using a SOAPReply node. A single SOAPInput node can receive any SOAP request message, and is not configured with a WSDL.

Consumer scenario
In a consumer scenario, IBM App Connect Enterprise can route a SOAP request to any external web service provider by using the SOAPRequest node or a pair of SOAPAsyncRequest and SOAPAsyncResponse nodes. Endpoint information can be specified in the local environment, which is used dynamically at run time to send the outbound request message.

Façade scenario
In a façade scenario, IBM App Connect Enterprise can receive SOAP requests from multiple different clients, and route them to any one of multiple back end web service providers, or existing systems. Endpoint information for the back-end web service provider can be specified dynamically at run time by setting values in the local environment.

The SOAP nodes act and are configured differently in the two different operation modes.

- If you configure a node in Gateway mode, some node properties are disabled because they are not applicable in Gateway mode.
  - The WSDL-specific properties are disabled when the node is switched to Gateway mode. The values are not cleared, and can be used if the node is switched back to WSDL mode.
  - The Response Message Parsing properties on the SOAPRequest node are disabled in Gateway mode.
  - Validation of the operation according to the WSDL does not take place because no WSDL exists against which to validate in Gateway mode. If a SOAPAsyncRequest and SOAPAsyncResponse

node pair is used in Gateway mode, the validation properties on the SOAPAsyncResponse node are disabled at run time, regardless of the validation settings in the BAR file.

  - No message set is associated with the node, and no schema is used. Therefore, no message validation takes place in Gateway mode. You can configure the flow downstream to enable validation.
  - Outbound MTOM is not supported in Gateway mode because validation cannot take place. However, you can enable validation, and therefore enable MTOM, by setting the Message Set in the local environment. For example:

    ```
    SET OutputRoot.Properties.MessageSet = 'myMessageSet';
    ```

    You might need to also enable validation on the Compute node or the SOAPReply node.
  - In the `User-defined SOAP headers` table on the SOAPInput node, all operations are set to `*`. The `WSDL-defined SOAP headers` table is cleared.

- Transport properties must be configured. The transport-specific properties are mandatory depending on the `Transport` property; for example, the JMS transport properties are mandatory if the selected transport is `JMS`.
- A SOAPInput node can only be configured to receive messages of a single specified transport, for example, HTTP. Use separate input nodes to send or receive messages with different transports.
- A SOAPRequest node can only be configured to send messages of a single specified transport, for example, JMS. However, you can change the transport for any message using the local environment.
- A SOAPAsyncRequest node can only be configured to send and receive messages over a single transport, for example, JMS, and this transport is always used for the paired SOAPAsyncResponse node to receive the response message. However, you can change the outbound request transport for any message by using the local environment. For example, if a SOAPAsyncRequest node is configured to use JMS transport, its paired SOAPAsyncResponse node always expects to receive responses over JMS, and this cannot be changed. At run time, the SOAPAsyncRequest node also then assumes JMS as the default transport. However, you can instruct it to instead send the request over HTTP by using the local environment. This request includes the WSA:ReplyTo JMS address for the SOAPAsyncResponse node.
- If a SOAPInput node receives a one-way SOAP request, the node attempts to detect that it is a one-way message. However, the node cannot detect all cases, and therefore it is sometimes necessary to instruct the SOAPReply node that it is a one-way message, by using the local environment. For example:

  ```
  SET OutputLocalEnvironment.Destination.SOAP.Reply.Gateway.OneWay = True;
  ```

  For more information, see “One-way messages in Gateway mode” on page 829.
- If you use the SOAPAsyncRequest node in Gateway mode, you must set the WS-Addressing `Action` property in the local environment in the message flow before the SOAPAsyncRequest node. Set this property by using `OutputLocalEnvironment.Destination.SOAP.Request.WSA.Action`.
- If you use the SOAPRequest node in Gateway mode and the remote service provider expects a SOAPAction, set the SOAPAction in the flow. In Gateway mode the SOAPAction from a WSDL is not available to the node. For example, to set the SOAPAction using ESQL:

  ```
  SET OutputRoot.HTTPRequestHeader.SOAPAction = 'mySoapAction';
  ```

  By default the SOAPRequest node sends an empty SOAPAction of `""`.
- If you use the SOAPRequest node in Gateway mode and are using WS-Addressing, you must set the WS-Addressing `Action` property in the local environment in the message flow before the SOAPRequest node. Set this property by using `OutputLocalEnvironment.Destination.SOAP.Request.WSA.Action`.
- In Gateway mode, you can add inbound "must understand" headers to the SOAPInput node or to the SOAPRequest and SOAPAsyncRequest nodes by specifying the details on the node property. However, if you will be adding services dynamically, where all the "must understand" headers cannot be known in advance, you can add these headers with a wildcard (`*`) for name, namespace, operation, or any combination of the three. This removes the need to redeploy your message flow when new services are

added. However, consider that if you add a wildcard for the name, namespace, and also operation, this means that all headers with a "must understand" flag are allowed into the flow.

- If you use the SOAPReply node as part of a façade message flow, with the SOAPInput node set to Gateway mode, and the SOAPRequest node acting in WSDL mode, disable validation on the SOAPReply node or add an explicit Message Set in the Properties folder as documented above. If you do not disable validation or reference a Message Set in the Properties folder, parsing errors occur when the message is serialized.
- In Gateway mode, the SOAP nodes send SOAP 1.1 messages by default, although they also accept inbound SOAP 1.2 messages. To send an outbound SOAP 1.2 message, set the `SOAP.Context` field to indicate that SOAP 1.2 is required. For example, to set this field using ESQL:

  ```
  SET OutputRoot.SOAP.Context.SOAP_Version = '1.2';
  ```

  The outbound message then uses a SOAP 1.2 SOAP Envelope. You can also set the namespace prefix used by the SOAP Envelope. For example, by using ESQL:

  ```
  DECLARE soapenc NAMESPACE 'http://www.w3.org/2003/05/soap-envelope';
  SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soap12 = soapenc;
  SET OutputRoot.SOAP.Context.SOAP_Version = '1.2';
  ```

  In this example, `soap12` is the prefix used in the outbound message.

One-way messages in Gateway mode
When you configure a SOAP node using WSDL, the WSDL specifies whether a given node operation is one-way or not. However, configuring a node in Gateway mode without WSDL means that this WSDL information is not available. Therefore, SOAP nodes configured as Gateways automatically attempt to detect one-way Operations based on the message content.

SOAPInput node one-way Operation detection

The SOAPInput node detects one-way messages in different ways depending on the transport used, and whether or not WS-Addressing is configured on the node.

- If the node uses HTTP transport and has WS-Addressing configured, the operation is determined to be one-way if the inbound message uses the special `WSA:None` address for the `WSA:ReplyTo` and `WSA:FaultTo` addresses.
- If the node uses HTTP transport and does not have WS-Addressing configured, no auto detection of one-way messages takes place.
- If the node uses JMS transport and has WS-Addressing configured, the operation is determined to be one-way if either of the following conditions are true:
  - The inbound message uses the special `WSA:None` address (http://www.w3.org/2005/08/addressing/none) for the `WSA:ReplyTo` and `WSA:FaultTo` addresses.
  - There is no JMS ReplyTo destination specified in the inbound message, and the inbound message uses the special `WSA:Anonymous` address (http://www.w3.org/2005/08/addressing/anonymous or http://schemas.xmlsoap.org/ws/2004/08/addressing/role/anonymous) for the `WSA:ReplyTo` and `WSA:FaultTo` addresses.
- If the node uses JMS transport and does not have WS-Addressing configured, the operation is determined to be one-way if there is no JMS ReplyTo destination specified in the inbound message.

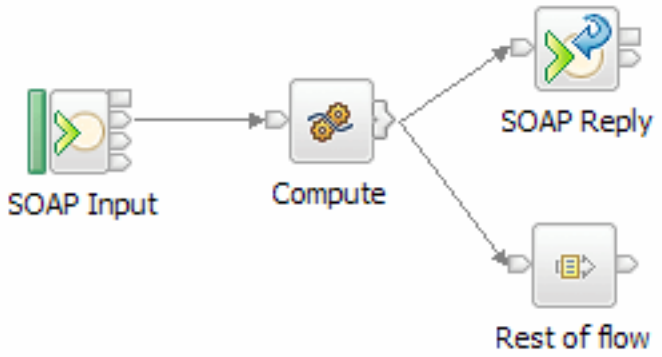
In Gateway mode, the `SOAP.Context.operationType` field is set to `GATEWAY` if the Operation is determined to be request-response, or `GATEWAY_ONE_WAY` if the Operation is determined to be one-way. If the operation is determined to be one-way, no reply is necessary or allowed. However, if the Operation is not determined to be one-way, the flow is configured with the assumption that the flow sends a reply. Therefore, if the Operation is one-way, you must specify that the Operation is one-way in order to allow the flow to free up resources, and, if HTTP is being used, to send an HTTP 202 acknowledgment back

to the originating client. Do this by setting the following field in the local environment before wiring the message to a SOAPReply node:

```
SET OutputLocalEnvironment.Destination.SOAP.Reply.Gateway.OneWay = 'true';
```

This setting instructs the SOAPReply node to complete the Message Exchange Pattern before sending an HTTP 202 acknowledgment, if required, and freeing up its resources.

One approach for using this setting would be in a Gateway flow like this:



In this flow, the Compute node determines if the message is one-way. If the message is one-way, the Compute node sets the local environment one-way setting, and sends a message to the SOAPReply node to complete the Message Exchange Pattern. If the flow is a Gateway flow and the one-way local environment option is set, any message received by the SOAPReply node causes it to ignore the message content and complete the Message Exchange Pattern. The flow can then continue through the other terminal of the Compute node.

It is not an error to send a message to the SOAPReply node with the one-way local environment option set if the message has been automatically determined to be a one-way message.

SOAPRequest node one-way Operation detection

In Gateway mode, the SOAPRequest node automatically detects whether a message is one-way only if WSA is used and the `WSA:ReplyTo` and `WSA:FaultTo` addresses are set to the special `WSA:None` address. To manually instruct the node that the message is one-way, set the following option in the local environment:

```
SET OutputLocalEnvironment.Destination.SOAP.Request.Gateway.OneWay = 'true';
```

For the SOAPRequest node, specifying that a message is one-way indicates to the node that a response is not expected, except for an HTTP 202 acknowledgment if HTTP transport is used. If JMS transport is used, it also allows the message to be sent under the control of any existing transaction, if the `Transaction mode` is to `Yes` or `Automatic`.

WS-Addressing overview
Use the following topics to learn more about WS-Addressing.

- "WS-Addressing" on page 831
- "WS-Addressing with the SOAPInput node" on page 831
- "WS-Addressing with the SOAPReply node" on page 832
- "WS-Addressing with the SOAPRequest node" on page 832
- "WS-Addressing with the SOAPAsyncRequest and SOAPAsyncResponse nodes" on page 833
- "WS-Addressing information in the local environment" on page 834

WS-Addressing
An overview of how you use WS-Addressing with IBM App Connect Enterprise.

Sending a message to an endpoint reference (EPR)

When sending a message to an endpoint reference, the following processes take place:

- The [destination] Message Addressing Property (MAP) is completed from the [address] property in the EPR.
- [reference parameters] are copied to top level SOAP headers from the [reference parameters] property of the EPR.
- The [action] property is required, but is not populated from the EPR.

  In this context, action is an absolute Internationalized Resource Identifier (IRI) that uniquely identifies the semantics implied by this message, and it must be the same as the HTTP SOAPAction if a non-empty SOAPAction is specified.
- The [message id] property must be specified if this message is part of a request-response Message Exchange Pattern (MEP); the message id is generated by default.

When replying with a non-fault message, the following processes take place:

- The EPR to reply to is selected from the [reply endpoint] MAP.
  - If this property contains the special address none, no reply is sent.
  - If this property contains the special address anonymous, the reply is sent on the return channel of the transport on which the request was received. This is the default value in the absence of any other supplied EPR.
  - Otherwise, the reply is sent to the [address] property in the Reply EPR,
- The [message id] property of the inbound message request is placed into the [relationship] property of the response, along with the predefined relationship of the reply part of the Universal Resource Identifier (URI) - which indicates that this message is a reply.

  For further information on the URI see Web Services Addressing URI Specification.
- A new [message id] property is specified for the reply, and this is generated by default.

WS-Addressing with the SOAPInput node
Various options are available when you use WS-Addressing with the SOAPInput node.

The SOAPInput node has a property for processing WS-Addressing information present in the incoming message called Use WS-Addressing.

If you select this property, the WS-Addressing information is processed and the process itself is called engaging WS-Addressing. The default is that WS-Addressing is not engaged.

You can also specify this property in the WSDL, and this property is configurable from the WSDL, automatically by the IBM App Connect Enterprise Toolkit, when the WSDL is dropped onto the node. The behavior of the node when WS-Addressing is engaged or not engaged is as follows:

Addressing not engaged
No WS-Addressing processing is performed. If a message is received that contains any WS-Addressing headers they are ignored, and no WS-Addressing processing of any kind is performed, unless they are marked as MustUnderstand.

The inbound WS-Addressing headers in this case are visible in the message when it leaves the SOAPInput node under the Header folder of the SOAP parser in the message tree.

A fault is returned to the client if WS-Addressing headers exist in the incoming message, and they meet both of the following criteria:

- Marked as MustUnderstand
- Targeted at the role the SOAPInput node is operating in

Engaging WS-Addressing is how you instruct the node to 'understand' the WS-Addressing headers. In this case the WS-Addressing headers remain in the SOAP Header section of the SOAP parser, and no other SOAP node acts upon them. In all cases, they are treated as a SOAP header with no special meaning assigned to the WS-Addressing headers.

Addressing engaged:
WS-Addressing processing is performed as stated in the WS-Addressing specification. This processing means that messages that contain either submission addressing headers or final addressing headers are accepted.

A fault is returned if both submission addressing headers and final headers are present, and either of the following conditions is met:

- Neither is marked with a role.
- They are both marked with same role and the SOAPInput node is acting in that role.

Assuming that the WS-Addressing headers are valid and the `Place WS-Addressing Headers into LocalEnvironment` check box is selected on the SOAPInput node, all headers (including detectable inbound reference parameters) are removed from the inbound message tree and are placed into the local environment tree under the `SOAP.Input.WSA` folder. Moving the WS-Addressing headers to the local environment indicates that they have been processed by the integration node. The headers are removed from the message tree because they have been processed on input; otherwise they would not be valid if the message tree was sent out without further changes. They are stored in the local environment to allow you to inspect them.

Only reference parameters from the final specification are detectable because they have an attribute called `IsReferenceParameter` that allows them to be detected. Submission reference parameter headers do not have this attribute, therefore they are not detectable, and they are not moved into the local environment tree from the message tree.

You can change WS-Addressing reply headers before the SOAPReply node is reached. For more information about changing WS-Addressing information in the local environment, see "WS-Addressing information in the local environment" on page 834.

WS-Addressing with the SOAPReply node
Various options are available when you use WS-Addressing with the SOAPReply node.

The SOAPReply node uses WS-Addressing if WS-Addressing is engaged on the SOAPInput node that is referenced by the reply identifier of the message entering the reply node.

The SOAPReply node uses addressing information in the `Destination.SOAP.Reply.WSA` folder of the local environment to determine where to send the reply and with what Message Addressing Properties (MAPs).

If the `Destination.SOAP.Reply.WSA` does not exist, or is completely empty when inspected by the SOAPReply node, the node uses the default addressing headers that were part of the incoming message. Therefore, you do not have to propagate the local environment in the default case, and addressing still works as expected.

In the case where folders exist beneath the `Reply.WSA` folder, these folders are used to update the output message. Therefore, you can change, add, or remove parts of the default reply information generated by the input node, because any changes that you made to the tree are reflected in the outgoing message by the SOAPReply node. For details about WS-Addressing information in the local environment, see "WS-Addressing information in the local environment" on page 834.

If WS-Addressing is not engaged, this node does not perform any WS-Addressing processing.

WS-Addressing with the SOAPRequest node
Various options are available when you use WS-Addressing with the SOAPRequest node.

The SOAPRequest node has a property called `Use WS-Addressing`, for processing WS-Addressing information that is present in the incoming message.

If you select this property, the WS-Addressing information is processed and the process itself is called `engaging WS-Addressing`. The default is that WS-Addressing is not engaged.

You can also specify this property in the WSDL and this is configurable from the WSDL, automatically by the IBM App Connect Enterprise Toolkit, when the WSDL is dragged onto the node. The behavior of the node when WS-Addressing is engaged or not is as follows:

Addressing not engaged
The node does not add any WS-Addressing headers to the outgoing message, and does not process any WS-Addressing headers that might be present in the response message that is received by the node.

Addressing engaged:
The node first looks at the `Destination.SOAP.Request.WSA` folder in the local environment. If this folder is empty, the node automatically generates all required WS-Addressing Message Addressing Properties (MAPs) in the outgoing message, by using the following default values:

- `Action`, from the WSDL configuration file. If this is not explicitly specified, this defaults to the value that is defined in the WSDL Binding specification.
- `To`, from the `Web Service URL` node property.
- `ReplyTo`, by using the special `Anonymous` address (assuming that the Operation being used is not a one-way message exchange program, in which case a `ReplyTo` by using the special `None` address is specified).
- `MessageID`, a unique UUID is used.

If the `Destination.SOAP.Request.WSA` folder in the LocalEnvironment is not empty, any user supplied MAPs override the default ones that were listed previously, on a property by property basis.

After the response to the request is received and if the `Place WS-Addressing Headers into LocalEnvironment` check box is selected on the SOAPRequest node, the SOAPRequest node removes all WS-Addressing headers from the response message and places them in the `SOAP.Response.WSA` folder. This folder allows you to query the headers in a similar manner to the way the SOAPInput node deals with the Input WS-Addressing headers.

WS-Addressing with the SOAPAsyncRequest and SOAPAsyncResponse nodes
The remote web service must understand WS-Addressing to be able to work with SOAPAsyncRequest and SOAPAsyncResponse nodes.

The SOAPAsyncRequest and SOAPAsyncResponse nodes require WS-Addressing; therefore, the remote web service must understand WS-Addressing to process the WS-Addressing headers that are sent from the SOAPAsyncRequest node, and to allow the response to be sent back to the corresponding SOAPAsyncResponse node, which is specified in the `address` property of the `ReplyTo` Message Addressing Property (MAP).

SOAPAsyncRequest node

The SOAPAsyncRequest node has a property called `Use WS-Addressing` that is read-only and has a default value of `true`, indicating that WS-Addressing is mandatory for this node. This property has the effect of permanently engaging WS-Addressing for this node and cannot be changed by the node, or by the WSDL that is used to configure this node.

The node first looks at the `Destination.SOAP.Request.WSA` folder in the local environment. If this folder is empty, the node automatically generates all required WS-Addressing MAPs in the outgoing message, using the following default values:

- `Action`, from the WSDL configuration file. If this value is not specified explicitly, the default value is defined by the WSDL Binding specification.
- `To`, from the `Web Service URL` node property.
- `ReplyTo`, the address of the corresponding SOAPAsyncResponse node.
- `MessageID`, a unique UUID is used.

If the Destination.SOAP.Request.WSA folder in the local environment is not empty, any user-supplied MAPs override the default ones listed previously on a property by property basis.

However, because of the nature of the SOAP asynchronous node pair, you cannot specify the address property of the ReplyTo Message Exchange Program (MEP), and this property is ignored if specified.

When the main MAPs are generated, the node looks in several places to obtain various pieces of context information to send in a <wmb:context> element under the ReferenceParameters section of the ReplyTo endpoint reference. If these locations exist and are not empty, the following additional information is added to the <wmb:context>:

- Destination.SOAP.Request.UserContext

  This information is added under a subfolder called UserContext.
- Destination.SOAP.Reply.ReplyIdentifier

  This information is added under a subfolder called ReplyID.

Use the user context to specify an arbitrary amount of data that will be sent with the message from the SOAPAsyncRequest node to the SOAPAsyncResponse node. By using the user context, you can pass state from one node to the other. Ensure that the amount of data that you send is small because this data is placed in the message.

Use the reply identifier to automatically correlate a SOAPInput node in the flow that contains the SOAPAsyncRequest node, with a SOAPReply node in the flow that contains the SOAPAsyncResponse node.

SOAPAsyncResponse node

After the response to the request is received, the SOAPAsyncResponse node can remove all WS-Addressing headers from the response message and places them in the SOAP.Response.WSA folder so that you can query the headers, if you select the node property Place WS-Addressing headers in local environment.

If the response message contains a user context that was specified by the SOAPAsyncRequest node, the user context is placed in the SOAP.Response.UserContext folder in the local environment.

If the response message contains a reply identifier that was specified by the SOAPAsyncRequest node, the reply identifier is placed in the Destination.SOAP.Reply.ReplyIdentifier folder in the local environment.

WS-Addressing information in the local environment
WS-Addressing header information can be placed in the local environment tree where it is visible to a message flow. WS-Addressing header information is only processed by the SOAP nodes.

Inbound messages

Inbound information is placed in the local environment by the SOAP node only if addressing is engaged on the node and you select the Place WS-Addressing Headers into LocalEnvironment property on the SOAPInput, SOAPAsyncResponse, or SOAPRequest nodes.

The following table describes the node specific WS-Addressing information in the local environment tree.

Node	Populates local environment property
SOAPInput	LocalEnvironment.SOAP.Input.WSA.*type*
SOAPAsyncResponse	LocalEnvironment.SOAP.Response.WSA.*type*
SOAPRequest	LocalEnvironment.SOAP.Request.WSA.*type*

Where *type* is the structure of the subsection of the local environment WS-Addressing XML schema. For details about how *type* maps to the WS-Addressing properties defined by the WS-Addressing specification, see the "Local environment property type" on page 835 section of this topic.

The local environment information for inbound messages is for your information only. If you engage addressing on the node, and select the `Place WS-Addressing Headers into LocalEnvironment` property on the node, WS-Addressing information is available for you to look at and use in your flow. The WS-Addressing properties are placed in the local environment after processing by the node. Note that the WS-Addressing folder and all its children are owned by an XMLNSC parser, therefore you can copy elements directly into any other tree that is owned by an XMLNSC parser. However, be aware that if you copy this folder (or any of its children) to a tree that is not owned by an XMLNSC parser, information in the tree is discarded unless you create an XMLNSC parser in the target tree first. This behavior can occur if you, for example, copy from the `InputLocalEnvironment` tree to the `OutputLocalEnvironment` tree.

Outbound messages

You can place outbound WS-Addressing header information in the local environment; however, this practice is necessary only to override the defaults that are generated by the node automatically . Outbound addressing headers are created only if WS-Addressing is enabled on the node.

The following table describes the node specific WS-Addressing information in the local environment tree that can be used to override the defaults for outbound messages.

Node	Populates local environment property
SOAPReply	`LocalEnvironment.Destination.SOAP.Reply.WSA.`*`type`*
SOAPRequest	`LocalEnvironment.Destination.SOAP.Request.WSA.`*`type`*
SOAPAsyncRequest	`LocalEnvironment.Destination.SOAP.Request.WSA.`*`type`*

Where *type* is the structure of the subsection of the local environment WS-Addressing XML schema. For details about how the *type* maps to the WS-Addressing properties defined by the WS-Addressing specification, see the "Local environment property type" on page 835 section of this topic.

You can modify local environment information for outbound messages. The SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes generate default local environment settings that you can override. One exception to this table is that any attempt to override the WS-Addressing `ReplyTo` address on the SOAPAsyncRequest node is ignored.

For example, the following code shows how to set WS-Addressing information in the local environment for the SOAPRequest node. The WS-Addressing ReplyTo.Address and FaultTo.Address values should be entered as a single string, without line breaks.

```
 SET OutputRoot = InputRoot;
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.To.Address = 'jms:jndi:INPUTQ';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.Address = 'jms:jndi:RESPONSEQ?
jndiConnectionFactoryName=QCF&
jndiInitialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&
jndiURL=file://C:/SOAPJNDIBindings';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.From.Address = 'jms:jndi:INPUTQ';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.Address = 'jms:jndi:RESPONSEQ?
jndiConnectionFactoryName=QCF&
jndiInitialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&
jndiURL=file://C:/SOAPJNDIBindings';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.Action = 'http://WMB_BankImport/NewOperation';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.MessageID = 'test:my:msg:ID:1234578';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.Version = 'Submission-2004/08';
```

Local environment property *type*

The local environment property *type* in the preceding tables corresponds to the WS-Addressing part of the local environment XML schema. The following table shows the corresponding message addressing properties (MAPs) of the WS-Addressing local environment schema for all nodes.

Element	Corresponds to abstract WS-Addressing MAP name
To	[destination endpoint]

Element	Corresponds to abstract WS-Addressing MAP name
From	[source endpoint]
ReplyTo	[reply endpoint]
FaultTo	[fault endpoint]
Action	[action]
MessageId	[message id]
RelatesTo	[relationship]
ReferenceParameters	[reference parameters]
Version	This element does not correspond to a MAP, but it is used to identify the version of WS-Addressing. The two main versions of WS-Addressing are Submission and Final. The default version that is used by all nodes is Final. Therefore, for outbound messages, set this element only if you want the version to be Submission. In the code example, the version is set to Submission by the inclusion of `'Submission-2004/08'` in the element. For incoming messages, this element is populated automatically with the version of the WS-Addressing headers that the inbound message used.

For more details about the message addressing properties defined by the WS-Addressing specification, see “What is WS-Addressing?” on page 816.

For outbound WS-Addressing, you can set an additional local environment property.

Element	Description
AddMustUnderstandAttribute	This element places the SOAP `mustUnderstand` attribute on each WS-Addressing header before the message is sent.

Example use of WS-Addressing information in the local environment
This example shows the setting of reference parameters in the local environment along with the corresponding messages as they appear on the wire.

In this example the web service exposes a simple ping operation.

ESQL to add reference parameters

The following ESQL example shows how to specify addressing headers in the local environment.

```
DECLARE Example_ns NAMESPACE 'http://ibm.namespace';

SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.ReferenceParameters.Parameter1 =
 'Integration node';
SET
 OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.ReferenceParameters.Example_ns:Parameter2.
 (SOAP.NamespaceDecl)xmlns:Example_ns = 'http://ibm.namespace';
SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.ReferenceParameters.Example_ns:Parameter2
 = 'Ping';

SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.ReferenceParameters.Parameter1 = 'Ping';
SET
 OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.ReferenceParameters.Example_ns:Parameter2.
 (SOAP.NamespaceDecl)xmlns:Example_ns = 'http://ibm.namespace';
SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.ReferenceParameters.gns:Parameter2 =
 'FAULT';
```

Request message

The following example is of an outgoing SOAP envelope in a message from a SOAPRequest node with `ReplyTo` and `FaultTo` reference parameters generated after using the above ESQL. It also shows the

other message addressing properties (MAPs) that are not set in the local environment, but are generated automatically by the node as a result of engaging WS-Addressing.

```
<NS1:Envelope xmlns:NS1="http://www.w3.org/2003/05/soap-envelope" xmlns:wsa="http://www.w3.org/2005/08/
addressing">
  <NS1:Header>
    <wsa:To>http://localhost:7801/Service</wsa:To>
    <wsa:ReplyTo>
      <wsa:Address>http://www.w3.org/2005/08/addressing/anonymous</wsa:Address>
      <wsa:ReferenceParameters>
        <Example_ns:Parameter2 xmlns:Example_ns="http://ibm.namespace">Ping</Example_ns:Parameter2>
        <Parameter1>Integration node</Parameter1>
      </wsa:ReferenceParameters>
    </wsa:ReplyTo>
    <wsa:FaultTo>
      <wsa:Address>http://www.w3.org/2005/08/addressing/anonymous</wsa:Address>
      <wsa:ReferenceParameters>
        <Example_ns:Parameter2 xmlns:Example_ns="http://ibm.namespace">FAULT</Example_ns:Parameter2>
        <Parameter1>Ping</Parameter1>
      </wsa:ReferenceParameters>
    </wsa:FaultTo>
    <wsa:MessageID>urn:uuid:020C911C16EB130A8F1204119836321</wsa:MessageID>
    <wsa:Action>http://ibm.com/Service/Ping</wsa:Action>
  </NS1:Header>
  <NS1:Body>
    <NS2:Ping xmlns:NS2="http://ibm.com"></NS2:Ping>
  </NS1:Body>
</NS1:Envelope>
```

In the above example, reference parameters are set for the `ReplyTo` and `FaultTo` endpoint references (EPRs). If this message is sent to a SOAPInput node with WS-Addressing engaged, these `ReferenceParameters` are placed in the local environment of the flow that contains the SOAPInput node for use by the flow if the `Place WS-Addressing Headers into LocalEnvironment` property is selected. This option changes only what is placed in the local environment; it does not change the contents of the response message.

Response message

The following SOAP envelope is a response to the outgoing preceding message, as sent by a SOAPReply node. This example shows the MAP processing that happens automatically by the SOAPReply node. In this example, the `FaultTo` reference parameters are not present because the reply is not a SOAP fault. This response also shows where the reference parameters that belonged to the `ReplyTo` EPR appear in the response message.

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/" xmlns:wsa="http://
www.w3.org/2005/08/
 addressing">
  <soapenv:Header>
    <wsa:To>http://www.w3.org/2005/08/addressing/anonymous</wsa:To>
    <Example_ns:Parameter2 wsa:IsReferenceParameter="true" xmlns:Example_ns="http://ibm.namespace">Ping</
Example_ns:
 Parameter2>
    <Parameter1 wsa:IsReferenceParameter="true">Integration node</Parameter1>
    <wsa:ReplyTo>
      <wsa:Address>http://www.w3.org/2005/08/addressing/anonymous</wsa:Address>
    </wsa:ReplyTo>
    <wsa:Action>http://ibm.com/Service/PingResponse</wsa:Action>
    <wsa:RelatesTo RelationshipType="http://www.w3.org/2005/08/addressing/
reply">urn:uuid:020C911C16EB130A8F1204119836321
 </wsa:RelatesTo>
  </soapenv:Header>
  <soapenv:Body>
    <NS1:PingResponse xmlns:NS1="http://ibm.com">
      <NS1:PingResult>Ping</NS1:PingResult>
    </NS1:PingResponse>
  </soapenv:Body>
</soapenv:Envelope>
```

WSDL overview

Use the following topics to learn more about WSDL files.

- "WSDL validation" on page 838

- “Message flow configuration with a WSDL file” on page 839
- “WSDL URI formats for JMS” on page 842
- “WSDL styles” on page 844
- “rpc-encoded SOAP messages” on page 845

WSDL validation
The WS-I Validator can be used to check your WSDL definitions against the Basic Profile.

For more information about the WS-I Basic Profile refer to the WS-I, and in particular the WS-I Basic Profile document:

- Web Services Interoperability Organization (WS-I)
- WS-I deliverables index

You can use the WS-I Validator to check your WSDL definitions against the Basic Profile; see WS-I Basic Profile Version 1.1.

You can run the validator in either of the following ways:

- Manually against a specific `.wsdl` resource in the workbench.

  This option enables you to investigate and fix WS-I compliance problems; all validation issues are displayed as task list errors and warnings.
- Automatically, when WSDL is imported or generated.

  You can import WSDL definitions by using the Message Model wizard.

You can control the behavior of the validator by setting a compliance level for your profile.

1. Select **Preferences** > **web services**.
2. Click **Service Policies**, and expand **Profile Compliance**.
3. Select one of the following profiles:
   - WS-I AP compliance level (WS-I Attachments Profile 1.0)
   - WS-I SSBP compliance level (WS-I Simple SOAP Binding Profile 1.0)
4. Select a compliance level:
   - Select **Suggest compliance** to run the validator with errors treated as unrecoverable, but warnings only notified. This is the default setting.
   - Select **Require compliance** to run the validator with errors and warnings treated as unrecoverable.
   - Select **Ignore compliance** if you do not want to run the validator.

The AP selection applies automatically to the SSBP field, therefore Ignore is not explicitly selectable unless the AP selection is set to Ignore.

The following terms refer to the three broad categories of WSDL definition:

- `document-literal` means the combination `style="document"` and `use="literal"`
- `rpc-literal` means the combination `style="rpc"` and `use="literal"`
- `rpc-encoded` means the combination `style="rpc"` and `use="encoded"`

The following are typical validation problems using the preceding terminology:

Your WSDL is rpc-encoded
WSDL with `use="encoded"` is not WS-I compliant and can lead to operational problems because products of different vendors can make different assumptions about the expected SOAP payload.

WS-I: (BP2406) The use attribute of a `soapbind:body`, `soapbind:fault`, `soapbind:header`, and `soapbind:headerfault` does not have the value of "literal".

Your WSDL is document-literal, but one or more WSDL part definitions refer to XML Schema types.
In `document-literal` WSDL, the SOAP body payload is the XML Schema element that is referred to by the appropriate WSDL part.

If a type is specified instead of an element, the SOAP payload is potentially ambiguous (the payload name is not defined) and interoperability problems are likely.

WS-I: (BP2012) A `document-literal` binding contains `soapbind:body` elements that refer to message part elements that do not have the element attribute.

Your WSDL is rpc-literal or rpc-encoded, but one or more WSDL part definitions refer to XML Schema elements.
In rpc-style WSDL, the SOAP body payload is the WSDL operation name, and its children are the WSDL parts that are specified for that operation.

If an element is specified instead of a type, the SOAP message payload is potentially ambiguous (the payload name might be the WSDL part name or the XML Schema element name), and interoperability problems are likely.

WS-I: (BP2013) An rpc-literal binding contains `soapbind:body` elements that refer to message part elements that do not have the type attribute.

Your WSDL includes SOAP header, headerfault or fault definitions that refer to XML Schema types.
In rpc-style WSDL, the SOAP body is correctly defined through XML Schema types as described above.

SOAP headers and faults, however, do not correspond to an rpc function call in the same way as the body.

In particular, there is no concept of 'parameters' to a header or fault, and a header or fault must always be defined in terms of XML Schema elements to avoid potential ambiguity. Effectively, header and fault definitions in WSDL are always `document-literal`.

WS-I: (BP2113) The `soapbind:header`, `soapbind:headerfault`, or `soapbind:fault` elements refer to `wsd:part` elements that are not defined using only the "element" attribute.

Your WSDL is rpc-literal or rpc-encoded, but no namespace was specified for an operation.
In rpc-style WSDL, the SOAP message payload is the WSDL operation name, qualified by a namespace that is specified as part of the WSDL binding.

If no namespace is specified then the SOAP message payload is potentially ambiguous (the payload name might be in no namespace, or might default to use a different namespace, such as the target namespace of the WSDL definition) and interoperability problems are likely.

WS-I: (BP2020) An rpc-literal binding contains `soapbind:body` elements that either do not have a namespace attribute, or have a namespace attribute value that is not an absolute URI.

Your WSDL includes a SOAP/JMS binding.
If your WSDL uses a SOAP/JMS transport URI it is not WS-I compliant. An error is shown if strict WS-I validation is enabled. To disable strict WS-I validation, click **Window** > **Preferences** > **Integration Development** > **WSDL** > **Validation** and select the **WS-I BP 1.1: Allow SOAP/JMS as transport URI**. By default strict WS-I validation is disabled.

Web service interoperability is improved if you implement the following actions:

- Use document-style WSDL whenever possible.
- Use literal encoding, if rpc-style WSDL is necessary.
- Ensure that the WSDL operation definitions are qualified by a valid namespace attribute, if rpc-encoded WSDL must be used.

Message flow configuration with a WSDL file
You can use a WSDL file to configure message flows.

Message flows that work with web services typically use the SOAP nodes. For details about the SOAP nodes, see “IBM App Connect Enterprise and web services” on page 806. You can change the operation mode of the SOAP nodes so that they act in gateway mode. In gateway mode, a WSDL file is not required

to configure the nodes because they handle generic request and response and one-way SOAP messages that are not tied to a specific WSDL file.

You can create a web service in IBM App Connect Enterprise in the following ways:

- By importing a WSDL file.
- By dragging a WSDL file onto a SOAP node to configure that node.
- By specifying the WSDL file in the `WSDL file name` property of a SOAP node.
- By defining a new interface with the **New Integration Service** wizard.

When you drag a WSDL file onto a SOAP node, the node properties are configured from the properties in the WSDL `address` URI. The transport properties on the SOAP node are populated according to the first binding imported from the WSDL file. Therefore, if the first imported binding describes a JMS transport, the JMS Transport properties are populated; if the first imported binding describes an HTTP transport, the HTTP Transport properties are populated. If you select another imported binding, the transport properties are populated accordingly. The `portType` appears differently depending on the transport selected.

The WSDL `address` element URI can exist in two different formats, W3C format, or IBM (deprecated) format. The format of the WSDL URI affects the names of the WSDL properties that the parser looks for to populate the SOAP node properties. For example, the `JNDI context parameters` table is not populated when you import an IBM-style WSDL because it does not support these properties in the WSDL address URI. The table is populated only if JNDI context parameters are present in a W3C-style WSDL. For details, see "WSDL URI formats for JMS" on page 842.

If you supply a service definition, endpoint properties are set automatically, but you can also set or override these properties manually.

Optionally, WSDL definitions can be split into multiple files. The typical arrangement is that a top-level service definition file imports a binding file, the binding file imports an interface file, and this interface file imports or includes schema definition files.

A WSDL `portType` (the logical WSDL interface) is not sufficient on its own to configure a SOAP node; a specific binding is required so that the SOAP payload is well-defined at run time.

A binding defines a use, which can be `document` (the default) or `rpc`. If the use is `document`, the SOAP payload is described by an XML Schema element in the WSDL. If the use is `rpc`, the SOAP payload is the WSDL operation name in a specified namespace.

If you drag a WSDL file onto a SOAP node from a shared library, the `WSDL file name` and `Message model` properties on the node specify the name of the shared library.

Configuring the SOAP nodes

The following nodes are configured explicitly by WSDL files:

- node
- node
- node

The following nodes are configured implicitly by WSDL files, because they inherit the WSDL configuration of the node with which they are paired:

- node
- node

A SOAPReply node is always used with a SOAPInput node.

A SOAPAsyncResponse node is always used with a SOAPAsyncRequest node, associated by the `Unique Identifier` property.

Using WSDL with the SOAPAsyncRequest node
A SOAPAsyncRequest node must be associated with a WSDL file unless it is operating in gateway mode.

About this task

In WSDL mode, when you select a WSDL file for the `WSDL file name` field on the SOAPAsyncRequest node, the WSDL file is validated to ensure that it is WS-I compliant. If the WSDL file uses a SOAP/JMS transport URI, it is not WS-I compliant, but by default no error is shown. To enable strict WS-I validation and display a warning when a SOAP/JMS transport is used, click **Window** > **Preferences** > **Integration Development** > **WSDL** > **Validation** and clear the **WS-I BP 1.1: Allow SOAP/JMS as transport URI** check box.

After a valid WSDL file is selected, the project that contains the WSDL file is added as a referenced project to the corresponding application or library, if the reference does not exist. To use a WSDL file in a shared library, the container that contains your message flow must reference that shared library. If the WSDL file is not valid, or an incorrect file name is entered, an error message is displayed in the Properties view and all WSDL properties are blank.

If the SOAPAsyncRequest node is created by dragging a WSDL file onto the Message Flow editor, this property is preset to the name of the WSDL file. If the name of the WSDL file is not preset, you can set this property in one of the following ways.

Procedure

- If you have Deployable WSDL, you can select from the Deployable WSDL files by clicking **Browse**.
- If you have WSDL definitions, but no message set, then you can create a message set:
  a) Click Browse to open the WSDL Selection window.
  b) Click **Import/Create New** to open the **Import WSDL file** wizard.
  c) Enter the message set name and message set project name. Click Next.
  d) Select the relevant option:
     – If your WSDL file exists in your workspace, select **Use resources from the workspace**, and select the WSDL file.
     – If your WSDL file is in the file system, select **Use external resources**. Select the WSDL file. Click **Next**.
  e) Select the WSDL bindings to import. Any warnings or errors are displayed in the wizard banner.
  f) Click **Finish**. Result: Creates a new message set project and message set, with message definitions. The WSDL definitions are added to the Deployable WSDL folder.
  g) You can now select the WSDL file from the **WSDL Selection** window. Click **OK**.
- If you have a message set but no WSDL definition, you must generate a WSDL definition. See "Message Sets: Generating a WSDL definition from a message set" on page 2317.
- Drag a WSDL file from a message set onto the node.
- Type in a file name that is relative to the message set project in which the deployable WSDL file exists.

Results

When you save the flow file, it is validated that the `WSDL file name` exists in the message set. If it is does not, an error is generated, and you will not be able to add a flow that contains this SOAPAsyncRequest node to the BAR file.

Querying WSDL with ?wsdl
You can interrogate web services using ?wsdl.

A web service client can send an HTTP GET request with a `?wsdl` query string to an IBM App Connect Enterprise web service, and receive a representation of the WSDL that was used to configure the input node that provides the endpoint for the service. You can do this only for input nodes that use HTTP and

not JMS transport. The protocol of the HTTP GET request must match the protocol of the flow; therefore if the flow uses SSL, the HTTP GET request must begin `https://`.

The client starts by sending a simple `?wsdl` query and retrieves the complete WSDL definition by following a chain of referenced imports or includes. For example, if the web service endpoint is `http://localhost:7800/test1`, the initial client request is:

```
GET http://localhost:7800/test1?wsdl
```

This request returns the top-level WSDL service definition, which might include imports for further sections of the WSDL definition. For example, if the returned WSDL has a line:

```
<wsdl:import ... location="http://localhost:7800/test1?wsdl=wsdl0"/>
```

then the client sends a corresponding request to retrieve that section of the WSDL:

```
GET http://localhost:7800/test1?wsdl=wsdl0
```

One or more WSDL sections can also have imports for XML Schema data, for example:

```
<xsd:import ... schemaLocation="http://localhost:7800/test1?xsd=xsd0"/>
```

The client again sends a corresponding request to retrieve that data:

```
GET http://localhost:7800/test1?xsd=xsd0
```

Only semantically correct references can be followed:

- `<wsdl:import>` elements that are immediate children of `wsdl:definition` elements
- `<xsd:import>` and `<xsd:include>` elements that are immediate children of `xsd:schema` elements

where `wsdl` is a shorthand (namespace prefix) for `http://schemas.xmlsoap.org/wsdl/`, and `xsd` is a shorthand for `http://www.w3.org/2001/XMLSchema`. A request made to a URI from an element which superficially looks like an `<import>` or `<include>`, for example, an element in a comment, results in a SOAP Fault being returned. Only the simple `?wsdl` query string, and subsequent queries that exactly match those queries specified in semantically valid imports and includes, result in data being returned.

The WSDL definition returned is logically equivalent to the deployable WSDL in the IBM App Connect Enterprise Toolkit, with inline schemas externalized. It might not be physically identical to the original imported WSDL definition. Although a SOAPInput is configured with a specific WSDL binding, the WSDL returned also includes other bindings that are not used by the flow if these were part of the original WSDL definition that was imported.

WSDL URI formats for JMS

You must use WSDL to configure SOAP nodes. When using WSDL with a JMS transport, different URI formats can exist in the `address` element in the WSDL, which affect how properties are parsed and applied to the configured nodes.

Two different URI formats can exist in the WSDL `address` element. Several node properties are initially set from properties in the imported WSDL, which is parsed according to which type of URI is found in the WSDL element. The first type is the W3C SOAP JMS specification format. For example:

```
<soap:address location="jms:jndi:REPLYTOQ2?jndiConnectionFactoryName=QCF&amp;
 jndiInitialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&amp;
 jndiURL=file:/C:/mqsi6/webservices/SOAP/JMS/JNDI&amp;
 targetService=SOAPJMSGenMessageSetSOAP_JMS_Service&amp;
 timeToLive=30000"
/>
```

The second URI format for the `address` element is a proprietary IBM format which is currently deprecated. For example:

```
<soap:address location="jms:/queue?destination=jms/RequestQ&amp;
 connectionFactory=jms/WMBQCF&amp;
```

```
  targetService=SOAPJMSGenMessageSetSOAP_JMS_Service&amp;
  initialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&amp;
  jndiProviderURL=file:/C:/mqsi6/webservices/SOAP/JMS/JNDI"
 />
```

There are several differences between these URI formats. IBM App Connect Enterprise accepts both URI formats. Different WSDL properties are used to set the SOAP node properties depending on which URI format is used in the WSDL address element.

The following table shows how WSDL properties are parsed into SOAPInput node properties. The columns headed "W3C names in URI" and "W3C allowed values" indicate the property names that the parser looks for when a W3C-style URI is found, and the allowed values for those properties. The columns headed "IBM names in URI" and "IBM allowed values" indicate the property names that the parser looks for when an IBM-style URI is found in the WSDL, and the allowed values for those properties. Where more than one property name is shown in a table cell, the node property is set to the value of the first of those property names found in the WSDL `address` element. Any properties found in the WSDL `address` element that are not parsed into node properties are discarded.

SOAPInput node property name	W3C SOAP/JMS specification names	W3C names in URI	W3C allowed values	IBM names in URI	IBM allowed values
Source	`soapjms:destinationName`	`jms-name` (in URI)	`<string>`	`destination`	`<string>`
Connection factory name	`soapjms:jndiConnectionFactoryName`	`jndiConnectionFactoryName`	`<string>`	`connectionFactory`	`<string>`
Initial context factory	`soapjms:jndiInitialContextFactory`	`jndiInitialContextFactory`	`<string>`	`initialContextFactory`	`<string>`
JNDI URL bindings location	`soapjms:jndiURL`	`jndiURL`	`<URL>`	`jndiProviderURL`	`<URL>`
JNDI parameters	`soapjms:jndiContextParameter`	`name=value`	`<string for name and value>`	N/A	`<string>`
Delivery mode	`soapjms:deliveryMode`	`deliveryMode`	`NON_PERSISTENT` `PERSISTENT`[1]	`deliveryMode` `persistence`	`<int 1 | 2>`
Message priority	`soapjms:priority`	`priority`	`<int 0-9>`	`priority` `Priority`	`<int 0-9>`
Target service	`soapjms:targetService`	`targetService`	`<string>`	`targetService`	`<string>`

Notes:

1. IBM App Connect Enterprise accepts the values 1 and 2 when parsing a W3C-style URI for compatibility reasons, but the W3C specification allows only the string values `NON_PERSISTENT` and `PERSISTENT` for this property.

The following table shows how WSDL properties are parsed into SOAPRequest andSOAPAsyncRequest node properties. The columns headed "W3C names in URI" and "W3C allowed values" indicate the property names that the parser looks for when a W3C-style URI is found, and the allowed values for those properties. The columns headed "IBM names in URI" and "IBM allowed values" indicate the property names that the parser looks for when an IBM-style URI is found in the WSDL, and the allowed values for those properties. Where more than one property name is shown in a table cell, the node property is set to the value of the first of those property names found in the WSDL address element. Any properties found in the WSDL `address` element that are not parsed into node properties are populated in the `User Parameters` table.

SOAPRequest or SOAPAsyncRequest node property name	W3C SOAP/JMS specification names	W3C names in URI	W3C allowed values	IBM names in URI	IBM allowed values
Destination	soapjms:destination	jms-dest (in URI)	<string>	destination	<string>
Connection factory name	soapjms:jndiConnectionFactoryName	jndi-ConnectionFactoryName	<string>	connectionFactory	<string>
Initial context factory	soapjms:jndiInitialContextFactory	jndi-InitialContextFactory	<string>	initialContextFactory	<string>
JNDI URL bindings location	soapjms:jndiURL	jndiURL	<URL>	jndiProviderURL	<URL>
JNDI parameters	soapjms:jndiContextParameter	jndi-Parameter name=value	<string for name and value>	N/A	<string>
Delivery mode	soapjms:deliveryMode	deliveryMode	NON_PERSISTENT PERSISTENT[1]	deliveryMode persistence	<int 1 | 2>
Message expiration	soapjms:timeToLive	timeToLive	<int>	timeToLive	<int>
Message priority	soapjms:priority	priority	<int 0-9>	priority Priority	<int 0-9>
Reply to destination	soapjms:replyToName	replyToName	<string>	replyToName replyTo replyToDestination replyDestination	<string>
Target service	soapjms:targetService	targetService	<string>	targetService	<string>
User parameters	UserProperties	<any other property name>	<string>	<any other property name>	<string>

Notes:

1. IBM App Connect Enterprise accepts the values 1 and 2 when parsing a W3C-style URI for compatibility reasons, but the W3C specification allows only the string values NON_PERSISTENT and PERSISTENT for this property.

WSDL styles

The SOAP nodes are configured by using a specific WSDL binding that has a style of either document (the default) or rpc. All operations that are defined in a specific WSDL binding are usually defined with the same use, which can be either literal (the default) or encoded.

The following terms are used to describe the three general types of WSDL bindings:

- document-literal (style="document", use="literal")
- rpc-literal (style="rpc", use="literal")
- rpc-encoded (style="rpc", use="encoded")

The shape of the runtime SOAP message that is defined by the WSDL file depends on the binding type, as shown in the following table:

WSDL binding type	Description
`document-literal`	The SOAP payload is described by XML schema. The `wrapped document-literal` convention constructs the XML schema so that the first child of the SOAP Body matches the operation name.
`rpc-literal`	The SOAP payload is described by the WSDL (operation and part name) and then by XML schema.
`rpc-encoded`	The SOAP payload has the same general shape as `rpc-literal`, but can carry SOAP encoding annotations designed to give the receiver additional information about the message that is sent. The annotations are slightly different between SOAP 1.1 and SOAP 1.2.

All three WSDL styles are supported by IBM App Connect Enterprise. The best style for a new service is `document-literal`, and it is also the least likely to cause interoperability problems. You can use the `wrapped document-literal` convention to explicitly associate the SOAP payload with the operation.

Both `document-literal` and `rpc-literal` are WS-I compliant. The `rpc-encoded` style is not WS-I compliant and can cause interoperability problems if the web service client and server use different technologies. Some common issues encountered with WSDL styles are described in "WSDL validation" on page 838.

It is simple to create and parse SOAP messages described by `document-literal` or `rpc-literal` WSDL, because the payload is standard XML described by the message set created from the WSDL.

For more information, see "rpc-encoded SOAP messages" on page 845.

rpc-encoded SOAP messages

The SOAP nodes are configured using a specific WSDL binding that has a style of either `document` (the default) or `rpc`. All the operations defined within a particular WSDL binding are usually defined with the same use, which can be either `literal` (the default) or `encoded`.

SOAP messages that are `rpc-encoded` can carry SOAP encoding annotations that are designed to give the receiver additional information about the message being sent. The following four types of annotations are common:

- xsi:type
- encodingStyle
- Arrays
- Multi-reference

Arrays and multi-reference elements can cause interoperability problems, and require specific intervention by the message flow developer, as follows:

- If the message flow builds outbound messages incorporating SOAP arrays, use ESQL to add any required attributes, as follows:
  - `arrayType` for SOAP 1.1
  - `arraySize` and `itemType` for SOAP 1.2
- If the message flow receives messages using SOAP arrays, disable validation.
- If the message flow receives messages using multi-reference encoding, disable validation and, if necessary, navigate the resulting logical tree using the `href` (or `ref`) and `id` attributes.

xsi:type

An `xsi:type` attribute can be added to an element to specify its type. For example:

```
<data xsi:type="xsd:string">text</data>
```

where the namespace prefix `xsi` is defined as follows:

```
xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
```

For a web service built from WSDL and XML schema, the type information is already available and the `xsi:type` is redundant.

Generally, when building an outbound message, you do not add `xsi:type` information. The following ESQL example shows how to add `xsi:type` information if it is required:

```
DECLARE xsd NAMESPACE 'http://www.w3.org/2001/XMLSchema';
DECLARE xsi NAMESPACE 'http://www.w3.org/2001/XMLSchema-instance';

SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsd = xsd;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsi = xsi;

SET OutputRoot.SOAP.Body.rpc:op1.part1.data.(SOAP.Attribute)xsi:type = 'xsd:string';
```

When parsing an inbound message, any `xsi:type` information is added to the logical tree in the same way as other attributes, as follows:

```
(0x03000000:PCDataField):data = 'text' (CHARACTER)
(
  (0x03000100:Attribute)http://www.w3.org/2001/XMLSchema-instance:type =
 'xsd:string' (CHARACTER)
)
```

encodingStyle

An `encodingStyle` attribute can be added to an element to specify the SOAP encoding style used. For example:

```
<tns:op1 soapenv:encodingStyle="http://schemas.xmlsoap.org/soap/encoding/">
```

where the namespace prefix `soapenv` is defined as the namespace of your SOAP Envelope, as follows:

```
xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/" (SOAP 1.1)
xmlns:soapenv="http://www.w3.org/2003/05/soap-envelope"   (SOAP 1.2)
```

The value itself is a list of URIs, but the values in common use are as follows:

```
"http://schemas.xmlsoap.org/soap/encoding/" (SOAP 1.1)
"http://www.w3.org/2003/05/soap-encoding"   (SOAP 1.2)
```

In SOAP 1.1, the `encodingStyle` attribute can be added to any element. In SOAP 1.2 the `encodingStyle` attribute can be added only to children of Body, Header and Detail.

Generally, you build an outbound message, you do not add the `encodingStyle` attribute. The following ESQL example shows how to add `encodingStyle` information, if it is required:

```
DECLARE soapenv NAMESPACE 'http://schemas.xmlsoap.org/soap/envelope/';
DECLARE soapenc NAMESPACE 'http://schemas.xmlsoap.org/soap/encoding/';

SET OutputRoot.SOAP.Body.tns:op1.(SOAP.Attribute)soapenv:encodingStyle = soapenc;
```

When parsing an inbound message, any `encodingStyle` attributes are added to the logical tree in the same way as other attributes, as follows:

```
(0x03000100:Attribute)http://schemas.xmlsoap.org/soap/envelope/:encodingStyle =
```

```
     'http://schemas.xmlsoap.org/soap/encoding/' (CHARACTER)
```

Arrays

A SOAP array is an element containing a sequence of child elements of the same type. In the following XML schema example, there is a type called *data* with two elements: a simple string and an array. In the schema, the field called *array* has an unspecified number of children of type string. The name of those child elements is not specified.

```
<xsd:complexType name="ArrayOfString">
  <xsd:complexContent mixed="false">
    <xsd:restriction base="soapenc:Array">
 <xsd:attribute wsdl:arrayType="xsd:string[]" ref="soapenc:arrayType"/>
    </xsd:restriction>
  </xsd:complexContent>
</xsd:complexType>

<xsd:complexType name="data">
  <xsd:sequence>
     <xsd:element name="simple" type="xsd:string"/>
     <xsd:element name="array"  type="tns:ArrayOfString"/>
  </xsd:sequence>
</xsd:complexType>
```

The namespaces used in the example are from WSDL 1.1 and SOAP 1.1, as follows:

```
xmlns:xsd="http://www.w3.org/2001/XMLSchema"
xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/"
xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
```

The following example is part of a valid instance document matching the schema:

```
<array soapenc:arrayType="xsd:string[]">
  <item>item1</item>
  <item>item2</item>
</array>
```

When you build an outbound message, you must add the appropriate attributes. For example, the following ESQL shows how to add the `arrayType` attribute:

```
DECLARE xsd     NAMESPACE 'http://www.w3.org/2001/XMLSchema';
DECLARE soapenc NAMESPACE 'http://schemas.xmlsoap.org/soap/encoding/';

SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsd = xsd;

SET OutputRoot.SOAP.Body.rpc:op1.p1.array.(SOAP.Attribute)soapenc:arrayType = 'xsd:string[]';
```

The attributes used by SOAP 1.1 and SOAP 1.2 are different. SOAP 1.1 uses the `arrayType` attribute. The size of the array can be specified, but is not required. SOAP 1.2 uses two separate attributes. The equivalent SOAP 1.2 attributes for the previous example are `soapenc:itemType="xsd:string"` and `soapenc:arraySize="2"`, where the namespace prefixes are defined as follows:

```
xmlns:xsd="http://www.w3.org/2001/XMLSchema"
xmlns:soapenc=" http://www.w3.org/2003/05/soap-encoding"
```

You must disable validation if your message flow receives SOAP encoded messages containing SOAP arrays. The instance document cannot be validated against the schema when parsing an inbound message, because the name of the array items is not defined by the schema.

Multi-reference

The following example shows a SOAP 1.1 request message for a WSDL `rpc-encoded` operation called op1:

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/"
                  xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/">
  <soapenv:Body   xmlns:xsd="http://www.w3.org/2001/XMLSchema"
```

```
                  xmlns:rpc="http://example/rpc">
    <rpc:op1>
       <p1>
         <simple>text</simple>
         <array soapenc:arrayType="xsd:string[]">
           <Item>item1</Item>
           <Item>item2</Item>
         </array>
       </p1>
    </rpc:op1>
  </soapenv:Body>
</soapenv:Envelope>
```

A SOAP implementation can reorganize this logical message to use multi-reference elements, as follows:

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/"
                  xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/">
  <soapenv:Body   xmlns:xsd="http://www.w3.org/2001/XMLSchema"
                  xmlns:rpc="http://example/rpc">
    <rpc:op1>
      <p1 href="#id1"/>
    </rpc:op1>
    <rpc:data id="id1">
      <simple>text</simple>
      <array href="#id2"/>
    </rpc:data>
    <soapenc:Array id="id2" soapenc:arrayType="xsd:string[]">
      <Item>Array Element 0</Item>
      <Item>Array Element 1</Item>
    </soapenc:Array>
  </soapenv:Body>
</soapenv:Envelope>
```

The message is logically equivalent to the first example, but the children of elements `p1` and `array` have been split out into separate sibling elements and then referenced using the `href` attribute.

The introduced elements, such as `<data>`:

- Can be referenced from more than one location, which allows the message to state that such elements are identical, as opposed to separate items which have the same value. The message size could be reduced if a shared element is large and referenced many times.
- Can directly or indirectly reference themselves, which allows the message to represent a graph that contains circular references.

Neither of these considerations applies to the previous example.

Generally, when you build an outbound message, you do not encode multi-reference elements unless the message represents a graph. Otherwise, the multi-reference encoding is optional. The following ESQL example shows how to encode multi-reference elements:

```
-- ESQL namespace prefixes
DECLARE soapenc NAMESPACE 'http://schemas.xmlsoap.org/soap/encoding/';
DECLARE xsd     NAMESPACE 'http://www.w3.org/2001/XMLSchema';
DECLARE rpc NAMESPACE 'http://example/rpc';

-- define XML namespace prefixes
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soapenc = soapenc;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsd = xsd;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:rpc = rpc;

-- build request message
SET OutputRoot.SOAP.Body.rpc:op1.p1.(SOAP.Attribute)href = '#id1';

SET OutputRoot.SOAP.Body.rpc:data.(SOAP.Attribute)id = 'id1';
SET OutputRoot.SOAP.Body.rpc:data.simple = 'text';
SET OutputRoot.SOAP.Body.rpc:data.array.(SOAP.Attribute)href = '#id2';

SET OutputRoot.SOAP.Body.soapenc:Array.(SOAP.Attribute)id = 'id2';
SET OutputRoot.SOAP.Body.soapenc:Array.(SOAP.Attribute)soapenc:arrayType = 'xsd:string[]';
SET OutputRoot.SOAP.Body.soapenc:Array.Item[1] = 'item1';
SET OutputRoot.SOAP.Body.soapenc:Array.Item[2] = 'item2';
```

When parsing an inbound message, multi-reference elements do not match the XML schema from the web service WSDL. If validation is enabled on a SOAP node, then an exception is thrown. If you use multi-reference encoding, then you must disable validation.

When you have a logical tree built from the message, you can propagate this tree to another SOAP node for output. For example, with a façade flow as shown in the following diagram, if the SOAPRequest node receives a response using multi-reference encoding, you can propagate the logical tree for the response to the SOAPReply node, and a SOAP message with multi-reference encoding is returned to the original client.

The original client must also understand the multi-reference encoding.

To manipulate the logical tree for a multi-reference encoded message, navigate the `href` and `id` attributes in ESQL. These attributes are slightly different in SOAP 1.1 and SOAP 1.2, as follows:

- In SOAP 1.1, the referencing element has an attribute `href="#id"` and the item referenced `id="id"`.
- In SOAP 1.2, the referencing element has an attribute `ref="id"` and the item referenced `id="id"`.

SOAP MTOM and the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes
The use of outbound MTOM messages can be configured on the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes.

The nodes have a property called `Allow MTOM`, which defines whether MTOM can be used.

An MTOM output message is written if all of the following criteria are met:

- The `Allow MTOM` property is selected on the **WS Extensions** tab.
- Validation is enabled. The `Validate` property on the SOAPRequest and SOAPAsyncRequest nodes controls validation of the anticipated response message and not validation of the outgoing request. MTOM output is therefore suppressed unless you set `Validate` to `Content and value` on a preceding input node or transformation node.
- No child elements exist below `SOAP.Attachment` in the logical tree. If child elements are present, SOAP with Attachments (SwA) is used.
- Elements exist in the output message that are identified as base64Binary in the associated XML Schema and whose length does not fall below a default threshold size of 1000 bytes.

You can use the local environment setting `MTOMThreshold` to override the MTOM element size threshold. The MTOM element size threshold is set to a default value of 1000 bytes.

The `Allow MTOM` node property and the `MTOMThreshold` setting can both be overridden in the local environment.

The overrides that apply at a SOAPReply node are:

- `LocalEnvironment.Destination.SOAP.Reply.AllowMTOM`, which can have a value of true or false
- `LocalEnvironment.Destination.SOAP.Reply.MTOMThreshold`, which is an integer value in bytes

The equivalent overrides for a SOAPRequest or SOAPAsyncRequest node are:

- `LocalEnvironment.Destination.SOAP.Request.AllowMTOM`, which can have a value of true or false

- `LocalEnvironment.Destination.SOAP.Request.MTOMThreshold`, which is an integer value in bytes

Configuring message flows to process timeouts
Connect the HTTP Timeout terminal of the HTTPInput or SOAPInput nodes to further nodes to process timeouts.

Before you begin

- Read the message flows overview.
- Read about the options that you have for processing web service messages, and learn more about SOAP and HTTP.

About this task

You can configure message flows that start with an HTTPInput or SOAPInput node by connecting the HTTP Timeout terminal to further nodes for processing timeouts:

- On HTTPInput nodes, messages are propagated through this terminal only when you have configured your integration servers such that the HTTP nodes are using the embedded integration server listener.
- On SOAPInput nodes, messages are propagated through this terminal only when you are using an HTTP binding, and you have configured your integration servers such that the SOAP nodes are using the embedded integration server listener.

If these conditions are not met when you deploy the BAR file for the message flow that includes one of these nodes, a warning is generated, and the path of the message flow that you have connected to the HTTP Timeout terminal is ignored. No further warnings are generated until the next restart.

To set a static timeout value in an input node:

1. Create a message flow, or open an existing flow.
2. In the Message Flow editor, select the input node for this message flow. The node properties are displayed in the Properties view (below the editor pane).
3. Set an appropriate time for the timeout interval in the property `Maximum client wait time`. The default interval is 180 seconds.

   If this time expires, and you have not connected one or more nodes to the HTTP Timeout terminal, the listener that received the client request message responds with a SOAP Fault message indicating that a timeout has occurred.
4. If you want to provide customized timeout processing, connect one or more nodes to the HTTP Timeout terminal. You must include in this sequence the reply node that matches the input node. Therefore, if your message flow starts with an HTTPInput node, you must include an HTTPReply; if your message flow starts with a SOAPInput node, you must include a SOAPReply node.

To set a dynamic timeout value in an input node:

- Override the timeout value set on the input node by using the Java plug-in API to update it in a JavaCompute node using the `MbUtilities.changeIdentifierTimeout()` method. The following code shows an example of the `changeIdentifierTimeout` method:

```
MbMessage localEnv = assembly.getLocalEnvironment();
MbElement rootElem = localEnv.getRootElement();
MbElement repIdElement = rootElem.getFirstElementByPath(
   "/Destination/SOAP/Reply/ReplyIdentifier");
Object repId = repIdElement.getValue();
boolean success = changeIdentifierTimeout((byte[])repId, timeout);
```

- Override the timeout value set on the input node by using the CHANGEIDENTIFIERTIMEOUT function.

You can derive the value that you use to replace the existing value by several means; for example:

- Read a record from a database.

- Use a value from a field within the message body.

By propagating from the HTTP Timeout terminal you can then change the contents of the responses that your message flow sends to the client. The processing on the sequence of nodes that you connect to the HTTP Timeout terminal is also subject to a further timeout, so that the client always gets a response within a known timeout interval.

When a message is propagated from the HTTP Timeout terminal the message tree contains the input headers of the original input message and a message body that is the fault timeout message. The original message body along with other information relating to the timeout can be accessed in the LocalEnvironment message tree. For example, the following record can be found in the LocalEnvironment:

```
(0x01000000:Name):HTTP = (
  (0x01000000:Name):Input = (
    (0x01000000:Name):Timeout = (
      (0x03000000:NameValue):OriginalClientLastWaitTime = 10 (INTEGER)
      (0x03000000:NameValue):OriginalClientWaitTime     = 15 (INTEGER)
      (0x03000000:NameValue):OriginalMessageMadeTheFlow = TRUE (BOOLEAN)
      (0x03000000:NameValue):OriginalRequestIdentifier  =
         X'485454500000000000000000000000c00c000000000000' (BLOB)
      (0x03000000:NameValue):OriginalInboundMessage     = X'3c3e' (BLOB)
    )
  )
)
```

For SOAPInput nodes the SOAPReply node connected on the HTTP Timeout terminal path must send a SOAP fault response message and the reply status code of 500 cannot be altered. For HTTPInput nodes any response message can be sent from the HTTP Timeout terminal and the reply status code can be changed by updating the `LocalEnvironment.Destination.HTTP.ReplyStatusCode` message tree field.

Processing JMS messages

JMS is the standard Java EE messaging API for building enterprise messaging applications. IBM App Connect Enterprise provides built-in input and output nodes for its supported protocols.

The JMS specification offers an abstract, provider-independent messaging interface, so that you can write messaging applications to this common API regardless of the underlying messaging implementation.

JMS offers two common ways of messaging on which to build messaging applications: point-to-point and publish/subscribe (pub/sub). JMS applications send messages to JMS destinations, which can be queues (in the point-to-point domain) or topics (in the pub/sub domain).

JMS is defined in the following documents from Sun Microsystems:

- JMS specifications from Sun Microsystems

JMS can be used as a transport for SOAP as described in the following document issued by the World Wide Web Consortium (W3C):

- SOAP over Java Message Service 1.0 (W3C recommendation)

Java Message Service (JMS) API

IBM App Connect Enterprise supports the Java Message Service (JMS) application programming interface (API).

The JMS is an application programming interface that provides Java language functions for handling messages. Developed by messaging vendors, including IBM, in partnership with Sun Microsystems, Inc., the JMS API provides a common interface to access different enterprise messaging systems, including IBM MQ. This interface is appropriate for point-to-point and publish/subscribe applications.

Messaging clients in JMS are called *JMS clients*, and the messaging system is called the *JMS provider*. A *JMS application* is a business system that comprises JMS clients and at least one JMS provider. Client applications that use the JMS interface are written in the Java programming language, and are therefore restricted to the levels of JVM that are supported on the operating system in the business environment.

If you have existing end-user applications that are written to these interfaces, they can typically run unchanged in an integration node environment. You must create the message flows to interact with these applications from the supported protocols by using the appropriate input and output nodes. IBM App Connect Enterprise provides built-in input and output nodes for its supported protocols, and other nodes that support transformation to and from JMS message formats. You can also create your own user-defined nodes to support additional protocols.

You can also create end-user applications to interact with the integration node.

Using JMS in IBM App Connect Enterprise

Use IBM App Connect Enterprise to connect to applications that send and receive messages that conform to the Java Message Service (JMS) standard.

You can use the built-in JMS nodes in IBM App Connect Enterprise to support the following operations:

- Receive a JMS message as input.
- Receive a JMS message in the middle of a message flow.
- Create a JMS message for output.
- Work with message flows that do not expect JMS messages.

All JMS messages must conform to the Java Message Service Specification version 1.1 or 2.0.

You can create message flows to receive messages from JMS destinations, and send messages to JMS destinations. These destinations are accessible through a connection to a JMS provider. In sending and receiving messages, the JMS nodes behave like JMS clients.

You can also use two transformation nodes, the JMSMQTransform node and the MQJMSTransform node, with the JMSInput, JMSReceive and JMSOutput nodes so that they can interact with nodes that expect a propagated message to contain an MQMD (and MQRFH2) header.

- The JMSMQTransform node takes the output of the JMSInput or JMSReceive node, and produces a message that can be handled by an MQOutput node.
- The MQJMSTransform node transforms a message with an MQMD (and optional MQRFH2) header into a message that is expected by the JMSOutput node.

If you want to change or add content to the headers in JMS messages, you can include a JMSHeader node in the message flow to modify fields without programming.

You can configure the JMS nodes to work with the IBM MQ JMS provider, WebSphere Application Server, and all JMS providers that conform to the Java Message Service Specification version 1.1 or 2.0. IBM App Connect Enterprise supports Java 7(also known as Java 1.7).

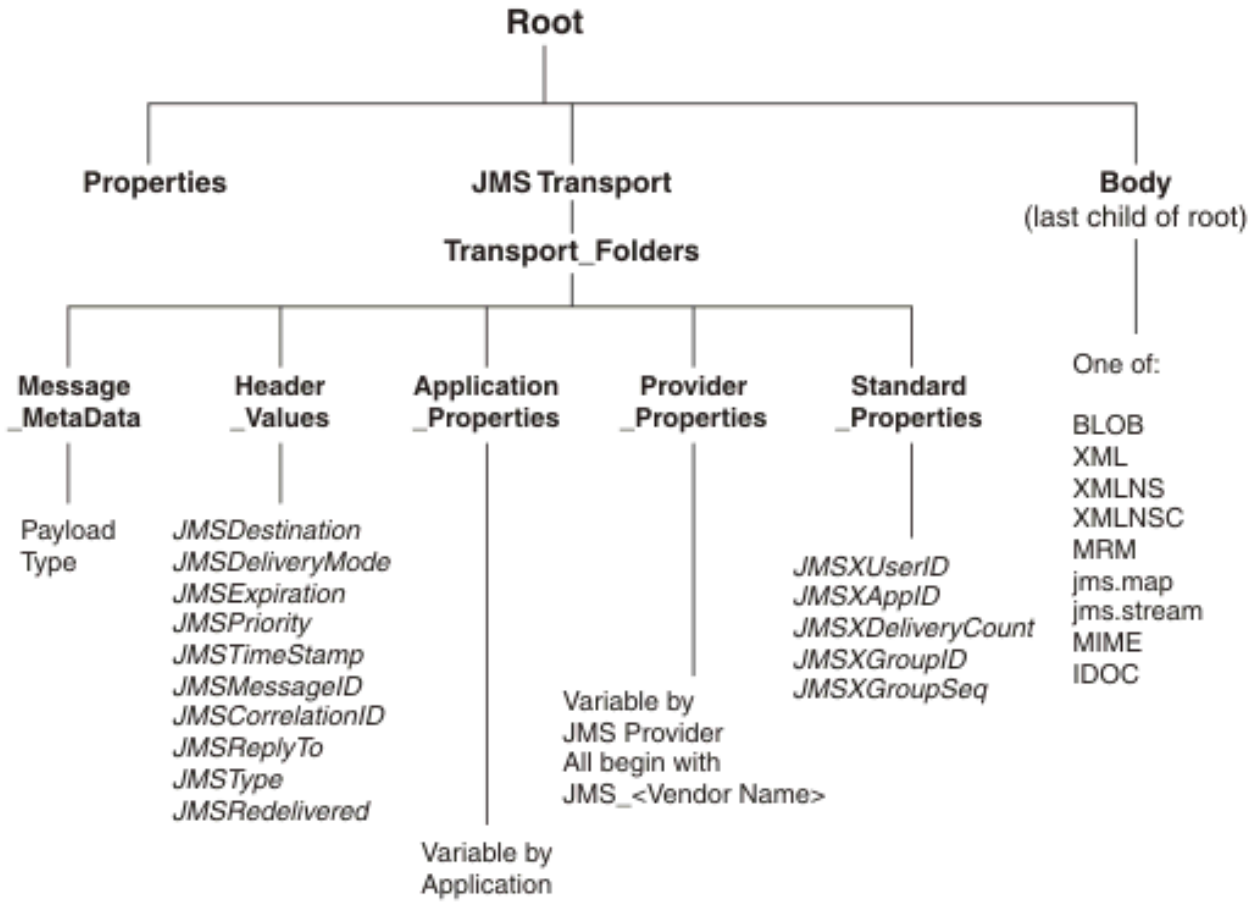
Refer to the following topics for further information about JMS messages and JMS providers:

- “Simplified JMS message representation” on page 852
- “JMS message transformation” on page 853
- “JMS message structure” on page 856
- “JMS message selector” on page 866
- “JMS Transactionality” on page 868
- “JMS message domain properties” on page 869
- “JMS properties for application communication models” on page 869

Simplified JMS message representation

The JMSInput node receives an input message as a Java object, and not as a bit stream wire format (as is the case with an MQInput node). The message does not populate an MQMD and RFH2 header, but instead populates a new message tree that represents a JMS message in a more native way.

To represent a JMS message in a message tree, a new canonical form has been created. This message tree allows for representation of JMS message header data, and message properties. The JMS message tree is in a format that is recognizable to Java programmers.



For details about the structure and content of the JMS message tree, see "Representation of messages in the JMS Transport" on page 858.

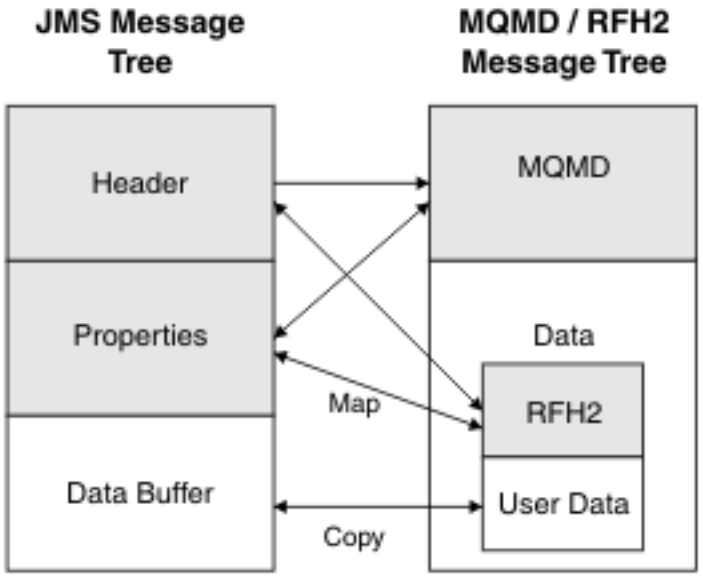
JMS message transformation
The JMSInput and JMSOutput nodes expect JMS messages, and therefore expect a native JMS message tree representation.

You can use the following nodes to transform messages between a WebSphere MQ JMS message tree and a JMS message tree:

- JMSMQTransform node
- MQJMSTransform node

These nodes do not have any configurable properties. The JMSMQTransform node transforms a native JMS message tree to an IBM MQ JMS message tree, and the MQJMSTransform node performs the transformation in the opposite direction.

The following diagram provides an overview of the mapping scheme that is used:



This mapping diagram uses the same scheme as the IBM MQ JMS provider to convert between a JMS message and an MQMD or MQRFH2 message.

When transforming between an IBM MQ message tree and a native JMS message tree, the transformation nodes copy elements from different parts of a message tree:

- The following fields are copied from the JMS message to the MQMD, if they exist in the incoming JMS message:

JMS field	**MQMD field**
JMSMessageID	MsgId
JMSCorrelationID	CorrelId
JMSPriority	Priority
JMSDeliveryMode	Persistence
JMSQApplid	PutApplName
JMSUser	UserIdentifier
JMSXDeliveryCount	BackoutCount - 1
JMSTimeStamp	PutDate, PutTime

- The following fields are copied from the JMS message to the MQRFH2 JMS folder:

JMS field	**MQRFH2 JMS field**
JMSDestination	Dst
JMSDeliveryMode	Dlv
JMSExpiration	Exp
JMSPriority	Pri
JMSTimestamp	Tms
JMSCorrelationID	Cid
JMSReplyTo	Rto

- The following fields are copied from the MQMD to the JMS message:

MQMD field	JMS field
Expiry	JMSExpiration
Persistence	JMSDeliveryMode
Priority	JMSPriority
MsgId	JMSMessageID
CorrelId	JMSCorrelationID
BackoutCount = 0	JMSRedelivered = false
BackoutCount > 0	JMSRedelivered = true
GroupId	JMSGroupid
MsgSeqNumber	JMSGroupseq
UserIdentifier	JMSUser
PutApplName	JMSApplid
PutDate, PutTime	JMSTimeStamp

- The following fields are copied from the MQRFH2 JMS folder to the JMS message:

MQRFH2 JMS field	JMS field
Dst	JMSDestination
Dlv	JMSDeliveryMode
Pri	JMSPriority
Cid	JMSCorrelationID
Rto	JMSReplyTo

Example message flow scenario: JMSInput node to MQOutput node

1. A JMSInput node is configured to subscribe to topic ABC.
2. An application that is connected to the JMS server publishes on topic ABC.
3. A publication is received at the JMSInput node.
4. The node extracts data from the JMS message.
5. The JMS message is passed to the JMSMQTransform node where the message is converted to an IBM MQ message.
6. The MQOutput node receives the IBM MQ message, and publishes the message on an IBM MQ queue.

The final destination is an IBM MQ queue, therefore the message must pass through a JMSMQTransform node to convert the message tree to an IBM MQ JMS format before it reaches the MQOutput node.

Example message flow scenario: MQInput node to JMSOutput node

1. An MQInput node receives a message from an IBM MQ queue.
2. The MQInput node creates an IBM MQ message.
3. The MQ message is passed to the MQJMSTransform node where the message tree is converted to a JMS format.
4. The JMSOutput node receives the JMS message and publishes the JMS message on topic XYZ.

Additional examples

These examples show some of the solutions that you can achieve when you use the JMS Transport. Other solutions are possible; for example, the message can be passed to a Compute node or a JavaCompute node and the contents can be modified as required.

JMS message structure
JMS messages have a defined structure that includes headers and payloads.

The following figure depicts the JMS message structure:

Header

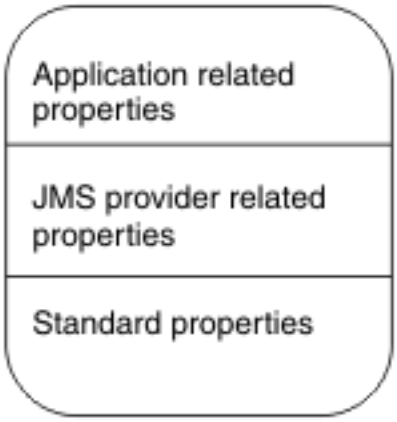
A header must be present in every JMS message, and it is assigned automatically. Most of the values in the header are set by the JMS provider when the message is put to a JMS destination. Some values can be declared by the JMS client when it creates a JMS session, or when it creates the message consumer or

producer; for example, *JMSDeliveryMode*, *JMSExpiration*, *JMSReplyTo*, and *JMSCorrelationID* are created when the JMS client creates a JMS session or creates the message consumer or producer.

The data elements of each header comprise name-value pairs and they can be any of the Java following types: Boolean, byte, short, char, long, int, float, double, string, or byte[].

Properties

The properties are optional, and can be divided into the following subsections:



- *Application-related properties*

  A Java application can assign application-related properties, which are set before the message is delivered. The property names of the application are meaningful only to the sending and receiving applications.
- *Provider-related properties*

  Every JMS provider can define proprietary properties that can be set either by the client or automatically by the provider. Provider-related properties are prefixed with *JMS_* followed by the vendor name and the specific property name. For example, the IBM MQ JMS client sets the provider property to be *JMS_IBM_MsgType*.
- *Standard properties*

  These properties are set by the JMS provider when a message is sent. The JMS provider vendor can choose to not support any standard properties, to support some standard properties, or to support all standard properties. Standard property names start with *JMSX*; for example: *JMSXUserid* or *JMSXDeliveryCount*.

The properties are handled as name-value pairs, and they can be any of the following Java types: Boolean, byte, short, char, long, int, float, double, string, or byte[].

Payload

The payload type defines the JMS message. It can be one of the six JMS message types that are described in "JMS message types" on page 857.

JMS does not define a wire format. The Java Message Service Specification describes the physical representation of how a message is structured.

JMS message types
JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where the payload is the body of a message that holds the content.

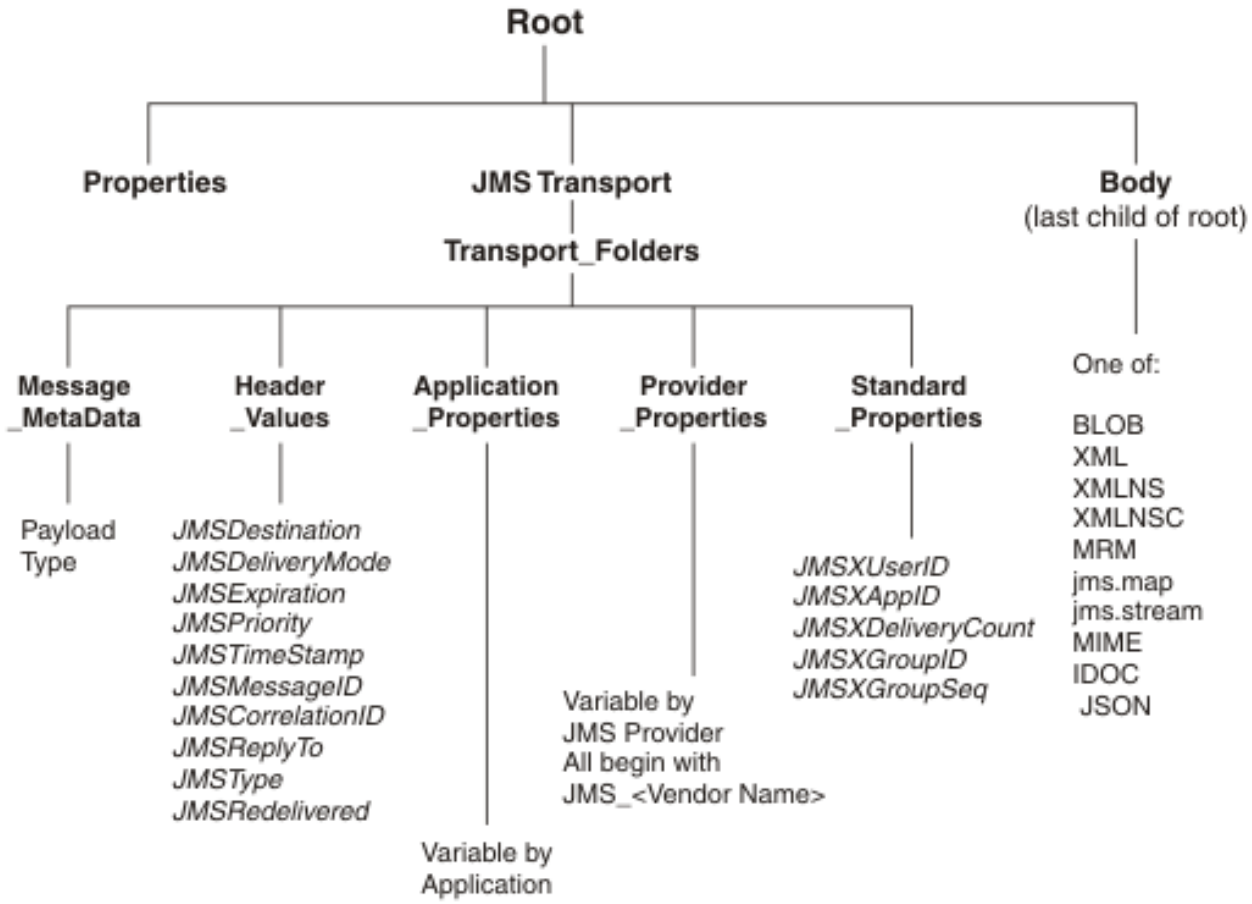
JMS specifies only the interface and does not specify the implementation. This approach allows for vendor-specific implementation and transportation of messages while using a common interface.

The following table describes the six message types:

Message type	Description
Message	The base class. This message type is used for event notification, and does not have a payload.
BytesMessage	The payload is stored as an array of bytes. This message type is useful for exchanging data in a format that is native to the application, and when JMS is used as a transport between two systems, where the JMS client does not know the message payload type. Use this message type to transmit XML messages to ensure that the message is transmitted efficiently, and is not subject to unnecessary data conversion.
TextMessage	Data is stored as a string. This message type is useful for exchanging simple text messages.
StreamMessage	A Stream message is a sequence of primitive Java types. The message object tracks the order and the types of these primitives within the stream. Formal conversion rules apply; for example, an exception is thrown if a JMS application tries to read a double value as a short value. Refer to the Java Message Service Specification version 1.1 or 2.0 for a full list of the conversion rules. `21ABCDEFGH32.345` is an example of a StreamMessage payload. It consists of the following three fields: • An Integer, 21 • A String, ABCDEFGH • A Float, 32.345 If the data structure is unknown, the generic method `readObject()` can be used to return the next object in the stream. If the structure of the data is known, the JMS client can be specific about the type of object being accessed.
MapMessage	The payload of a MapMessage is stored as a set of name-value pairs. The name is defined as a string and the value is typed. The MapMessage is useful for delivering keyed data that can change from one message to the next. `NumberOfCopies:5` is an example of a MapMessage payload, where `NumberOfCopies` is the key and 5 is the value. Data can be accessed by using `getMapNames()`, which returns a Java Enumeration object. It is possible to iterate through the MapMessage by using `hasMoreElements()` to retrieve the mapped name-value pairs.
ObjectMessage	The Object message carries a serializable Java Object as its payload. It is useful for exchanging Java objects.

Representation of messages in the JMS Transport
Messages that are sent in the JMS Transport are represented by the JMS Transport message tree.

The following figure depicts the JMS message tree that is propagated from the JMSInput node and can be propagated to the JMSOutput and JMSReply nodes. The JMSOutput and JMSReply nodes populate details of the JMS message that is sent to the LocalEnvironment WrittenDestination folder, as described in node.



JMSTransport

- *Header_Values* subfolder:

  This subfolder is mandatory and is always created.

- Properties subfolders:

  JMS message properties are optional; if they are present in the message, they are stored in the appropriate properties subfolder.

- *Message_MetaData* subfolder:

  This subfolder is included to preserve the payload type of the JMS message. The folder is used by the JMSOutput node when it creates a JMS message. The payload type can be one of the values shown in the following table.

Message type	Payload values
Base JMS message with no payload	jms_none
TextMessage	jms_text
BytesMessage	jms_bytes
MapMessage	jms_map
StreamMessage	jms_stream
ObjectMessage	jms_object

Body

The message payload is stored in the body folder, which is the last child of Root. The payload is transferred by using one of the following message domain parsers:

- DFDL
- XMLNSC
- JSON
- BLOB
- JMSMap
- JMSStream
- MIME
- XMLNS
- MRM
- IDOC

JMS message as input
The JMS message is a Java object, and therefore you cannot parse the message as a bit stream. When the message is received, the header data, property data, and payload data are extracted by using the JMS API.

For information on the header, properties, and payload of JMS messages, refer to "JMS message structure" on page 856.

The following topics describe how the different parts of the JMS message are obtained, and how the message is parsed:

- "JMS input message header and property data" on page 860
- "JMS Message payload" on page 862
- "JMS message payload and appropriate parser" on page 863

JMS input message header and property data
The JMSInput node obtains header and property data from JMS messages.

Header data

The JMSInput node extracts header data from messages by using JMS API methods. Header data is stored as name-value pairs in the *Header_Values* folder. The API methods return the value; for example, to get the value for the header field *JMSTimestamp*, the JMSInput node uses the `getJMSTimestamp( )` method. A similar method is provided for each of the following fixed header fields:

- JMSDestination
- JMSDeliveryMode
- JMSExpiration
- JMSPriority
- JMSTimeStamp
- JMSMessageID
- JMSCorrelationID
- JMSReplyTo
- JMSType
- JMSRedelivered

Property data

In a similar way to how the header data is obtained, the JMSInput node extracts property data from messages by using JMS API methods. Property data is stored as name-value pairs in the properties folders. The API method returns a value for every property name with which it is supplied.

XML representation of header and property data

The JMSInput node uses the header and property data to create an XML representation of the JMSTransport folders. The node passes the XML data to the JMSTransport parser as a byte array. The byte array is then used to populate or to refresh the elements in the message tree.

Preservation of Java type

A scheme is not required to preserve knowledge of the Java type because the header value Java types are fixed and known. The JMS message properties are optional, therefore a scheme is required to preserve the Java type of the property values. The scheme used is that which is implemented by the IBM MQ JMS client and the Real-timeInput node.

Java type information is represented as a metadata in the form of a keyword `dt='DataType'` where *Datatype* is a string. The Java type is passed in the XML as part of the element name `<ElementName dt='DataType'>Value</ElementName>`. *Datatype* can be any of the following values:

Datatype value	Definition
String	Any sequence of characters, excluding < and &
Boolean	The character `0` or `1`, where `1` is equal to "true"
bin.hex	Hexadecimal digits representing octets
I1	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -128 to 127 inclusive.
I2	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -32768 to 32767 inclusive.
I4	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -2147483648 to 2147483647 inclusive.
I8	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -9223372036854775808 to 9223372036854775807 inclusive.
int	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the same range as the datatype value`I8`. This number can be used in place of one of the `I*` types if the sender does not want to associate a particular precision with the property.
R4	A floating point number, expressed by using the digits 0..9, optional sign, optional fractional digits, optional exponent. Magnitude <= 3.40282347E+38, and>= 1.175E-37

Datatype value	Definition
R8	A floating point number, expressed by using the digits 0..9, optional sign, optional fractional digits, optional exponent. Magnitude <= 1.7976931348623E+308, and>= 2.225E-307

JMS Message payload
How payload is extracted from the JMS message for each of the JMS Message types.

The payload for some of the JMS message types can be extracted as a whole from the message object by using the JMS API. The payload is passed as a bit stream to an integration node parser. This is true for the following message types:

- BytesMessage
- TextMessage
- ObjectMessage

  Additional processing is required to deal with the ObjectMessage payload because the JMS ObjectMessage payload is a serialized Java Object.

  The JMSInput node obtains the payload by calling `getObject( )` on the message. `getObject( )` returns a de-serialized object of the original class. This class definition must be made available to the JMSInput node, and you should ensure that it is accessible through the integration node's Java class path. (The class path is defined in the mqsiprofile batch file, which is in the integration node's executable directory; for example, on Windows, this is `mqsiprofile.cmd` in the *`install_dir`*`/bin` directory.) The JMSInput node invokes the BLOB parser, which creates the message body by using a bit stream that is created from the object.

  The Java Object can be subsequently re-serialized in a JavaCompute node or a user-defined extension, and is updated by using its method calls.

The payload for MapMessage and StreamMessage can be extracted only as individual elements and must be reformatted by the JMSInput node before it can be used to create the message body.

- **MapMessage payload**

  The JMSMap domain is a synonym for the integration node XML parser, which expects a stream of XML data. MapMessage payload data however, is extracted as sets of name-value pairs from the message object. The JMS API is used to obtain the name-value pairs.

  The JMSInput node appends each name-value pair to a bit stream as an XML element and value, and preserves the type of the value by using the `dt=` attribute.

  The following example shows the XML that is generated by the JMSInput node for the MapMessage payload:

```
<map>
    <Item_8_of_10_Char dt='char'>A</Item_8_of_10_Char>
     <Item_5_of_10_Double dt='r8'>999999.0</Item_5_of_10_Double>
     <Item_10_of_10_String>Last Map Item</Item_10_of_10_String>
     <Item_9_of_10_Boolean dt='boolean'>0</Item_9_of_10_Boolean>
     <Item_2_of_10_Integrer dt='i4'>999</Item_2_of_10_Integrer>
     <Item_3_of_10_Short dt='i2'>9999</Item_3_of_10_Short>
     <Item_7_of_10_Byte dt='i1'>9</Item_7_of_10_Byte>
     <Item_6_of_10_Float dt='r4'>2.24</Item_6_of_10_Float>
     <Item_1_of_10_String>P2P Map Msg Number:1</Item_1_of_10_String>
     <Item_4_of_10_Long dt='i8'>99999</Item_4_of_10_Long>
```

```
            </map>
```

In this example, the message contains 10 fields. The field names have been generated by a JMS Client application, and take the form `item_n_of_x_t`, where:

- n is the sequence number in which the item was added to the message,
- x is the total number of items in the map,
- `t` is the type of the value.

The map data is not returned from the JMS API the order in which it was received.

If a JMSInput node receives a JMS MapMessage that contains characters that would be invalid in an XML tag, it escapes the names as follows:

1. The XML tag of the name element is formed by truncating the JMS message name element up to the location of the first invalid character.
2. The original name from the JMS name element is preserved in an attribute of the XML tag.
3. The closing XML tag matches the opening tag, without the tag attribute.

For example, a name-value pair of `<ORDER_ITEM[5]><WIDGET>` in a JMS MapMessage would be converted to XML and written to the message tree as `<ORDER_ITEM ibm_original_name="ORDER_ITEM[5]">WIDGET</ORDER_ITEM>`

- **StreamMessage payload**

  The StreamMessage payload data is a sequence of fields, where each field has a specific type. The fields do not have associated names and so a default element name `elt` is used to generate the XML elements. Similar to the MapMessage, the JMS API allows for fields only to be retrieved individually. The JMSInput node extracts fields from the JMS message and appends each to a bit stream in XML format.

  The following is an example of the XML that is generated by the JMSInput node for the StreamMessage payload:

```
<stream>
     <elt>P2P Stream Message  Number :7</elt>
     <elt dt='i4'>999</elt>
     <elt dt='i2'>9999</elt>
     <elt dt='i8'>99999</elt>
     <elt dt='r8'>999999.0</elt>
     <elt dt='r4'>2.24</elt>
     <elt dt='i1'>9</elt>
     <elt dt='char'>A</elt>
     <elt dt='boolean'>0</elt>
     <elt>Last Stream Item</elt>
</stream>
```

  In this example, 10 typed values are added to the StreamMessage by a JMS client application.

JMS message payload and appropriate parser
Configure the JMSInput node properties to specify the message domain that will be used to parse the JMS message payload.

When the JMSInput node creates a message tree from the JMS message payload, the appropriate message domain for that payload must be used. Therefore, the JMSInput node must know the type of JMS message that it expects to receive. The JMSInput node extracts the payload from the JMS message using the appropriate JMS API, then passes the payload data to the parser for the domain. The parser creates the body portion of the message tree.

The message domain is derived according to the following criteria and in the following order of precedence:

1. “The Message domain property is set to a specific domain” on page 864
2. “The Message domain property is left blank (default) and the JMSType header field from the JMS input message is used to indicate the domain” on page 864

3. "The Message Domain property is left blank (default) and the JMSType header field from the JMS input message is also left blank" on page 865

The Message domain property is set to a specific domain

In this case, the node expects to receive only the allowed JMS message types for that domain, as shown by the following table:

Message domain	Valid JMS message types				
	BytesMessage	**TextMessage**	**MapMessage**	**StreamMessage**	**ObjectMessage**
BLOB	•	•			•
XMLNS		•			
XMLNSC		•			
JMSMap			•		
JMSStream				•	
MIME	•	•			
IDOC	•	•			
MRM	•	•			
XML		•			

- If the JMSInput node receives a JMS message type that is not valid for the message domain that is configured in the JMSInput node, the node issues a warning and backs out the message either to the source JMS provider destination, or to the backout destination.
- If you specify the MRM domain, you must also specify the `Message model`, `Message` and `Physical format` node properties.
- If you specify the IDOC domain, you must also specify the `Message model` and `Physical format` node properties.
- If you specify the XMLNSC domain, and you want to validate input messages, you must also specify the `Message model` node property.

The Message domain property is left blank (default) and the JMSType header field from the JMS input message is used to indicate the domain

The JMSType header field must be set according to the URI format shown in the following table. The domain in the `mcd:` string can be uppercase or lowercase.

JMSType	Message domain
`mcd://BLOB`	BLOB
`mcd://MRM/[set]/[type]/[?format=fmt]`	MRM
`mcd://XMLNS`	XMLNS
`mcd://XMLNSC/[set]`	XMLNSC
`mcd://IDOC/[set]/[?format=fmt]`	IDOC
`mcd://MIME`	MIME
`mcd://XML`	XML

- If the JMSInput node receives a JMS message type that is not valid for the message domain configured in the JMSType header, the node issues a warning and backs out the message either to the source JMS provider destination, or to the backout destination.
- If the JMSType field does not conform to this URI format, the message is handled in the BLOB domain.
- For details of the `[type]` syntax, refer to "Specifying namespaces in the Message property" on page 2160 .
- If the XMLNSC domain is specified, use `[set]` only if you want to validate input messages.

The Message Domain property is left blank (default) and the JMSType header field from the JMS input message is also left blank

The message domain is set according to the JMS message Java class as follows:

JMS message type	Message domain
TextMessage	XML
BytesMessage	BLOB
MapMessage	JMSMap
StreamMessage	JMSStream
ObjectMessage	BLOB

JMS message for output
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

The node extracts the *Message_MetaData* and obtains the payload type information to identify which JMS message type to create for output. If the *Message_MetaData* folder is not present, the output node creates a BytesMessage by default.

Header data

The JMSOutput node extracts the JMS header data from the XML string, and uses this data to populate the values for the JMS header fields in the message.

Property data

The JMSOutput node extracts the property values from the XML string. The XML elements contain type information that identifies which Java Object type to create for each property value.

Message payload

The message payload is obtained from the JMS message as a bit stream. For TextMessage and BytesMessage payloads, the bit stream can be passed to the JMS API directly to create the appropriate payload.

For MapMessage and StreamMessage payloads, the individual elements must be extracted from the XML bit stream. The output node calls the appropriate JMS API method to create the map or stream fields in the message.

For an ObjectMessage payload, the JMSOutput node reserializes the bit stream payload by using the object class. The object class must be available in the Java class path for the integration node. The class path is defined in the **mqsiprofile** batch file, which is in the directory that contains the executable files for the integration node; for example, on Windows, the file is `mqsiprofile.cmd` in the *install_dir*`/bin` directory.

Sending JMS messages

The JMSOutput node generates and supports:

Sending a datagram message
A message with sufficient information to reach its destination, but without an expectation of there being a response as defined in the node attributes.

Sending a Reply message
The message is treated as a reply as defined by the JMSReplyTo property value.

Sending a Request message
The JMSOutput node sends a message to a defined JMS destination with the expectation of a response from the recipient.

See Using the Message Destination Mode for more information about how you perform these tasks.

Message publication

The message is published to the JMS destination that has been specified as a property of the JMSOutput node. However, if the JMSReplyTo header field is set in the JMS message, the JMSOutput node treats the message as a reply to a previous request, and publishes the message to the JMS destination of the previous request.

JNDI administered objects
JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

JMS clients use JNDI to browse a naming service to obtain references to administered objects. *Administered objects* are JMS connection factory and JMS destination objects, where JMS destination objects are topics and queues. Administered objects are created and configured by a system administrator.

To create and configure JNDI administered objects, refer to the JMS provider documentation. If you are using the IBM MQ JMS provider, see the sample JMSAdmin definitions file that is included with IBM MQ and refer to the *Using Java* section in the IBM MQ product documentation online.

Location of JNDI administered objects

JNDI administered objects are stored in the bindings. This storage can be either file system based or based on LDAP (Lightweight Directory Access Protocol). LDAP is a software protocol that enables everyone to locate organizations, individuals, and other resources; for example, locating files and devices in a network, either on the public Internet or on a corporate intranet.

LDAP is part of X.500, which is a standard for directory services in a network.

Naming service

A naming service associates names with distributed objects so that the administered objects are located by using names and not complex network addresses. JNDI provides an abstraction that hides the specifics of the naming service, which makes client applications more portable.

A JMS client specifies a *JNDI InitialContext* to obtain a JNDI connection to the JMS messaging server. The InitialContext is the starting point in any JNDI lookup and acts like the root of a file system. The JMS directory service that is being used determines the properties that are used to create an InitialContext.

JMS message selector
A message selector allows a JMS consumer to be more selective about the messages that it receives from a particular topic or queue.

A message selector uses message properties and headers as criteria in conditional expressions. These expressions use Boolean logic to declare which messages are delivered to a client, such as the JMSInput node.

The following table demonstrates the construction of a message selector. It comprises an identifier, such as the *JMSPriority* header, or an application controlled property *myProperty1*. The selector string must specify an operator followed by a literal.

Element	Valid values
Identifiers	• Property or header field reference (such as *JMSPriority*, *myProperty1*) • The following values are not possible: NULL, TRUE, FALSE, NOT, AND, OR, BETWEEN, LIKE, IN, IS
Operators	AND, OR, LIKE, BETWEEN, =, <>, <,>, <=, >=, IS NULL, IS NOT NULL
Literals	• The two Boolean literals, TRUE and FALSE • Exact number literals that have no decimal point; for example, +25, -399, 40 • Approximate number literals. These literals can use scientific notation or decimal; for example, -21.4E4, 5E2, +34.4928 • String literals, for example `TargetFunctionName='createOrderOnSuccess'`

The JMSInput and JMSReceive nodes provide a free format string *PropertySelector*, to specify selectors that filter or include application properties. These nodes also have properties for specific header properties, where the identifier is implicit and is generated by the node. For the header selectors, the operator and literal part of the string must be specified.

If more than one selector is specified the node generates a composite selector string, where the individual selector strings are concatenated with the AND operator, and each selector string part is wrapped with parentheses.

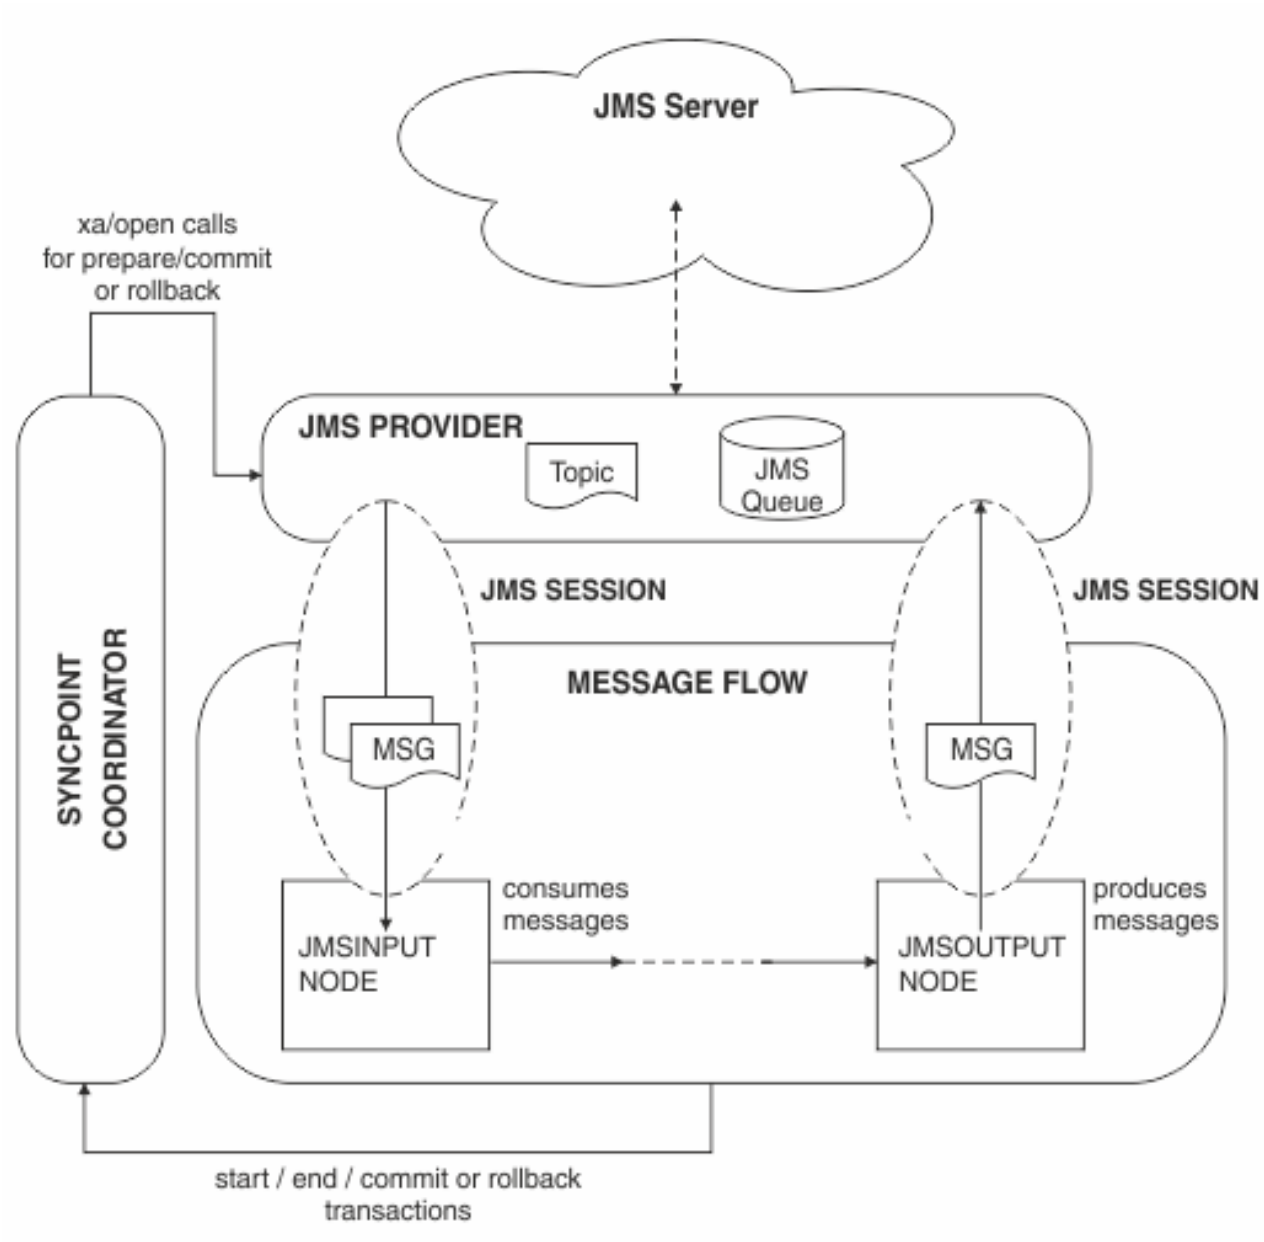
The following are examples for each of the selector properties:

Selector property	Description
PropertySelector	`OrderValue> 100.00` This string is used directly as shown. In the JMSInput node, this property is configured by the **Application property** field.
TimeStamp	`BETWEEN 1057576423231 AND 10575788993265` Messages that are put between these two Java times only (where Java time is milliseconds since 01 Jan 1970) is delivered to the JMSInput node. In this case, the string generated is prefixed with the identifier *JMSTimestamp*.
Delivery Mode	`PERSISTENT` This setting means that only messages marked by the sender as being PERSISTENT should be delivered to the JMSInput node. In this case, the string that is generated is prefixed with the identifier *JMSDeliveryMode*.
Priority	`>= 5 AND <= 8` This setting means that only messages marked by the sender as having a priority 5, 6, 7, or 8 are delivered to the JMSInput node. In this case, the string generated is prefixed with the identifier *JMSPriority*.
Message ID	`> WMBRK123456` This setting returns messages with a Message ID that is greater than the value specified. In this case, the string generated is prefixed with the identifier *JMSMessageID*.

Selector property	Description
Redelivered	FALSE This setting means that messages that have not been redelivered are received by the node. In this case, the string generated is prefixed with the identifier *JMSRedelivered*.
Correlation ID	= WMBRKABCDEFG This setting returns messages whose Correlation ID is equal to the value WMBRKBABCDEFG. In this case, the string generated is prefixed with the identifier *JMSCorrelationID*.

JMS Transactionality
JMS destinations that supply messages to an input node, or receive messages from an output node, can be sync-point coordinated as part of a message flow XA coordinated transaction.

Transactions involving the sync-point coordinator



In this diagram, messages are consumed from a queue by a JMSInput node, and are produced to a JMS queue by a JMSOutput node. The nodes are connected to, and are in session with, a JMS provider. Any message flow input node can inform the external sync-point coordinator when a message flow transaction starts and ends, and whether any resources that have been affected by the flow should be committed or rolled back.

The sync-point coordinator sends XA/Open compliant requests to all participating resource managers to inform them to prepare. Any changes are either committed or rolled back. Resource managers, for example, IBM MQ, DB2 and any XA compliant JMS provider can participate in an XA coordinated transaction.

On distributed systems, IBM MQ is the external sync-point coordinator (transaction manager), which means that IBM App Connect Enterprise must have access to IBM MQ when it is processing the messages in the flow. On z/OS, Resource Recovery Services (RRS) is the external sync-point coordinator. For more information about using IBM MQ with IBM App Connect Enterprise, see “Installing IBM MQ” on page 96.

On z/OS, the only JMS provider that is supported is the IBM IBM MQ Java Client, and the only transport mode supported for that client is BIND mode.

Nodes that use JMS transport, such as the JMS and SOAP nodes, can participate in an XA coordinated transaction only if the JMS provider to which they connect supports the XA/Open interface through the JMS XA`Resource` Class. An example JMS provider is the IBM MQ Java Client.

You can specify a generic connection factory (`recover`XAQCF) for recovery of XA coordinated transactions.

In-doubt transactions

In-doubt transactions can occur when a resource manager does not reply to a call from the sync-point manager, where the call is to commit or to rollback resources. During start up of the integration node's IBM MQ queue manager, an initial recovery step is taken to ensure that any in-doubt transactions are resolved before the integration node message flows start to process new input. A JMS provider that participates in integration node global transactions is included in this recovery step.

On operating systems other than z/OS, IBM MQ requires an administration task to be carried out before deployment. This task registers an integration node component, which is a shared library, with the queue manager by referring the shared library to a switch file.

When the integration node's IBM MQ queue manager starts up, it loads the switch file. The switch file forwards XA/Open transaction calls from the sync-point coordinator to the JMS Provider. This ensures that the JMS resources that participate in the transaction can be coordinated in synchronization with other resource managers that are involved in the same transaction.

Additional configuration is required to enable XA coordinated transaction support for the nodes using JMS transport; see “Configuring JMS and SOAP nodes to support globally coordinated transactions” on page 721.

JMS message domain properties
The JMSInput node and the JMSReceive node can receive message payloads that correspond to all of the JMS message types that are specified in the JMS Specification, versions 1.1 and 2.0.

The JMS Specification is defined in Java Message Service Specification. For more information, see “JMS message types” on page 857.

Set the JMSInput node and JMSReceive node properties to specify how the message payload is to be parsed. For more information, see node, node and “JMS message payload and appropriate parser” on page 863.

The JMSOutput node has no message domain properties.

JMS properties for application communication models
JMS clients can operate with both publish/subscribe and point-to-point messages. The publish/subscribe and point-to-point application communication models use virtual channels called *destinations*. In the

publish/subscribe model, the destinations are *topics*. For the point-to-point model, the destinations are known as *queues*.

The following application communication model properties can be configured for JMSInput, JMSReceive and JMSOutput nodes:

Property	Description
Connection Factory Name	A string name that is passed to JNDI to look up the administered connection factory object. The connection factory object is used to create a connection to the JMS destination. • For a client operating as a publish/subscribe client, the connection factory name is for a TopicConnectionFactory. • For a client operating as a point-to-point client, the connection factory name is for a QueueConnectionFactory.
Subscription Topic	The string name that is passed to JNDI to look up the JMS topic destination. The topic is used to create a JMS session when the node is being used to process publish/subscribe messages.
Durable Subscription ID	This is a JMSInput node property only. It is a string identifier that is specified if the node is to subscribe to a durable subscription topic. A durable subscription is one that outlasts the client's connection to a message server. When a durable subscriber is disconnected from the server, the server stores messages that are published. Therefore, when the durable subscriber reconnects, the message server sends all the unexpired messages. Durable subscriptions cannot be unsubscribed from a message flow. A separate administration task unsubscribes a previously registered durable subscription. Some JMS providers supply an administration tool to perform this action.
Source Queue	The string name that is passed to JNDI to look up the JMS queue destination. The queue is used to create a JMS session when the node is being used to process point-to-point messages.

The `Subscription Topic` and `Source Queue` properties are mutually exclusive because they configure the node to work with either the publish/subscribe message model or the point-to-point message model.

The JMSReceive node operates only with point-to-point messages.

A `Durable subscription ID` is not valid without a `Subscriber Topic` property.

Working with JMS

Learn about the concepts and tasks involved in configuring message flows to support JMS messages.

Before you begin

Read the following topics for an overview of the concepts related to processing JMS messages

- "Using JMS in IBM App Connect Enterprise" on page 852
- "Java Message Service (JMS) API" on page 851
- "JMS Transactionality" on page 868
- "JMS message selector" on page 866
- "JMS properties for application communication models" on page 869
- "JMS message domain properties" on page 869

About this task

The following areas are included:

- “Configuring resources for processing JMS messages” on page 874
- “Troubleshooting JMS nodes” on page 885

Connection to different JMS providers
The JMSInput, JMSReceive and JMSOutput nodes are compatible with all JMS providers that conform to the Java Message Service Specification, versions 1.1 and 2.0.

If you want these nodes to participate in coordinated transactions, the JMS provider must support the XAResource interface, as defined in the Java Message Service Specification.

JBoss exception handling

If you use JBoss from a JMSInput node, set the `Handle connection exceptions asynchronously` property to **`True`** on the JMS Providers policy so that the integration node can detect a failure in the JMS connection.

Configuring JMS nodes to communicate with WebSphere Application Server service integration bus
You can configure a stand-alone JMS client and JMS nodes to communicate with service integration bus (SIBus) in WebSphere Application Server Version 6 and Version 7.

About this task

Procedure

1. Complete the following steps in WebSphere Application Server. For more information, see the WebSphere Application Server documentation.
   a) Create a messaging bus.
   b) Add a bus member.
   c) Restart the WebSphere Application Server server.
   d) Create a queue destination on the bus.
   e) Create a JMS queue on the default messaging provider.
   f) Create a Queue Connection Factory (QCF) on the default messaging provider.

      Ensure that the messaging provider URL is specified in the QCF definition, particularly if the JMS client and messaging bus are on different computers. The provider endpoint URL must have the following format:

      ```
      bus_member_host_name:7276:BootstrapBasicMessaging
      ```

      where 7276 is the default SIB endpoint address. Do not use 127.0.0.1 or localhost for the bus member host name.

2. Test the WebSphere Application Server configuration by using a stand-alone JMS client and completing the following steps.
   a) Put the following two JAR files in your class path: `com.ibm.ws.sib.client.thin.jms_7.0.0.jar` and `com.ibm.ws.ejb.thinclient_7.0.0.jar`.

      Copy these JAR files from the WebSphere Application Server Version 7 installation directory under the runtimes subdirectory. If you are using a non-IBM JRE, you also need the `com.ibm.ws.orb_7.0.0.jar` file.
   b) Ensure that the provider URL is set to `iiop://`*`WAS_server_host_name`*`:`*`boot_strap_port`*.
   c) Ensure that you specify the correct boot strap port.
   d) Ensure that the Queue Connection Factory and JMS Queue properties are set to the values defined in the WebSphere Application Server configuration.
   e) Compile the JMS client code.
   f) Run the JMS client with the following IBM ORB debug parameters turned on.

      ```
      java -Dcom.ibm.CORBA.Debug=true -Dcom.ibm.CORBA.CommTrace=true -Dcom.ibm.CORBA.D
       ebug.Output=client.log JMS_Client_Class
      ```

      This command produces CORBA debug output in the `client.log` file in the same directory.
3. Complete the following steps in IBM App Connect Enterprise.
   a) Stop the integration server.
   b) Create a directory (for example, `c:\WebSphere_WAS_Client`) and copy the following two JAR files from WebSphere Application Server Version 7 Thin Client for JMS.
      - `com.ibm.ws.sib.client.thin.jms_7.0.0.jar`
      - `com.ibm.ws.ejb.thinclient_7.0.0.jar`

      Alternatively, you can copy these files from the WebSphere Application Server installation directory *`WAS home`*`/runtimes`.
   c) Configure the JMS service in IBM App Connect Enterprise by using the **mqsichangeproperties** command. The JMS provider WebSphere_WAS_Client exists; therefore you can change the client JAR file path for that provider.

      ```
      mqsichangeproperties integrationNodeName -c JMSProviders -o WebSphere_WAS_Client -n
       jarsURL -v WAS_thin_client_JAR_file_path
      ```
   d) Optional: Verify that your JMS service is configured correctly.
   e) Configure the JMSInput node as shown in the following example.

      For more information about these properties, see node.
      - Specify the name of the JMS provider; for example, Client for WebSphere Application Server.
      - Specify the initial context factory; for example, `com.ibm.websphere.naming.WsnInitialContextFactory`.
      - Specify the location of the JNDI bindings in the format `iiop://`*`WAS_server_host_name`*`:`*`WAS_server_boot_strap_port`*.
      - Set the connection factory name to QCF.
   f) Ensure that the JMS connection has been established before the message flow starts by using the Windows Event Viewer.

Configuring JMS nodes to communicate with Oracle AQ
You can configure the JMS nodes to communicate with Oracle AQ (Oracle 11g and above). This communication requires an LDAP 3 compliant server to hold definitions for JNDI lookup by the JMS nodes.

About this task

Procedure

1. Complete the following steps in Oracle AQ, referring to Oracle documentation for the specific details of each step.
   a) You must install the Oracle Internet Directory Server (OID) to host the JNDI administered objects for Oracle AQ.
      - You can configure Oracle AQ to register JMS connection factories and destinations (queues and topics) automatically with the OID server when these JMS connection factories and destinations are created in the Oracle database.
   b) Create the database tables to hold the JMS queues and topics.
   c) Create the JMS queues and topics and associate them with the tables created in step 1b.
2. Add definitions for the JMS connections to the LDAP server to permit the integration node JMS nodes to complete JND lookup and connect to the Oracle AQ server.
   a) Register JMS connection factories with the OID LDAP server by using the administrative tools provided by Oracle.
   b) The following diagram describes the shape of the directory tree for JNDI administered objects for Oracle

   AQ.
3. Copy the Oracle AQ JMS client JAR files to a local directory that is accessible by the integration node.
   - The `aqapi.jar` file is found on the Oracle AQ server in directory *`oracle_install_path`*`/rdbms/jlib`.
   - The `ojdbc5.jar` file is found on the Oracle AQ server in directory *`oracle_install_path`*`/jdbc/lib`.
   - The orai18n.jar found on the Oracle AQ server in directory *`oracle_install_path`*`/jlib`.
4. Modify the JMS Providers policy for Oracle AQ to identify the location of the Oracle JAR files.

5. Configure the properties on the JMS Connection tab of the JMS node (input, output, or reply node) as shown in the following example. For more information about these properties, see node.
   - Set the `JMS provider name` property to `Oracle_AQ`.
   - Set the `Initial context factory` property; for example:

     ```
     com.sun.jndi.ldap.LdapCtxFactory
     ```

     For all nodes that refer to the JMS Providers policy, if this property is set on the policy, it overrides the property that is set on the node.
   - Set the `Location JNDI bindings` property; for example:

     ```
     ldap://LDAP_server_address:LDAP_listener_port
     ```

     For all nodes that refer to the JMS Providers policy, if this property is set on the policy, it overrides the property that is set on the node.
   - Set the `Connection factory name` property. This name must be the fully qualified path in the LDAP directory; for example:

     ```
     cn=QCF,cn=oracledbconnections,cn=ORCL,cn=OracleContext,
     ou=MyDept,o=MyCompany
     ```

     Where
     - cn=QCF is the JMS connection factory name.
     - cn=oracledbconnections is the branch for JMS connection factory definitions.
     - cn=ORCL is the Oracle AQ database name.
     - cn=OracleContext is the root of the Oracle RDBMS schema.
     - ou=MyDept, o=MyCompany is the installation-specific LDAP administrative context.
6. On the Basic tab, configure the JMS destinations (queue or topic) properties.
   - Set the `Source queue` property on the JMSInput node. This queue must be the fully qualified path in the LDAP directory; for example:

     ```
     cn=JMS.Queue,cn=oracleDBQueues,cn=ORCL,cn=OracleContext,
     ou=MyDept,o=MyCompany
     ```

     Where
     - cn=JMS.Queue is the JMS queue.
     - cn=oracleDBQueues is the branch for JMS queues and topic definitions.
     - cn=ORCL is the Oracle AQ database name.
     - cn=OracleContext, is the root of the Oracle RDBMS schema.
     - ou=MyDept, o=MyCompany is the installation-specific LDAP administrative context.
7. Before the message flow starts, ensure that the JMS connection has been established by using the Windows Event Viewer.

Configuring resources for processing JMS messages
A number of nodes are provided in IBM App Connect Enterprise for processing and routing JMS messages. Follow the links in this topic to find out how to configure the JMS nodes and other resources for processing JMS messages.

About this task

IBM App Connect Enterprise provides the following nodes for working with JMS messages:

JMSInput node
Use a JMSInput node if the messages are received from a JMS application.

JMSOutput node
Use a JMSOutput node if the messages are sent to a JMS destination.

JMSReceive node
Use a JMSReceive node to receive JMS messages in the middle of a message flow. The JMSReceive node has a similar function to the JMSInput node, but the JMSReceive node can consume or browse JMS queues in the middle of a message flow. The result message is combined with the input message and propagated to the out terminal.

JMSReply node
The JMSReply node has a similar function to the JMSOutput node, but the JMSReply node sends JMS messages only to the reply destination that is supplied in the JMSReplyTo header field of the JMS message tree. Use the JMSReply node to treat a JMS message that is produced from a message flow as a reply to a JMS input message, and when you have no other routing requirements.

JMSMQTransform node
Use the JMSMQTransform node to transform a message with a JMS message tree into a message that has a tree structure that is compatible with the format of messages that are produced by the IBM MQ JMS provider.

The JMSMQTransform node can be used to send messages to existing message flows and to interoperate with IBM MQ JMS and IBM MQ Publish/Subscribe.

MQJMSTransform node
Use the MQJMSTransform node to receive messages that have an IBM MQ JMS provider message tree format, and transform them into a format that is compatible with messages that are to be sent to JMS destinations.

You can use the MQJMSTransform node to send messages to existing message flows and to interoperate with IBM MQ JMS and IBM MQ Publish/Subscribe.

JMSHeader node
Use a JMSHeader node to change JMS Header_Values properties, or add, modify, or delete JMS Application properties without programming.

SOAPInput node
Use a SOAPInput node for SOAP messages received from a JMS application.

SOAPReply node
The SOAPReply node sends SOAP messages using JMS transport only to the reply destination specified in the received message. Use the SOAPReply node to treat a JMS message that is produced from a message flow as a reply to a JMS input message.

SOAPRequest node
Use a SOAPRequest node to send a SOAP request to a remote web service. This node is a synchronous request and response node, and blocks after sending the request until the response is received.

SOAPAsyncRequest and SOAPAsyncResponse nodes
Use a SOAPAsyncRequest node with a SOAPAsyncResponse node to construct a pair of message flows that call a web service asynchronously.

To use JMS nodes in your message flows, there are additional configuration steps that you might need to complete. See the following topics for information about additional configuration tasks that you might need to complete.

Procedure

- “Windows systems: modifying the queue manager authorization” on page 882
- “Securing JMS connections and JNDI lookups” on page 882
- “Enabling a JMS provider's proprietary API” on page 227
- “Processing bytes messages with JMS nodes” on page 884
- “Configuring JMS and SOAP nodes to support globally coordinated transactions” on page 721.

Configuring JMS and SOAP nodes to support globally coordinated transactions
To include message flow nodes that use JMS transport, such as the JMS and SOAP nodes, in globally coordinated transactions, you must complete additional configuration.

Before you begin

Review "Configuring JMS and SOAP nodes for local transactions" on page 700 to understand what properties you must set on a SOAP or JMS node to use globally coordinated transactions.

Note: Global (XA) transaction coordination for nodes that use JMS transport is supported only if the message flow that contains the nodes is deployed to an integration node that has a dedicated queue manager; the integration node cannot share a queue manager with other integration nodes.

About this task

If you require global transaction coordination, choose a JMS provider that conforms to the Java Message Service Specification version 1.1 or 2.0, and that supports the JMS XAResource API through the JMS session.

If you specify your own JMS provider by using the JMS Providers policy, set the `XA is supported` property of the policy to true to indicate that the selected JMS provider supports XA coordinated transactions. If you set this property to true, and the selected JMS provider does not support XA transactions, an exception is raised. If you set this property to false, but the `Transaction mode` property on the node is set to `Yes` and the `Coordinated Transaction` message flow property is selected, an exception is raised.

If the message designer specified a non-XA-compliant provider, only the non-transactional mode is supported. In this case, you must set the `Transaction mode` property to `None` for all JMS and SOAP nodes that use JMS transport.

On distributed systems, an IBM MQ queue manager provides the coordinated transaction support, which means that IBM App Connect Enterprise must have access to IBM MQ when it is processing the messages in the flow. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

Procedure

To configure the message flow nodes, complete the following steps:

1. In the IBM App Connect Enterprise Toolkit, switch to the Integration Development perspective.
2. In the BAR file properties, set the `Coordinated Transaction` message flow property value to **yes**.
3. In the Message Flow editor, set the **Transaction mode** property to `Yes` for each node that uses JMS transport that is required in the XA coordinated transaction.
4. Create a Queue Connection Factory, and use either the default name, *recoverXAQCF*, or supply your own name.

   For more information about creating JNDI administered objects, see "JNDI administered objects" on page 866.

5. There are two modes for enlisting an XAResource with the transaction coordinator:
   a. Static enlistment, which means that the XAResource is called to perform a start transaction when any message flow in the same Integration Bus starts a global coordinated transaction.
   b. Dynamic enlistment where the JMS node registers an interest in joining a global transaction when it has work to perform.

   Before deployment on distributed systems, you must set up a stanza for each JMS provider that you want to use. For Windows, the JMS provider switch file is called `DynJMSSwitch.dll`. For all other operating systems, the JMS provider switch file is called `libDynJMSSwitch.so`.

   Follow the steps in the appropriate topic for the operating system, or systems, that your enterprise uses:

   - Linux Linux and UNIX systems
   - Windows Windows systems

     On Windows only, you must also modify the queue manager authorization, as described in "Windows systems: modifying the queue manager authorization" on page 882.

What to do next

The JMS provider might supply additional JAR files that are required for transactional support; for more information, see the documentation that is supplied with the JMS provider. For example, on distributed systems, the IBM MQ JMS provider supplies an extra JAR file, `com.ibm.mqetclient.jar`.

You must add any additional JAR files to the `shared_classes` directory:

- Linux On Linux and UNIX: `var/mqsi/shared-classes`.
- Windows On Windows: `C:\ProgramData\IBM\MQSI\shared-classes`.

For more information, see the section about making the JMS provider client available to the JMS nodes in node.

Configuring the queue manager to coordinate JMS resources on Linux and UNIX

Configure the global (XA) resource managers for the queue manager by defining a stanza in the integration node's queue manager `qm.ini` file for each new JMS provider.

About this task

The JMS provider can be specified by a JMS or SOAP node that is included in a message flow that is running on the integration node.

Before you deploy a message flow in which the `Transaction mode` property is set to `Global` or `Yes`, and is intended to use XA coordinated transactions, modify the queue manager `.ini` file to include extra definitions for each JMS provider resource manager that participates in globally coordinated transactions.

To configure the queue manager for Linux and UNIX:

Procedure

1. Add a stanza to the queue manager `.ini` file for each JMS provider, in the following format:

```
XAResourceManager:
    Name=<Name>
    SwitchFile=/install_dir/server/lib/libDynJMSSwitch.so
    XAOpenString=<Initial Context Factory>,
              <location of JNDI bindings>'
              <LDAP Principal>,
              <LDAP Credentials>,
              <Recovery Connection Factory Name>,
              <JMS Principal>,
              <JMS Credentials>
```

```
                ThreadOfControl=THREAD
```

The parameters for the stanza are as follows:

<Name>
Required. The name of the defined JMS provider resource manager.

<SwitchFile>
Required. The file system path to the Switch library that is supplied in the `bin` directory of the integration node. There are two options:

a. The library called JMSSwitch, which manages XAResources that statically enlist with the transaction coordinator.

b. The library called DynJMSSwitch, which manages dynamically enlisted XAresources.

install_dir
The location of the IBM App Connect Enterprise installation. This value is required where the LDAP parameters are omitted, but a user-defined Queue Connection Factory is specified for recovery.

<Initial Context Factory>
Required. The Initial Context Factory identifier for the JMS provider. This value is set in the JMSInput node property `Initial context factory`.

<Location of JNDI bindings>
Required. Use either the filepath to the bindings file, or the LDAP directory location of the JNDI administered objects that can be used to create an initial context factory for the JMS connection. If you supply a file path to the bindings file, do not include the file name. For more information about creating the JNDI administered objections, see node or node.

The values for the *Initial Context factory* and *Location of JNDI bindings* in the stanza must match the values that you specified in the JMS or SOAP nodes in the message flows.

<LDAP Principal>
Optional. Specify the principal (user ID) that might be required when an LDAP database is used to hold the JNDI administered objects. `LDAP Principal` must match the value that is set for the integration node by using the **`mqsicreatebroker`** command. `LDAP Principal` is not currently supported, it is reserved for future use.

<LDAP Credentials>
Optional. Specify the Credentials (password) that might be required if a password protected LDAP database is used to hold the JNDI administered objects. `LDAP Credentials` must match the value that is set for the integration node by using the **`mqsicreatebroker`** command. `LDAP Credentials` is not currently supported, it is reserved for future use.

<Recovery Connection Factory Name>
Optional. Specify the name of a Queue Connection Factory object in the JNDI administered objects for recovery purposes. If a value is not specified, you must add a default value for `recover`XAQCF to the bindings file. In either case, the Recovery Connection Factory must be defined as an XA Queue Connection Factory for the JMS provider that is associated with the `Initial context factory`.

<JMS Principal>
Optional. Provide the user ID required to connect to a JMS provider, by using a secure JMS Connection Factory. `JMS Principal` is not currently supported, it is reserved for future use.

<JMS Credentials>
Optional. Provide the password that is required to connect to the same JMS provider in conjunction with the JMS principal. `JMS Credentials` is not currently supported, it is reserved for future use.

The JMS Principal and JMS Credentials must be configured together.

The optional parameters are comma-separated and are positional. Therefore, any parameters that are missing must be represented by a comma, as seen in the following example stanza.

The example stanza describes IBM MQ Java as the JMS provider for global transactions:

```
XAResourceManager:
```

```
    Name=XAJMS_PROVIDER1
    SwitchFile=/install_dir/server/lib/libDynJMSSwitch.so
    XAOpenString= com.sun.jndi.fscontext.RefFSContextFactory,
              /Bindings/JMSProvider1_Bindings_Directory,
              ,
              ,
              ,
              myJMSuser1,
              passwd
              ThreadOfControl=THREAD
```

where:

- XAJMS_PROVIDER1 is the user-defined name for the resource manager
- /*install_dir*/server/lib/libDynJMSSwitch.so is the installation path
- com.sun.jndi.fscontext.RefFSContextFactory is the *<Initial Context Factory>*
- /Bindings/JMSProvider1_Bindings_Directory is the location of the bindings file
- myJMSuser1 is the *<JMS Principal>*
- passwd is the password used in *<JMS Credentials>*

In this example, the optional fields <LDAP Principal>, <LDAP Credentials>, and <Recovery Connection Factory Name> are not required, therefore the positional comma delimiters only are configured in the XAOpenString stanza.

2. Update the Java PATH environment variable for the queue manager of the integration node to point to the bin directory in which the switch file is located.
   For example:

```
install_dir/server/bin
```

Switch files are installed in the *install_dir*/server/lib directory. To simplify the contents of the qm.ini file, create a symbolic link to the switch file for the queue manager to retrieve from the /var/mqm/exits64 directory. For example:

```
ln -s install_dir/server/lib/libDynJMSSwitch.so /var/mqm/exits64/libDynJMSSwitch
```

What to do next

Check your configuration:

- In the message flow, ensure that the coordinated property is enabled by using the IBM App Connect Enterprise Archive editor.
- Ensure that each message flow node that is part of the XA transaction is set to the global transaction mode.
- Ensure that the service ID that is used for the integration node and the queue manager is the same user ID.
- Ensure that the JNDI connection factory objects that the JMS nodes use for a global transaction are configured to be of the type MQXAConnectionFactory, MQXAQueueConnectionFactory, or MQXATopicConnectionFactory.
  - If you create the bindings by using JMSAdmin, use the command **DEF XAQCF** or **DEF XATCF**, instead of **DEF QCF** or **DEF TCF**, when you define your connection factory.

For more information, see Transactional support in the IBM MQ product documentation online.

Configuring the queue manager to coordinate JMS resources on Windows
Use IBM MQ Explorer to configure the global (XA) resource managers for the queue manager.

About this task

Before you deploy a message flow in which the `Transaction mode` property is set to `Global` or `Yes`, and is intended to use XA coordinated transactions, modify the queue manager `.ini` file to include extra definitions for each JMS provider resource manager that participates in globally coordinated transactions.

To configure the queue manager for Windows:

Procedure

1. Open IBM MQ Explorer.
2. Select the queue manager for your integration node and click **Properties**.
3. Select **XA resource managers** in the left pane and click **Add**.
4. Complete the fields to define a new resource manager:
   a) **Name**: Enter the name of the resource manager; for example, `IIBWMQJMS`.
   b) **SwitchFile**: Enter **DynJMSSwitch**.
   c) On **XAOpenString**, enter the following values, which are comma delimited and positional. Represent missing optional parameters by a comma if you include other parameters later in the string.

   Initial Context Factory
   The Initial Context Factory identifier for the JMS provider; this value is required.

   Location of JNDI bindings
   Either the file path to the bindings file, or the LDAP directory location of the JNDI administered objects that can be used to create an initial context factory for the JMS connection. If you supply the file path to the bindings file, do not include the file name. See the JMSInput or JMSOutput node for further details about creating the JNDI administered objects; this value is required.

   The values for the *Initial Context factory* and *Location of JNDI bindings* in the stanza must match the values that you specified in the JMS or SOAP nodes in the message flows.

   LDAP Principal
   Optional: The principal (user ID) that might be required when an LDAP database is used to hold the JNDI administered objects. `LDAP Principal` is not currently supported, it is reserved for future use.

   LDAP Credentials
   Optional: The credentials (password) that might be required if a password protected LDAP database is used to hold the JNDI administered objects.

   All LDAP parameters must match the values that you specified on the **`mqsicreatebroker`** command. `LDAP Credentials` is not currently supported, it is reserved for future use.

   Recovery Connection Factory Name
   Optional: The name of a Queue Connection Factory object in the JNDI administered objects for recovery purposes, when the non-default name is required.

   The Recovery Factory Name must match a Queue Connection Factory name that is created in the JNDI administered objects. If you do not specify a name, a default factory that is called

recoverXAQCF is used. In either case, this value must refer to a JNDI administered object that has already been created.

JMS Principal
The user ID that is required to connect to a JMS provider, using a secure JMS Connection Factory. `JMS Principal` is not currently supported, it is reserved for future use.

JMS Credentials
The password that is required to connect to the same JMS provider with the JMS principal. `JMS Credentials` is not currently supported, it is reserved for future use.

The JMS Principal and JMS Credentials must be configured together.

a) **XACloseString**: Leave this field blank.

b) **ThreadOfControl**: Set the value to `Thread`.

5. Click **OK** to complete the XA resource manager definition.
6. Click **OK** to close the queue manager properties dialog.
7. Click **File** > **Exit** to close IBM MQ Explorer.
8. Copy the `DynJMSSwitch.dll` file to the `\exits64` folder in the IBM MQ installation directory.
9. Copy the `DynJMSSwitch32.dll` file to the `\exits` directory in the IBM MQ installation directory and then rename the file to `DynJMSSwitch.dll`.
10. Set the `XAOpenString` property to a string value as follows: *`Initial Context,location JNDI,Optional_parms`*.
11. Set the `ThreadOfControl` property to `Thread`.

What to do next

- Check your configuration:
  - In the message flow, ensure that the coordinated property is enabled by using the IBM App Connect Enterprise Archive editor.
  - Ensure that each node that must be part of the XA transaction is set to the global transaction mode.
  - Ensure that the service ID that is used for the integration node and the queue manager is the same user ID.
  - Ensure that the JNDI connection factory objects that the JMS nodes use for a global transaction are configured to be of the type MQXAConnectionFactory, MQXAQueueConnectionFactory, or MQXATopicConnectionFactory.
    - If you create the bindings by using JMSAdmin, use the command **DEF XAQCF** or **DEF XATCF**, instead of **DEF QCF** or **DEF TCF**, when you define your connection factory.
- Authorize the integration node and queue manager to access shared resources that are associated with the JMS provider; see "Windows systems: modifying the queue manager authorization" on page 882.

For more information, see Transactional support in the IBM MQ product documentation online.

Troubleshooting

IBM App Connect Enterprise examines the IBM MQ registry to determine if the queue manager is XA enabled. If IBM App Connect Enterprise is unable to locate the location of the queue managers working directory, an error is issued at startup. You can specify this location by setting the following environment variable in the `mqsiprofile` script: `MQ_DATA_PATH` For example:

```
MQ_DATA_PATH="C:\Program Files (x86)\IBM\IBM MQ"
```

Windows systems: modifying the queue manager authorization
Authorize the integration server and queue manager to access shared resources that are associated with the JMS provider.

Before you begin

Set up the JMS Providers policy (see Making the JMS provider client available to the JMS nodes (in the JMSInput node topic) or Making the JMS provider client available to the JMS nodes (in the JMSOutput node topic).

About this task

If you specified an existing queue manager when you created the integration node, check that its administrative ID is the same ID as that used for the service ID of the integration node. If the ID is not the same, change the queue manager ID to be the same as the integration node service ID.

Complete the following steps on the Windows system on which the integration node is running:

Procedure

1. Click **Start** > **Run** and enter dcomcnfg. The Component Services window opens.
2. In the left pane, under Console Root, expand **Component Services** > **Computers** > **My Computer** and click **DCOM Config**.
3. In the right pane, under DCOM Config, right-click the IBM MQ service labelled **IBM MQSeries Services**, and click **Properties**.
4. Click the **Identity** tab.
5. Select **This user** and enter the user ID and password for the integration node service ID to associate that ID with the queue manager.
6. Click **OK** to confirm the change.

Securing JMS connections and JNDI lookups
If you want additional security for JMS connectivity and the JMS nodes or SOAP nodes using JMS transport, two configuration options are supported.

About this task

When you include JMS nodes in your message flow, you can optionally secure JMS connection resources. You can secure one, both, or neither of these options, depending on the level of security and access that you want to enforce.

Procedure

1. To secure a JMS connection:
   a) Specify the Connection Factory Name property on the node.
      You must set this property for every node using JMS transport.
   b) Use the **mqsisetdbparms** command to authorize the user ID and password for the specified connection factory.
      For example:

```
mqsisetdbparms -w c:\workdir\ACEServ1 -n jms::tcf1 -u myuserid -p secret
```

      where `tcf1` is the name of the connection factory that matches the node property that you set.

2. To secure JNDI bindings lookups:
   a) Specify the Initial Context Factory property on the node.
      You must set this property for every node using JMS transport.
   b) Use the **mqsisetdbparms** command to authorize the user ID and password for the specified context factory.
      For example:

```
mqsisetdbparms -w c:\workdir\ACEServ1 -n jndi::com.sun.jndi.fscontext.RefFSContextFactory
     -u myuserid -p secret
```

      where `com.sun.jndi.fscontext.RefFSContextFactory` is the name of the initial context factory that you set.

Enabling a JMS provider's proprietary API
Some JMS providers provide an alternative interface to the standard JMS specification for particular JMS API calls. In these cases, IBM supplies a Java class to interface with that proprietary API.

About this task

For example, BEA WebLogic uses a component called a *Client Interposed Transaction Manager* to allow a JMS client to obtain a reference to the XAResource that is associated with a user transaction.

If the WebSphere IBM Integration JMS nodes use BEA WebLogic as the JMS provider, and the nodes must participate in a globally coordinated message flow, you must modify the policy properties that are associated with that vendor (see JMS Providers policy (JMSProviders)). The following table shows the properties that have been added to the policy for BEA WebLogic.

JMS provider	Property	Purpose	Default value
BEA_WebLogic	`Proprietary API handler`	The name of the IBM supplied Java class to interface with a JMS provider's proprietary API.	`com.ibm.broker.apihandler.BEAWebLogicAPIHandler`
	`Proprietary API attribute 1`	The Initial Context Factory class name for the vendor	`weblogic.jndi.WLInitialContextFactory`
	`Proprietary API attribute 2`	The URL of the WebLogic bindings	*URL JNDI bindings*
	`Proprietary API attribute 3`	The DNS name of the JMS server	*Server name*

In the list of JMS provider policy templates, the name of the IBM supplied Java class is set to the default value for the `Proprietary API handler` property. Typically, you do not need to change this value, unless you are instructed to do so by an IBM Service team representative.

Procedure

- Use the Policy editor to modify values of the properties for this JMS provider.
- If you have defined a JMS provider policy, set the value for the `Proprietary API handler` property manually.

Enabling batch acknowledgment for JMS messages
Configure JMS message flows to send a batch acknowledgment for receipt of non-transactional JMS messages.

About this task

You can configure message flows that use the JMS transport to send an acknowledgment to the JMS server of all non-transactional JMS messages that have not previously been acknowledged. You might want to enable batch acknowledgment if there is high network latency and want to send an acknowledgment of received messages only after a threshold has been reached.

JMS flows send acknowledgment responses in accordance with the acknowledge setting on the JMS Session created by the integration server. The default setting is `AUTO_ACKNOWLEDGE`, which causes JMS flows to send an acknowledgment response after receiving each non-transactional message. You can change this setting to use `CLIENT_ACKNOWLEDGE` instead by setting the properties `Client acknowledgment batch size` and `Client acknowledgment batch interval` in the JMS Providers policy. If `CLIENT_ACKNOWLEDGE` is used, the integration server calls the acknowledge() method only after a set time interval has passed, or a set number of messages are received.

Processing bytes messages with JMS nodes
The default behavior of IBM App Connect Enterprise when processing bytes messages can affect clients that are designed to use the readUTF() and writeUTF() methods. Construct an equivalent UTF bit stream by using a Compute node.

About this task

By default, IBM App Connect Enterprise processes bytes messages by using the readBytes() and writeBytes() JMS methods. By using these methods, the payload is written or read as a raw byte array. For the input message, the behavior is based on the serialization of the message tree; for the output message, the resulting bit stream is passed to the user-specified parser to construct a logical tree.

This behavior can affect clients that are designed to use the readUTF() and writeUTF() methods. A UTF string contains encoded length information as well as the raw bit stream. To construct an equivalent UTF bit stream that can be read by the readUTF() method, complete the following steps.

Procedure

1. Add a Compute node immediately before a JMSOutput node.
2. Double-click the Compute node to open the corresponding ESQL file.
3. Use the ESQL shown in the following example to construct an equivalent UTF bit stream from an XMLNSC input message. This bit stream can be understood by a client that uses the readUTF() message.

```
CALL CopyMessageHeaders();

DECLARE byteData BLOB ASBITSTREAM (InputRoot.XMLNSC ccsid
InputProperties.CodedCharSetId);
DECLARE stringData CHARACTER CAST(byteData AS CHARACTER ccsid
InputProperties.CodedCharSetId );
DECLARE dataLen INTEGER LENGTH (byteData);

DECLARE blobLen BLOB CAST(dataLen AS BLOB ENCODING
InputProperties.Encoding);
DECLARE str2byteBlobLen CHARACTER SUBSTRING (CAST(blobLen AS
CHARACTER) FROM 15 FOR 4);

SET OutputRoot.BLOB.BLOB = CAST(str2byteBlobLen as BLOB) ||
byteData ;
```

Troubleshooting JMS nodes
Review possible problems with nodes using JMS transport.

Use Activity log as the first step in diagnosing a problem when something unexpected happens in a JMS message flow. Activity log shows recent activities in your message flows and associated external resources, and can show you at a high level any problems with your JMS resources. You can also view the event log for information about errors that occur.

The following errors might occur:

- "Managing badly formed messages" on page 885
- "Diagnosing problems when using XA coordinated transactions" on page 885
- "Problems with JNDI Administered Objects" on page 886

In all cases of error, if the underlying cause is a JMS exception that has been thrown by the JMS provider, the integration node BIP event message includes the text message from the JMS exception to help diagnosis.

Managing badly formed messages

If a message cannot be processed by the JMS input node, or has been rolled back as part of an XA coordinated transaction, the message is backed out to the source destination. The message is then delivered again to the input node.

To prevent badly formed messages from interrupting the processing of valid messages, the node properties can be configured as described in the following table.

Property	Description
`Backout destination`	This property specifies a JMS destination to which backed out messages are routed if the JMS message property *JMSX_DeliveryCount*, which is set by the JMS provider, exceeds the backout threshold. The JMS destination must be applicable to the message model being used by the node; for example, if a subscription topic has been configured on the node, the JMS destination must also be a topic.
`Backout threshold`	This property specifies the integer value that controls a message that is sent to the backout destination. A threshold value of 3 indicates that if the input node receives a message where the value of the *JMSX_DeliveryCount* property exceeds 3, the message is sent to the backout destination and is removed from the source destination. See node.

Diagnosing problems when using XA coordinated transactions

This problem is not applicable to z/OS.

In addition to the integration node service trace, another trace log is provided to diagnose problems that could occur when a node using JMS transport participates in an XA coordinated message flow transaction. That is, at least one JMS node in the message flow has the `Transaction Mode` property set to `Yes`, and the message flow property `Coordinated Transaction` set to `yes`.

To capture the trace log, complete the following steps:

1. Define an environment variable called *XAJMS_TRACEFILE* that is available to the integration node queue manager.
2. Set the value of the environment variable. This value must be a character string that represents the location and file name of the trace log. For example, on Windows, the variable can be configured as shown in the following example:

```
XAJMS_TRACEFILE = c:\JMSSwitchLog
```

3. When the integration node queue manager starts, it performs a recovery step to resolve any previous integration node transactions that the JMS provider considers to be in doubt. This queue manager process writes to two trace logs during this stage. The two trace logs are:
   - *XAJMS_TRACEFILE valuePID*.txt, where *PID* is the process ID of the queue manager start process. This file is produced from the integration node JMSSwitch library; for more information, see "JMS Transactionality" on page 868.

     The previous example produces a file called JMSSwitchLog2596.txt, where the queue manager start up process ID is 2596.
   - *XAJMS_TRACEFILEXARecoveryTrace*.txt, which is produced by the recovery component of the integration node that connects to the JMS provider.
4. After the integration node queue manager has completed recovery, the integration node starts and creates a file called *XAJMS_TRACEFILE valuePID*.txt, where *PID* is the process ID of the queue manager start process. This file is produced from the integration node JMSSwitch library; for more information, see "JMS Transactionality" on page 868.

Neither of these trace files require extra formatting.

Problems with JNDI Administered Objects

Description of problem: The JMS node is unable to obtain the Initial Context Factory or a JNDI administered object, such as the Connection Factory or JMS destination, and message BIP4640 is issued.

Corrective action

1. Verify that the JNDI bindings have been built correctly, and can be reached at the location specified in the node.
2. Check that the values specified in the node for the Connection Factory Name and Source Queue or Destination Queue properties exist in the JNDI bindings.
3. Ensure that the correct keyword is used to match the location of the bindings:
   - file:// when the administered objects have been created in a .bindings file
   - ldap:// when the administered objects exist in an LDAP directory
   - iiop:// when CORBA is used to access the administered objects
4. When the bindings are file based, do not specify the .bindings file name in the node property.
5. Ensure that the Initial Context Factory Class name is set correctly, as specified in the documentation for the JMS provider.
6. Ensure that the Initial Context Factory Class name does not include a file path.
7. Ensure that a JMS destination (Topic or Source Queue or Destination Queue) specified in the node property exists in the JNDI administered objects.
8. Ensure that the JMS Provider jarsURL property has been set correctly by using the **mqsichangeproperties** command. To verify the value, use the following command:

```
mqsireportproperties INODE -c JMSProviders -o JMSProvider -r
```

The JMS nodes continue to attempt to obtain the JNDI administered objects. Correct any problems and rebuild the bindings. The JMS node should automatically detect the changes and attempt to start.

- If the problem is resolved by rebuilding the bindings, the JMS node detects the changes automatically and attempts to start.
- If the problem is resolved by updating the node properties, you must redeploy the flow before it can connect successfully.

Description of problem: A JMS node is unable to connect for a JMS provider and issues message BIP4648.

Corrective action:

1. Verify that the JMS provider server is running. If it is offline, start the server.

2. Verify that the JMS provider server is available from the integration node environment.
3. Ensure that the JMS provider Java `.jar` files have been placed into the integration node shared-classes directory on distributed systems, or that on z/OS, that these `.jar` files have been defined to the integration node CLASSPATH and any native libraries defined in the integration node LIBPATH.

The JMS nodes continue to attempt to connect to the JMS provider. Correct any problems and the JMS node should automatically detect the changes and attempt to connect to the provider.

Description of problem: A JMS node is unable to obtain a JMS destination and issues message BIP4642.

Corrective action

1. Investigate the cause of the problem described by the JMS exception message that might be included in the BIP event message.
2. Check that the name of the JMS destination that is defined in the relevant node property (Topic, Source Queue or Destination Queue) has been defined correctly in the JNDI administered objects.
3. Verify that the underlying system resource that is used by the JMS provider for the JMS destination has been configured correctly

Description of problem: A JMS input node does not attempt to reconnect to a JMS provider following a connection failure, or a restart of the JMS provider.

Corrective action: If the JMS provider is implemented by using a model that pushes on the JMS client, rather than a traditional polling model, the JMS provider might not throw an exception when calling receive() on an integration node connection. To resolve this problem, set the **`Handle connection exceptions asynchronously`** property of the JMS Providers policy to `True` for this JMS provider.

Processing MQTT messages

MQ Telemetry Transport (MQTT) is a lightweight publish/subscribe messaging protocol. IBM App Connect Enterprise provides built-in input and output nodes for processing MQTT messages.

The MQTT messaging protocol provides robust messaging features for communicating with remote systems and devices, and also minimizes network bandwidth and device resource requirements. The protocol is designed for devices in constrained environments, such as embedded systems, cell phones, and sensors with limited processing ability and memory, and for systems that are connected to unreliable networks. MQTT uses the publish/subscribe style of messaging that enables the information provider (publisher) to be decoupled from the consumer of the information (subscriber). Consequently, the MQTT protocol is ideal for the machine-to-machine, or Internet of Things, world of communication.

The MQTT V3.1 Protocol Specification is defined in the following document:

- MQTT Protocol Specification

For information on how to use MQTT with IBM App Connect Enterprise, see the following topics:

- “Using MQTT with IBM App Connect Enterprise” on page 887
- “Quality of service and connection management” on page 888
- “Using local environment variables with MQTT nodes” on page 890

Using MQTT with IBM App Connect Enterprise

Use IBM App Connect Enterprise to connect to applications and devices that send and receive messages by using the MQ Telemetry Transport (MQTT) messaging protocol.

You can use the built-in MQTTSubscribe and MQTTPublish nodes in IBM App Connect Enterprise to support the following operations:

- Receive a message that is published to one or more topics hosted on an MQTT server.
- Publish a message, from within a flow, to a topic hosted on an MQTT server.

All MQTT messages must conform to the MQTT Protocol Specification.

You can create message flows to receive an MQTT message by using the MQTTSubscribe node to subscribe to one or more topics on an MQTT server. You can send an MQTT message by using the MQTTPublish node in your message flow to publish messages to a topic on an MQTT server. In receiving and sending messages, the MQTT nodes behave like MQTT clients.

For more information on how to use the MQTT nodes in a message flow, including how to use the **Security identity** node property to connect to an MQTT server that requires authentication, see the following reference topics:

- MQTTSubscribe node
- MQTTPublish node

An example of how an MQTT application or device can be integrated with other technologies by using IBM App Connect Enterprise is available on GitHub as part of the mqtt-client-connector project. The example includes a simple Java application that simulates a blood pressure monitor, and a message flow that performs content-based routing. The message flow includes an MQTTSubscribe node to subscribe to the messages published by the blood pressure monitor application, and MQTTPublish nodes to publish blood pressure monitor readings to different topics. For more details on this example, see the MQTT Connector Sample on GitHub.

Client IDs for MQTT connections

The client ID is a string, 1 - 23 characters long, which identifies an MQTT client to an MQTT server. Each client that is connecting to a single server must use a unique client ID. If a client attempts to connect to an MQTT server with a client ID that is already in use, the server disconnects the first client connection, and the new connection is accepted instead.

When you develop a message flow, you must assign a unique client ID to each MQTT node in that message flow. Client IDs can be managed operationally by overriding the value in the BAR file, or by attaching a node policy. For more information, see command and “Overriding properties at run time with policies” on page 324. At deployment time, you must ensure that any MQTT nodes that are connecting to the same server have unique client IDs.

If you specify a client ID that is longer than 23 characters, only the last 23 characters are used when the MQTT node connects to the MQTT server.

Scalability

To increase the rate at which a message flow can process messages that are received by an MQTTSubscribe node, use the **Additional instances** property. This property increases the number of threads that the node can use to process messages, within a single integration server. Increasing the value of this property does not affect the number of input connectors available to receive messages.

Deploying the message flow across extra integration servers does not improve scalability, for the following reasons:

- The MQTTSubscribe node in each integration server will use the same client ID, and the MQTT server only allows one instance to connect with a particular client ID.
- If you configure each node instance to use a unique client ID, and to subscribe to the same topic, every message that is published to that topic is sent to all subscribers.

Quality of service and connection management
In MQTT, quality of service (QoS) controls the assurance of message delivery over the underlying transport. IBM App Connect Enterprise handles messages in different ways, depending on whether the QoS level is 0, 1, or 2.

The three levels of QoS are defined in the MQTT Protocol Specification. The following list provides a summary of the three levels:

QoS 0
At most once delivery (fire and forget)

QoS 1
At least once delivery (acknowledged delivery)

QoS 2
Exactly once delivery (assured delivery)

The open source Eclipse Paho MQTT client, which implements the MQTT protocol specification, is embedded in IBM App Connect Enterprise. The MQTT nodes use the Paho client to handle the exchange of MQTT protocol messages that are associated with the different QoS levels.

When IBM App Connect Enterprise connects to an MQTT server to publish a message with QoS 1 or QoS 2, the clean session flag is set to 0 (false). Therefore, any publications that are in flight when a connection is lost are delivered when IBM App Connect Enterprise reconnects to the server. For subscriptions, the clean session flag is set to 1 (true). When an MQTTSubscribe node connects, or reconnects, to an MQTT server, the connection is treated as a new connection.

Behavior of the MQTTSubscribe node

The QoS level for received messages applies only to the transfer of the messages from the MQTT server to IBM App Connect Enterprise. When a message with QoS 0 is successfully received by the Paho client, the MQTTSubscribe node propagates the message to the Out terminal. When a message with QoS 1 or QoS 2 is successfully received, the Paho client must acknowledge the receipt of the message before it can be processed by the node. After the transfer is successfully acknowledged and completed, the QoS level has no further effect on how the message is handled by IBM App Connect Enterprise.

If the network connection to the MQTT server is lost, the MQTTSubscribe node retries the connection after 5 seconds. The interval between reconnection attempts increases by 5 seconds on each attempt, up to a maximum of 2 minutes. There is no limit to the number of reconnection attempts. These attempts are logged in the MQTT Activity Log.

If messages arrive faster than they can be processed by IBM App Connect Enterprise, message receipt is blocked until the message flow is able to process them.

When an MQTTSubscribe node receives a message, the local environment is populated with the QoS of the message by using the **QualityOfService** variable. For more information about the local environment variables, see MQTTSubscribe node.

Behavior of the MQTTPublish node

The QoS level for published messages applies to the transfer of the message from IBM App Connect Enterprise to the MQTT server. When the MQTTPublish node publishes a message with QoS 0, an acknowledgment of the transfer is not expected. When the MQTTPublish node publishes a message with QoS 1 or QoS 2, the node waits for up to 30 seconds for the Paho client to confirm that the MQTT server has acknowledged receipt of the message. If no acknowledgment is received after this time, the node retries the publish. If this second attempt fails, an exception is produced with message BIP12099, and the node propagates the message to the Failure terminal if the node has a Failure terminal connected. If a Failure terminal is not connected, the message is rolled back to the input node.

Diagnosing transport issues

A connection failure at the network level generates an exception with message BIP12096. The MQTT resource statistics measurement **FailedConnections**, which reports the total number of attempted connections to an MQTT server that have failed since the last integration server restart, is also incremented.

The following connection issues are logged in the MQTT Activity Log:

- Failed to connect to an MQTT server
- Reattempted the connection to an MQTT server
- Lost the connection to an MQTT server
- Failed to disconnect from an MQTT server

The Activity Log also records both successful and unsuccessful attempts to publish a message to a topic, together with the QoS of the message. When an MQTTSubscribe node successfully subscribes to a topic, or receives a message from a topic, this success is also logged, together with the QoS of the subscription or the message.

Securing MQTT connections
The connection between MQTT nodes in a message flow and the MQTT server can be encrypted by using SSL.

Before you can encrypt the connection to the MQTT server, you must complete the following tasks:

- Create a truststore (if a truststore does not already exist), and import the MQTT server public certificate into the truststore.
- Configure the integration server to use the truststore.
- Obtain a user name and password (from the MQTT server administrator) that you can use to connect to the MQTT server.
- Set a value for the Security identity property on the MQTT message flow node.
- Link the Security identity property on the MQTT message flow node with the user name and password by using the **mqsisetdbparms** command; see command.

You can encrypt the connection between the MQTT server and a MQTTSubscribe or MQTTPublish message flow node by using one the following methods:

During development
Select the **Use SSL** check box in the MQTT message flow node properties, and set the appropriate port number. The default SSL port number is 8883.

During deployment
Set the connectionUrl property by using the **mqsiapplybaroverride**. The connectionUrl property must include, the protocol, the host name, and the port. For example:

```
mqsiapplybaroverride -b my.bar -k myApplication -m myFlow#MQTTPublish.connectionUrl=ssl://
myMQTTserver.com:8883
```

To configure the connection so that SSL is not used, change the protocol to tcp. For example:

```
mqsiapplybaroverride -b my.bar -k myApplication -m myFlow#MQTTPublish.connectionUrl=tcp://
myMQTTserver.com:1883
```

If set, the value of the connectionUrl property takes precedence over the values of the following MQTT message flow node properties:

- Host name
- Port
- Use SSL

For more information about the **mqsiapplybaroverride**, see command.

At run time
Set the connectionUrl local environment variable in the LocalEnvironment.Destination.MQTT.Output subtree; see “Using local environment variables with MQTT nodes” on page 890.

Using local environment variables with MQTT nodes
You can find the values that were used by the MQTTSubscribe and MQTTPublish nodes to process the MQTT message. You can also use fields in the local environment to dynamically alter the behavior of the MQTTPublish node.

These fields are available in the following message tree structures:

- LocalEnvironment
- LocalEnvironment.Destination

- LocalEnvironment.WrittenDestination

LocalEnvironment fields

When you use the MQTTSubscribe node, it stores information that you can access in the LocalEnvironment.MQTT.Input message tree. The fields in this structure are described in the following table.

Table 16. List of elements in the LocalEnvironment.MQTT.Input subtree

Element Name	Element Data Type	Description
Duplicate	BOOLEAN	Whether the message is a duplicate of a previous message. Set to TRUE or FALSE.
Retained	BOOLEAN	Whether the message is a retained message. Set to TRUE or FALSE. Retained is set to TRUE if the message was kept by the server and is now being sent when the client first connects to the server.
Topic	CHARACTER	The name of the MQTT topic the received message was published to.
QualityOfService	INTEGER	Quality of service of the received message. Set to 0 (at most once), 1 (at least once), or 2 (exactly once).

This structure is populated with each message written to the Out terminal of the MQTTSubscribe node.

LocalEnvironment.Destination fields

When you use the MQTTPublish node, you can override certain properties with elements in the LocalEnvironment.Destination.MQTT.Output message tree. The fields in this structure are described in the following table.

Table 17. List of elements in the LocalEnvironment.Destination.MQTT.Output subtree

Element Name	Element Data Type	Description
retained	BOOLEAN	Whether the message is a retained message. Set to TRUE or FALSE. The default is FALSE. Set to TRUE if the message for a topic must be held by the MQTT server after delivery to all currently connected clients, and then delivered to new clients when they connect to that topic. Each retained message for a topic replaces the previous retained message for that topic. In this way, devices can receive the most recent retained message immediately on connecting to a topic.
TopicName	CHARACTER	The name of the MQTT topic the message will be published to.
qos	INTEGER	Quality of service of the published message. Set to 0 (at most once), 1 (at least once), or 2 (exactly once).

Table 17. List of elements in the LocalEnvironment.Destination.MQTT.Output subtree (continued)		
Element Name	**Element Data Type**	**Description**

connectionUrl	CHARACTER	The URL that is used to connect to the MQTT server. The URL includes the protocol, the host name, and the port. For example:
		`tcp://myMQTTserver.com:1883`
		or, if the connection is encrypted:
		`ssl://myMQTTserver.com:8883`
		If set, the value of the connectionUrl property takes precedence over the values of the following MQTT message flow node properties:
		• Host name
		• Port
		• Use SSL

LocalEnvironment.WrittenDestination fields

When you use the MQTTPublish node, it stores information that you can access in the LocalEnvironment.WrittenDestination.MQTT message tree. The fields in this structure are described in the following table.

Table 18. List of elements in the LocalEnvironment.WrittenDestination.MQTT subtree		
Element Name	**Element Data Type**	**Description**
ClientId	CHARACTER	The unique name of the client.
DeliveryToken.isComplete	BOOLEAN	Whether the message was successfully published to the MQTT topic. Set to TRUE or FALSE.

This structure is populated with each message written to the Out terminal of the MQTTPublish node.

Processing Kafka messages

Apache Kafka is an open source project that provides a messaging service capability, based upon a distributed commit log, which lets you publish and subscribe data to streams of data records (messages). IBM App Connect Enterprise provides built-in input and output nodes for processing Kafka messages. A mid-flow node is also provided for reading individual messages on a Kafka topic.

The Kafka messaging protocol is a TCP based protocol that provides a fast, scalable, and durable method for exchanging data between applications. Messaging providers are typically used in IT architectures in order to decouple the processing of messages from the applications that produce them. IBM App Connect Enterprise has very strong existing support for many kinds of messaging, including IBM MQ, JMS messaging providers, and the MQTT messaging protocol. The Kafka nodes expand this support to help IBM App Connect Enterprise interact with Kafka applications.

For information about the supported versions of Kafka, see IBM App Connect Enterprise system requirements. For more information about Kafka version compatibility, see the Apache Kafka documentation.

Kafka is a very popular choice for cloud-based architectures, where the numbers of connected clients can change frequently without impacting the scaling characteristics. Common use-cases where Kafka is considered as a messaging transport include:

General messaging
You can decouple producer and consumer applications from each other. Data flowing between multiple processing stages in a distributed application could use Kafka as a means of connecting the steps. The built-in features that Kafka provides for partitioning, replication, and fault tolerance can make it a good choice for this type of large-scale messaging.

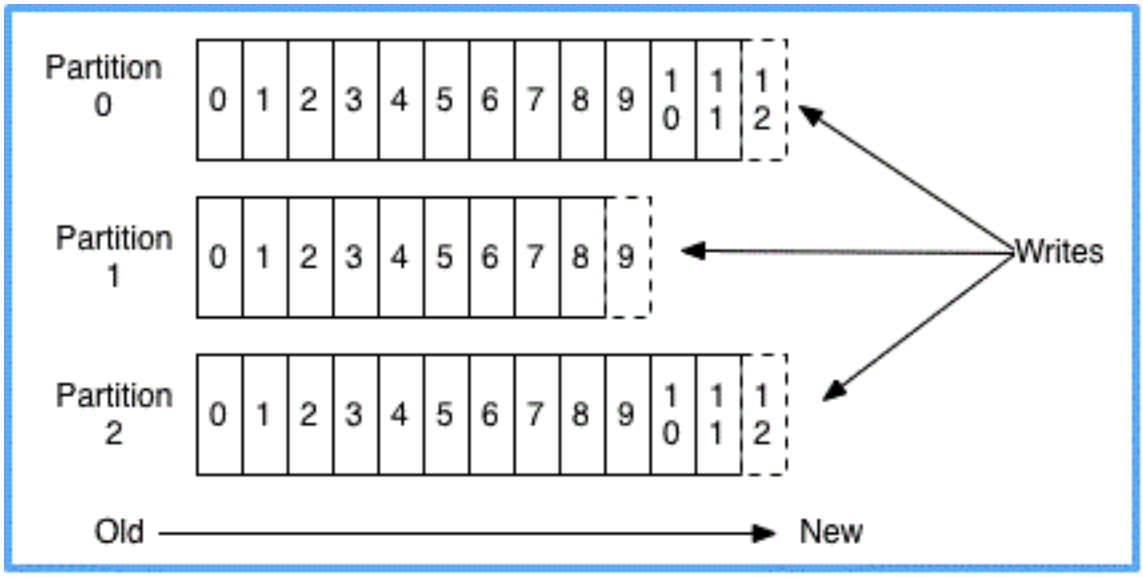
Web site activity tracking
When Kafka was first developed, it was used for helping to track page views, searches, or other actions taken on a web site. This activity was published to a set of central topics for different activity types. Subscribers could then use the data for real-time processing and monitoring, and persisting to other data warehouse systems.

Logging and metrics
You can use Kafka to aggregate operational data from multiple sources.

Apache Kafka maintains feeds of messages in categories called topics. IBM App Connect Enterprise provides built-in nodes for processing Kafka messages, which use the Apache Kafka Java client:

- node, which publishes messages to a Kafka topic
- node, which subscribes to a Kafka topic and propagates the feed of published messages to nodes connected downstream in the flow
- node, which reads a specified message from a Kafka topic.

IBM App Connect Enterprise acts as a Kafka client, and can communicate with your Kafka implementation by sending messages over the network to the Kafka cluster. A Kafka cluster implementation is made up of one or more servers, known as Kafka brokers. Kafka brokers replicate data between themselves in order to cope with specific server failures without losing any messages that have been committed to the Kafka log. Each instance of a Kafka node is configured with the name of a topic. For each topic maintained by Kafka, the Kafka brokers maintain a partitioned commit log, as shown in the following diagram:



Each partition is an ordered sequence of messages, whose state cannot be altered after they have been created. Each of the messages in a partition is assigned a sequential ID number, called the *offset*, which uniquely identifies each message in the partition. These messages are all retained for a configurable period of time, regardless of whether they have been consumed by another application, after which the messages are discarded to free up space. This approach to message queuing is very different from the approach of traditional messaging products such as IBM MQ.

Message ordering is preserved only within a partition, not across all topics in a partition; therefore, if message order is important, ensure that you either use a single partition per topic, or associate a message

key with each message published. A hash of the key for a message is used to select the partition to which the message is sent, so all messages published with the same key are stored on the same partition.

For more information about Kafka messaging, see the Apache Kafka documentation.

For information about how to use Kafka with IBM App Connect Enterprise, see the following topics:

Using Kafka with IBM App Connect Enterprise

You can use the IBM App Connect Enterprise Kafka nodes to produce and consume messages on Kafka topics.

Before you begin

- Read the topic "Processing Kafka messages" on page 892

About this task

You can use the node to publish messages that are generated from within your message flow to a topic that is hosted on a Kafka server. The published messages are then delivered by the Kafka server to all topic consumers (subscribers). You can use a node in a message flow to subscribe to a specified topic on a Kafka server. The KafkaConsumer node then receives messages that are published on the Kafka topic, as input to the message flow. You can also read an individual message that is published on a Kafka topic, by using a node in a message flow to specify the offset position of the message in the topic partition.

For more information about the supported versions of Kafka, see IBM App Connect Enterprise system requirements. For more information about Kafka version compatibility, see the Apache Kafka documentation.

Procedure

Use the KafkaProducer, KafkaConsumer, and KafkaRead nodes to complete the following tasks:

- "Producing messages on Kafka topics" on page 895.
- "Consuming messages from Kafka topics" on page 898.
- "Reading an individual message from a Kafka topic" on page 901.

For more information about configuring and using Kafka nodes, see the following topics:

- "Using local environment variables with Kafka nodes" on page 907.
- "Setting and retrieving Kafka custom header properties" on page 903,
- "Using Kafka nodes with IBM Event Streams" on page 909.
- "Configuring security credentials for connecting to Kafka" on page 904.
- "Authenticating connections to a Kafka cluster by using SASL/SCRAM" on page 905.
- Kafka policy.
- "Resolving problems when using Kafka nodes " on page 2941.

Producing messages on Kafka topics
You can use the KafkaProducer node to connect to the Kafka messaging system and publish messages on Kafka topics.

Before you begin

Read the following topics:

- "Processing Kafka messages" on page 892
- "Using Kafka with IBM App Connect Enterprise" on page 894

About this task

You can use the KafkaProducer node to publish messages that are generated from within your message flow to a topic that is hosted on a Kafka server. The published messages are then available to be received by consumers (subscribers) reading from the topic.

You can use a KafkaConsumer node in a message flow to subscribe to a specified topic on a Kafka server. You can also use a KafkaRead node to read an individual message on a specified topic. For more information about using these nodes, see "Consuming messages from Kafka topics" on page 898 and "Reading an individual message from a Kafka topic" on page 901.

The KafkaProducer node publishes messages non-transactionally to the Kafka server, and they are available to be read by consuming applications as soon as they are published. Because the publish operation is non-transactional, if the flow is rolled back after the message passes through the KafkaProducer node, the publication of the message to the Kafka server is not rolled back. However, you can use the **Acks** property on the KafkaProducer node to configure synchronous processing of the message, by specifying that the KafkaProducer node must wait for confirmation that the message was successfully received by the Kafka server before continuing in the flow. The options that you can specify for the **Acks** property are described in the steps of this task topic.

You can use Kafka custom header properties to add metadata to Kafka messages for use during message processing. These properties are set in the LocalEnvironment, in a folder called `KafkaHeader`. For more information, see "Setting and retrieving Kafka custom header properties" on page 903.

Procedure

Complete the following steps to use IBM App Connect Enterprise to publish messages to a topic on a Kafka server:

1. Create a message flow that contains an input node, such as an HTTPInput node, and a KafkaProducer node.

   For more information about how to create a message flow, see "Creating a message flow" on page 574.
2. Configure the KafkaProducer node by setting the following properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Topic name` property, specify the name of the Kafka topic on which you want to publish messages.

        The topic name can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash). The topic name can be changed dynamically

by setting a local environment override. For more information, see “Using local environment variables with Kafka nodes” on page 907.

- In the `Bootstrap servers` property, specify the hostname and port of the Kafka server that you want to connect to; for example, if you are using IBM Event Streams (Kafka on IBM Cloud), specify the address of that server.
- In the `Client ID` property, specify the client name to be used when connecting to the Kafka server.

  The client name can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash).
- Use the `Add server name suffix to client ID` property to specify whether you want to suffix the client ID with the name of the integration server and integration node. This property is

selected by default, and adds the integration server and integration node name to the end of the client ID, in the following format:

```
'integration_server_name'-'integration_node_name'
```

- In the Acks property, select the number of acknowledgments that are expected from the kafka cluster in order to consider the message successfully published.

  If this property is set to 0, the KafkaProducer node does not wait for any acknowledgment that the publish request has been processed by the Kafka server. This is equivalent to a 'fire and forget' mode of operation.

  If this property is set to 1, the KafkaProducer node waits for a single acknowledgment from the Kafka server.

  If this property is set to All, the KafkaProducer node waits for acknowledgments from all replicas of the topic. This option provides the strongest available guarantee that the record was received.
- In the Timeout property, specify the time (in seconds) to wait for a request to complete. The default value is 60 seconds.

b) On the **Security** tab, set the following properties:

- In the Security protocol property, select the protocol to be used when communicating with the integration node. Valid values are:
  - PLAINTEXT
  - SSL
  - SASL_PLAINTEXT
  - SASL_SSL

  The default value for this property is PLAINTEXT.

  Note: If you are using Event Streams, this property must be set to SASL_SSL.

  If either SASL_PLAINTEXT or SASL_SSL is selected, you must configure the user ID and password to use for authenticating with the Kafka server by configuring the security identity. For more information, see "Configuring security credentials for connecting to Kafka" on page 904.
- In the SSL protocol property, select the SSL protocol to be used if the Security protocol property is set to either SSL or SASL_SSL. You can select one of the following values from the editable list, or you can specify an alternative value:
  - TLSv1
  - TLSv1.1
  - TLSv1.2
  - TLSv1.3

  The default value for this property is TLSv1.2.

For more information about other properties that you can set for the KafkaProducer node, see node. For more information about setting properties by using a policy, see Kafka policy.

For more information about how to diagnose connection problems between IBM App Connect Enterprise and Kafka, see "Resolving problems when using Kafka nodes " on page 2941.

What to do next

For more information about properties that can be overridden dynamically in the flow, see "Using local environment variables with Kafka nodes" on page 907.

Consuming messages from Kafka topics
You can use the KafkaConsumer node to receive messages that are published on a Kafka topic.

Before you begin

Read the following topics:

- "Processing Kafka messages" on page 892
- "Using Kafka with IBM App Connect Enterprise" on page 894

About this task

You can use a KafkaConsumer node in a message flow to subscribe to a specified topic on a Kafka server. The KafkaConsumer node then receives messages that are published on the Kafka topic, as input to the message flow.

You can use a KafkaProducer node to publish messages from your message flow to a topic that is hosted on a Kafka server, and you can use a KafkaRead node to read an individual message on a Kafka topic. For more information about using these nodes, see "Producing messages on Kafka topics" on page 895 and "Reading an individual message from a Kafka topic" on page 901.

Each KafkaConsumer node consumes messages from a single topic; however, if the topic is defined to have multiple partitions, the KafkaConsumer node can receive messages from any of the partitions. For more information about partitions in Kafka topics, see the Apache Kafka documentation.

The KafkaConsumer node reads messages from Kafka non-transactionally, which means that, if an error occurs or the message is rolled back to the input node, and no catch terminal is connected, the message is not reprocessed by the input node.

In order to process messages that are received concurrently, you can configure additional instances on the KafkaConsumer node. When additional instances are configured, a single Kafka message consumer is created, and the messages are distributed to the additional flow instances. As messages are processed concurrently, message ordering is not preserved when additional instances are being used. For more information about specifying additional instances, see node.

You can also increase concurrency by deploying multiple KafkaConsumer nodes that share the same **`Group ID`**; Kafka ensures that messages that are published on the topic are shared across the consumer group. For more information about how Kafka shares the message across multiple consumers in a consumer group, see the Apache Kafka documentation.

You can use Kafka custom header properties to add metadata to Kafka messages for use during message processing. These properties are set in the LocalEnvironment, in a folder called `KafkaHeader`. For more information, see "Setting and retrieving Kafka custom header properties" on page 903.

Procedure

Complete the following steps to receive messages that are published on a Kafka topic:

1. Create a message flow containing a KafkaConsumer node and an output node.

2. Configure the KafkaConsumer node by setting the following properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Topic name` property, specify the name of the Kafka topic to which you want to subscribe.

        The topic name can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash).
      - In the `Bootstrap servers` property, specify the host name and port of the Kafka server; for example, if you are using IBM Event Streams (Kafka on IBM Cloud), specify the address of that server.
      - In the `Consumer group ID` property, specify the ID of the consumer group to which this consumer belongs. This ID can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash).
      - In the `Default message offset` property, specify the message offset that is used by the consumer when it starts, if no valid message offset exists; for example, when the consumer starts for the first time, or when the consumer is not committing its offset to Kafka. Possible values are:
        - `Earliest`
        - `Latest`

        This property defines the starting position in the log of messages from where the KafkaConsumer node starts reading messages. The default setting is `Latest`, which means that only messages published after the flow is started will be read.

        If `Earliest` is selected, the KafkaConsumer node starts reading messages from the first message in the log of messages for the specified topic.

        If the `Commit message offset in Kafka` property is not selected, this action is repeated each time the flow containing the KafkaConsumer node is started. If the `Commit message offset in Kafka` property is selected, the consumer position in the log of messages for the topic is saved in Kafka as each message is processed; therefore, if the flow is stopped and then restarted, the input node starts consuming messages from the message position that had been reached when the flow was stopped.
      - Use the `Commit message offset in Kafka` property to specify whether the current message offset in Kafka is saved automatically, which allows messages to be consumed from the saved position when the consumer is restarted. This property is selected by default. If the integration server or integration node is restarted, the last saved position is used.
      - Use the `Wait for message offset commit to complete` property to control whether the KafkaConsumer node waits for the message offset to be committed to Kafka before delivering the message to the message flow. If this property is not selected, the KafkaConsumer node does not wait for the response from the commit operation to be received before delivering the message to the flow. As a result, message throughput is increased in exchange for a reduction in message reliability, as messages can be redelivered to the message flow if the request to commit the consumer offset subsequently fails. This property is selected by default.
      - In the `Client ID` property, specify the client name to be used when connecting to the Kafka server.

        The client name can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash).
      - Use the `Add server name suffix to client ID` property to specify whether you want to suffix the client ID with the name of the integration server and integration node. This property is

selected by default, and adds the integration server and integration node name to the end of the client ID, in the following format:

```
'integration_server_name'-'integration_node_name'
```

b) On the **Advanced** tab, set the following properties:

- In the `Connection timeout (sec)` property, specify the maximum time that the KafkaConsumer node will wait to establish a connection with the Kafka server. The default value for this property is 15 seconds.

  Note: The value specified for the `Connection timeout` must be greater than the value specified for the `Session timeout`.
- In the `Session timeout (sec)` property, specify the maximum time that the Kafka server should wait to receive confirmation (in the form of periodic 'heartbeats') that the KafkaConsumer node is live. This property is used to detect KafkaConsumer node failures when using Kafka's group management facility. The KafkaConsumer node sends periodic heartbeats to indicate its liveness to the Kafka server. If no heartbeats are received by the Kafka server before the expiration of this session timeout, the Kafka server removes this consumer from the group and initiates a rebalance. The minimum valid value for this property is `10` seconds, which ensures that the session timeout is greater than the length of time between heartbeats. The `Session timeout` value must be less than the `Connection timeout` value.
- In the `Receive batch size` property, specify the maximum number of records that are received from the Kafka server in a single batch. This property is used for the *max.poll.records* value specified by the KafkaConsumer node when receiving messages from the Kafka server.

c) On the **Security** tab, set the following properties:

- In the `Security protocol` property, select the protocol to be used when communicating with the integration node. Valid values are:
  - `PLAINTEXT`
  - `SSL`
  - `SASL_PLAINTEXT`
  - `SASL_SSL`

  The default value for this property is `PLAINTEXT`.

  Note: If you are using Event Streams, this property must be set to `SASL_SSL`.

  If either `SASL_PLAINTEXT` or `SASL_SSL` is selected, you must configure the user ID and password that will be used to authenticate with the Kafka server by configuring the security identity, as described in “Configuring security credentials for connecting to Kafka” on page 904.
- In the `SSL protocol` property, select the SSL protocol to be used if the `Security protocol` property is set to either `SSL` or `SASL_SSL`. You can select one of the following values from the editable list, or you can specify an alternative value:
  - TLSv1
  - TLSv1.1
  - TLSv1.2
  - TLSv1.3

  The default value for this property is `TLSv1.2`.

For information about other properties that you can set for the KafkaConsumer node, see node. For information about setting properties by using a policy, see Kafka policy.

For more information about how to diagnose connection problems between IBM App Connect Enterprise and Kafka, see “Resolving problems when using Kafka nodes ” on page 2941.

What to do next

For information about properties that can be overridden dynamically in the flow, see "Using local environment variables with Kafka nodes" on page 907.

Reading an individual message from a Kafka topic

You can use the KafkaRead node to read an individual message published on a Kafka topic, by specifying the offset position of the message in the topic.

Before you begin

Read the following topics:

- "Processing Kafka messages" on page 892
- "Using Kafka with IBM App Connect Enterprise" on page 894

About this task

You can use a node to help with error processing in a Kafka flow. For example, if the processing of a message fails in a Kafka consumer message flow, you can use the KafkaRead node to reprocess that individual message. You can also use a KafkaRead node in a flow with a Timer node to control the processing of a range of messages in a partition on a topic. For more information, see Processing Kafka messages.

You can specify a message in a partition on a Kafka topic, by using the **partition** property on the KafkaRead node. For more information about partitions in Kafka topics, see the Apache Kafka documentation.

For more information about subscribing to topics on a Kafka server by using a node, see "Consuming messages from Kafka topics" on page 898. For more information about publishing messages to a Kafka topic by using a node, see "Producing messages on Kafka topics" on page 895.

By default, if the message at the specified offset is not available, the input message is sent to the No match terminal. Alternatively, you can choose to read either the earliest or the latest message in the partition if the specified message is unavailable, by setting one of those values in the **Action when message unavailable** property of the KafkaRead node. You can also override this value dynamically by using the command.

Procedure

Complete the following steps to read an individual message that is published on a Kafka topic:

1. Create a message flow that contains an input node, a KafkaRead node, and an output node.
   For more information about how to do this, see "Creating a message flow" on page 574.
2. Configure the KafkaRead node by setting the following properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Topic name` property, specify the name of the Kafka topic that contains the message that you want to read.

        The topic name can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash).
      - In the `Partition number` property, specify the number of the Kafka partition for the topic that you want to use (valid values are between `0` and 255). The default value is `0`.
      - In the `Bootstrap servers` property, specify the host name and port to be used for establishing the initial connection to the Kafka cluster; for example, if you are using IBM Event Streams (Kafka

on IBM Cloud), specify the address of that server. You can specify multiple servers by defining a list of host/port pairs, separated by commas.

- In the `Message offset` property, specify the offset position of the message to be read. This property defines the position in the log of messages from where the KafkaRead node will read the message. The default value is `0`.
- In the `Action when message unavailable` property, select the action that will be taken if the message at the specified offset is not available:
  - Select `no match` to propagate the input message to the `No match` terminal. This is the default value.
  - Select `earliest` to read the message with the earliest offset for the topic partition.
  - Select `latest` to read the message with the latest offset for the topic partition.
- In the `Client ID` property, specify the client name to be used when connecting to the Kafka server.

  The client name can be up to 255 characters in length, and can include the following characters: a-z, A-Z, 0-9, . (dot), _ (underscore), and - (dash).
- Use the `Add server name suffix to client ID` property to specify whether you want to suffix the client ID with the name of the integration server. This property is selected by default, and adds the integration server name to the end of the client ID, in the following format:

  ```
  -integrationServerName
  ```

  for an independent integration server, or

  ```
  integration_node_name-integration_server_name
  ```

  for an integration server that is managed by an integration node.
- In the `Timeout (s)` property, specify the length of time (in seconds) in which the KafkaRead node must read the message. If the message has not been read within this timeout period, the action specified by the `Action when message unavailable` property is taken.

b) On the **Security** tab, set the following properties:

- In the `Security protocol` property, select the protocol to be used when communicating with the Kafka server. Valid values are:
  - `PLAINTEXT`
  - `SSL`
  - `SASL_PLAINTEXT`
  - `SASL_SSL`

  The default value for this property is `PLAINTEXT`.

  If you are using Event Streams, this property must be set to `SASL_SSL`.

  If either `SASL_PLAINTEXT` or `SASL_SSL` is selected, you must configure the user ID and password that will be used to authenticate with the Kafka server by configuring the security identity, as described in "Configuring security credentials for connecting to Kafka" on page 904.
- In the `SSL protocol` property, select the SSL protocol to be used if the `Security protocol` property is set to either `SSL` or `SASL_SSL`. You can select one of the following values from the editable list, or you can specify an alternative value:
  - TLSv1
  - TLSv1.1
  - TLSv1.2
  - TLSv1.3

  The default value for this property is `TLSv1.2`.

For information about other properties that you can set for the KafkaRead node, see node. For information about setting properties by using a policy, see Kafka policy.

For more information about how to diagnose connection problems between IBM App Connect Enterprise and Kafka, see “Resolving problems when using Kafka nodes ” on page 2941.

What to do next

For information about properties that can be overridden dynamically in the flow, see “Using local environment variables with Kafka nodes” on page 907.

Setting and retrieving Kafka custom header properties

You can use Kafka custom header properties to associate metadata with a Kafka message.

Before you begin

Read the following topics:

- “Processing Kafka messages” on page 892
- “Using Kafka with IBM App Connect Enterprise” on page 894

About this task

Kafka custom header properties enable you to add metadata to the Kafka message, which can then be used during message processing; for example, the header properties can carry information about the format of the data, such as a schema name.

Kakfa custom header properties are a set of `name:value` pairs, which can be associated with a Kafka message as it is published and then retrieved when the message is retrieved. IBM App Connect Enterprise supports Kafka header properties that consist of a name and a value, both of which must be strings in Java String format.

The properties are set in the Local Environment, in a folder called `KafkaHeader`. For the KafkaProducer node, all property values must be supplied as a string in the Local Environment. For the KafkaConsumer and KafkaRead nodes, the values of header properties in the received message are converted to string values when they are written into the Local Environment.

Before calling the KafkaProducer node, you can set the Kafka custom header properties in the `Environment.Destination.Kafka.Output.KafkaHeader` Local Environment folder. For example:

```
# To set Kafka custom header properties called 'Name' and 'Occupation'
      SET OutputLocalEnvironment.Destination.Kafka.Output.KafkaHeader.Name = 'Bob';
      SET OutputLocalEnvironment.Destination.Kafka.Output.KafkaHeader.Occupation = 'Builder';
```

On return from a KafkaConsumer node, the Local Environment folder `LocalEnvironment.Kafka.Input` is updated with any custom headers properties contained in the received message, which can then be processed by using a Compute node. For example:

```
 # To retrieve the value of the custom header property called 'Name'
       SET Name = InputLocalEnvironment.Kafka.Input.KafkaHeader.Name;
```

On return from a KafkaRead node, the Local Environment folder `LocalEnvironment.Kafka.Read` is updated with any custom headers properties contained in the received message, which can then be processed by using a Compute node. For example:

```
# To retrieve the value of the custom header property called 'Occupation'
       SET Occupation = InputLocalEnvironment.Kafka.Read.KafkaHeader.Occupation;
```

For more information about the Kafka nodes, see the following topics:

- node
- node
- node

For information about properties that can be overridden dynamically in the flow, see "Using local environment variables with Kafka nodes" on page 907.

Configuring security credentials for connecting to Kafka

Use the **mqsisetdbparms** or **mqsicredentials** command to associate security credentials with a connection to a Kafka cluster, and configure the Kafka nodes to authenticate by using the required username and password.

Before you begin

Read the following topics:

- "Processing Kafka messages" on page 892
- "Using Kafka with IBM App Connect Enterprise" on page 894

About this task

Before you can connect to a Kafka cluster that requires authentication with a username and password, you must use either the **mqsisetdbparms** or **mqsicredentials** command to configure the credentials that the KafkaConsumer, KafkaRead, and KafkaProducer nodes use to authenticate to the Kafka cluster.

To configure the Kafka nodes to authenticate using the username and password, you set the **Security protocol** property on the node to either SASL_PLAINTEXT or SASL_SSL.

If you are using the IBM Event Streams service on IBM Cloud, the **Security protocol** property on the Kafka node must be set to SASL_SSL. For more information about configuring the security credentials for connecting to Event Streams, see "Using Kafka nodes with IBM Event Streams" on page 909.

For more information about configuring Kafka nodes to authenticate by using Salted Challenge Response Authentication Mechanism (SCRAM), see "Authenticating connections to a Kafka cluster by using SASL/SCRAM" on page 905.

Procedure

Follow these steps to configure a connection to a secured Kafka cluster:

1. Use either the **mqsisetdbparms** or **mqsicredentials** command to associate a username and password with a connection to a Kafka cluster:
   - Configure security credentials by using the **mqsisetdbparms** command, specifying the required username (**-u**), password (**-p**), and resource name (**-n**). The resource name is in the form `kafka::` followed by the name of the security identity that is specified on the Kafka node; for example, `kafka::myKafkaSecId`. Alternatively, you can use the default security identity, by specifying a resource name of `kafka::KAFKA` or `kafka::KAFKA::integrationServerName`.

     The following example shows how to specify a username, password, and named Kafka security identity:

     ```
     mqsisetdbparms -w workDir -n kafka::myKafkaSecId -u myUsername -p myPassword
     ```

     The following example shows how to specify a username and password, and specifies that the default Kafka security identity for the integration server will be used:

     ```
     mqsisetdbparms -w workDir -n kafka::KAFKA::myIntegrationServer1 -u myUsername -
     p myPassword
     ```

     For more information, see command.
   - Configure security credentials by using the **mqsicredentials** command, specifying the username (**--username**), password (**--password**), credential type (**--credential-type**), and credential name (**--credential-name**). Specify the credential type as `kafka`, and specify a credential name that matches the value of the **Security identifier** parameter that is specified in the node.

Alternatively, you can use the default security identity that is specified by the **--set-as-default** parameter on the **mqsicredentials** command.

The following example shows how to specify a username, password, and named Kafka security identity:

```
mqsicredentials --create --work-dir workDir --credential-type kafka --credential-name
 myKafkaSecId --username myUsername --password myPassword
```

The following example shows how to specify a username and password, and specifies that the default Kafka security identity for the integration server will be used:

```
mqsicredentials --create --work-dir workDir --credential-type kafka --credential-name
 myKafkaSecId --username myUsername --password myPassword
```

```
mqsicredentials --set-as-default --work-dir workDir --credential-type kafka --credential-
name myKafkaSecId
```

For more information, see command.

2. In your message flow, set the following properties on the KafkaConsumer, KafkaRead, and KafkaProducer nodes:
   a) Set the **Security protocol** property to either SASL_PLAINTEXT or SASL_SSL.

      If you are using the Event Streams service on IBM Cloud, the **Security protocol** property must be set to SASL_SSL.

   b) If either SSL or SASL_SSL is specified by the **Security protocol** property, you must also specify the **SSL protocol** to be used.

      You can select one of the following values from the supplied list, or you can specify an alternative value:

      - TLSv1
      - TLSv1.1
      - TLSv1.2
      - TLSv1.3

   c) In the **Security identifier** property, specify the name of the security credential that you created in step 1. Alternatively, if you configured a default security identity in step 1 (for example, myKafkaSecId), you can leave the **Security identifier** property empty and the default security identity is used.

   For more information about the Kafka nodes, see the following topics:

   - node
   - node
   - node

   For more information about how to diagnose connection problems between IBM App Connect Enterprise and Kafka, see “Resolving problems when using Kafka nodes ” on page 2941.

What to do next

You can use the command or the command to show information about the credentials that are being used for connecting to a Kafka cluster.

Authenticating connections to a Kafka cluster by using SASL/SCRAM

You can configure KafkaConsumer, KafkaRead, and KafkaProducer nodes to authenticate with a Kafka cluster by using Salted Challenge Response Authentication Mechanism (SCRAM) or SASL/SCRAM.

Before you begin

Read the following topics:

- “Processing Kafka messages” on page 892
- “Using Kafka with IBM App Connect Enterprise” on page 894

About this task

Salted Challenge Response Authentication Mechanism (SCRAM), also known as SASL/SCRAM, is an SASL mechanism that performs password-based authentication between the client and server, and resolves some of the security concerns that are associated with SASL_PLAIN authentication.

To authenticate a connection between Kafka nodes and a Kafka cluster that uses SCRAM for authentication, you must configure the nodes to use a Kafka policy that is configured with the connection details.

Procedure

Follow these steps to enable Kafka nodes to authenticate a connection to a Kafka cluster by using SCRAM:

1. Use either the command or the command to associate a username and password with a security identity.
   - Configure security credentials by using the **mqsisetdbparms** command, specifying the required username (**-u**), password (**-p**), and resource name (**-n**). The resource name is in the form `kafka::` followed by the name of the security identity that is specified on the Kafka node; for example, `kafka::myKafkaSecId`.

     The following example shows how to specify a username, password, and named Kafka security identity:

     ```
     mqsisetdbparms -w workDir -n kafka::myKafkaSecId -u myUsername -p myPassword
     ```

     For more information, see command.
   - Configure security credentials by using the **mqsicredentials** command, specifying the username (**--username**), password (**--password**), credential type (**--credential-type**), and credential name (**--credential-name**). Specify the credential type as `kafka`, and specify a credential name that matches the value of the **Security identifier** parameter that is specified in the node.

     The following example shows how to specify a username, password, and named Kafka security identity:

     ```
     mqsicredentials --create --work-dir workDir --credential-type kafka --credential-name
      myKafkaSecId --username myUsername --password myPassword
     ```

     For more information, see command.

2. Create a Kafka policy in a policy project by using the IBM App Connect Enterprise Toolkit, and set the following properties:
   a) Set the value of the **Bootstrap servers** property to the list of bootstrap servers for the Kafka cluster. You can specify a single *hostname:port* value or a comma-separated list of multiple *hostname:port* values.
   b) Set the **Security protocol** property to SASL_SSL.
   c) Set the **Security mechanism** property to either SCRAM-SHA-256 or SCRAM-SHA-512, as required by the Kafka cluster.
   d) Set the **Security identity** property to the name of the security identity that you created in step 1 (for example, myKafkaSecId).
   e) Set the **SASL config** property to `org.apache.kafka.common.security.scram.ScramLoginModule required;`

      This value specifies the SASL configuration to use when you connect to the Kafka cluster.
   f) Optional: Set the **SSL truststore location** to the location of the truststore that contains the public or CA certificate for the Kafka cluster.
   g) Optional: Set the **SSL truststore type** to the type of truststore that is specified in the **SSL truststore location** property. Possible values are JKS and PKCS12.
   h) Optional: Set the **SSL truststore security identity** to specify the security identity used to access the truststore.

   For more information, see Kafka policy.
3. On the **Policy** tab of the Kafka nodes, set the **Policy** property to the name of the policy created in step 1, in the form *{PolicyProjectName}:PolicyName*

   For more information about the Kafka nodes, see node, node, and node.

   For more information about how to diagnose connection problems between IBM App Connect Enterprise and Kafka, see "Resolving problems when using Kafka nodes " on page 2941.

Using local environment variables with Kafka nodes

The KafkaConsumer, KafkaRead, and KafkaProducer nodes support local environment message tree variables, which you can use to dynamically alter the node properties.

The following table shows the elements in the **LocalEnvironment.Destination.Kafka.Output** message tree, which can be used to override the **Topic name** property in the KafkaProducer node. The table includes an example of how to set the values by using ESQL; however, you can also set them by using transformation nodes, such as the Mapping node. To access the LocalEnvironment from a Mapping node, see Customizing a message map to include a message assembly component.

Table 19. Input local environment properties

Element name	Type	Description
topicName	string	The name of the topic where the message will be published. This environment variable overrides the **Topic name** property on the node. For example: `SET OutputLocalEnvironment.Destination.Kafka.Output.topicName = 'customers';`
key	string	A string value to associate with the message. When the message is being published to a topic with multiple partitions, a hash of the key value is used to select the partition on which the message is stored. If no key is provided, messages are distributed across the topic partitions by Kafka. All messages published using the same key value are sent to the same partition.

The following table shows the data that is written by the KafkaProducer node to the LocalEnvironment when propagating an output message:

Table 20. Output local environment properties generated by the KafkaProducer node		
Element	**Type**	**Description**
LocalEnvironment.WrittenDestination.Kafka.partition	string	The partition (in the topic) that contains the message.
LocalEnvironment.WrittenDestination.Kafka.topicName	string	The topic where the message was published.
LocalEnvironment.WrittenDestination.Kafka.offset	integer	The offset number in the partition, for the message that was published.
LocalEnvironment.WrittenDestination.Kafka.checksum	integer	The checksum of the message.
LocalEnvironment.WrittenDestination.Kafka.key	string	The key value that was provided in the input local environment.

After a KafkaConsumer node has read a message, these properties are put into the LocalEnvironment. The KafkaRead node can take these values as input for re-reading the message in a failure scenario for which the KafkaRead node is being used (during catch processing).

The following table shows the data that is written by the KafkaConsumer node to the LocalEnvironment when propagating an output message:

Table 21. Output local environment properties generated by the KafkaConsumer node		
Element	**Type**	**Description**
LocalEnvironment.Kafka.Input.partition	string	The partition (in the topic) that contains the message.
LocalEnvironment.Kafka.Input.topicName	string	The topic where the message was published.
LocalEnvironment.Kafka.Input.offset	integer	The offset number in the partition, for the message that was received.
LocalEnvironment.Kafka.Input.checksum	integer	The checksum of the message.
LocalEnvironment.Kafka.Input.key	string	The key (if any) that was associated with the received message. This field exists only if a key was associated with the message when it was published. The received key value is received as a string by the KafkaConsumer node.

The following table shows elements that can be used to override the properties in the KafkaRead node:

Table 22. Input local environment properties that can be used by the KafkaRead node		
Element name	**Type**	**Description**
LocalEnvironment.Destination.Kafka.Read.PartitionNumber	integer	The partition (in the topic) that contains the message.
LocalEnvironment.Destination.Kafka.Read.TopicName	string	The topic where the message was published.
LocalEnvironment.Destination.Kafka.Read.Offset	integer	The offset number in the partition for the message that was received.
LocalEnvironment.Destination.Kafka.Read.TimeoutInterval	integer	Timeout interval for reading the message from the Kafka topic.

The following table shows the data that is written by the KafkaRead node to the LocalEnvironment after reading a message:

Table 23. Data written by the KafkaRead node to the LocalEnvironment		
Element name	**Type**	**Description**
LocalEnvironment.Kafka.Read.partitionNumber	integer	The partition (in the topic) that contains the message.
LocalEnvironment.Kafka.Read.topicName	string	The topic where the message was published.
LocalEnvironment.Kafka.Read.offset	integer	The offset number in the partition for the message that was received.
LocalEnvironment.Kafka.Read.checksum	integer	The checksum of the message.
LocalEnvironment.Kafka.Read.key	string	The key (if any) that was associated with the received message. This field exists only if a key was associated with the message when it was published. The received key value is received as a string by the KafkaRead node.

You can use Kafka custom header properties to add metadata to Kafka messages for use during message processing. These properties are set in the LocalEnvironment, in a folder called `KafkaHeader`. For more information, see "Setting and retrieving Kafka custom header properties" on page 903.

Using Kafka nodes with IBM Event Streams

You can configure KafkaConsumer, KafkaRead, and KafkaProducer nodes to connect to the Event Streams service in IBM Cloud.

Before you begin

Read the following topics:

- "Processing Kafka messages" on page 892
- "Using Kafka with IBM App Connect Enterprise" on page 894

About this task

IBM Event Streams for IBM Cloud is a scalable, distributed, high-throughput message bus, which supports a number of client protocols including Kafka. You can use the KafkaConsumer, KafkaRead, and KafkaProducer nodes in IBM App Connect Enterprise to receive messages from and send messages to Event Streams.

Before you can connect to Event Streams, you must create a set of credentials, which the IBM App Connect Enterprise Kafka nodes can then use to make a connection. You can use either the **`mqsisetdbparms`** or **`mqsicredentials`** command to configure the credentials that the Kafka nodes use to authenticate to Event Streams.

To enable the Kafka nodes to authenticate by using the username and password, you must set the **`Security protocol`** property on the node to SASL_SSL.

For more information about configuring security credentials for connecting to Kafka, see "Configuring security credentials for connecting to Kafka" on page 904.

Procedure

Follow these steps to configure a connection to IBM Event Streams:

1. Create a set of credentials in Event Streams, which the Kafka nodes use for the connection.
2. In Event Streams, view the credentials and make a note of the list of servers in the **`kafka_brokers_sasl`** property.

   You use this list of servers to populate the **`Bootstrap servers`** property on the KafkaConsumer, KafkaRead, and KafkaProducer nodes when you are creating your message flow.

   You will use the values in the **`User`** and **`Password`** fields to configure the security credentials that IBM App Connect Enterprise uses to connect to Event Streams.

3. Use either the **mqsisetdbparms** or **mqsicredentials** command to associate a username and password with a connection to Event Streams:

   - Configure security credentials by using the **mqsisetdbparms** command, specifying the required username (**-u**), password (**-p**), and resource name (**-n**). The resource name is in the form `kafka::` followed by the name of the security identity that is specified on the Kafka node; for example, `kafka::myKafkaSecId`. Alternatively, you can use the default security identity, by specifying a resource name of `kafka::KAFKA` or `kafka::KAFKA::integrationServerName`.

     The following example shows how to specify a username, password, and named Kafka security identity:

     ```
     mqsisetdbparms -w workDir -n kafka::myKafkaSecId -u myUsername -p myPassword
     ```

     The following example hows how to specify a username and password, and specifies that the default Kafka security identity for the integration server will be used for connecting to Event Streams:

     ```
     mqsisetdbparms -w workDir -n kafka::KAFKA::myIntegrationServer1 -u myUsername -
     p myPassword
     ```

     For more information, see command.
   - Configure security credentials by using the **mqsicredentials** command, specifying the username (**--username**), password (**--password**), credential type (**--credential-type**), and credential name (**--credential-name**). Specify the credential type as `kafka`, and specify a credential name that matches the value of the **Security identifier** parameter specified in the node. Alternatively, you can use the default security identity specified by the **--set-as-default** parameter on the **mqsicredentials** command.

     The following example shows how to specify a username, password, and named Kafka security identity:

     ```
     mqsicredentials --create --work-dir workDir --credential-type kafka --credential-name
      myKafkaSecId --username myUsername --password myPassword
     ```

     The following example shows how to specify a username and password, and specifies that the default Kafka security identity for the integration server will be used for connecting to Event Streams:

     ```
     mqsicredentials --create --work-dir workDir --credential-type kafka --credential-name
      myKafkaSecId --username myUsername --password myPassword
     ```

     ```
     mqsicredentials --set-as-default --work-dir workDir --credential-type kafka --credential-
     name myKafkaSecId
     ```

     For more information, see command.
4. On the **Security** tab of the Kafka nodes, set the **Security protocol** property to SASL_SSL, and set the **SSL protocol** property to `TLSv1.2`.

   If the username and password that are to be used for connecting to Event Streams were configured by using the **mqsicredentials** command, specify the **Security identifier** property on the Kafka node, which will be used to access those credentials in the App Connect Enterprise vault.

What to do next

You can use the command or the command to show information about the credentials that are being used for connecting to Event Streams.

For more information about the Kafka nodes, see the following topics:

- node

Processing TCP/IP messages

You can use IBM App Connect Enterprise to connect to applications that use raw TCP/IP sockets for transferring data.

About this task

If you have existing applications that use raw TCP/IP sockets for transferring data, you can use the IBM App Connect Enterprise TCP/IP nodes to connect to the applications, without needing to enable them for IBM MQ.

IBM App Connect Enterprise implements access to the TCP/IP input and output streams through the following nodes:

- node
- node
- node
- node
- node
- node

For information about how to use the TCP/IP support, see “Working with TCP/IP” on page 923.

The following topics contain information that you need to understand before you can use TCP/IP in an IBM App Connect Enterprise application:

- “TCP/IP data transfer” on page 911
- “TCP/IP nodes” on page 914
- “Connection management” on page 917
- “Configuring TCP/IP client nodes to use SSL” on page 2625
- “Scenarios for IBM App Connect Enterprise and TCP/IP” on page 919

TCP/IP data transfer

You can use IBM App Connect Enterprise to connect to applications that use raw TCP/IP sockets for transferring data.

TCP/IP sockets provide a simple way of connecting computer programs together, and this type of interface is commonly added to existing stand-alone applications. TCP/IP provides a mechanism for transferring data between two applications, which can be running on different computers. The transfer of data is bidirectional; provided that the TCP/IP connection is maintained and no data is lost, the sequence of the data is kept. A significant advantage of using TCP/IP directly is that it is quick and simple to configure, which makes it a useful mechanism for processes that do not require message persistence (for example, monitoring).

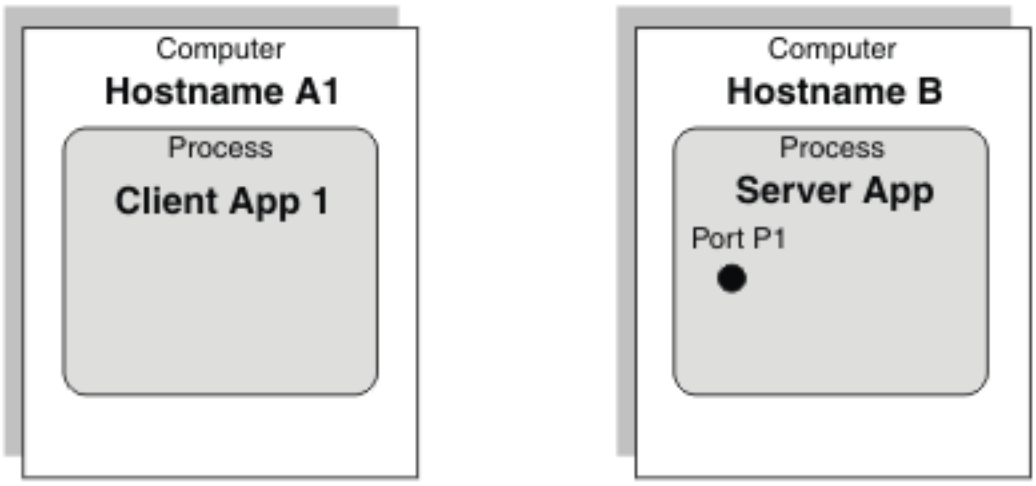
However, the use of TCP/IP sockets for transferring information between programs does have some limitations:

- It is non-transactional
- It is not persistent (the data is written to an in-memory buffer between the sender and receiver)
- It has no built-in security
- It provides no standard way of signaling the start and end of a message

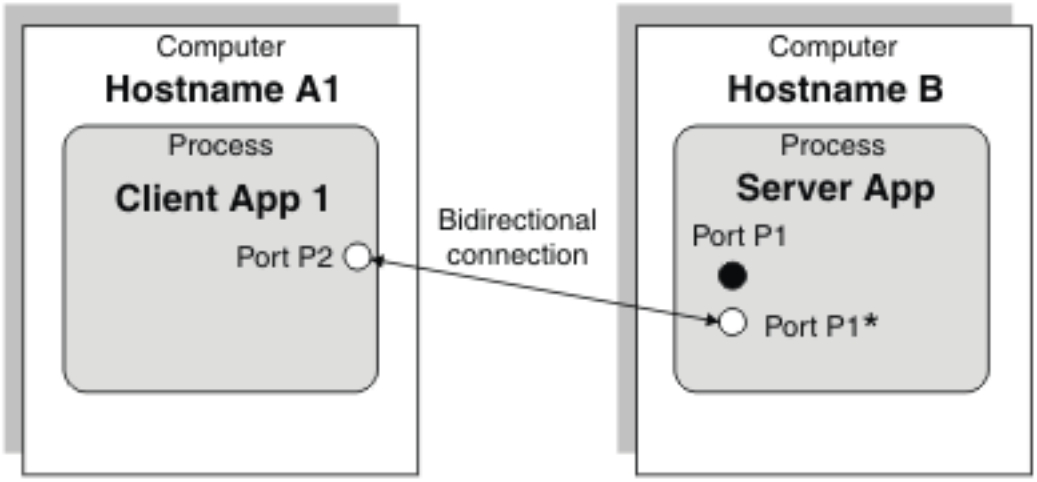
For these reasons, it can be preferable to use a transport mechanism like IBM MQ, which has none of these limitations. However, if you have existing applications that use raw TCP/IP sockets for transferring data, you can use the IBM App Connect Enterprise TCPIP nodes to connect to the applications without

needing to enable them for WebSphere MQ, so that you can develop an IBM App Connect Enterprise solution quickly.

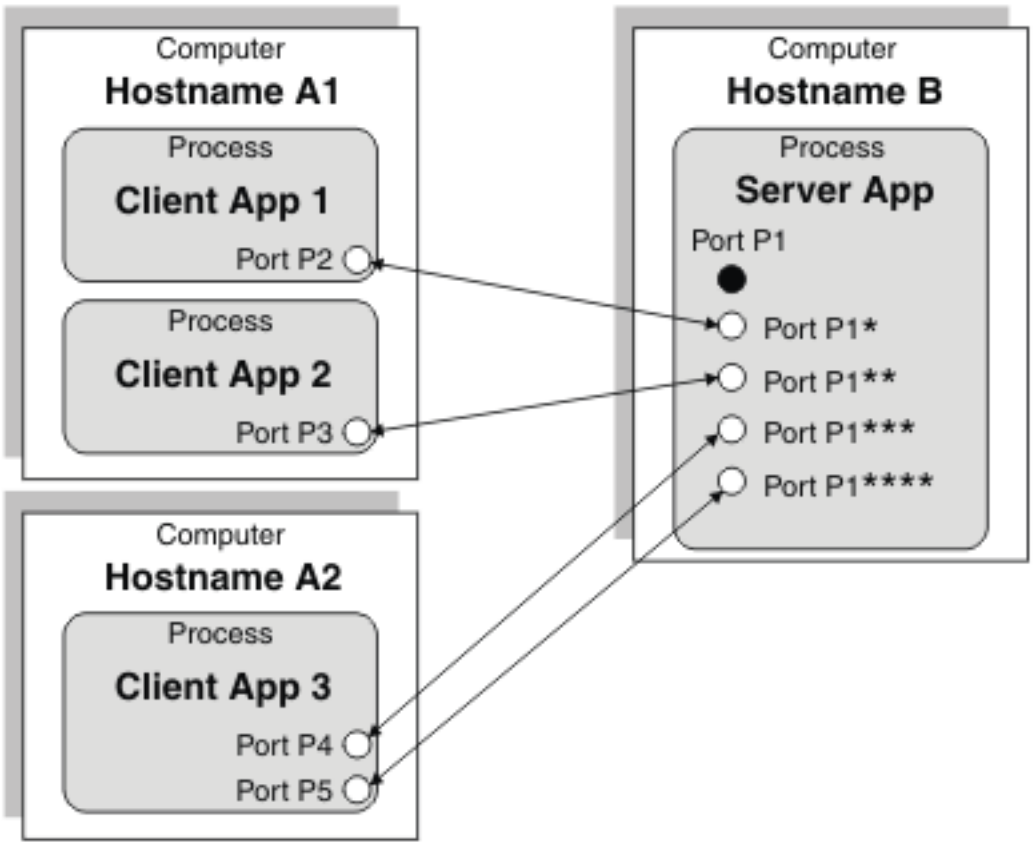
A TCP/IP connection between two applications has a client end and a server end, which means that one application acts as a server and the other as a client. The terms client and server refer only to the mechanism used to establish a connection; they do not refer to the pattern of data exchange. When the connection has been established, both client and server can perform the same operations and can both send and receive data. The following diagram illustrates the locations of client and server applications:



1. The server application listens on a local port (on the computer that is running the application) for requests for connections to be made by a client application.
2. The client application requests a connection from the server port, which the server then accepts.
3. When the server accepts the request, a port is created on the client computer and is connected to the server port.
4. A socket is created on both ends of the connection, and the details of the connection are encapsulated by the socket.
5. The server port remains available to listen for further connection requests:



The server can accept more connections from other client applications. These connections can be in the same process, in a different process on the same computer, or on a different computer:



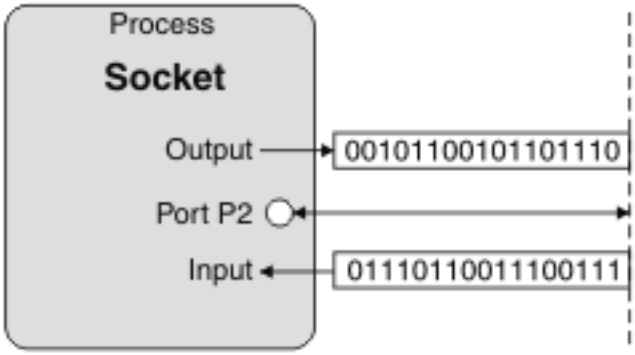
Only one server application can exist, but any number of different client processes can connect to the server application. Any of these applications (client or server) can be multithreaded, which enables them to use multiple connections.

When the connection has been established, two data streams exist: one for inbound data and another for outbound data:

The client and server ends of the connection are identical and both can perform the same operations. The only difference between them is that the output stream of the client is the input stream of the server, and the input stream of the client is the output stream of the server.

The two streams of data are independent and can be accessed simultaneously from both ends. The client does not need to send data before the server.

The example illustrated in the previous diagram can be simplified in the following way, showing that the client and server have access to a socket that has an input stream and an output stream:



TCP/IP nodes

IBM App Connect Enterprise implements access to the TCP/IP input and output streams through a series of message flow nodes.

Two sets of TCP/IP message flow nodes exist: TCPIPServer nodes and TCPIPClient nodes. Both sets have identical function in terms of accessing the data streams; however, one set uses client connections and the other set uses server connections. As a result, the nodes establish the connections in different ways but they use the streams in the same way when the connections have been established.

The main difference between the properties of the nodes is that the TCPIPServer nodes do not allow the host name to be changed (because it must always be `localhost`). All TCPIPServer nodes that use the same port must be in the same integration server because the port is tied to the running process. TCPIPClient nodes on the same port can be used in different integration servers, but client connections cannot be shared because the client connections are tied to a particular integration server, which maps to a process. Within the two sets of nodes (TCPIPClient and TCPIPServer), are three types of node:

- TCPIPServerInput and TCPIPClientInput
- TCPIPServerReceive and TCPIPClientReceive
- TCPIPServerOutput and TCPIPClientOutput

The input and receive nodes access the input stream to retrieve data, and the output nodes access the output stream to send data. No single node can access both streams at the same time. To access both streams simultaneously, you must connect multiple nodes in a message flow.

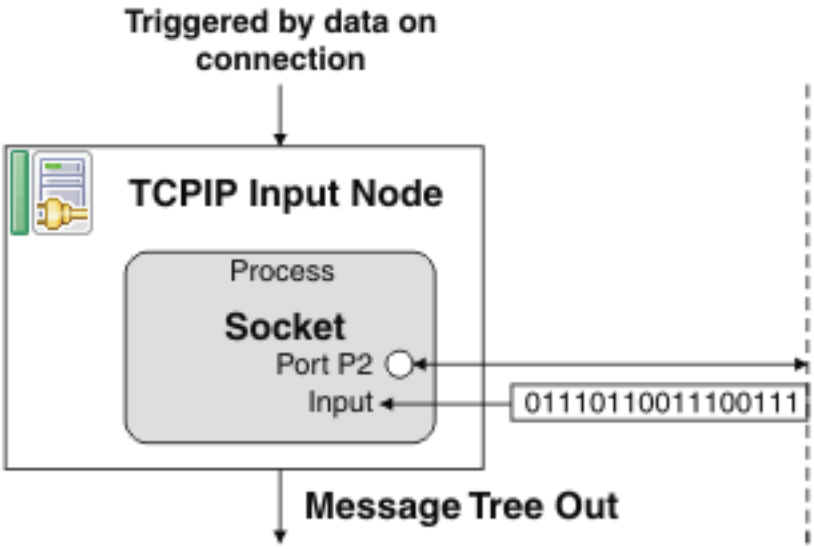
Policies for TCPIPServer and TCPIPClient nodes must be predefined by an administrator. TCP/IP policies must be defined before a message flow that uses them is deployed, even in a test environment.

Input nodes

The input node allows access to a connection's input stream. The node is triggered by the arrival of data in the stream and starts processing the message flow. The input node controls thread and transaction management. The TCP/IP nodes are not transactional in the way that they interact with TCP/IP, but other nodes in the same flow can be transactional (for example, WebSphere MQ nodes). The input node does not create a thread for every connection being used, but waits for two requirements to be met:

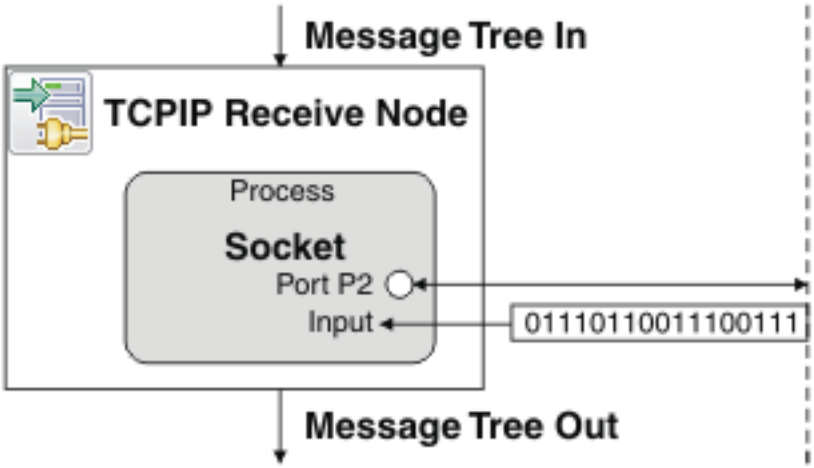
- A connection is available that still has an open input stream
- Data is available on the input stream (at least 1 byte)

For example, 1,000 TCP/IP connections can be handled by one input node that has only one additional instance. This situation is possible because the node does not poll the connections, but is triggered when the specified conditions are met.



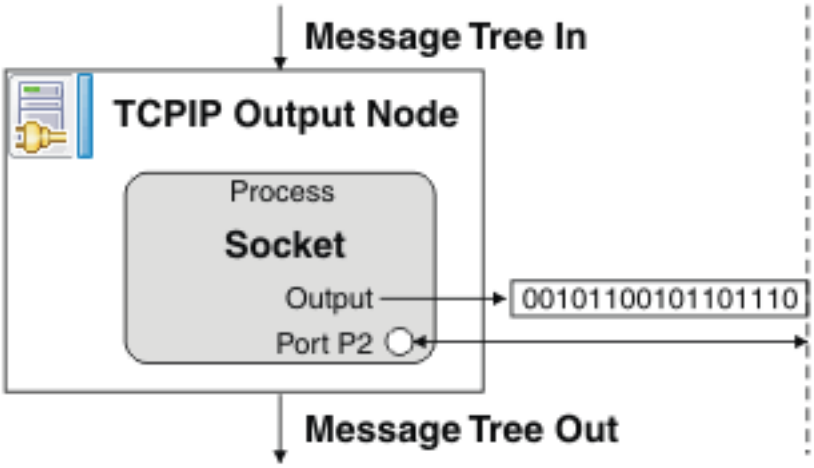
Receive nodes

The receive node is triggered to read data from a connection when a message arrives on its In terminal. It waits for data to arrive, then sends it to the Out terminal. You can configure the receive node to use a particular connection (by specifying a connection's ID) or to use any available connection. If the node is configured to use any available connection, it receives data from the first connection that has data available.



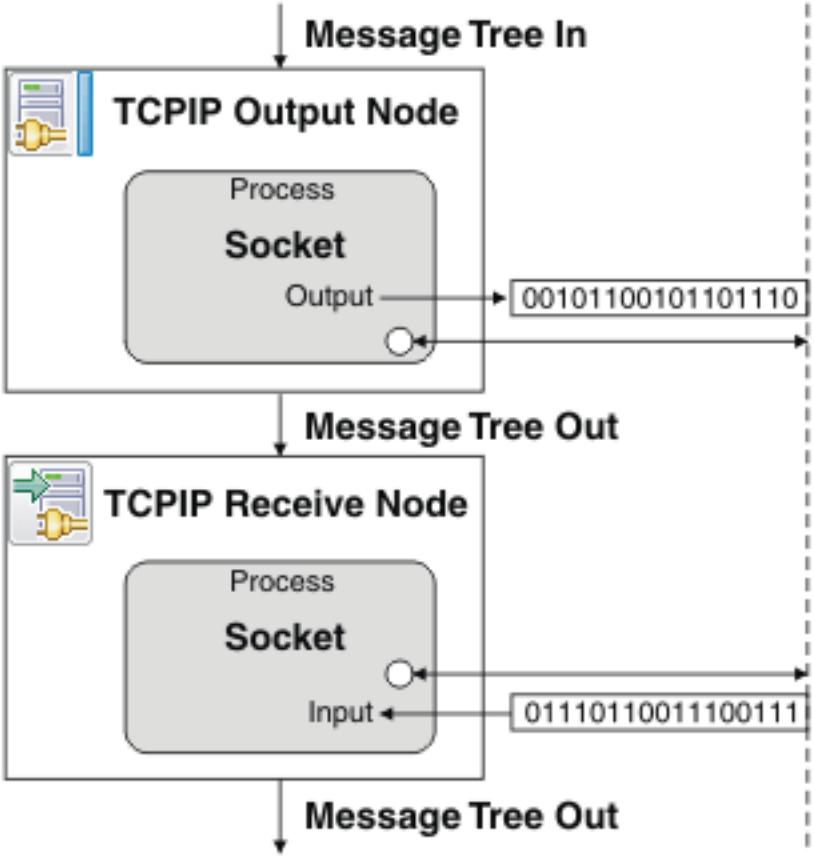
Output nodes

The output node sends data to a connection. It is triggered by a message arriving on its In terminal, then it sends the data contained in the message to the stream. The same message that is received in the node is sent to the Out terminal.



Combining nodes

The six client and server nodes can be combined to provide more complex operations. For example, an output node followed by a receive node enables a synchronous request of data:



If the message flows used are single threaded and only one connection ever exists, the sequence of nodes requires no further configuration. Two additional mechanisms are included to enable multithreading and multiple connections:

- A connection ID to ensure that the same connection is used by multiple nodes
- The ability to reserve connections so that they can be accessed only when the ID is specified

One connection in multiple nodes

Every connection has a unique identifier assigned to it when it is created. Whenever a node uses a connection, the ID that is used is written to the local environment. Any nodes that use it later in the flow can access the same connection by specifying the ID; the receive and output nodes find the ID by searching in a specified location in the local environment. By default, the location in which a node writes its connection details is different from the location in which the next node looks to see if there is an ID to use. The nodes can be configured to use the ID that was sent by a previous node. For example, the combination of the output and receive nodes shown in "Combining nodes" on page 916 can be configured so that the receive node uses the WrittenDestination data from the preceding output node.

The use of the ID enables a series of nodes to access the same connection, but does not prevent two message flow threads accessing the same connection. When a connection is used for the first time, it can be reserved so that no other nodes can access it unless they know the ID. For example, the combination of the output and receive nodes shown in "Combining nodes" on page 916 reserves the connection so that no other threads can access it before the receive node uses it. By default, the receive node then releases the connection when it has finished.

The ability to reserve connections (and access them by specifying the correct ID) enables you to build up complex interactions with TCP/IP connections that span whole flows and even multiple message flows. As a result, the TCP/IP interactions can be used with other asynchronous transport mechanisms like WebSphere MQ.

Reserved connections must be released at some time, otherwise they remain unavailable indefinitely. For more information about reserved and available connections, see "Connection management" on page 917.

Correlating replies across flows

You can use the TCP/IP nodes in asynchronous patterns, in which data is sent out through a TCP/IP output node and received back through a TCP/IP input node. The spanning of two message flows causes any state in the first flow to be lost and therefore inaccessible from the second flow. The TCP/IP nodes enable you to store some reply details on a connection, and these details are then available for the input node to use when a new event arrives on the same connection. By default, this data is taken from the local environment, but you can configure the nodes to take the data from any location, including the Correlid field and message IDs in IBM MQ headers.

Connection management

TCP/IP connections are requested by the client connection manager and accepted by the server connection manager.

The integration server process contains the connection manager, which makes the connections. Only one integration server can have TCPIP server nodes using a specific port at any one time; deployment to a second integration server causes a deployment error. TCPIP client nodes can be deployed to different integration servers, but each integration server has its own pool of connections, and therefore its own minimum and maximum number of connections.

TCPIP nodes do not directly create or manage any TCP/IP connections, but acquire them from the connection manager's internal pool. For example, two output nodes that use the same connection details share the same connection manager. The TCPIP nodes can define the connection details to be used by specifying one of the following values:

- Host name and port
- Name of a policy

If a host name and port are specified, the TCPIP node uses these values when it requests connections. If a policy is specified, the node obtains the values for the port and host name from the values that are defined in the policy. The connection manager supports other configurable parameters in addition to the host name and port, and you can define all of these values when you are using a policy. When the host name and port are specified on the node, the connection manager obtains the rest of the required values

from the default policy. However, if a policy is defined that is using the host name and port number, the values from that policy are used.

The connection manager is created when the first TCPIP node that requires connections from it is deployed. The connection manager is deleted when the last remaining node that uses it is removed from the integration server (which means that the connection manager is no longer being used by any deployed nodes). For example, this process can occur when existing flows are redeployed, because redeployment involves deleting all existing nodes before creating them again.

The connection manager applies any changes that are made to a TCPIP Client policy without requiring a restart of integration servers. The connection manager applies the TCPIP policy changes to all of the message flows that use that service. Applying TCPIP policy changes implies restarting the TCPIP connection managers, so all flows that use policies to specify TCPIP parameters can be expected to pick up new TCPIP connections.

The connection manager updates the affected TCPIP nodes only after every affected message flow has processed the current message. When an affected message flow has processed the current message, that message flow is locked until the updates to all affected message flows are complete. This process is to ensure that each node that is contained in the same integration server uses the same value for the modified policy. For this reason, there might be a delay of several seconds between applying the update to the policy, and the properties that are used by the message flow being updated.

You can view the statistics associated with TCPIP connections by using the **mqsireportproperties** command. For example:

```
mqsireportproperties INODE -e default -o TCPIP -r
```

Server connections

The server connection manager starts listening for server connections when it starts, and it keeps accepting connections until the maximum number of connections (as specified in the policy) is reached. Any attempts to make connections after this point are refused. TCP/IP servers do not create connections; they accept connection requests only from other applications. As a result, you cannot force the creation of connections within a message flow.

Connections to servers can be started, stopped, or quiesced. If you quiesce a connection, you must set a timeout value, or else quiescing continues forever. You can administer the connections by using the IBM Integration API, or the **mqsichangeproperties** command.

Client connections

The client connection manager starts and keeps making client connections until the minimum number of connections (as defined in the policy) is reached. By default, the minimum number of connections is zero, which means that no connections are made. Whenever the number of connections drops below the minimum value, the connection manager starts creating more client connections. The TCPIP client output and receive nodes initiate the creation of new client connections whenever none are available for them to use, unless the maximum number (as defined in the policy) has been reached.

Reserving and releasing connections

Each connection has an input stream and an output stream, both of which have two main states within the connection manager: available and reserved.

When a TCPIP node requests a connection for input or output, without specifying the ID of a particular connection, it is given any available connection on the required stream. If no connections are available, and if the node is a client node, a new connection is made, but only if the maximum number of connections has not yet been reached. Any connection in the available state can be used by only one node at a time, but when a node has finished using it, any other node (from any flow or thread) can access it.

You can restrict access to a stream on a connection by reserving the connection. When a connection is in the reserved state, no other node can access the stream without specifying the ID of the connection. For

example, an input node can request an available connection, and, when it has finished reading the data, put the stream into the reserved state. While the stream is in the reserved state, no input node (including the node that put the stream into the reserved state) can access it because input nodes can access only available streams. The only nodes that can access the stream must have the connection ID, which is written to the outgoing local environment when the data is passed down the message flow. As a result, receive nodes can read more data on the same connection, but only if the receive node is configured to use the ID from the local environment of the input node.

When a connection is reserved, ownership of the connection is given to a current thread of processing. This processing can span separate message flows, if required.

The reserve mechanism provides the following options:

- Leave unchanged
- Reserve
- Release
- Reserve and release at the end of the flow

For all nodes, the stream is left available (not reserved) by default. For many types of processing you can leave this default unchanged; for example, when you are moving data from an input stream to a file. The main purpose of reserving a stream is to connect a series of nodes to give complex processing on a stream in an ordered, controlled, synchronous sequence.

You can use the `Reserve and release at end of flow` option to reserve a connection and to ensure that the connection's stream is released when one iteration of the message flow has finished processing (including any error conditions that might occur).

If you require the processing to span multiple message flows (for example, for asynchronous request and reply), you must reserve a stream without releasing it at the end of the message flow.

A disadvantage of reserving a stream between message flows is the potential for a stream never to be released. To avoid this problem, set an expiry time on the connection so that it is closed after a specified period of inactivity.

Another benefit of reserving an input stream is that the connection cannot be closed until it is either released or expired (even if an end application closes its end of the connection), which is useful when the end of the stream is being used to delimit messages in the stream.

File descriptors

If your IBM App Connect Enterprise application is running on Sun Solaris 10 on SPARC, you might need to increase the number of file descriptors. The following error in the `syslog` indicates that additional file descriptors are required:

```
Failed to create a client connection using hostname: '', port: ''. Reason: 'Invalid argument'
```

You can also try the following two methods to resolve the error:

- Change the *MQSIJVERBOSE* environment variable, for example:

```
export MQSIJVERBOSE=-Djava.nio.channels.spi.SelectorProvider=sun.nio.ch.PollSelectorProvider
```

- Change the limit of maximum file handles to *value* instead of *RLIM64_INFINITY*

Scenarios for IBM App Connect Enterprise and TCP/IP

Two example scenarios show how you might use TCP/IP and IBM App Connect Enterprise as part of a business solution.

- “Scenarios: TCP/IP” on page 920
- “Scenarios: IBM App Connect Enterprise using TCP/IP” on page 922

Scenarios: TCP/IP

Two scenarios illustrate how TCP/IP might be used as part of a business solution.

- "Expense submission" on page 920
- "Price-change notification" on page 921.

Expense submission

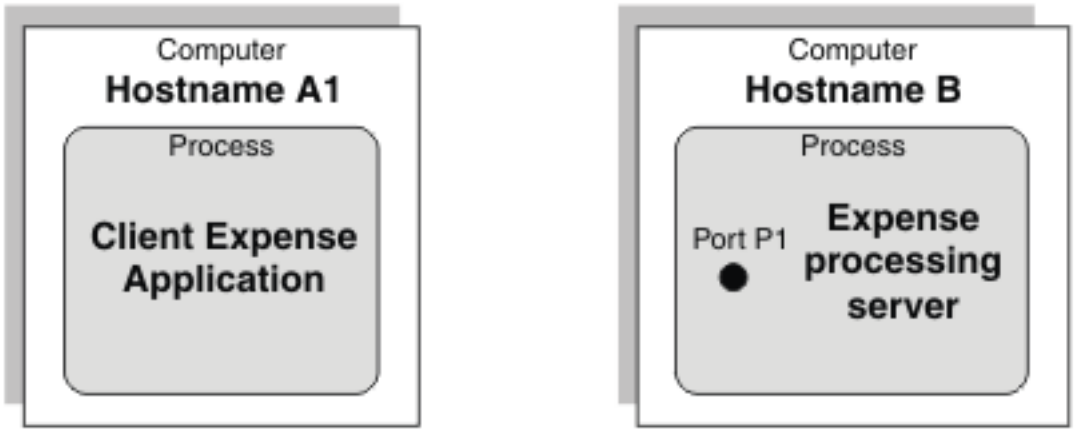
Scenario:

A company has an expense-submission system based on a central expense-processing application, which receives completed expense forms from end users. The users complete the forms by using a local application, which stores the form until it is completed. When it has been completed, the form is transferred to the central system where it is processed. Any further notifications are sent to the user by email.

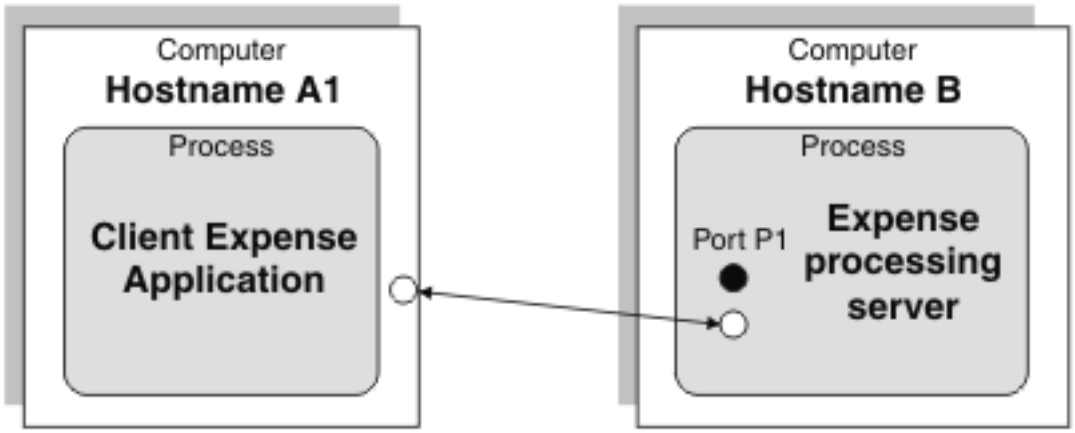
How TCP/IP is used:

One client application exists for each end user, and one central application processes all the expense forms. Each client application connects to a TCP/IP server port on the server application and sends the expense form in a fixed-field-size structure similar to a COBOL structure. The flow of processing is:

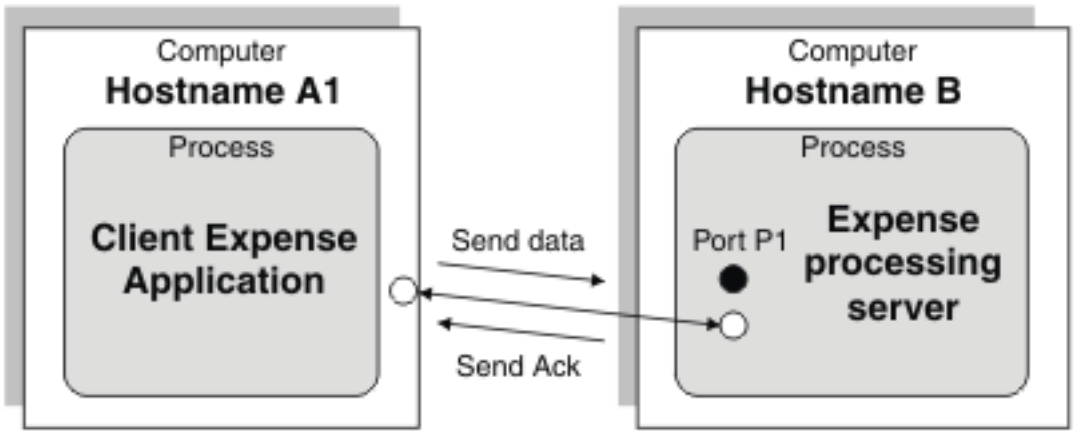
1. The user enters information into the form in the client expense application.



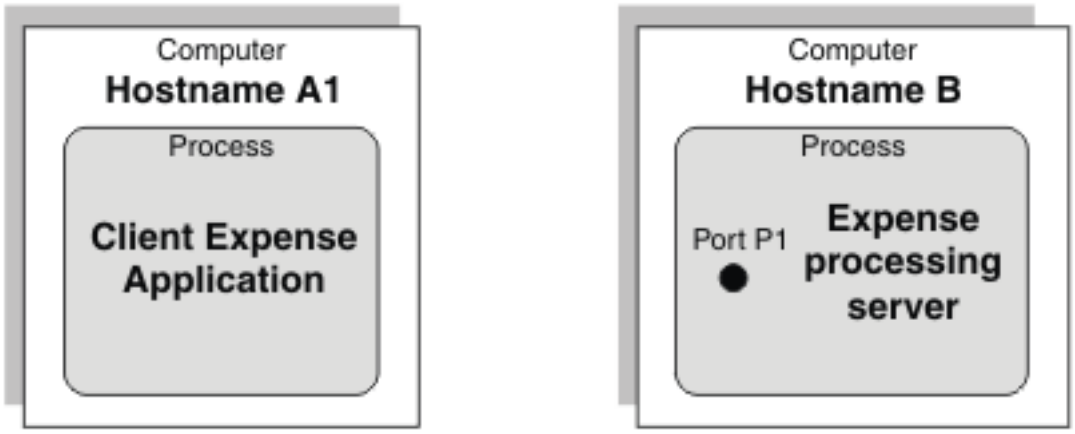
2. The user submits the completed form and the client application connects to the server.



3. The client application sends the data to the server and receives an acknowledgment.



4. The connection is closed by the client.



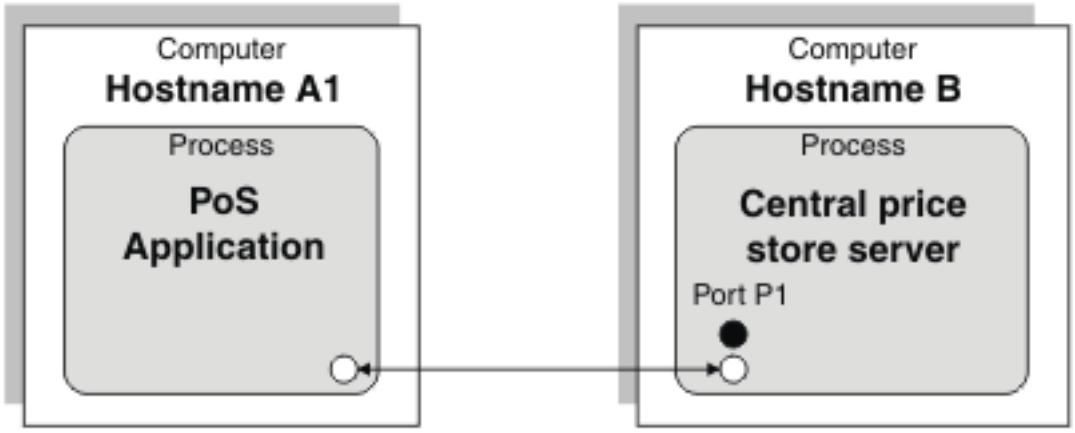
Price-change notification

Scenario:

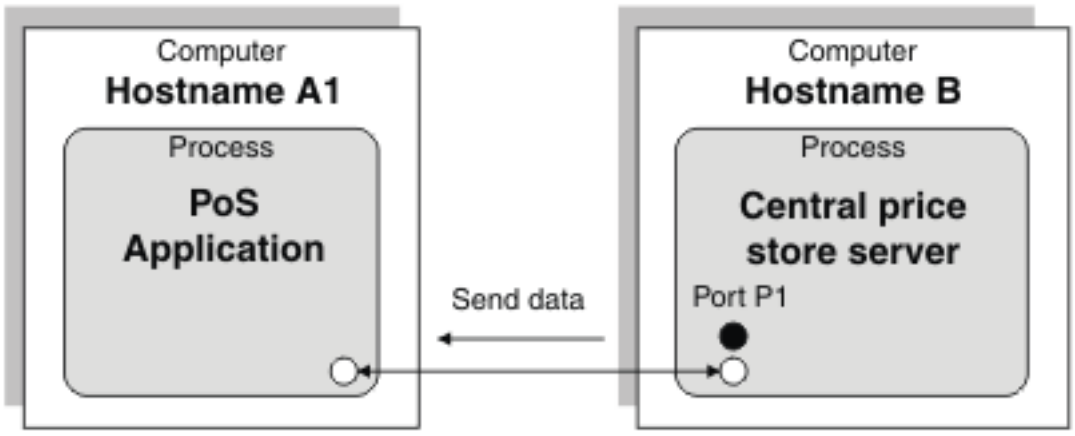
A company has a central server, which stores the catalog price of everything that the company sells. This information is required by all Point of Sale (PoS) terminals in all the stores, and each PoS terminal must be notified when any price changes. The PoS terminals connect to the central server and wait for any process changes. The server sends any process changes to all connected client applications.

How TCP/IP is used:

1. When the PoS application starts, it connects to the central server.



2. Whenever the server has a new price, it publishes it to all the connected clients.



3. The PoS stays connected until it shuts down.

See “Scenarios: IBM App Connect Enterprise using TCP/IP” on page 922 for an example of how these scenarios can be modified to use IBM App Connect Enterprise.

Scenarios: IBM App Connect Enterprise using TCP/IP

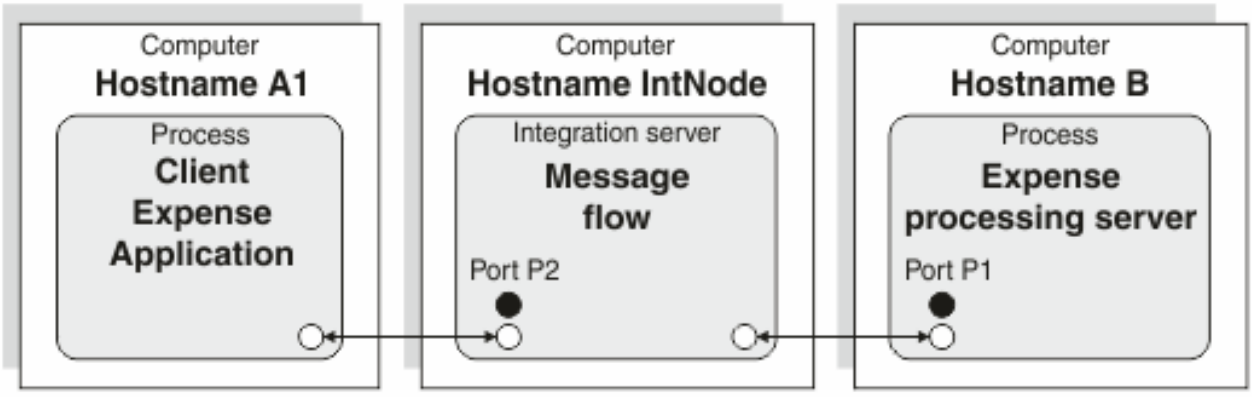
IBM App Connect Enterprise can be added to systems that use TCP/IP for transport, to generate a more flexible architecture for communication between components.

The scenarios in the “Scenarios: TCP/IP” on page 920 topic show how systems can be created to use TCP/IP as a transport mechanism. The following sections show how IBM App Connect Enterprise can be added to those systems to generate a more flexible architecture for communication between components:

- “Expense submission” on page 922 illustrates TCP/IP to TCP/IP routing
- “Price-change notification” on page 922 illustrates routing and transformation to other formats

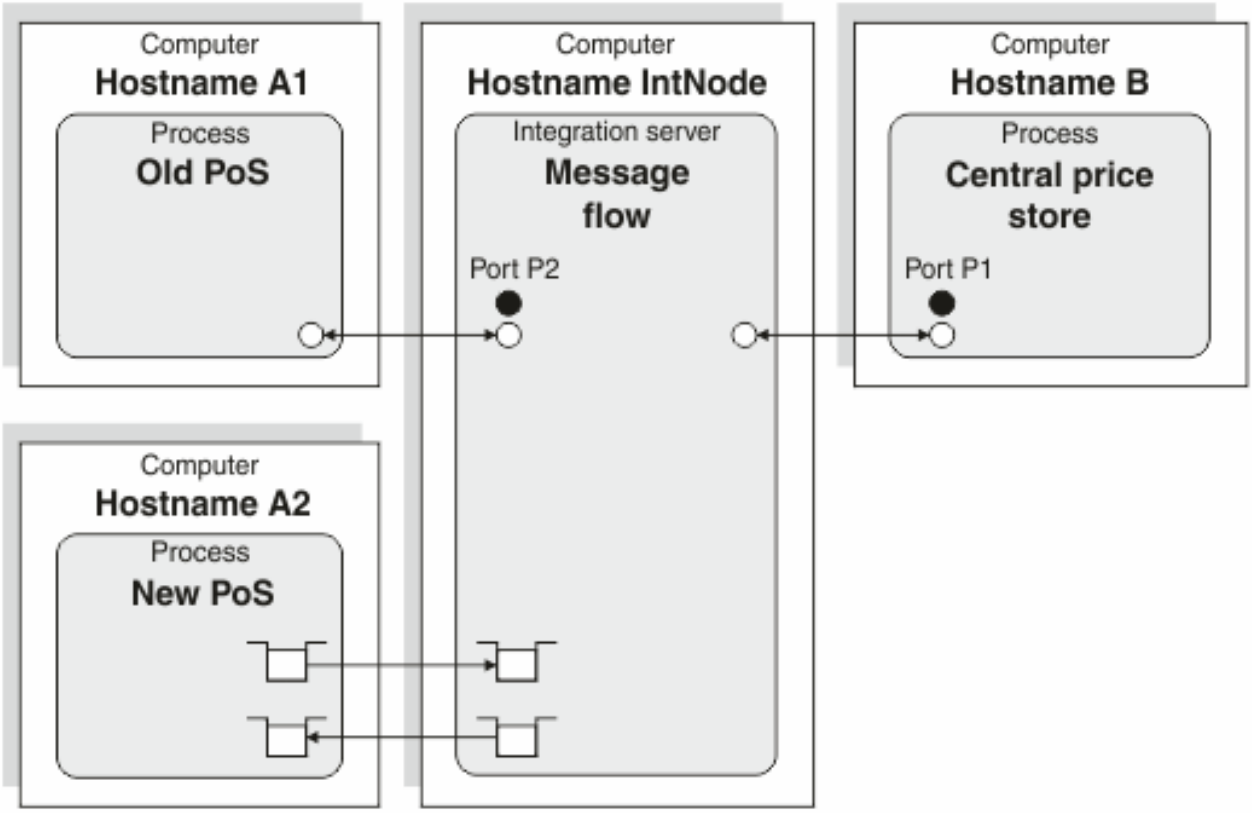
Expense submission

The expense submission scenario shown in the “Scenarios: TCP/IP” on page 920 topic requires a direct connection from the client applications to the end server. With that model it is difficult to add new consumers of the expense submission information, and it is also difficult to change the end application that processes them. However, by adding IBM App Connect Enterprise as an intermediary router, the two systems can be separated without any changes to their interfaces, as shown in the following diagram:



Price-change notification

The price-change notification scenario shown in the “Scenarios: TCP/IP” on page 920 topic can be modified to use an integration node for routing and transformation. It could also allow support for other protocols like IBM MQ, which would allow new applications to be written to different interfaces without the need for changing the current client or server applications:



Working with TCP/IP

You can use IBM App Connect Enterprise TCPIP nodes and TCP/IP policies to perform various tasks.

About this task

- “Sending and receiving data on the same TCP/IP client connection, closing input and output streams (synchronous)” on page 937.
- “Configuring TCP/IP client nodes to use SSL” on page 2625

Transferring XML data from a TCP/IP server socket to an IBM MQ queue
Transfer XML data from a TCP/IP server socket to an IBM MQ queue, by creating a message flow with TCPIPServerInput and MQOutput nodes.

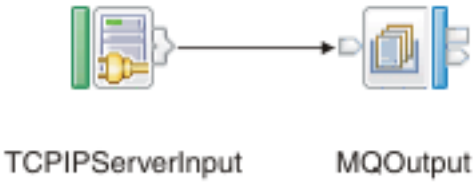
About this task

Scenario: A client application opens a TCP/IP socket and sends an XML document. The end of the document is signalled by the closure of the client connection.

Instructions: The following steps describe how to write a message flow that can receive the XML document and write it to an IBM MQ queue:

Procedure

1. Create a message flow called TCPIP_Task1 with a TCPIPServerInput node and an MQOutput node.
   For more information about how to do this, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the MQOutput node.



3. Set the following properties of the TCPIPServerInput node:
   a) On the **Basic** tab, set the `Connection details` property to 14141.
   b) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
4. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK1.OUT1`.
5. Save the message flow.

Transferring binary (CWF) data from a TCP/IP server socket to a flat file
Transfer binary Custom Wire Format (CWF) data from a TCP/IP server socket to a flat file, by the use of a message set and a message flow with TCPIPServerInput and FileOutput nodes.

About this task

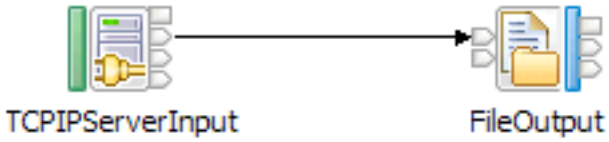
Scenario: A client application opens a TCP/IP socket and sends a binary (CWF) document. The end of the document is signaled by the closure of the client connection.

Instructions: The following steps describe how to write a message flow that can receive the binary document and write it to a flat file. Each message is written to a separate file, the name of which is based on the ID of the connection.

Procedure

1. Create a message set called Task2_MsgSet.
   For more information, see “Message Sets: Creating a message set” on page 2250.
2. Create a message flow called TCPIP_Task2 with a TCPIPServerInput node and a FileOutput node.
   For more information, see “Creating a message flow” on page 574.

3. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the FileOutput node.



4. Set the following properties of the TCPIPServerInput node:
   a) On the **Basic** tab, set the `Connection details` property to 14142.
   b) On the **Input Message Parsing** tab, set the following properties:
      - Set the `Message domain` property to `MRM`.
      - Set the `Message model` property to `Task2_MsgSet`.
      - Set the `Message` property to `Task2_MsgType`.
      - Set the `Physical format` property to `Binary1`.
5. Set the following properties of the FileOutput node:
   a) On the **Basic** tab, set the following properties:
      - Set the `Directory` property to `c:\temp\task2`.
      - Set the `File name or pattern` property to `Task2.out`.
   b) On the **Request** tab, set the `Request file name property location` property to `$LocalEnvironment/TCPIP/Input/ConnectionDetails/Id`.
6. Save the message flow.
7. Create a project reference between the integration project and the message set project.
   For more information, see "Referencing resources in other libraries" on page 1976.

Receiving data on a TCP/IP server socket and sending data back to the same connection
Receive data on a TCP/IP server socket, then send the data to the same connection, by the use of a message flow with TCPIPServerInput and TCPIPServerOutput nodes.

About this task

Scenario: A client application opens a TCP/IP socket and sends an undefined document (of any format or size). The end of the document is signalled by the client closing the output stream (but not the connection), and waiting for the same data to be sent back.

Instructions: The following steps describe how to write a message flow that can receive the data and echo it back to the same connection:

Procedure

1. Create a message flow called TCPIP_Task3 with a TCPIPServerInput node and a TCPIPServerOutput node.
   For more information, see "Creating a message flow" on page 574.

2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the TCPIPServerOutput node.

3. Set the following properties of the TCPIPServerInput node:
   a) On the **Basic** tab, set the `Connection details` property to 14143.
   b) On the **Advanced** tab, set the `Input stream modification` property to `Reserve input stream and release at end of flow`.
4. Set the following properties of the TCPIPServerOutput node:
   a) On the **Basic** tab, set the `Connection details` property to 14143.
   b) On the **Request** tab, set the `ID location` property to `LocalEnvironment/TCPIP/Input/ConnectionDetails/Id`.
   c) On the **Advanced** tab, set the `Close connection` property to `After data has been sent`.
5. Save the message flow.

Sending XML data from an IBM MQ queue to a TCP/IP client socket
Send XML data from an IBM MQ queue to a TCP/IP client socket, by the use of a message flow with MQInput and TCPIPClientOutput nodes.

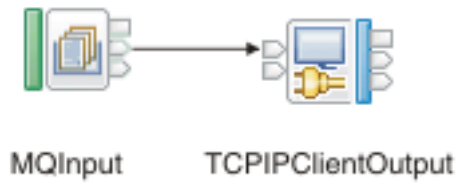
About this task

Scenario: A server application listens on a TCP/IP socket and waits for a TCP/IP client to connect and send data. The end of the document is signalled by the client closing the connection.

Instructions: The following steps describe how to write a message flow that can take a message from an IBM MQ queue, make the client connection, and send the data to the server application:

Procedure

1. Create a message flow called TCPIP_Task4 with an MQInput node and a TCPIPClientOutput node.
   For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.



3. Set the following properties of the MQInput node:
   a) On the **Basic** tab, set the `Queue name` property to `TCPIP.TASK4.IN1`.
   b) On the **Input message parsing** tab, set the `Message domain` property to `XMLNSC`.
4. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to 14144.
   b) On the **Advanced** tab, set the `Close connection` property to `After data has been sent`.
5. Save the message flow.

Sending CWF data from a flat file to a TCP/IP client socket
Send Custom Wire Format (CWF) data from a flat file to a TCP/IP client socket, by the use of a message flow with FileInput and TCPIPClientOutput nodes.

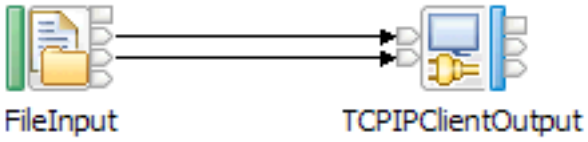
About this task

Scenario: An application writes 100-byte binary records into a flat file.

Instructions: The following steps describe how to open a new client TCP/IP connection and send the binary data with a binary termination character x'00FF'. When the whole file is finished, the client connection is closed:

Procedure

1. Create a message flow called TCPIP_Task5 with a FileInput node and a TCPIPClientOutput node.
   For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the FileInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the End of Data terminal of the FileInput node to the Close terminal of the TCPIPClientOutput node.



4. Set the following properties of the FileInput node:
   a) On the **Basic** tab, set the `Input directory` property to `c:\temp\task5`.
   b) On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
5. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to `14145`.
   b) On the **Advanced** tab, set the `Close connection` property to `After data has been sent`.
   c) On the **Records and elements** tab, set the following properties:
      - Set the `Record definition` property to `Record is delimited data`.
      - Set the `Delimiter` property to `Custom delimiter (Hexadecimal)`.
      - Set the `Custom delimiter` property to `00FF`.
6. Save the message flow.

Sending data to a TCP/IP client connection and receiving data back on the same connection (synchronous)
Send fixed-size data to a TCP/IP client connection and receive fixed-size data back on the same connection (synchronously), by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientReceive, and MQOutput nodes.

About this task

Scenario: An application sends synchronous data between TCP/IP client connections.

Instructions: The following steps describe how to create a message flow that sends data out from a client connection and waits on the same connection for a reply to be returned. The request is synchronous in the same flow, because the TCPIPClientReceive node waits for data to be returned.

Procedure

1. Create a message flow called TCPIP_Task6 with an MQInput node, a TCPIPClientOutput node, a TCPIPClientReceive node, and an MQOutput node.

   For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientOutput node to the In terminal of the TCPIPClientReceive node.
4. Connect the Out terminal of the TCPIPClientReceive node to the In terminal of the MQOutput node.

5. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK6.IN1`.
6. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to `14146`.
   b) On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
7. Set the following properties of the TCPIPClientReceive node:
   a) On the **Basic** tab, set the `Connection details` property to `14146`.
   b) On the **Advanced** tab, set the following properties:
      - Set the `Output stream modification` property to `Reserve output stream and release at end of flow`.
      - Set the `Input stream modification` property to `Reserve input stream and release at end of flow`.
   c) On the **Request** tab, set the `ID location` property to `$LocalEnvironment/WrittenDestination/TCPIP/Output/ConnectionDetails[1]/Id`.
   d) On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
8. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK6.OUT1`.
9. Save the message flow.

Sending data to a TCP/IP client connection and receiving data back on the same connection (asynchronous)

Send fixed-size data to a TCP/IP client connection and receive fixed-size data back on the same connection (asynchronously), by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientInput, and MQOutput nodes.

About this task

Scenario: An application sends asynchronous data between TCP/IP client connections.

Instructions: The following steps describe how to create a message flow to send data through a client connection and wait on the same connection for a reply to be returned. The request is performed asynchronously in two different flows (the TCPIPClientInput does not wait for data to be returned on this connection, but instead monitors all available connections).

Procedure

1. Create a message flow called TCPIP_Task7 with an MQInput node, a TCPIPClientOutput node, a TCPIPClientInput node, and an MQOutput node.

   For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientInput node to the In terminal of the MQOutput node.

4. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK7.IN1`.
5. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to `14147`.
   b) On the **Advanced** tab, set the `Output stream modification` property to `Reserve output stream`.
   c) On the **Records and elements** tab, set the following properties:
      - Set the `Record definition` property to `Fixed length`.
      - Set the `Length` property to `100`.
6. Set the following properties of the TCPIPClientInput node:
   a) On the **Basic** tab, set the `Connection details` property to `14147`.
   b) On the **Advanced** tab, set the `Output stream modification` property to `Release output stream and reset Reply ID`.
   c) On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
7. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK7.OUT1`.
8. Save the message flow.

Establishing a client session over a TCP/IP connection
Configure a TCPIPClientInput node to open a session over an existing TCP/IP connection, before any data is sent or received.

About this task

You can use the Open terminal of the TCPIPClientInput node to enable processing to start when a connection is opened, rather than when data first arrives. If the Open terminal is connected, an empty message is sent to the Open terminal when a connection is created. This message has the local environment set to the connection details.

The connection associated with the message is reserved from the general connection pool until propagation to the Open terminal has finished. However, the connection can be accessed using the connectionId specified in the local environment. Each connection that is created is sent to the Open terminal, including any connections that are created mid-flow by a TCPIPClientReceive node or TCPIPClientOutput node.

If the Open terminal is not attached, open events are automatically made available in the connection pool.

The following steps show how to configure a message flow that contains a TCPIPClientInput node, with the Open terminal configured to start processing when a TCP/IP connection is created.

Procedure

1. Create a message flow containing a TCPIPClientInput node, a Compute node, and a TCPIPClientOutput node.

   For information about how to do this, see “Creating a message flow” on page 574“Creating a message flow” on page 574.
2. Connect the Open terminal of the TCPIPClientInput node to the In terminal of the Compute node.
3. Connect the Out terminal of the TCPIPClientInput node to the In terminal of the TCPIPClientOutput node.
4. On the TCPIPClientInput node, set the `Connection details` property (on the **Basic** tab) to 14143.
5. On the Compute node, set the ESQL property (on the **Basic** tab) to:

```
CREATE COMPUTE MODULE test_Compute1
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  -- CALL CopyMessageHeaders();
  CALL CopyEntireMessage();
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;

 CREATE PROCEDURE CopyEntireMessage() BEGIN
  SET OutputRoot = InputRoot;
 END;
END MODULE;
```

6. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to 14143.
   b) On the **Request** tab, set the `ID location` property to `LocalEnvironment/TCPIP/Input/ConnectionDetails/Id`.
7. Save the message flow.

Broadcasting data to all currently available connections
Broadcast data to all current connections, by the use of a message flow with MQInput and TCPIPServerOutput nodes.

About this task

Scenario: Several applications connect into the message flow and wait to be sent data.

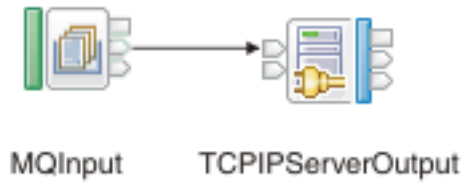
Instructions: The following steps describe how to send data to all the connected client applications:

Procedure

1. Create a message flow called TCPIP_Task8 with an MQInput node and a TCPIPServerOutput node.

   For more information, see “Creating a message flow” on page 574.

2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPServerOutput node.



3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK8.IN1`.
4. Set the following properties of the TCPIPServerOutput node:
   a) On the **Basic** tab, set the `Connection details` property to 14148.
   b) On the **Advanced** tab, set the `Send to:` property (in the **Broadcast options** group) to `All available connections`.
5. Save the message flow.

Configuring a server socket to receive XML data ending in a null character
Configure a server TCP/IP socket to receive XML data ending in a null character, by the use of a message flow with TCPIPServerInput and MQOutput nodes.

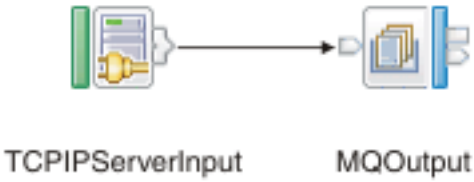
About this task

Scenario: A client application sends XML data that is delimited by a null character (hex code '00').

Instructions: The following steps describe how to break up the record based on the null character, then parse the data.

Procedure

1. Create a message flow called TCPIP_Task11 with a TCPIPServerInput node and an MQOutput node. For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the MQOutput node.



3. Set the following properties of the TCPIPServerInput node:
   a) On the **Basic** tab, set the `Connection details` property to 14151.
   b) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
   c) On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Delimited`.
      - Set the `Delimiter` property to `Custom delimiter`.
      - Set the `Custom delimiter` property to `00`.
4. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK11.IN1`.
5. Save the message flow.

Configuring a server socket to receive XML data and discover the end of a record (by using the message model)
Configure a server socket to receive XML data and use the message model to determine the end of a record, by the use of a message flow with TCPIPServerInput and MQOutput nodes.

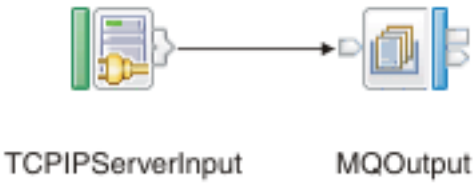
About this task

Scenario: A client application sends an XML document with no clear indication of the end of the record.

Instructions: The following steps show how to break up the record by the use of the XML parser to signal when the whole XML document as been received. The parser uses the end XML tag to signal the end of the message.

Procedure

1. Create a message flow called TCPIP_Task12 with a TCPIPServerInput node and an MQOutput node.
   For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the MQOutput node.



3. Set the following properties of the TCPIPServerInput node:
   a) On the **Basic** tab, set the `Connection details` property to `14151`.
   b) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
   c) On the **Records and elements** tab, set the `Record detection` property to `Parsed record sequence`.
4. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK12.IN1`.
5. Save the message flow.

Configuring a server output node to close all connections
Configure a server output node to close all connections on a specified port.

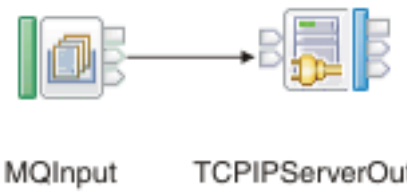
About this task

Scenario: A server output node is configured to close all connections on a specified port.

Instructions: The following steps show how to create a message flow that closes all TCP/IP connections on port 14153:

Procedure

1. Create a message flow called TCPIP_Task13 with an MQInput node and a TCPIPServerOutput node.
   For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the MQInput node to the Close terminal of the TCPIPServerOutput node.



3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK13.IN1`.
4. Set the following properties of the TCPIPServerOutput node:
   a) On the **Basic** tab, set the `Connection details` property to `14153`.
   b) On the **Advanced** tab, set the `Send to:` property (in the **Broadcast options** group) to `All available connections`.
5. Save the message flow.

Configuring a client socket to store reply correlation details
Configure a client TCP/IP socket to store reply correlation details, by the use of a message flow with MQInput and TCPIPClientOutput nodes.

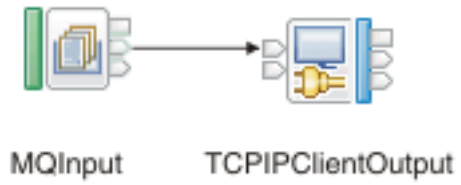
About this task

Scenario: A client TCP/IP socket is configured to store response returned on the input stream.

Instructions: The following steps show how to set the Reply ID on a connection, which can be used when a response is returned on the input stream:

Procedure

1. Create a message flow called TCPIP_Task14 with an MQInput node and a TCPIPClientOutput node.
   For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.



3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK14.IN1`.
4. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to `14154`.
   b) On the **Request** tab, set the `Reply ID location` property to `$Root/MQMD/MsgId`.
5. Save the message flow.

Writing close connection details to a file
Configure a message flow to write details of a connection closure to a file, by the use of TCPIPServerInput, Compute, and FileOutput or FTEOutput nodes.

About this task

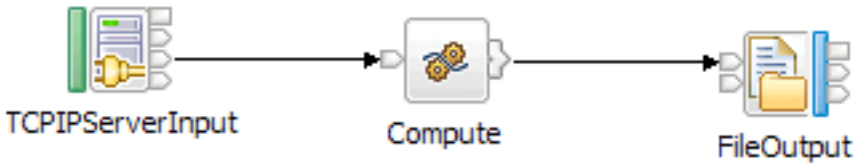
Scenario: A message flow writes close connection details to a file. The scenario uses the FileOutput node; the steps shown also apply to the FTEOutput node.

Instructions The following steps show how to configure a message flow to write details of the closure of any connection to a file:

Procedure

1. Create a message flow called TCPIP_Task15 with a TCPIPServerInput node, a Compute node, and a FileOutput node.
   For more information, see “Creating a message flow” on page 574.
2. Connect the Close terminal of the TCPIPServerInput node to the In terminal of the Compute node.

3. Connect the Out terminal of the Compute node to the In terminal of the FileOutput node.



4. On the TCPIPServerInput node, set the `Connection details` property (on the **Basic** tab) to 14155.
5. On the Compute node, set the ESQL property (on the **Basic** tab) to:

```
BROKER SCHEMA Tasks

CREATE COMPUTE MODULE TCPIP_Task15_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  -- CALL CopyMessageHeaders();
  -- CALL CopyEntireMessage();
  Set OutputRoot.XMLNSC.CloseEvent = InputLocalEnvironment.TCPIP;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;

 CREATE PROCEDURE CopyEntireMessage() BEGIN
  SET OutputRoot = InputRoot;
 END;
END MODULE;
```

6. Set the following properties of the FileOutput node.
   a) On the **Basic** tab, set the following properties:
      - Set the `Directory` property to `c:\temp\Task15`.
      - Set the `File name or pattern` property to `CloseEvents.txt`.
   b) On the **Records and elements** tab, set the `Record definition` property to `Record is unmodified data`.
7. Save the message flow.

Configuring a client node to dynamically call a port
Configure a client node to dynamically use a port and hostname that are set in the local environment, by the use of a message flow with MQInput, Compute, and TCPIPClientOutput nodes.

About this task

Scenario: A client node dynamically calls a port.

Instructions: The following steps show how to override the connection details specified on a client output node to dynamically use a port and hostname that are set in the local environment:

Procedure

1. Create a message flow called TCPIP_Task16 with an MQInput node, a Compute node, and a TCPIPClientOutput node.
   For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the Compute node.

3. Connect the Out terminal of the Compute node to the In terminal of the TCPIPClientOutput node.

4. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK16.IN1` .
5. On the Compute node, set the ESQL property (on the **Basic** tab) to:

```
BROKER SCHEMA Tasks
CREATE COMPUTE MODULE TCPIP_Task16_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  -- CALL CopyMessageHeaders();
  CALL CopyEntireMessage();
  set InputLocalEnvironment.Destination.TCPIP.Output.Hostname = 'localhost';
  set InputLocalEnvironment.Destination.TCPIP.Output.Port = 14156;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;

 CREATE PROCEDURE CopyEntireMessage() BEGIN
  SET OutputRoot = InputRoot;
 END;
END MODULE;
```

6. On the TCPIPClientOutput node, set the `Connection details` property (on the **Basic** tab) to 9999.
7. Save the message flow.

Configuring a server receive node to wait for data on a specified port
Configure a TCPIPServerReceive node to block the message flow and wait for data to arrive on any connection.

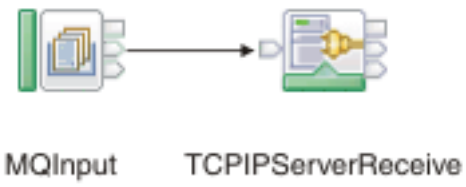
About this task

Scenario: A server receive node is configured to wait for data on a specified port.

Instructions: The following steps show how to configure a TCPIPServerReceive node to wait for data on port 14157:

Procedure

1. Create a message flow called TCPIP_Task17 with an MQInput node and a TCPIPServerReceive node. For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPServerReceive node.



3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK17.IN1`.

4. On the TCPIPServerReceive node, set the `Connection details` property (on the **Basic** tab) to 14157.
5. Save the message flow.

Sending and receiving data through a TCP/IP client connection, delimiting the record by closing the output stream (asynchronous)
Send data through a TCP/IP client connection and receive data back on the same connection (asynchronously), by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientInput, and MQOutput nodes.

About this task

Scenario: An application sends asynchronous data between TCP/IP client connections.

Instructions: The following steps describe how to create a message flow to send data through a client connection and wait on the same connection for a reply to be returned. The request is performed asynchronously in two different flows; the TCPIPClientInput node does not wait for data to be returned on this connection, but monitors all available connections. The outgoing record is delimited by closing the output stream, and the reply message is delimited by the remote server closing the input stream. The connection is then completely closed by the node.

Procedure

1. Create a message flow called TCPIP_Task18 with an MQInput node, a TCPIPClientOutput, a TCPIPClientInput node, and an MQOutput node.
   For more information, see "Creating a message flow" on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientInput node to the In terminal of the MQOutput node.

4. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK18.IN1`.
5. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to 14158.
   b) On the **Advanced** tab, select `Close output stream after a record has been sent`.
   c) On the **Records and elements** tab, set the `Record definition` property to `Record is unmodified data`.
6. Set the following properties of the TCPIPClientInput node:
   a) On the **Basic** tab, set the `Connection details` property to 14158.
   b) On the **Advanced** tab, set the `Close connection` property to `After data has been received`.
   c) On the **Records and elements** tab, set the `Record detection` property to `End of stream`.
7. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK18.OUT1`.
8. Save the message flow.

Sending and receiving data on the same TCP/IP client connection, closing input and output streams (synchronous)

Send data through a TCP/IP client connection and wait on the same connection for a reply to be returned, by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientReceive, and MQOutput nodes.

About this task

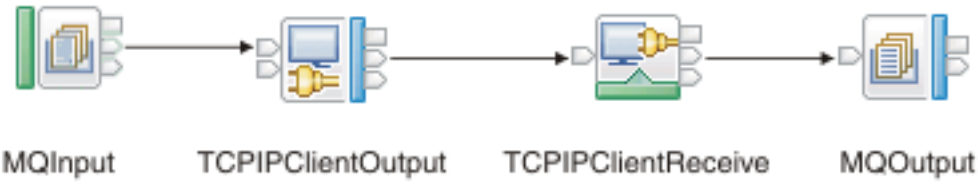
Scenario: An application sends synchronous data on the same TCP/IP client connection.

Instructions: The following steps describe how to create a message flow that sends out data through a client connection and waits on the same connection for a reply to be returned. The request is synchronous within the same flow, as a result of the TCPIPClientReceive node waiting for data to be returned. The outgoing message is delimited by closing the output stream, and the reply data is delimited by the remote application closing the input stream.

Procedure

1. Create a message flow called TCPIP_Task19 with an MQInput node, a TCPIPClientOutput node, a TCPIPClientReceive node, and an MQOutput node.

   For more information, see “Creating a message flow” on page 574.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientOutput node to the In terminal of the TCPIPClientReceive node.
4. Connect the Out terminal of the TCPIPClientReceive node to the In terminal of the MQOutput node.



5. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK19.IN1`.
6. Set the following properties of the TCPIPClientOutput node:
   a) On the **Basic** tab, set the `Connection details` property to `14159`.
   b) On the **Advanced** tab, set the following properties:
      - Select `Close output stream after a record has been sent`.
      - Set the `Input stream modification` property to `Reserve input stream and release at end of flow`. It is important to reserve the input stream so that it is not closed before the receive node processes the return data.
   c) On the **Records and elements** tab, set the `Record definition` property to `Record is Unmodified Data`.
7. Set the following properties of the TCPIPClientReceive node:
   a) On the **Basic** tab, set the `Connection details` property to `14159`.
   b) On the **Advanced** tab, set the `Close connection` property to `After data has been received`.
   c) On the **Request** tab, set the `ID location` property to `$LocalEnvironment/WrittenDestination/TCPIP/Output/ConnectionDetails[1]/Id`.
   d) On the **Records and elements** tab, set the `Record detection` property to `Connection closed`.
8. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK19.OUT1`.
9. Save the message flow.

Processing email messages

You can configure the EmailOutput node to deliver an email from a message flow to an email server that supports Simple Mail Transfer Protocol (SMTP). You can also configure the EmailInput node to retrieve an email from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

About this task

The topics in the following sections describe how the EmailOutput and the EmailInput nodes work, and how to use them to send and receive email messages.

- "Sending emails" on page 938
- "Receiving emails" on page 947

Sending emails

You can use the EmailOutput node to send email messages, with or without attachments, to one or more recipients. The EmailOutput node delivers an email message from your message flow to an email server that supports Simple Mail Transfer Protocol (SMTP), which you specify.

The following topics describe how the EmailOutput node works and how to use it to send email messages.

- "Sending emails" on page 938
- "Sending an email" on page 939
- "Sending an email with an attachment" on page 940
- "Producing dynamic email messages" on page 940
- "Sending a MIME message" on page 944
- "Changing connection information for the EmailOutput node" on page 946

Receiving emails

You can use the EmailInput node to receive email messages, with or without attachments, from one or more recipients. The EmailInput node retrieves an email message from an email server that you specify, which supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

The following topics describe how the EmailInput node works, and how to use it to receive email messages.

- "Receiving emails" on page 947
- "Receiving an email" on page 948
- "Processing responses from an EmailInput node" on page 950
- "Changing connection information for the EmailInput node" on page 951

Sending emails

You can configure IBM App Connect Enterprise to send an email, with or without attachments, to a static or dynamic list of recipients.

About this task

You can configure the EmailOutput node to send an email, with or without a single attachment, with a static subject and static text, to a static list of recipients. You can also construct a message flow that can produce an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time.

You can use the SMTP `Server and Port` property of the EmailOutput node to specify the host name of the SMTP server that the integration server uses to send emails, or to specify an alias that refers to an SMTP policy that is defined on the integration server. If the value of the SMTP `Server and Port` property is set to the defined alias, any values that are set in the policy are used in preference to any statically defined value or override value in the local environment.

The order of preference for SMTP value selection is:

1. The value that is specified in the policy if an alias exists with the name that was supplied in the SMTP `Server and Port` property.
2. The server name that is specified in the local environment.
3. The value of the SMTP `Server and Port` property that is specified on the node.

The topics in this section describe the different ways in which you can use the EmailOutput node to send email messages.

Procedure

- To send an email with a static subject and static text to a static list of recipients, see "Sending an email" on page 939.
- To send an email with an attachment, see "Sending an email with an attachment" on page 940.
- To send an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time, see "Producing dynamic email messages" on page 940.
- To send an email that is constructed from a MIME message, see "Sending a MIME message" on page 944.
- To configure the SMTP server, port number, and security identity for the EmailOutput node as an integration node external resource, see "Changing connection information for the EmailOutput node" on page 946.

Sending an email
You can send an email with a static subject and static text to a static list of recipients.

About this task

Use the IBM App Connect Enterprise Toolkit to configure the properties on the EmailOutput node so that you can send an email with a statically defined subject and text, and no attachments, to a statically defined list of recipients. The same email is sent to the same recipients. This method is useful when you want to test the EmailOutput node, or when notification alone is sufficient.

Procedure

1. Switch to the Integration Development perspective.
2. Add an EmailOutput node to your message flow.
3. Edit the following properties of the EmailOutput node.
   a) On the **Basic** tab, add the SMTP Server and Port information (for example, *smtp.server.com:25*).
   b) On the **Email** tab, add the email addresses of recipients by using the `To Addresses`, `Cc Addresses`, and `Bcc Addresses` properties.
   c) On the **Email** tab, add the email address of the sender by using the `From Address` and `Reply-To Address` properties.
   d) On the **Email** tab, provide a subject for the email by using the `Subject of email` property.
   e) On the **Email** tab, provide the text of the email by using `Email message text` property.
4. Save the changes.
5. Add the message flow to the BAR file and deploy.

Results

When a message is passed into the deployed EmailOutput node, an email is sent to the defined set of recipients, containing the subject and text specified on the node.

Sending an email with an attachment
You can send an email with a fixed subject and fixed text, and an attachment, to a static list of recipients.

About this task

You can configure an EmailOutput node to send an email with a single attachment. To send an email with multiple attachments, see "Producing dynamic email messages" on page 940.

Use the IBM App Connect Enterprise Toolkit to configure the properties on the EmailOutput node so that you can send an email with a statically defined subject and text, and an attachment, to a statically defined list of recipients. This method causes the email message to be constructed as a MIME message. The subject, text, and list of recipients remains static, but the content of the attachment is sought dynamically from the message that is passed to the EmailOutput node at run time. The location of the attachment in the message is defined statically.

Procedure

1. Switch to the Integration Development perspective.
2. Add an EmailOutput node to your message flow.
3. Edit the following properties of the EmailOutput node.
   a) On the **Basic** tab, add the SMTP Server and Port information (for example, *smtp.server.com:25*).
   b) On the **Email** tab, add the email addresses of recipients by using the `To Addresses`, `Cc Addresses`, and `Bcc Addresses` properties.
   c) On the **Email** tab, add the email address of the sender by using the `From Address` and `Reply-To Address` properties.
   d) On the **Email** tab, provide a subject for the email by using the `Subject of email` property.
   e) On the **Email** tab, provide the text of the email by using `Email message text` property.
   f) On the **Attachment** tab, set the `Attachment Content` property by using either an ESQL or XPath expression, referring to an element in the message tree; for example, *Body.BLOB*.
   g) On the **Attachment** tab, set the `Attachment Content Name` property with the name of the attachment as it appears in the email.
   h) On the **Attachment** tab, set the `Attachment Content Type`, `Attachment Content Encoding`, and `Multipart Content Type` properties to determine the type of attachment that is sent in the MIME message.
4. Save the changes.
5. Add the message flow to the BAR file and deploy.

Results

When a message is passed into the deployed EmailOutput node, an email is sent to the defined set of recipients, containing the subject, text, and attachment specified on the node.

Producing dynamic email messages
You can produce an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time.

About this task

You can create a message flow that produces an email with multiple attachments. To configure an EmailOutput node to send an email with a single attachment, static subject, and static text to a static list of recipients, see "Sending an email with an attachment" on page 940.

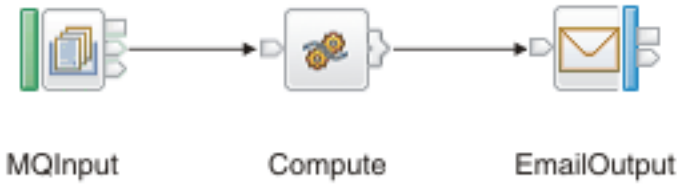
The node properties that you set when sending an email can be optional, and can be overridden at run time by values that you specify in the local environment, email output header (EmailOutputHeader), or the body of the message. To use this method, previous nodes in the message flow must construct these

overrides. Where a text value is not specified in the node properties for the main body of the email, the body of the message that is passed to the EmailOutput node is used.

The following examples show how to set up the recipient, sender, subject, SMTP server, and message body information in ESQL (with a Compute node) and Java (with a JavaCompute node).

Using a Compute node

About this task



```
CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  CALL CopyMessageHeaders();

  -- Add recipient information to the EmailOutputHeader
  SET OutputRoot.EmailOutputHeader.To = '<recipient email address>';
  SET OutputRoot.EmailOutputHeader.Cc = '<recipient email address>';
  SET OutputRoot.EmailOutputHeader.Bcc = '<recipient email address>';

  -- Add sender information to EmailOutputHeader
  SET OutputRoot.EmailOutputHeader.From = '<sender email address>';
  SET OutputRoot.EmailOutputHeader."Reply-To" = '<reply email address>';

  -- Add subject to EmailOutputHeader
  SET OutputRoot.EmailOutputHeader.Subject = 'Replaced by ESQL compute node.';

  -- Add SMTP server information to the LocalEnvironment
  SET OutputLocalEnvironment.Destination.Email.SMTPServer ='<smtp.server:port>';

  -- Create a new message body, which will be sent as the main text of the email.
  SET OutputRoot.BLOB.BLOB = CAST('This is the new text for the body of the email.' AS BLOB CCSID 1208);

  RETURN TRUE;
 END;
```

Note: When using a BLOB parser on z/OS, the CCSID of the message should be 500. In the previous example, the CAST would be:

```
SET OutputRoot.BLOB.BLOB = CAST('This is the new text for the body of the email.' AS BLOB CCSID
 500);
```

To write white space characters (such as newline (NL), carriage return (CR), and line feed (LF) characters) in the text string that is produced as the email body, you can add the following lines of code.

```
DECLARE crlf CHAR CAST(X'0D0A' AS CHAR CCSID 1208);
DECLARE myEmailBodyTxt CHAR;
SET myEmailBodyTxt [equals char] 'this is the first line' || crlf ||
    'this is the second line' || crlf ||
    'this is the third line';
SET OutputRoot.BLOB.BLOB = CAST(myEmailBodyTxt AS BLOB CCSID 1208);
```

Using a JavaCompute node

About this task

```
public void evaluate(MbMessageAssembly assembly) throws MbException {
  MbOutputTerminal out = getOutputTerminal("out");

  // Create a new assembly to propagate out of this node, as we want to update it
  MbMessage outMessage = new MbMessage();
  copyMessageHeaders(assembly.getMessage(), outMessage);
  MbMessage outLocalEnv = new MbMessage(assembly.getLocalEnvironment());
  MbMessage outExceptionList = new MbMessage(assembly.getExceptionList());
  MbMessageAssembly outAssembly = new MbMessageAssembly(assembly, outLocalEnv, outExceptionList,
 outMessage);
  MbElement localEnv = outAssembly.getLocalEnvironment().getRootElement();

  // Create the EmailOutputHeader parser. This is where we add recipient, sender and subject information.
  MbElement root = outMessage.getRootElement();
  MbElement SMTPOutput = root.createElementAsLastChild("EmailOutputHeader");

  // Add recipient information to EmailOutputHeader
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "To", "<recipient email address");
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Cc", "<recipient email address");
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Bcc", "<recipient email address");

  // Add sender information to EmailOutputHeader
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "From", "<sender email address>");
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Reply-To", "<reply email address>");

  // Add subject information to EmailOutputHeader
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Subject", "Replaced by Java compute
 node.");

  // Create Destination.Email. This is where we add SMTP server information
  MbElement Destination = localEnv.createElementAsLastChild(MbElement.TYPE_NAME, "Destination", null);
  MbElement destinationEmail = Destination.createElementAsLastChild(MbElement.TYPE_NAME, "Email", null);

  destinationEmail.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "SMTPServer",
 "<smtp.server:port>");

  // Set last child of root (message body)
  MbElement BLOB = root.createElementAsLastChild(MbBLOB.PARSER_NAME);
  String text = "This is the new text for the body of the email";
  BLOB.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB", text.getBytes());

  outMessage.finalizeMessage(MbMessage.FINALIZE_VALIDATE);

  out.propagate(outAssembly);  }
```

Using the local environment

About this task

Use the local environment to specify overrides to the SMTP server connection information and attachments.

Local environment	Description
Destination.Email.SMTPServer	The Server:Port of the SMTP server. Port is optional; if you do not specify it, the default value is 25.

Local environment	Description
Destination.Email.SecurityIdentity	The security identity for authentication with the SMTP server, which can be the name of the userid and password pair that is defined using the **mqsisetdbparms** command, or it can reference an external resource that has a securityIdentity attribute that references a userid and password that are defined using the **mqsisetdbparms** command. In both cases, the value is appended after the string "smtp::". For example, if you use the **mqsisetdbparms** command to create a userid and password of *smtp::myUseridPassword*, the securityIdentity that is specified on the node, or indirectly in an external resource, is *myUseridPassword*.
Destination.Email.BodyContentType	Identifies that the body of the email message contains HTML rather than plain text. You can set this property to text/plain, text/html, or text/xml; text/plain is the default value.
Destination.Email.MultiPartContentType	The type of multipart, including related, mixed, and alternative. You can set any value here.
Destination.Email.Attachment.Content	Either the actual attachment (BLOB/text), or an XPath or ESQL expression that references an element; for example, an element in the message tree or LocalEnvironment. The value of the referenced element is taken as the content of the attachment. • If the element is a BLOB, it is an attachment. • If the element is text, check to see if it can be resolved to another element in the message tree or LocalEnvironment. If it can be resolved, use that element. If it cannot be resolved, add this element as the attachment.
Destination.Email.Attachment.ContentType	The type of attachment (also known as Internet Media Type), including text/plain, text/html, and text/xml. You can set any value here.
Destination.Email.Attachment.ContentName	The name of the attachment.
Destination.Email.Attachment.ContentEncoding	The encoding of the attachment: 7bit, base64, or quoted-printable. • 7bit is the default value that is used for ASCII text. • Base64 is used for non ASCII, whether non English or binary data. This format can be difficult to read. • Quoted-printable is an alternative to Base64, and is appropriate when most of the data is ASCII with some non-ASCII parts. This format is more readable; it provides a more compact encoding because the ASCII parts are not encoded.

Using the email output header

About this task

Use the email output header to specify overrides to the SMTP server connection information and attachments. The EmailOutputHeader is a child of Root. Values that you specify in this header override equivalent properties that you set on the EmailOutput node. Use the SMTP output header to specify any of the email attributes, such as its recipients.

Location	Description
Root.EmailOutputHeader.To	A comma-separated list of email addresses.
Root.EmailOutputHeader.Cc	A comma-separated list of email addresses.
Root.EmailOutputHeader.Bcc	A comma-separated list of email addresses.
Root.EmailOutputHeader.From	A comma-separated list of email addresses.
Root.EmailOutputHeader.Reply-To	A comma-separated list of email addresses.
Root.EmailOutputHeader.Subject	The subject of the email.
Root.EmailOutputHeader.Sender	A single email address. This header is mandatory if multiple email addresses are specified in the Root.EmailOutputHeader.From field.

Any other children of the Root.EmailOutputHeader element are treated as custom headers and are also added to the outgoing email.

Sending a MIME message
You can send an email that is constructed from a MIME message.

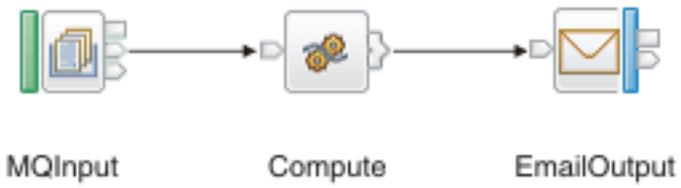
About this task

You can pass a MIME message to the EmailOutput node, which uses the MIME parser to write the MIME message to a bit stream. This message is then sent to the list of recipients in the EmailOutputHeader. Local environment overrides are not considered when a MIME message is passed. You do not need to configure the EmailOutput node in the following examples.

The following examples show how to set up the recipient, sender, subject, SMTP server, and message body information in ESQL (with a Compute node) and Java (with a JavaCompute node).

Using a Compute node

About this task



```
CREATE FUNCTION Main() RETURNS BOOLEAN
BEGIN

   CALL CopyMessageHeaders();

   -- Add recipient information to the EmailOutputHeader
   SET OutputRoot.EmailOutputHeader.To = '<recipient email address>';
   SET OutputRoot.EmailOutputHeader.Cc = '<recipient email address>';
   SET OutputRoot.EmailOutputHeader.Bcc = '<recipient email address>';

   -- Add sender information to EmailOutputHeader
   SET OutputRoot.EmailOutputHeader.From = '<sender email address>';
   SET OutputRoot.EmailOutputHeader."Reply-To" = '<reply email address>';

   -- Add subject to EmailOutputHeader
   SET OutputRoot.EmailOutputHeader.Subject = 'Dynamic MIME message in ESQL.';

   -- Add SMTP server information to the LocalEnvironment
   SET OutputLocalEnvironment.Destination.Email.SMTPServer ='<smtp.server:port>';

   -- Create a new MIME message body, which will be sent as the main text of the email,
```

```
   -- including an attachment.
   CREATE FIELD OutputRoot.MIME TYPE Name;
   DECLARE M REFERENCE TO OutputRoot.MIME;

   -- Create the Content-Type child of MIME explicitly to ensure the correct order. If we set
   -- the ContentType property instead, the field could appear as the last child of MIME.
   CREATE FIELD M."Content-Type" TYPE NameValue VALUE 'multipart/related; boundary=myBoundary';
   CREATE FIELD M."Content-ID"   TYPE NameValue VALUE 'new MIME document';

   CREATE LASTCHILD OF M TYPE Name NAME 'Parts';
   CREATE LASTCHILD OF M.Parts TYPE Name NAME 'Part';
   DECLARE P1 REFERENCE TO M.Parts.Part;

   -- First part:
   --   Create the body of the email.
   --   The body of the email has the text 'This is the main body of the email.'.
   CREATE FIELD P1."Content-Type" TYPE NameValue VALUE 'text/plain; charset=us-ascii';
   CREATE FIELD P1."Content-Transfer-Encoding" TYPE NameValue VALUE '8bit';
   CREATE LASTCHILD OF P1 TYPE Name NAME 'Data';
   CREATE LASTCHILD OF P1.Data DOMAIN('BLOB') PARSE(CAST('This is the main body of the email.'
AS BLOB CCSID 1208));

   CREATE LASTCHILD OF M.Parts TYPE Name NAME 'Part';
   DECLARE P2 REFERENCE TO M.Parts.Part[2];

   -- Second part:
   --   Create the attachment of an email.
   --   The attachment is called 'attachment.txt' and contains the text 'This is an attachment.'.
   CREATE FIELD P2."Content-Type" TYPE NameValue VALUE 'text/plain; charset=us-ascii;
 name=attachment.txt';
   CREATE FIELD P2."Content-Transfer-Encoding" TYPE NameValue VALUE '8bit';
   CREATE LASTCHILD OF P2 TYPE Name NAME 'Data';
   CREATE LASTCHILD OF P2.Data DOMAIN('BLOB') PARSE(CAST('This is an attachment.' AS BLOB CCSID 1208));

   RETURN TRUE;
END;
```

Using a JavaCompute node

About this task

```
public void evaluate(MbMessageAssembly assembly) throws MbException {
   MbOutputTerminal out = getOutputTerminal("out");
   MbOutputTerminal fail = getOutputTerminal("fail");

   // Create a new assembly to propagate out of this node, as we want to
   // update it
   MbMessage outMessage = new MbMessage();
   copyMessageHeaders(assembly.getMessage(), outMessage);
   MbMessage outLocalEnv = new MbMessage(assembly.getLocalEnvironment());
   MbMessage outExceptionList = new MbMessage(assembly.getExceptionList());
   MbMessageAssembly outAssembly = new MbMessageAssembly(assembly, outLocalEnv, outExceptionList,
 outMessage);
   MbElement localEnv = outAssembly.getLocalEnvironment().getRootElement();

   // Create the EmailOutputHeader parser. This is where we add recipient,
   // sender and subject information.
   MbElement root = outMessage.getRootElement();
   MbElement SMTPOutput = root.createElementAsLastChild("EmailOutputHeader");

   // Add recipient information to EmailOutputHeader
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "To", "<recipient email address>");
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Cc", "<recipient email address>");
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Bcc", "<recipient email address>");

   // Add sender information to EmailOutputHeader
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "From", "<sender email address>");
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Reply-To", "<reply email address>");
```

```
   // Add subject information to EmailOutputHeader
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Subject", "Dynamic MIME message in
 Java.");

   // Create Destination.Email. This is where we add SMTP server information.
   MbElement Destination = localEnv.createElementAsLastChild(MbElement.TYPE_NAME, "Destination", null);
   MbElement destinationEmail = Destination.createElementAsLastChild(MbElement.TYPE_NAME, "Email", null);
   destinationEmail.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "SMTPServer",
 "<smtp.server:port>");

   // Set last child of root (message body) as MIME.
   MbElement MIME = root.createElementAsLastChild("MIME");

   // Create the Content-Type child of MIME explicitly to ensure the correct order.
   MIME.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Type", "multipart/related;
boundary=myBoundary");
   MIME.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-ID", "new MIME document");
   MbElement parts = MIME.createElementAsLastChild(MbElement.TYPE_NAME, "Parts", null);
   MbElement part, data, blob;
   String text;

   // First part:
   //   Create the body of the email.
   //   The body of the email has the text 'This is the main body of the email.'.
   part = parts.createElementAsLastChild(MbElement.TYPE_NAME, "Part", null);
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Type", "text/plain; charset=us-
ascii");
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Transfer-Encoding", "8bit");
   data = part.createElementAsLastChild(MbElement.TYPE_NAME, "Data", null);
   blob = data.createElementAsLastChild("BLOB");
   text = "This is the main body of the email.";
   try {
  blob.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB", text.getBytes("UTF8"));
   } catch (UnsupportedEncodingException e) {
  fail.propagate(outAssembly);
   }

   // Second part:
   //   Create the attachment of an email.
   //   The attachment is called 'attachment.txt' and contains the text 'This is an attachment.'.
   part = parts.createElementAsLastChild(MbElement.TYPE_NAME, "Part", null);
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Type", "text/plain; charset=us-
ascii;
name=attachment.txt");
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Transfer-Encoding", "8bit");
   data = part.createElementAsLastChild(MbElement.TYPE_NAME, "Data", null);
   blob = data.createElementAsLastChild("BLOB");
   text = "This is an attachment.";
   try {
  blob.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB", text.getBytes("UTF8"));
   } catch (UnsupportedEncodingException e) {
  fail.propagate(outAssembly);
   }

   outMessage.finalizeMessage(MbMessage.FINALIZE_VALIDATE);
   out.propagate(outAssembly);
}
```

Changing connection information for the EmailOutput node

You can configure the SMTP server, port number, and security identity for the EmailOutput node as an integration node external resource.

About this task

Use an alias that is specified in the SMTP `Server and Port` property on the EmailOutput node. The security identity refers to a user ID and password pair that is defined on the integration server by using the **mqsisetdbparms** command. As documented for the **mqsisetdbparms** command, you must stop and start each integration server that uses a particular DSN, before the information that was modified by the **mqsisetdbparms** command is read and used by that integration server.

Procedure

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create an SMTP policy for the alias that is specified on the node (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. Set the SMTP `server name` property to an appropriate value in the form *server:port*.

   The port value is optional; if you do not specify it, the default value is 25. You can also use the SMTP policy to specify a security identity that can be resolved at run time to a user ID and password for authentication with the SMTP server. If you specify a policy name, use the format *{policyProjectName}:policyName*. You can use the **mqsisetdbparms** command to define the security identity at run time.

Receiving emails

You can configure the EmailInput node to receive an email, with or without an attachment, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

About this task

You can use the `Email server` property on the EmailInput node to specify the protocol, host name, and port of the email server that the integration server uses to receive emails. Alternatively, you can specify a policy name that refers to an Email Server policy that is defined on the integration server. If the value of the `Email server` EmailInput node property is set to the defined policy name, any values set by the administrator on the command line are used in preference to any statically defined value.

The following list details the order of preference for value selection:

1. The email server URL value that is specified in the Email Server policy `Email server name` property, if a policy exists that matches the name that is supplied in the `Email server` EmailInput node property.
2. The email server URL value of the `Email server` property that is specified directly on the EmailInput node.

While most policy properties are set by using the Policy editor, security identity support, such as an email server user ID and password pair, is typically set by using the **mqsisetdbparms** command. Security identity support can be configured by setting the `Security identity` EmailInput node property or Email Server policy `Security identity` property to reference a security identity object. However, the security identity object must first be created by using the **mqsisetdbparms** command, for example:

```
mqsisetdbparms INODE -n email::mySecurityIdentity -u myUserID -p myPassword
mqsichangeproperties INODE -c EmailServer -o myEmailConfigurableServiceName -n
securityIdentity -v mySecurityIdentity
```

For more information about email server security identity support, see command.

The topics in this section describe the different ways in which you can use the EmailInput node to receive email messages.

Procedure

- To receive an email, see "Receiving an email" on page 948.
- To configure the email server URL and security identity for the EmailInput node as an integration node external resource, see "Changing connection information for the EmailInput node" on page 951.

Receiving an email
You can receive an email, with or without attachments, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

Before you begin

This topic assumes that you have already created a message flow. For more information, see "Creating a message flow" on page 574.

About this task

Use the IBM App Connect Enterprise Toolkit to configure the properties on the EmailInput node so that you can receive an email, with or without attachments.

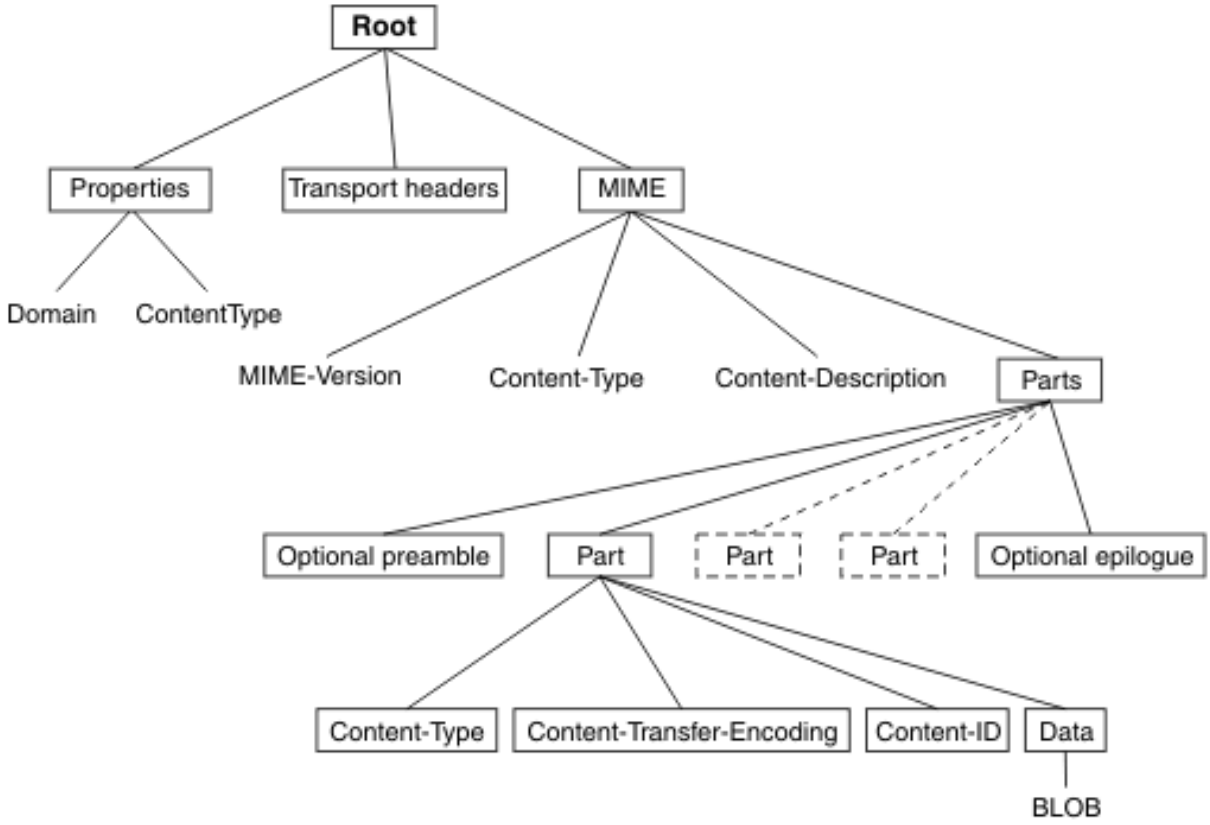
Procedure

1. Add an EmailInput node to your message flow.
2. Edit the following EmailInput node properties:
   a) On the **Basic** tab, add the email server URL, or the Email Server policy name as the `Email server` property value, as described in node. For example, `pop3://myemailserver.com:12345` or `imap://myemailserver.com:56789`.
   b) On the **Security** tab, add the security identity object name of the email server user ID and password pair as the `Security identity` property value. For more information about email server security identity support, see command.
   c) Configure the following properties on the **Retry** tab:
      - `Retry mechanism`: The Retry mechanism property defines how the EmailInput node handles a message flow failure. Valid values are `Failure`, `Short Retry`, or `Short and Long Retry`. The default value for this property is `Short and long retry`, which indicates that the email is retried until the short retry threshold is met, then long retry takes place, meaning that the email is never deleted from the email server, but also that the email is infinitely retried. Emails are deleted from the email server if the email message fails and this property value is not set to `Short and Long Retry`.
      - `Retry threshold`: The Retry threshold property is the number of times to try the message flow transaction again when the `Retry mechanism` property value is set to `Short Retry`. The default value for this property is `0`.
      - `Short retry interval (in seconds)`: The Short retry interval is the interval, in seconds, between each retry if the `Retry threshold` property value is not set to zero. The default value for this property is `0`. If the email is retried until the short retry threshold is met and the email fails, the email is routed to the failure terminal, and the email is deleted from the email server.
      - `Long retry interval (in seconds)`: The Long retry interval is the interval, in seconds, between each retry, if the `Retry mechanism` property value is `Short and Long Retry`, and the short retry threshold has been exhausted. The default value for this property is `300` seconds.
      - `Action on failing email`: The Action on failing email property determines the action that the EmailInput node takes with the input data source after all attempts to process the email contents fail. The Action on failing email property is a read only property that is set to a default value of `Delete Email`, which is used with the Retry mechanism property. If the Retry mechanism property is set to `Short and Long Retry`, the message flow continues to try to retrieve the email from the email server, meaning that the email is never deleted. If the Retry mechanism property is not set to `Short and Long Retry`, the Action on failing email property value `Delete Email` is used, and the email is deleted from the email server.
3. Save the changes.
4. Add the message flow to the BAR file and deploy.

   When a message is passed into the deployed EmailInput node, an email is received from the email server and the body of the email message, and any attachments, are propagated in the Multipurpose

Internet Mail Extensions (MIME) domain. All other information relating to the email is stored in the `Root.EmailInputHeader` MIME logical tree. For a complete list of the email elements that are propagated in the MIME logical tree when you use an EmailInput node, see node.

When an email containing an attachment is received, the EmailInput node places different parts of the email body in the MIME domain, so that they are associated with the MIME parser. The MIME tree location that the EmailInput node builds to house the information is the same location that the EmailOutput node expects email data to be in when sending an email. The attachment is stored in the MIME logical tree in directory `Root.MIME.Parts.Part.Data`. Where Content-Type describes the type of data that is in the attachment.



Viewing the `Root.Properties.ContentType` value in the MIME domain allows you to write logic to parse the attachment. For more information about the MIME logical tree, see "MIME parser and domain" on page 547.

Results

Received emails are deleted from an email server that supports POP3 or IMAP only when the emails have been successfully propagated after being processed by the EmailInput node Failure, Out, or Catch terminals, and the message flow has successfully executed. This does not form part of a globally coordinated transaction.

Emails are deleted from the email server under the following circumstances:

- The Failure terminal is not connected.
- An exception occurs in the Failure terminal.
- The email message fails and the `Retry mechanism` property value is not set to `Short and Long Retry`.
- The `Retry threshold` is not set to `0` and the `Short retry interval` property value has been exhausted.

For more information about processing responses from an EmailInput node, and for information about rollback handling, see "Processing responses from an EmailInput node" on page 950.

Processing responses from an EmailInput node
The EmailInput node can return different response messages that indicate the success or failure of receiving an email, with or without attachments, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

Before you begin

Ensure that you have developed a message flow with an EmailInput node, as described in "Receiving an email" on page 948.

About this task

The EmailInput node has three output terminals:

- Failure: The output terminal to which the message is routed if an EmailInput node failure is detected when a message is propagated, or an EmailInput node fails to access the email server. Connect the Failure terminal of this node to another node in the message flow to process errors.
- Out: The output terminal to which the message is routed if it has been propagated successfully. Connect the Out terminal of this node to another node in the message flow to process the message further, or send the message to an additional destination.
- Catch: The output terminal to which a message is routed if an exception is thrown downstream and caught by this node. Exceptions are caught only if this terminal is attached.

Procedure

- **Processing successful returns**

  When an EmailInput node successfully receives an email, the resulting message is propagated to the Out terminal.

- **Processing downstream message flow exceptions**

  If a message flow exception occurs downstream of the Failure terminal in the message flow, a message is routed to the Catch terminal. If you do not have the `Retry mechanism` property value set to `Short and Long Retry` on the EmailInput node Retry tab, the current transaction is rolled back.

- **Handling failures in the node**

  Any other failures are propagated to the Failure terminal. Possible failures include:

  – A problem retrieving an email message. For example, an inability to communicate with the target email server because of a connection or authentication error. If this occurs, the connection is re attempted when the polling interval expires. Each connection failure occurrence causes an appropriate message in user trace.
  – A problem parsing an email.
  – An internal EmailInput node exception or error is detected before the message is propagated to the Out terminal. For example, a malformed email is received, causing the EmailInput to propagate the message and an exception list to the Failure terminal.
  – The `Retry mechanism` property value is set to `Failure`, causing an immediate message to be sent to the Failure terminal.
  – The `Retry threshold` is not set to `0` and the `Short retry interval` property value has been exhausted, causing a message to be routed to the failure terminal, and the email being deleted from the email server.

  If the failure terminal is not connected, or an exception occurs down the Failure terminal, or the email message fails and you have not set the `Retry mechanism` property value to `Short and Long Retry`, the email is deleted from the email server.

Results

You can use the Email Server policy to change connection details for the EmailInput node (see "Changing connection information for the EmailInput node" on page 951).

Changing connection information for the EmailInput node

You can create a policy that the EmailInput node or message flow refers to at run time for email server connection information, instead of defining the connection properties on the node or the message flow. The advantage being that you can change the host name and security identity values without needing to redeploy your message flow.

Before you begin

- Read "Receiving emails" on page 947 for background information.

About this task

Use the Email Server policy to change the email server connection information for the EmailInput node.

Procedure

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create a policy and select **Email Server** as the policy type (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. Ensure that the name of the policy is the same as the name that is specified by the `Email server` property on the EmailInput node.
3. Set the `Email server name` property in the policy to the URL of the email server that contains incoming email messages.

   The URL must be in the format `protocol://hostname:port`, where:

   - `protocol` can be `pop3`, `pop3s`, `imap`, or `imops`.
   - `hostname` is the Internet Protocol version 4 (IPv4) TCP/IP address or DNS-resolvable host name of the email host.
   - `port` is the port number that the email server is listening on for connections over Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP). You can enter an integer in the range `1 - 65535`.

   For example:

   ```
   pop3://myemailserver.com:12345
   imap://myemailserver.com:56789
   ```

   For more information, see Email Server policy (EmailServer).
4. Set the `Security identity (DSN)` property in the policy to the name of the security identity object that contains the user ID and password that is used to authenticate the connection to the email server.
5. Set the timeout properties in the policy file to avoid hangs due to socket wait calls. For example:

   - Set **`Connection timeout (seconds)`** to 5.
   - Set **`Read timeout (seconds)`** to 5.
   - Set **`Connection idle timeout (seconds)`** to 300.
6. Deploy this policy before you start the associated message flow.

Working with files

You can use the FileInput, FileRead, CDInput, and FTEInput nodes in your message flows to process data from files. You can use the FileOutput node, CDOutput, and FTEOutput node to send data from a message flow into a file.

About this task

Using files is one of the most common methods of storing data. You can create message flows to process data in files, accepting data in files as input message data, and producing output message data for file-based destinations. The following file nodes are provided:

- FileInput node. Use this node to receive messages from files in the file system of the integration node or, by using FTP or SFTP, in a remote file system. The node generates output message data that any of the output nodes can use, which means that messages can be generated for clients using any of the supported transport protocols to connect to the integration node. For more information, see "Using a local file as input for your message flow" on page 975.
- FTEInput node. Use this node to start a message flow when files are received over a IBM MQ File Transfer Edition network. For more information, see "Receiving a file by IBM MQ File Transfer Edition" on page 983.
- CDInput node. Use this node to start a message flow when files are received over a IBM Sterling Connect:Direct network. For more information, see "Receiving a file using IBM Sterling Connect:Direct" on page 984.
- FileRead node. Use this node to read data from a file in the middle of a message flow. For more information, see "Routing or enriching a message based on the contents of a file" on page 976.
- FileOutput node. Use this node to write messages to a file in the file system of the integration node or, by using FTP or SFTP, in a remote file system. The node can create new files, replace existing files and append data to the end of an existing file. For more information, see "Writing a file to your local file system" on page 989 and "Writing a file to a remote FTP or SFTP server" on page 991.
- FTEOutput node. Use this node to send a file to a remote destination by using a IBM MQ File Transfer Edition network. For more information, see "Sending a file by IBM MQ File Transfer Edition" on page 994.
- CDOutput node. Use this node to send a file to a remote destination by using an IBM Sterling Connect:Direct network. For more information, see "Initiating a managed file transfer using IBM Sterling Connect:Direct" on page 1003.

The FileInput and FTEInput nodes start the message flow when a new file arrives, whereas the FileRead node must be connected to another node to start the message flow transaction. The FileRead node also provides keyed access to identify a record, unlike the FileInput node, which processes all records in order.

By using these five nodes, you can also process large files without the complete message being held in memory, and you can simplify the processing of files that have large numbers of repeating entries.

If you are accessing files on an NFS share, ensure that you are using NFS version 4. The server must support file locking.

If you want to work with files, read these topics:

IBM Sterling Connect:Direct overview and concepts

An overview of IBM Sterling Connect:Direct and its terminology when used with IBM App Connect Enterprise.

IBM Sterling Connect:Direct is a managed file transfer product that transfers files between, and within, enterprises.

IBM Sterling Connect:Direct, in conjunction with IBM App Connect Enterprise uses the following terminology:

Connect:Direct server

An application that runs on a machine requiring IBM Sterling Connect:Direct functionality. Files are transferred between two Connect:Direct servers.

- The primary Connect:Direct server, also referred to as the PNODE.
- The secondary Connect:Direct server, also referred to as the SNODE, that receives the transferred file and places the file on the local file system.

Connect:Direct-S

Connect:Direct server which transfers files to other Connect:Direct servers.

Connect:Direct-R

Connect:Direct application that connects to a Connect:Direct server and requests that server does some form of processing. IBM App Connect Enterprise acts as a Connect:Direct-R to request transfers or receive information about transfers.

IBM App Connect Enterprise CDInput node

Use the IBM App Connect Enterprise CDInput node to receive messages that have been transferred to a given Connect:Direct server.

If two or more input nodes are deployed to listen on the same Connect:Direct server, only one receives the file and which one that is cannot be determined. There is some distribution between the nodes, and this is equivalent to having two or more MQInput nodes listening on the same queue.

CDInput nodes can be used in different flows, and in different integration servers, against the same Connect:Direct server.

You can configure the CDInput node to process only a subset of files transferred to the server, based on the directory name and the file name. This allows for multiple CDInput nodes within the same integration server to receive specific files, depending on the filters used.

See “IBM Sterling Connect:Direct concepts” on page 954 for further information on the CDInput node, CDOutput node, and Connect:Direct server.

IBM App Connect Enterprise CDOutput node

Use the IBM App Connect Enterprise CDOutput node to serialize the message tree to a file and then transfer it to a secondary Connect:Direct server using a primary Connect:Direct server. A directory under the work path within the integration server is used as the staging area, until the file is ready to be transferred. Once the file is transferred, it is deleted from the staging area.

Initparm

The definition of the startup parameters for the primary Connect:Direct server (PNODE) and secondary Connect:Direct server (SNODE).

Netmap

The definition of a connection between the primary and secondary Connect:Direct servers.

Processname

The name given to a process that is run in IBM Sterling Connect:Direct. More than one process can be given the same name, and each process is identified uniquely using the process number.

Note that IBM App Connect Enterprise nodes work purely as clients connecting to the external Connect:Direct server, using the IBM Sterling Connect:Direct Java Application Interface.

By default, IBM App Connect Enterprise attempts to connect to a local Connect:Direct server, on the default port:

- When sending a file using CDOutput nodes, or
- To be notified of files to process using CDInput nodes.

To enable the CDOutput and CDInput nodes to connect to the local Connect:Direct server, you must set up a username and password using the command.

IBM Sterling Connect:Direct concepts

The CDInput node receives messages that have been transferred to a given Connect:Direct server.

The node receives both the contents of the file and meta data provided by IBM Sterling Connect:Direct on the transfer. One or more CDInput nodes can be used to receive transfers, either in the same flow, different flows, or different integration servers; for any given transfer only one CDInput node receives a message.

You can also specify which transfer a CDInput node can receive, using filters based on directory and file name of the transfer. Once the transfer has been processed there are a set of options of what to do with the transferred file; for further details see node.

A simple flow that takes all transferred files from a Connect:Direct server and writes them to an IBM MQ queue could contain a CDInput node and an MQOutput node.

Once the CDInput node has been notified of a file to be processed, it processes the file in the same way that a normal FileInput node does. The CDInput node is notified by the Connect:Direct server manager when a transfer occurs. The notification message is persistently stored on IBM MQ and survives queue manager restarts.

The Connect:Direct server manager is defined and runs using a Connect:Direct Server policy. This policy is used for administering the access, and processing files using IBM Sterling Connect:Direct (see Connect:Direct Server policy (CDServer)).

Information about file transfers is held on storage queues that are controlled by IBM MQ, so you must install IBM MQ on the same computer as IBM App Connect Enterprise if you want to use the capabilities that are provided by the CDInput and CDOutput nodes.

You must also create the system queues that are required by the CDInput and CDOutput nodes, including the two queues that are used to store transfer details from the Connect:Direct server:

- SYSTEM.BROKER.CD.STATS
- SYSTEM.BROKER.CD.TRANSFERS

For information about creating the system queues, see “Creating the default system queues on an IBM MQ queue manager” on page 99.

For each successful transfer to the Connect:Direct server, a message is placed on the TRANSFERS queue, which is used to trigger the CDInput node to process the file. The STATS queue contains internal data used by IBM App Connect Enterprise to record which transfers have been processed by IBM App Connect Enterprise. Clearing both sets of these queues causes all transfers that have occurred up to the current time to be ignored; there is no need, for example, for a restart.

The input node does not poll for transfers, but is triggered instead when they arrive. However, the Connect:Direct server manager does need to poll for events to notify the CDInput node about a transfer. The Connect:Direct server manager has a polling interval of one second.

The CDInput and CDOutput nodes go through the Connect:Direct server manager to both send and receive transfers from a given server, the name of which is set on the node. The Connect:Direct server manager properties are defined by using a Connect:Direct Server policy.

The Connect:Direct server manager organizes:

- Monitoring the Connect:Direct server for transfers which need to be processed by the CDInput nodes.
- Sending commands created by the CDOutput node to the Connect:Direct server to perform transfers.

In both cases, the Connect:Direct server manager can be used to configure the directory structure to a shared file system, used to both send and receive files from the Connect:Direct server.

The high-level structure of the directory might be different on the two different machines and you can define properties on the Connect:Direct server manager to give the correct mapping.

The *Default* policy connects to the Connect:Direct server on the local host by using the default port. You can modify the default policy to a more complex configuration with the CD server on different ports, or a different machine, or change the node to use a completely different policy that is set up to use a different port and host name.

As well as defining connections details, you can also configure other key properties, such as the location of staging directories and mapping between directories on different machines.

The Connect:Direct server manager is started and stopped by the CDInput and CDOutput nodes as required and is not an artifact that is deployed or seen in the deployment view; all of its function is defined by the properties in the policy. If transfers happen while IBM App Connect Enterprise is stopped (or IBM Sterling Connect:Direct flows are stopped) they are not missed and are processed as soon as the flows restart. All transfers are persistent and survive queue manager restarts.

The policy security identity must have adequate permission for the Connect:Direct server manager within the integration server to detect all transfers that are sent to the Connect:Direct server. For example: On UNIX systems, the user's stanza within the `userfile.cfg` in Connect:Direct must have `:cmd.selstats=A:\`. This property can either be set explicitly, or inherited from the higher level property `:admin.auth=y:\`. If this permission is not present, then the CDInput nodes do not detect or process files that were transferred by other users. For more information about the security identifier, see the `Security identity` property in Connect:Direct Server policy (CDServer).

IBM App Connect Enterprise makes a number of API connections to the local Connect:Direct server to process inbound transfers, and to request outbound transfers.

IBM App Connect Enterprise creates one API connection per policy per integration server. This connection enables CDInput nodes to process files sent to the local Connect:Direct server. If there are multiple policies that relate to the same Connect:Direct server, then multiple API connections are established.

In addition to these connections, each message flow instance that uses a CDOutput node also creates an API connection to submit transfer requests to the Connect:Direct server. Where there are multiple flows that contain CDOutput nodes, or where these flows have extra defined instances, IBM App Connect Enterprise creates multiple API connections. If the number of API connections that are required exceeds the maximum that is configured in the Connect:Direct server, then the connection fails causing a BIP7951E exception, containing the following information: "`Error: Logon failed! Attempted to exceed maximum API connections`". Avoid this error by increasing the maximum client connections for the Connect:Direct server. The maximum number of connections that are accepted by a Connect:Direct server on UNIX is controlled by the **`api.max.connects`** parameter. For more information about this parameter, and the equivalent settings on other operating systems, see the IBM Sterling Connect:Direct product documentation: http://www.ibm.com/support/knowledgecenter/SS4PJT_5.2.0/cd_52_welcome.html.

How the integration node processes files

The integration node reads files with the FileInput, FTEInput, CDInput, and FileRead nodes, and writes files with the FileOutput, CDOutput, and FTEOutput nodes.

IBM App Connect Enterprise can read messages from files and write messages to files in the local file system, or on a network file system that is local to the integration node. The following message flow

nodes provide this capability. Also described are the required access permissions for the directories and files they operate on:

- FileInput node: read and write permissions on the input directory and input files.
- FileOutput node: read and write permissions on the output directory.
- FileRead node: read permissions on the input directory and input files. Note: if a Finish File action is used (to move, rename or delete the file), write permissions on the input directory and input files is also required.

The FileInput, FileOutput, and FileRead nodes inherit the permissions assigned to the integration node's user ID and group. See your operating system documentation for details on how to set permissions and the impact on file access.

You can use the FTEInput and FTEOutput nodes to receive or send files to a destination on a IBM MQ File Transfer Edition network.

You can use the CDInput and CDOutput nodes to receive or send files to a destination on an IBM Sterling Connect:Direct network.

A file, or a record within a file, is analogous to a message in a queue. The directory that contains the file is analogous to a message queue.

How the integration node reads a file at the start of a flow

The FileInput node processes messages that are read from files. The FileInput node searches a specified input directory (in the file system attached to the integration node) for files that match specified criteria. The node can also recursively search the input directory's subdirectories. Files that meet the criteria are processed in age order, that is the oldest files are processed first regardless of where they appear in the directory structure. Optionally, files from a remote FTP or SFTP server can be moved to the local directory whenever the directory is to be scanned. You can find the file that you require by specifying an explicit file name or a file name pattern that includes wildcard characters. If the file is locked, it is ignored during the directory scan. You can also exclude files from being read by specifying a file exclusion pattern. Whether files are either processed or ignored is determined first according to the file name or pattern and second according to the file exclusion pattern.

The FileInput node creates an `mqsitransitin` subdirectory in the input directory. The `mqsitransitin` subdirectory holds and locks the input files while they are being processed. The integration node reads the file and propagates a message, or messages, by using the contents of the file.

If an integration server that processes files in this input directory is removed, check the `mqsitransitin` subdirectory for partially processed or unprocessed files. Move any such files back into the input directory and remove the integration server UUID prefix from the file names, so that they can be processed by a different integration server. For more information about the `mqsitransitin` subdirectory, see “How multiple file nodes share access to files in the same directory” on page 960.

In the FileInput node, you can specify how the records are derived from the file. The contents of a file can be interpreted as:

- A single record (whole file)
- Separate records, each of a fixed length (fixed-length records)
- Separate records each delimited by a specified delimiter (delimited records)
- Separate records that are recognized by a parser that you specify (parser record sequence)

After the file has been successfully processed, it is either deleted from the file system or moved to an archive subdirectory of the specified (local) directory.

When the last record of the file has been processed successfully, if the End of Data terminal of the FileInput node is connected in the message flow, an End of Data message is propagated to the End of Data terminal. The End of Data message consists of an empty BLOB message and a `LocalEnvironment.File` structure, and it allows explicit end-of-flow processing to be performed in another part of the message flow.

The message (or messages) propagated from the file can be used as input to any message flow and output node. You can create a message flow that receives messages from files and generates messages for clients that use any of the supported transports to connect to the integration node.

Whenever a message is propagated from a file, the FileInput node stores information about the file in the LocalEnvironment.File message tree. This information includes the offset of the record of the message in the file that is being processed, and the record number in that file. In addition, when a wildcard is used in a file name pattern, the characters matched in the file name are placed in the WildcardMatch element of the local environment tree.

If a file is backed out, or a file is left in the `mqsitransitin` subdirectory because processing failed, remove the integration server UUID prefix from the file name and move it back into the input directory. Processing is automatically retried, beginning at the first record in the file.

The FTEInput node receives files from the IBM MQ File Transfer Edition network. The integration node reads the file and propagates a message, or messages, by using the contents of the file. After an FTEInput node has processed a file, the file is deleted. For details of information that the FTEInput node provides in the local environment, see “Using local environment variables with file nodes” on page 962.

The CDInput node receives files from the IBM Sterling Connect:Direct network. The integration node reads the file and propagates a message, or messages, by using the contents of the file. After a CDInput node has processed a file, the file is deleted. For details of information that the CDInput node provides in the local environment, see “Using local environment variables with file nodes” on page 962.

The FileRead node can read a whole file, or a single, nominated record. A common use of the FileRead node is to route or enrich messages based on the contents of the file. When developing the message flow you can specify the name and location of the file to be read. You can override these values at run time based on the contents of a message. TheFileRead node reads a file in the middle of a message flow.

The FileRead node complements the existing FileInput and FileOutput nodes.

How the integration node reads a file from the middle of a flow

The FileRead node locks files when they are being read and does not move files to a subdirectory to read them. Files can be read completely or separated into records, in the same way as the FileInput node. After the file is processed by the FileRead node, it can be deleted, archived, or left unchanged.

When a FileRead Node has the `Remote Transfer` option selected, and a local file is not available, one is transferred from a remote server. Only one thread on a single integration server is permitted to transfer a particular file at any time. Any message flow invocations that require access to this same file wait until an in-flight transfer is completed and then use the local copy of the file. The FileRead node creates a lock in the `locks` subdirectory of the local input directory to prevent multiple integration servers from transferring the same file at the same time. This locking only functions correctly if the file system correctly implements Posix locking semantics, in particular NFS file systems must be at least NFS v4.

If the `Delete remote file after successful transfer` property is selected, then after successfully transferring a file it is deleted from the remote server, otherwise it is left in place.

If the FileRead Node has the **`Finish File Action`** property set to `No Action`, then it ensures that the input file referenced by the File Name pattern is unique in the input directory. This behavior means that if more than one file matches in the local directory due to a wildcard match, then an exception is thrown. This behavior is preserved for remote files, so if the **`Finish File Action`** is set to `No Action` and multiple files match the file pattern on the remote server, an exception is thrown. Under these conditions, the broker is unable to determine which of the multiple files present should be processed.

How the integration node writes a file

The FileOutput, CDOutput, and FTEOutput nodes write messages to files in the file system of the integration node. When a message is received on the In terminal of the node, it creates and writes a file as a series of one or more records. One record is written to a file for every message received. The name of the file is specified either by a file name pattern in the node or an explicit file name that is either specified in the node or derived from the message.

You can specify how the records are accumulated in files:

- A single record (whole file). The file that is created consists of one record.
- Concatenated records (unmodified records). The records are not padded to any required length, and they are not separated by a delimiter.
- Uniform length records (fixed-length records). Records that are shorter than the specified length are padded to the required length.
- Separate records (delimited records). Records are either terminated or separated by a specified delimiter.

The message flow informs the output node that there are no more records to write by sending a message to its Finish File terminal. The file is then delivered to the appropriate destination:

- FileOutput node: The file is then moved to the specified output directory. If this transfer fails, you can specify if the file is deleted, moved to the failure directory (`mqsifailure`), renamed before being moved to the failure directory, or no action is taken on the file.

  Optionally, the file can be moved to a directory on a remote FTP or SFTP server. The server is identified by the `Remote server and port` property on the node. Alternatively, you can override the node property by setting a value in the local environment (see Local environment overrides for the remote server on the node).
- FTEOutput node: The file is sent to the destination agent on the IBM MQ File Transfer Edition network.
- CDOutput node: The file is sent to the IBM Sterling Connect:Direct network.

If the output node produces a single record from the file (whole file), the file is moved immediately to the output directory without requiring a message to be propagated to the Finish File terminal. In this case, any message sent to the Finish File terminal of the node has no effect on any file, but the message is still propagated to a message flow attached to the End of Data terminal.

How data is appended to the end of a local file

There are two methods of appending to a local file by using the FileOutput node:

- The first method is to write directly to the output directory. Each record that is written is appended immediately to the specified file. The contents of the file can be read while data is being written to the file. The Finish File action, and subsequently the Action on Finial File failure, are not effective unless FTP options are used. If FTP options are used, the Finish File action transfers the file to the remote machine.
- The second method is to stage the file in the `mqsitransit` directory. The records are collected in the file. If a file exists in the output directory when the Finish File action occurs, the file is moved into the transit directory and the data is appended to the end of this file. The file is then moved back to the output directory and the new data is now visible to an application.

On the FTP tab if `Retain local file` and `Stage in the transit directory` are both selected then `Action if file exists` occurs on the Finish File action.

How the FileOutput node deals with failures

You can define the action that the node takes with the output file if the final processing of a file fails. The following table describes the outcome for each action taken by the node on final file processing failure given the write mode and the type of transfer:

Action on final file processing failure	Write Mode	Remote Transfer	Outcome
No Action	Stage in `mqsitransit` directory	Either	File is left in `mqsitransit` subdirectory unless **`Record Definition`** is `Whole File` then File is not written to output directory
No Action	Write directly to the output file	No	File is not written to output directory
No Action	Write directly to the output file	Yes	File is left in output directory unless there is a failure writing to the local output directory
Delete	Stage in `mqsitransit` directory	Either	File is deleted from `mqsitransit` subdirectory
Delete	Write directly to the output file	No	File is not written to output directory
Delete	Write directly to the output file	Yes	File is deleted from the local output directory
Move To `mqsifailure`, or move to `mqsifailure` and add timestampStage in `mqsitransit` directory	Stage in `mqsitransit` directory	Either	File is moved from `mqsitransit` subdirectory to `mqsifailure` subdirectory
Move To `mqsifailure`, or move to `mqsifailure` and add timestampStage in `mqsitransit` directory	Write directly to the output file	No	File is not written to output directory, and `mqsifailure` subdirectory is not created
Move To `mqsifailure`, or move to `mqsifailure` and add timestampStage in `mqsitransit` directory	Write directly to the output file	Yes	File is moved from the local output directory to `mqsifailure` subdirectory unless there is a failure that prevents the file being written to the local output directory. In this case, the file can not be moved to `mqsifailure` as it did not exist in the local output directory.

How data is appended to the end of a remote file

The FileOutput node builds a file either in the output directory or in the `mqsitransit` directory. On the FTP tab, if `Action if remote file exists` is set to Append, when the Finish File action occurs the file is transferred to the remote machine by using the FTP Append verb. The data is appended to the end of the remote file or, if the file does not exist, the file is created.

Recognizing file records as messages to be parsed
Use the FileInput, FTEInput and FileRead nodes to segment your input file into messages that are to be parsed.

The node segments your input file into messages that are to be parsed by one of the following parsers:

- XMLNSC
- MRM Custom Wire Format (CWF)
- MRM Tagged Delimited String Format (TDS)

The `Message domain` property of the node specifies the parser to use; XMLNSC or MRM. Specify `Parsed Record Sequence` for the `Record detection` property so that the node splits the file into messages to be parsed by either the XMLNSC parser or MRM parser.

The XMLNSC parser

If you select the XMLNSC parser, the end of the root tag marks the end of the message. XML comments, XML processing instructions, and white space that appear after the end of the XML message are discarded. The start of the next XML message is marked either by the next XML root tag or the next XML prolog.

The MRM parser

If you select an MRM parser, ensure that the message model has a defined message boundary and does not rely on the parse being stopped when it reaches the end of the bit stream. If the final element has a *maxOccurs* value of -1, the parser continues to read bytes until the end of the bit stream or until it encounters bytes that cause a parsing exception. In either case, the parser is unable to identify the end of one message and the start of the next. If you use *Data Element Separation* = `Use Data Pattern`, ensure that the pattern recognizes a specified number of bytes. Be aware, therefore, that a pattern of `*` identifies all available characters and so would read an entire input file.

If you use delimited separations with message group indicators and terminators, ensure that the combination of group indicator and terminator does not match a record delimiter. For example, a message might start with a left brace ({) and end with a right brace (}). If there is a delimiter of `}{` within the message, the delimiter matches the boundary between multiple messages; as a result, a delimiter within the current message might be identified as a message boundary. This might cause bytes in a subsequent message to be included in the current message causing parser exceptions or unexpected content in the parse tree.

How multiple file nodes share access to files in the same directory

IBM App Connect Enterprise controls access to files so that only one file node at a time can read or write to a file.

When a message flow uses the FileInput or FileOutput node, additional instances (threads) might be associated with the message flow, or file nodes in other message flows in the same or different integration servers might refer to files in the same directory. IBM App Connect Enterprise controls the way in which multiple processes read from and write to files by moving the files to the `mqsitransitin` directory during processing, and locking them while they are being processed. The `mqsitransitin` directory is a subdirectory of the input directory specified in the FileInput node.

If you are using the FileInput node and choose to include subdirectories, an `mqsitransitin` directory is created as needed in all places where there is a file to be processed.

The integration node locks the files that are being read by the FileInput node or written by the FileOutput node, to prevent other integration servers from reading or changing the files while they are being processed. The integration node unlocks the file:

- When a FileInput node finishes processing the input file.
- When a FileOutput node finishes writing the file and moves it from the transit directory to the output directory.

Note: The FTEInput node does not use a transit directory. Each integration server has its own IBM MQ File Transfer Edition agent, and a node processes only files sent to the agent for which the node is deployed. The integration server ensures that only one node in the integration server processes each file.

Reading a file

When the FileInput node reads a file, it first moves the file into the `mqsitransitin` directory, where it is held during processing. A prefix (containing the integration node name and integration server name) is added to the file name to indicate which integration server is processing the file. While the file is in this directory, no other integration servers can access the file. The integration node maintains a `lock` subdirectory in the `mqsitransitin` directory, to ensure that files in the input directory are accessed by only one integration server at a time.

If multiple message flows or instances within an integration server are reading from the same input directory, only one instance of one message flow is allocated to reading it. Each record in the file is serially processed by this instance. Other instances of the message flow, or other message flows, can simultaneously process other files, the names of which match the pattern specified in the `File name or pattern` property of the node.

While a file is being processed, the file system is used to lock the file. As a result, other programs (including other integration servers) are prevented from reading, writing, or deleting the file while it is being processed by the file nodes.

While a FileInput node is reading a file, the file remains in the `mqsitransitin` directory until it has been fully processed (or until an unrecoverable error occurs). If the file is to be retained, it is held in a subdirectory of the `mqsitransitin` directory.

When the file has been processed, it is moved from the `mqsitransitin` directory back to the input directory. However, if the integration server stops unexpectedly while the file is in the `mqsitransitin` directory, you can manually restore the input file to the input directory by removing the prefix (containing the integration node name and integration server name) from the file name, and then moving it to the input directory. The input file is then processed by the next FileInput node that scans the directory.

If you use an NFS server, and have File nodes in different integration servers that access the same directory on the NFS server, ensure that you are using NFS version 4 to correctly support file locking.

Writing a file

Files that are created and written by a FileOutput node are put in the output directory when they are finished. While records are being added to a file, it is kept in the `mqsitransit` subdirectory.

Each record is written by a single message flow instance. All message flow instances that are configured to write records to a specific file can append records to that file. Because instances can run in any order, records that they write might be interleaved, which means that the sequence of records might be altered. If you require the sequence of records in the output file to be maintained, ensure that only one FileOutput node instance uses the file. To ensure that only one FileOutput node instance uses the file, configure the message flow that contains the node to use the additional instances pool with zero instances, and ensure that other message flows do not write to the same file.

While a file is being processed, the file system is used to lock the file. As a result, other programs (including other integration servers) are prevented from reading, writing, or deleting the file while it is being processed by the file nodes. This lock is retained for a short period after a FileOutput node writes to the file without finishing it, leaving it in the transit directory. If message flows that are in the same integration server use the same output file and run sufficiently quickly, the integration node does not relinquish the lock before the file is finished. However, if the message flows have longer intervals between them, the integration node relinquishes the lock and another process or integration server can acquire a lock on the file. To prevent this situation, ensure that output directories are not shared between integration servers.

Using local environment variables with file nodes

You can use fields in the local environment to dynamically alter the behavior of the FileInput, FileOutput, FTEInput, and FTEOutput nodes. You can also find what values the output nodes used to process the file.

These fields are available in the following message tree structures:

- LocalEnvironment.File
- LocalEnvironment.File.Read
- LocalEnvironment.WrittenDestination.File
- LocalEnvironment.Destination.File
- LocalEnvironment.Destination.File.Remote
- LocalEnvironment.Wildcard.WildcardMatch
- LocalEnvironment.FTE
- LocalEnvironment.WrittenDestination.FTE
- LocalEnvironment.Destination.FTE
- LocalEnvironment.CD
- LocalEnvironment.CD.Transfer
- LocalEnvironment.Destination.CD
- LocalEnvironment.WrittenDestination.CD

LocalEnvironment.File fields

When you use the FileInput node, it stores information that you can access in the LocalEnvironment.File message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the input directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name and extension.
LastModified	TIMESTAMP	Date and time the file was last modified.
TimeStamp	CHARACTER	Date and time the input node started processing the file in the Coordinated Universal Time (UTC) zone, as a character string. This data is the string used to create archive and backout file names if a timestamp is included.
The following elements contain data about the current record:		
Offset	INTEGER	Start of the record within the file. The first record starts at offset 0. If this element is part of the End of Data message tree, this value is the length of the input file.
Record	INTEGER	Number of the record within the file. The first record is record number 1. If this element is part of the End of Data message tree, this value is the number of records.
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. If this element is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.

Element Name	Element Data Type	Description
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. It is set to TRUE if the current record is empty. If this element is part of the End of Data message tree, this value is always set to TRUE.

This structure is propagated with each message written to the Out terminal of the FileInput node and with the empty message written to the End of data terminal.

LocalEnvironment.File.Read fields

When the FileRead node propagates a message, it stores valid information about it in the LocalEnvironment.File.Read message tree. If the input file is empty, an empty message is propagated. The following table lists the LocalEnvironment.File.Read message tree structure.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the input directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`). Alternatively this path relates to the file nodes root directory, which can be overridden with the same environment variable as used for the FileInput and FileOutput nodes.
Name	CHARACTER	File name and extension.
LastModified	TIMESTAMP	Date and time the file was last modified.
TimeStamp	CHARACTER	Date and time the FileRead node started processing the file as a character string, in the Coordinated Universal Time (UTC) zone.
The following elements contain data about the current record:		
Offset	INTEGER	The offset in the file the record starts at. The first byte in the file is offset 0.
NextRecordOffset	INTEGER	The offset in the file that the next record starts at, relative to the start of the file, and is 1 byte after the end of the current record. If the end of the file is reached, then the value is not given in the local environment.
EndOfFile	BOOLEAN	The FileRead node sets this element to TRUE when it has read the last record of the input file. It is therefore always TRUE when the detection property is `Record is Whole File`.
RecordNumber	INTEGER	The number of the record in the file relative to the offset the read node starts reading from. The value is always 1 unless the filter expression is being used, in which case it reflects the number of the record that was selected.
NoMatchReason	STRING	The reason why a message is sent to the "No match" terminal. Null if the message is sent to the Out terminal. Possible reasons: • NoFile - the file does not exist. • NoData - the file exists but has no records. • NoRecord - the file exists and contains records but none match the filter expression.

Element Name	Element Data Type	Description
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. If this element is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. It is set to TRUE if the current record is empty.
Archive/Directory	STRING	The name of the directory where the file was archived.
Archive/Name	STRING	The name of the file where the file was archived.
TransferredFile.FileName	CHARACTER	If a file is transferred from a remote server, this field contains the name of the file.
TransferredFile.ServerDirectory	CHARACTER	If a file is transferred from a remote server, this field contains the directory on the remote server that the file was transferred from.
TransferredFile.LocalDirectory	CHARACTER	If a file is transferred from a remote server, this field contains the integration node's local file system directory that the file was transferred to.
TransferredFile.TimeStamp	GMTTIMESTAMP	If a file is transferred from a remote server, this field contains a time stamp that represents the time that the file was transferred.

This structure is propagated with each message written to the Out terminal of the FileRead node and with the empty message written to the End of data terminal.

LocalEnvironment.WrittenDestination.File fields

When you use the FileOutput node, it stores information that you can access in the LocalEnvironment.WrittenDestination.File message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Action	CHARACTER	Possible values are: • `Replace` if an output file of the same name is replaced. • `Create` if a new output file is created. • `Append` if this value is associated with a record that is appended to an output file. • `Finish` if a Finish File message is received and no file is found to finish (for example, if `Record is Whole File` is specified and a message is sent to the Finish File terminal). • `Transmit` if the file was transferred by FTP or SFTP and the file was not retained.

Element Name	Element Data Type	Description
Timestamp	CHARACTER	The date and time, in character string form, when the node started to process this file. This value prefixes the names of files that are archived if you specify `Time Stamp, Archive, Replace Existing File and Append to Existing File` in the `Action if file exists` property on the **Basic** tab.

LocalEnvironment.Destination.File fields

When you use the FileOutput and FileRead nodes, you can override the directory and name properties with elements in the message tree. The default location for these overrides is LocalEnvironment.Destination.File, although you can change this location by using the properties on the `Request directory property location` and `Request file name property location` on the FileOutput node. When you use the FileRead node, you can also override the length and offset properties. The fields of this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	This property specifies the absolute or relative directory path of the output directory in the form that is used by the file system of the integration node. For example, on Windows systems, this path starts with the drive letter prefix (such as C:) and use a backslash (\) as the directory delimiter. On UNIX systems, the path includes a slash (/) as the directory delimiter.
Name	CHARACTER	This property specifies the file name of the output file. The FileOutput node does not perform wildcard replacement on the value of the element. For example, if its value is `Input*.txt`, the FileOutput node tries to write to a file with an asterisk (*) in its name. It might or might not succeed, depending on whether an asterisk is a valid character for files in the file system to which it is writing.
Length	INTEGER	This property specifies the length of the record to read from the file. The value is only used if the record detection option fixed length is being used.
Offset	INTEGER	This property specifies the offset in the file to start searching for a record. Offset 0 means start from the beginning and is the default value if no override is given.
Archive/Directory	STRING	The directory where the file is archived to when using one of the file disposition archive options. By default the file is archived to 'mqsiarchive' under the file input directory. Any path is not relative to the input directory but relative to the `MQSI_FILENODES_ROOT_DIRECTORY`.
Archive/Name	STRING	The pattern to use to create an archive file name. Only one star is allowed in the file name and the star is replaced with the first star replace in the file pattern name. If `Archive with Time Stamp` is specified, then a time stamp is appended to the archive name.
PosixPermissions	CHARACTER	A 3-digit octal string that specifies the permissions that are required on the output file. This field uses the same syntax as the syntax that is used in the **chmod** command; for example, a value of 666 corresponds to **rw-rw-rw**.

LocalEnvironment.Destination.File.Remote fields

When you use the FileOutput node or the FileRead node with the `Remote Transfer` property selected, you can override the directory name with an element in the local environment tree. When you use the FileRead node, you can override the remote server with an element in the local environment tree. The fields of this structure are described in the following table.

Element Name	Element Data Type	Description
Remote.ServerDirectory	CHARACTER	This property specifies the absolute or relative directory path of the output directory on the remote server. The property has no effect if FTP or SFTP are not enabled on the FileOutput node. Format the path according to the path syntax that is accepted by the FTP server, typically by using UNIX-style slash (/) directory delimiters. This property is supported by the FileOutput and FileRead nodes.
Remote.Server	CHARACTER	This property can contain either the name of an FTP Server policy, or a string of the form `hostname:port`. If you set a policy name, all properties that are set to non-default values on the policy are used in preference to the properties that are defined on the node. For a `hostname:port` string, these values are used when connecting to a remote FTP or SFTP server.

LocalEnvironment.Wildcard.WildcardMatch field

On the FileInput, CDInput, and FTEInput nodes, you can specify a file name pattern that contains wildcard characters. The input nodes copy the characters in the file name matched by wildcards, together with any intermediate characters, to LocalEnvironment.Wildcard.WildcardMatch.

Element Name	Element Data Type	Description
WildcardMatch	CHARACTER	The character string in the file name matched by wildcards in the file name pattern.

On the FileOutput, CDOutput, and FTEOutput nodes, you can use a wildcard character in the file name pattern. If you include the single wildcard character, '*', in the file name pattern, the node uses the value that is stored in LocalEnvironment.Wildcard.WildcardMatch. This is useful if you have a message flow where the input and output nodes are working with the same file; you can preserve the name of the input file on the output nodes. You can also use standard methods for manipulating the value of the WildcardMatch element to whatever you want; you must not use a FileInput, CDInput, or FTEInput node.

See “File name patterns” on page 972 for more information.

LocalEnvironment.FTE fields

When you use the FTEInput node, it stores information that you can access in the LocalEnvironment.FTE and LocalEnvironment.FTE.Transfer message trees. The LocalEnvironment.FTE message tree stores information relating to the current record and is populated by the integration node. The fields in this structure are described in the following table:

Element Name	Element Data Type	Description
TimeStamp	CHARACTER	Date and time the input node started processing the file in the Coordinated Universal Time (UTC) zone, as a character string. This data is the string used to create archive and backout file names if a timestamp is included.
Offset	INTEGER	Start of the record within the file. The first record starts at offset 0 bytes. When Offset is part of the End of Data message tree, this value is the length of the input file.

Element Name	Element Data Type	Description
Record	INTEGER	Number of the record within the file. The first record is record number 1. When Record is part of the End of Data message tree, this value is the number of records.
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. When Delimiter is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. IsEmpty is set to TRUE if the current record is empty. When IsEmpty is part of the End of Data message tree, this value is always set to TRUE.

The LocalEnvironment.FTE.Transfer message tree contains information received from IBM MQ File Transfer Edition regarding the transfer or file; see WebSphere File Transfer Edition product documentation for more details. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the input directory.
JobName	CHARACTER	The name for the transfer.
Name	CHARACTER	File name and extension (per file).
LastModified	TIMESTAMP	Date and time the file was last modified (per file).
SourceAgent	CHARACTER	The name of the agent sending the file.
DestinationAgent	CHARACTER	The name of the agent to send the file to.
OriginatingHost	CHARACTER	The name of the host from which the transfer was submitted.
TransferId	CHARACTER	The unique name of the transfer.
MQMDUser	CHARACTER	The IBM MQ user ID in the MQMD of the transfer request message.
OriginatingUser	CHARACTER	The user ID of the user that submitted the transfer request.
TransferMode	CHARACTER	The mode of the transfer. Valid values are `Binary` or `Text`.
TransferStatus	CHARACTER	The status of the transfer of the file.
FileSize	INTEGER	The size of the file being transferred.
ChecksumMethod	CHARACTER	The only allowed value is `MD5`.
Checksum	CHARACTER	If the ChecksumMethod element is set to `MD5`, this element is the actual checksum in hex string format.
DestinationAgentQmgr	CHARACTER	The name of the queue manager of the destination agent to send the file to.
SourceAgentQmgr	CHARACTER	The name of the queue manager of the source agent that sent the file.
OverallTransferStatus	CHARACTER	The overall status of the transfer.
TotalTransfers	INTEGER	The total number of files successfully transferred.
TransferNumber	INTEGER	The number of the current file in the transfer.

These structures are propagated with each message written to the Out terminal of the FTEInput node and with the empty message written to the End of data terminal.

LocalEnvironment.WrittenDestination.FTE fields

When you use the FTEOutput node, it stores information that you can access in the LocalEnvironment.WrittenDestination.FTE message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
DestinationAgent	CHARACTER	The name of the agent to send the file to.
DestinationQmgr	CHARACTER	The name of the destination queue manager.
JobName	CHARACTER	The name for the transfer.
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Overwrite	BOOLEAN	Specifies whether files on the destination system can be overwritten when the destination agent moves files of the same name there. If the destination agent fails to overwrite the file, the transfer fails and the transfer logs report the failure. The FTEOutput node does not throw or log any errors.
TransferId	CHARACTER	The unique name of the transfer initiated by the FTEOutput node.

LocalEnvironment.Destination.FTE fields

When you use the FTEOutput node, you can override its Destination agent, Destination queue manager, Job name, Destination file directory, Destination file name, and Overwrite files on destination system properties with elements in the message tree. You can also call a program on the destination agent before starting the transfer, or when the transfer is finished. The default location for these overrides is LocalEnvironment.Destination.FTE. The fields of this structure are described in the following table.

Element Name	Element Data Type	Description
DestinationAgent	CHARACTER	The name of the agent to send the file to.
DestinationQmgr	CHARACTER	The name of the destination queue manager.
JobName	CHARACTER	The name for the transfer.
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Overwrite	BOOLEAN	Specifies whether files on the destination system can be overwritten when the destination agent moves files of the same name there. If the destination agent fails to overwrite the file, the transfer fails and the transfer logs report the failure. The FTEOutput node does not throw or log any errors.

Element Name	Element Data Type	Description
PreDestinationCall.Name	CHARACTER	Call a program on the destination agent before starting the transfer. This element supplies the name of an Ant script to run. The Ant script can access all the metadata that is defined for the transfer, including user metadata added by using the local environment override `LocalEnvironment.Destination.FTE.UserDefined`. You must be aware of the following restrictions: • You cannot call other programs that are not Ant scripts, or pass parameters to the calls. • The destination agent cannot be an FTE agent that is embedded in an integration server process. See WebSphere File Transfer Edition product documentation for more details of how to use the PreDestinationCall function.
PostDestinationCall.Name	CHARACTER	Call a program on the destination agent after completing the transfer. This element supplies the name of an Ant script to run. The Ant script can access all the metadata that is defined for the transfer, including user metadata added by using the local environment override `LocalEnvironment.Destination.FTE.UserDefined`. You must be aware of the following restrictions: • You cannot call other programs that are not Ant scripts, or pass parameters to the calls. • The destination agent cannot be an FTE agent that is embedded in an integration server process. See WebSphere File Transfer Edition product documentation for more details of how to use the PostDestinationCall function.

LocalEnvironment.CD fields

When you use the CDInput node, it stores information that you can access in the LocalEnvironment.CD and LocalEnvironment.CD.Transfer message trees. The LocalEnvironment.CD message tree stores information relating to the current record and is populated by the integration node. The fields in this structure are described in the following table:

Element Name	Element Data Type	Description
Transfer	Folder	Contains meta data from the IBM Sterling Connect:Direct transfer.
Timestamp	CHAR	Timestamp of the file.
Offset	INTEGER	Start of the record within the file. The first record starts at offset 0 bytes. When Offset is part of the End of Data message tree, this value is the length of the input file.
Record	INTEGER	Number of the record within the file. The first record is record number 1. When Record is part of the End of Data message tree, this value is the number of records.

Element Name	Element Data Type	Description
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. When Delimiter is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. IsEmpty is set to TRUE if the current record is empty. When IsEmpty is part of the End of Data message tree, this value is always set to TRUE.

These structures are propagated with each message written to the Out terminal of the CDInput node and with the empty message written to the End of data terminal.

LocalEnvironment.CD.Transfer

The LocalEnvironment.CD.Transfer message tree contains information received from IBM Sterling Connect:Direct regarding the transfer or file. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
ProcessName	CHARACTER	The process name of the script transferring the file.
StepName	CHARACTER	The step name causing the transfer to take place.
ProcessNumber	INTEGER	The number of the process running the process script.
Submitter	CHAR	The user ID submitting the process script.
Accounting	CHAR	The secondary node (SNODE) accounting details for the process script.
SourcePath	CHAR	The source path of the file on the primary node (PNODE) machine.
DestinationPath	CHAR	The destination path of the file on the secondary node (SNODE) machine
Directory	CHARACTER	The directory which the file is copied to.
Name	CHARACTER	The name of the file copied to.
PrimaryNodeName	CHARACTER	The name of the primary node from which the file was copied.
SecondaryNodeName	CHARACTER	The name of the secondary node.

LocalEnvironment.Destination.CD fields

When you use the CDOutput node, you can override various destination system properties with elements in the message tree. The default location for these overrides is LocalEnvironment.Destination.CD. The fields of this structure are described in the following table

Element Name	Element Data Type	Description
SNODE	CHARACTER	The name of the secondary Connect:Direct server (SNODE) to send the file to.
SNODEID	CHARACTER	The user ID and password of the secondary Connect:Direct server (SNODEID) to send the file to.
ProcessName	CHARACTER	The process name that the script uses to run.

Element Name	Element Data Type	Description
Accounting	CHARACTER	Accounting data shown when the script is running on both the primary Connect:Direct server (PNODE) and secondary Connect:Direct server (SNODE).
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Copy.From	CHARACTER	The final part of the path name is the IBM Sterling Connect:Direct process script property you want to change. This is either a direct `<option name>` on the FROM clause, or a value in the <SYSOPTS> option. You must take care to ensure that the created script is valid, because any existing value created by the node is overridden.
Copy.To	CHARACTER	The final part of the path name is the IBM Sterling Connect:Direct process script property you want to change. This is either a direct `<option name>` on the TO clause, or a value in the <SYSOPTS> option. You must take care to ensure that the created script is valid, because any existing value created by the node is overridden.

LocalEnvironment.WrittenDestination.CD fields

When you use the CDOutput node, it stores information that you can access in the LocalEnvironment.WrittenDestination.CD message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
ProcessName	CHARACTER	The name of the process sending the file.
ProcessNumber	CHARACTER	The number of the process sending the file.
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the integration node. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
PrimaryNodeName	CHARACTER	The name of the primary Connect:Direct server (PNODE)
PrimaryNodeOS	CHARACTER	The operating system of the primary Connect:Direct server
SecondaryNodeName	CHARACTER	The name of the secondary Connect:Direct server (SNODE)
SecondaryNodeOS	CHARACTER	The operating system of the secondary Connect:Direct server (this might not be the same as the IBM App Connect Enterprise operating system)

File name patterns

You can specify a file name pattern, using wildcard characters, to identify a file to be read by the FileInput, CDInput, and FTEInput nodes. You can also specify a file name pattern, using a single wildcard character, to name the file to be created by the FileOutput and FTEOutput nodes.

Using file name patterns with the FileInput, CDInput, and FTEInput nodes

The input nodes read files from a specified directory and propagate messages based on the contents of these files. Only files with names that match a pattern (the input pattern), as specified in the FileInput node's `File name or pattern` property or the FTEInput node's `File name filter` property, are read.

If you are using file name patterns to exclude files from the FileInput node, files with names that match the exclude pattern, as specified in the FileInput node's `File exclusion pattern` are not read or processed.

The match might be with a file name or a character sequence (a pattern). A pattern is a sequence containing at least one of the following wildcard characters:

Wildcard character	Description	Example
*	Any sequence of zero or more characters	`*.xml` matches all file names with an `xml` extension
?	Any single character	`f??????.csv` matches all file names consisting of the letter `f` followed by six characters, then the sequence `.csv`.

The default pattern is `*`, which matches all file names.

You cannot specify file names that contain the following characters: the asterisk ('*'), the question mark ('?'), or file name separator characters ('/' and' \').

For example:

- If you want the FileInput node to process all files that have a certain extension, such as `xml`, set its `File name or pattern` property to `*.xml` and the node will process all files in the directory (and subdirectories if selected) that have this extension.
- If you want the FileInput node to exclude all files with a certain extension from being processed, such as `.csv`, set its `File exclusion pattern` property to `*.csv` and the node will not process any of the files with this extension in the directory (and subdirectories if selected).

If you deploy the flow to a Windows server, file names match the pattern irrespective of case. However, if you deploy the flow to a Linux, UNIX, or z/OS server, file names must match the pattern character string and its case.

Pattern matching

The FileInput, CDInput, and FTEInput nodes set the LocalEnvironment.Wildcard.WildcardMatch element to the string matched by wildcards in the file name. The LocalEnvironment.Wildcard.WildcardMatch element is unaffected by file exclusion patterns. The following are some examples of pattern matching with the value in this element, where the value in the FileInput node's `File name or pattern` property is `File????.from*.xml`:

- If the FileInput node finds a file with the file name `File1234.fromHQ.xml`, there is a match. The value in the LocalEnvironment.Wildcard.WildcardMatch element is set to `1234.fromHQ` and the node processes the file.
- If the file name is `File123.fromHQ.xml`, there is no match because there are insufficient characters between the `File` and `.from` elements of the file name. The FileInput node ignores this file.

- If the file name is `File2345.from.xml`, there is a match. The value in the LocalEnvironment.Wildcard.WildcardMatch element is set to `2345.from` and the node processes the file. In this example, the `*` in the character string in the `File name or pattern` property matches a string of zero characters. If you require the character string between the `from` and `.xml` elements of the file name to always have at least one character, you specify the `File name or pattern` property with a value of `File????.from?*.xml`.

Using file name patterns with the FileOutput, CDOutput, and FTEOutput nodes

The node writes messages to files that it creates or replaces in the integration node's file system. Only patterns containing a single wildcard character (the asterisk, '*') are allowed in this property. The file name to be used is determined in the following way:

- If the file name property contains no wildcard, the value of this property is the name of the file created. This value must be a valid file name on the file system that hosts the integration node to which the message flow is deployed.
- If the file name property contains a single wildcard, the value of the element LocalEnvironment.Wildcard.WildcardMatch in the current message replaces the wildcard character, and the resulting value is the name of the file created. This value must be a valid file name on the file system that hosts the integration node to which the message flow is deployed. If the WildcardMatch value is not found, the wildcard character is replaced by the empty string.

You cannot specify file names that contain the following characters: the asterisk ('*'), the question mark ('?'), file name separator characters ('/' and' \'). The name of the file can be overridden by values in the current message.

If the `File name or pattern` property on the FileOutput node is empty, the name must be overridden by the current message. Wildcard substitution occurs only if this property is not overridden in this way.

File names are passed to the file system to which the integration node has access, and have to respect the conventions of these file systems. For example, file names on Windows systems are not case-sensitive; on UNIX systems, file names that differ by case are considered distinct.

Example: If the FileInput node has `*.out` in the `File name or pattern` property, and the incoming file is `myfile`, the name of the outgoing file is `myfile.out`.

FTP and SFTP considerations

You can use the FileInput node to transfer files from a remote FTP or SFTP server and process them. Only files with names that match the file name pattern specified in the node are read. You can also use a file exclusion pattern to prevent files from being read on a remote FTP or SFTP server. If your integration node is on an operating system that respects case sensitivity (such as UNIX), you might specify a pattern that includes a combination of uppercase and lowercase characters. If you then use this pattern to process files that are in a directory on a remote FTP or SFTP server, and this server is running on an operating system that does not respect case sensitivity (such as Windows), file name matching might fail with the result that no files are processed. This failure occurs because the file names on the remote server are not in mixed case. If your integration node is on an operating system that does not respect case sensitivity, any pattern that you specify might be matched by more than one file on a remote FTP or SFTP server that is running on an operating system on which case sensitivity is significant. Each of these files is then processed sequentially.

You can use the FileOutput node to write files to a remote FTP or SFTP server. Only files with names that match the pattern specified in the node are written. If your integration node is running on an operating system that respects case sensitivity (such as UNIX), you might specify a pattern that includes a combination of uppercase and lowercase characters. However, if you then use this pattern to write files to a directory on a remote FTP or SFTP server running on an operating system that does not respect case sensitivity (such as Windows), the file name is written in uppercase rather than in the way that it was specified in your pattern.

If the name of a file on a remote FTP server contains one or more characters that are not valid on the operating system on which the integration node where you specified the file name pattern is running, the file is not transferred from the FTP server for processing by the FileInput node.

Archiving

Files that are successfully processed by the FileInput node or FileOutput node can optionally be moved to the `mqsiarchive` subdirectory of the input or output directory.

The input directory of the FileInput node has a subdirectory called `mqsiarchive`. The output directory of the FileOutput node also has a subdirectory called `mqsiarchive`. Archiving is not enabled for the FTEOutput and FTEInput nodes.

FileInput node

Files that are processed successfully by the FileInput node are moved to the `mqsiarchive` subdirectory if the FileInput node's `Action on successful processing` property is set to `Move to Archive Subdirectory` or `Add Timestamp and Move to Archive Subdirectory`.

Select the `Replace duplicate archive files` check box to overwrite existing files in the `mqsiarchive` subdirectory. If you do not set this option, and a file with the same name already exists in the archive subdirectory, the node stops processing files. Every time that the node returns from its polling wait period, it issues a pair of messages, BIP3331 and a more specific one describing the problem. To avoid writing too many messages, duplicate messages are suppressed for increasing periods of time, until eventually they are issued only about once every hour. In this circumstance, the system administrator must stop the flow, correct the problem, then restart the flow.

Clear the `Replace duplicate archive files` check box only if you are sure either that the input files have unique names, or that some other process will remove a file from the archive directory before the FileInput node processes another of the same name. If you cannot ensure this, either specify `Add Timestamp and Move to Archive Subdirectory` in the `Action on successful processing` property so that archived files have unique names, or select the `Replace duplicate archive files` check box

FileOutput node

Files that are processed successfully by the FileOutput node are moved to the `mqsiarchive` subdirectory if the `Action if file exists` property of the FileOutput node is set to `Append to Existing File`, `Archive and Replace Existing File` or `Time Stamp, Archive and Replace Existing File`.

Select the `Replace duplicate archive files` check box to overwrite existing files in the `mqsiarchive` subdirectory. If you do not set this option, and a file with the same name already exists in the archive subdirectory, the node generates an exception when it tries to move the successfully processed file and the file remains in the transit subdirectory.

Reading files

Use the FileInput, CDInput, FTEInput, and FileRead nodes to read files.

About this task

This section contains the following topics:

Using a local file as input for your message flow
Learn how to use the FileInput node to read a file on your local file system and then propagate messages that are based on the contents of that file.

Before you begin

This example shows how one combination of values in the `Record detection`, `Delimiter`, and `Delimiter type` properties can be used to extract messages from a file. The example describes the FileInput node of a message flow and assumes that the rest of the flow has already been developed. It is also assumed that a Windows system is being used. To complete this example task, you must first have added a FileInput node to a message flow. You also need the following resources:

- An input file. To follow this example scenario, create an input file called `test_input1.xml` with the following content:

  ```
  <Message>test1</Message>
  <Message>testtwo</Message>
  <Message>testthree</Message>
  ```

  Each line ends with a line terminator; on a Windows system, this comprises carriage return and line feed characters (X'0D0A'). Put this file into directory `C:\FileInput\TestDir`.
- A message set. This example uses a message set called `xml1` which uses the XMLNSC parser. Message set `xml1` models messages of the following form:

  ```
  <Message>...</Message>
  ```

For more information about configuring the FileInput node, see Configuring the node.

Complete the following steps:

Procedure

1. Set the required node properties on the FileInput node.

   The following table summarizes the FileInput node properties that you should set, which tab they appear on and the value that you should set in order to follow this example:

Tab	Property	Value
Basic	Input directory	C:\FileInput\TestDir
	File name or pattern	test_input1.xml
	Action on successful processing	Move to Archive Subdirectory
	Replace duplicate archive files	Selected
Input Message Parsing	Message domain	XMLNSC
	Message model	xml1
Polling	Polling interval	3
Retry	Action on failing file	Add Time Stamp and Move to Backout Subdirectory
Records and Elements	Record detection	Delimited
	Delimiter	DOS or UNIX Line End
	Delimiter type	Postfix
FTP	FTP	Not selected

2. Deploy the message flow to the integration node. See Chapter 7, “Deploying integration solutions,” on page 2463.

Results

The following actions occur when you perform these steps:

1. The file is processed. In accordance with the values set in the properties on the **Records and Elements** tab, the FileInput node detects records that are separated by DOS or UNIX end-of-line characters and creates a message for each one that it finds. It propagates three messages to the flow attached to the Out terminal:
   - Message 1:

     ```
     <Message>test1</Message>
     ```

   - Message 2:

     ```
     <Message>testtwo</Message>
     ```

   - Message 3:

     ```
     <Message>testthree</Message>
     ```

2. If a flow is attached to the End of Data terminal, the End of Data message is propagated after the last record in the file has been processed.
3. When processing is complete, the file `test_input1.xml` is moved to the `mqsiarchive` subdirectory, `C:\FileInput\TestDir\mqsiarchive\test_input1.xml`. If a file called `test_input1.xml` already exists in the `mqsiarchive` subdirectory, it is overwritten.
4. If the message flow fails, retry processing is attempted according to the values set in the properties of the FileInput node. In this example task, a time stamp is added to the file name and the file is moved to the `mqsibackout` directory. Here is an example of the path to such a file: `C:\FileInput\TestDir\mqsibackout\20070928_150234_171021_test_input1.xml`.

What to do next

To see the effects of specifying other combinations of values in the `Record detection`, `Delimiter`, and `Delimiter type` properties of the FileInput node, see “Controlling how files are separated into records” on page 985.

To extend this example to process files from within subdirectories, put the input file in a subdirectory of `Input directory`, and select the property `Include local subdirectories`.

Routing or enriching a message based on the contents of a file

The FileRead node can route or enrich messages based on the contents of the file.

When developing the message flow you can specify the name and location of the file to be read. You can override these values at run time based on the contents of a message.

The node complements the existing FileInput and FileOutput nodes. The FileRead node reads a file in the middle of a message flow.

Using the node to route messages

A message is routed by using the contents of a file colocated with IBM App Connect Enterprise or on a network file system. The message from the source system is routed to a target system by using an external routing file. No response is expected.

The basic flow of events is as follows:

- IBM App Connect Enterprise receives a message through an input node.

- The IBM App Connect Enterprise message flow interrogates the contents of a message to identify routing key information.
- If the file consists of more than one record, you need to determine:
  - Where the first record starts. Unless you specify an offset byte, the node starts reading the file at the first byte.
  - How each record ends (fixed-sized, delimited, or parsed.)
  - Which record to propagate. You can use any combination of information from the input message and the file in deciding this. All records from the specified start point are read until a record is found that matches the record selection expression, this record is then propagated. Examples include:

    The third record, as identified by the local environment field `$OutputLocalEnvironment/File/Read/RecordNumber=3`. In this example, the first record is fully read and the expression evaluates to false. The second record is then fully read and the expression evaluates to false. When the third record is fully read, the expression evaluates to true and the record is propagated. No further records are read.

    A key field in the input message matches a key field in the file `$InputRoot/XMLNSC/FromMQInputMessage/Record1 = $ResultRoot/XMLNSC/FromFile/Record5`. In this example, records are read from the file until the value of the Record5 element of the record matches the value of the Record1 element of the incoming message. The location of the record in the file determines how many records the node must read before successfully matching the record selection expression.
- Within the message flow you can implement a local cache of records to reduce the performance cost of reading multiple static records.
- You can choose to take information from the file, and copy it to the outgoing message. The copy can be a subset of the data, and can be copied to any location in the message or the local environment. For more information, see "Combining a result message with an input message when fetching data from external systems" on page 1811.
- A target application receives the routed message.

Combining an IBM MQ message with an XML file using the contents of the message to identify which file to use
Combine an incoming message with the contents of an XML file, using fields in the message to determine which file to use.

Before you begin

Put a file on the file system that is local to the integration node, for the FileRead node to read. Here is an example of the file contents:

```
<Data>Purchase details</Data>
```

In this example, the contents of the data in the data tag are inserted into the incoming message. Any valid XML structures can be added to this section.

Make a note of the path to the file. For example: `c:\temp\FileRead\task3.xml` or `/tmp/FileRead/task3`.

Create the following queues on the integration node queue manager:

- FILEREAD.TASK3.IN1
- FILEREAD.TASK3.OUT1

Detailed information about configuring the node is given on the property panels for the node, in the IBM App Connect Enterprise Toolkit.

Procedure

1. Create a message flow that contains an MQInput node, a FileRead node, and an MQOutput node.

2. Wire the terminals as follows:
   a. Wire the Out terminal of the MQInput node to the In terminal of the FileRead node.
   b. Wire the Out terminal of the FileRead to the In terminal of the MQOutput node.
3. Configure the MQInput node:
   a. On the Basic panel, set the Queue name to `FILEREAD.TASK3.IN1`
   b. On the Input Message Parsing panel set the domain to `XMLNSC`.
4. Configure the FileRead node.
   a. On the Basic panel, set the directory and file name to refer to the XML file. For example: `c:\temp\FileRead` and `task3.xml` or `/tmp/FileRead` and `task3`.
   b. Configure the Result panel:
      i) Set the Result data location to `$ResultRoot/XMLNSC/Data`
      ii) Set the Output data location to `$InputRoot/XMLNSC/Data`
   c. Configure the Input Message Parsing panel:
      i) Set the Domain to `XMLNSC`
5. Configure the MQOutput node:
   a. On the Basic panel, set the Queue name to `FILEREAD.TASK3.OUT1`
6. Deploy the message set and message flow.
7. Change the Directory and Name fields to the correct location of the file, and then put the following XML message onto queue FILEREAD.TASK2.IN1:

```
<Invoice>
  <Directory>c:\temp\FileRead</Directory>
  <Name>task2.xml</Name>
  <Data/>
</Invoice>
```

Results

The integration node routes the message to the queue FILEREAD.TASK3.OUT1 and inserts data from the file into the Data field of the output message:

```
<Invoice>
  <Directory>c:\temp\FileRead</Directory>
  <Name>task2.xml</Name>
  <Data>Purchase details</Data>
</Invoice>
```

Record selection expressions
The record selection expression is used to select a record from a file to propagate to the rest of the flow.

Each record in turn is compared to the expression, and the first one to evaluate to true is propagated to the **Out** terminal. You can set the expression to any valid XPath expression that returns a Boolean value. The expression is not used when `Whole File` is selected as the `Record Detection` option.

Correlation names used in the expression

You can use any of the following correlation names in the expression:

`InputRoot` and `InputLocalEnvironment`
The Input names refer to the incoming message that enters the node through the **In** terminal

`ResultRoot`
The `ResultRoot` name refers to the message created by using the current record in the file.

OutputRoot
The OutputRoot name refers to the message that is propagated if the expression evaluates to true. This action is identical to ResultRoot, unless the Output data location or Result data location have been changed to copy the Result message found in the file to a different location in the outgoing message.

OutputLocalEnvironment
The OutputLocalEnvironment contains the normal local environment which is propagated down the **Out** terminal and contains useful information like the number of the record and its offset.

Any combination of data in these correlation names can be used, along with any valid XPath expression, to determine whether to propagate the record.

Examples

Expression is:

```
$InputRoot/XMLNSC/Invoice/AccountNumber=$ResultRoot/XMLNSC/Data/Key
```

In this example, each record is a valid XML document. The FileRead node reads each record from the file. In the incoming message the FileRead node compares the field /Data/Key to the field /Invoice/AccountNumber. If the record matches, it is propagated to the **Out** terminal.

Expression is:

```
$OutputLocalEnvironment/File/Read/RecordNumber=5
```

The FileRead node reads each record from the file and compares the record number to 5. The record is propagated when it reaches the fifth record.

Building an outgoing message by using an incoming message combined with a record from a file

The FileRead node reads a record from a file and combines it with the message coming in to the node. By default, it replaces the message with the contents of the record read from the file. However, by using properties on the Result panel, you can choose how to combine the incoming message and file record contents. The node has three logical trees:

Input
The Input message assembly contains all the data in the incoming message and is the basis for the propagated record.

Result
The Result message assembly contains the record read from the file.

Output
The Output message assembly is the actual object propagated from the node.

By default, the Output message assembly is constructed by copying the Input message assembly to the Output message assembly. The data part of the Output message assembly is then replaced by the contents of the Result message assembly and the OutputLocalEnvironment is updated with details of what happened in the node.

The following Result panel properties can be used to modify this behavior:

Result data location
Specifies which part of the read record is copied to the Output message. By default, the Result data location copies everything from ResultRoot but it can be changed to copy only part of the record. For example: ResultRoot.XMLNSC.Invoice.Name just copies the name field from the selected record to the output message.

Output data location
Specifies where the record is copied to in the outgoing message. By default, the Output data location copies everything to OutputRoot. The location specified can be in the data part of the message (under

ResultRoot) or in any other Output tree like OutputLocalEnvironment. For example: To copy the resulting record to a field in the message body OutputRoot.XMLNSC.Invoice.Data or to copy the result to local environment OutputRoot.Variables.Invoice.data.

Copy local environment
Causes the local environment to be copied from the InputLocalEnvironment. If the Copy local environment option is not selected, the InputLocalEnvironment is used directly without copying. This option allows nodes before the FileRead node to see changes to the Local environment.

For example, the following options copy the name field from a record to the output going message. The rest of the Output message is based on the input message:

```
Result data location= ResultRoot.XMLNSC.Invoice.Name
Output data location= OutputRoot.XMLNSC.Invoice.Name
```

The following options copy the message body from a record to the output going local environment. The Output message is the same as the input message:

```
Result data location= ResultRoot.XMLNSC.Invoice
Output data location= OutputLocalEnvironment.Variables.Invoice
```

Reading a file on a remote FTP or SFTP directory
Use a FileInput node to read a file in a directory on a remote FTP or SFTP server and then propagate messages that are based on the contents of that file.

Before you begin

This example is an extension of the example described in "Using a local file as input for your message flow" on page 975 and it describes how to use a FileInput node in a message flow. The instructions assume that you are using a Windows operating system and that you have created a message flow containing a FileInput node. You also require the following resources:

- An FTP or SFTP server. Ensure that an FTP or SFTP server exists, with the following settings:

  Server
  ftpserver.hursley.abc.com

  Port
  21 (for FTP) or *22* (for SFTP)

  Working directory
  /ftpfileinput

  Userid
  myuserid

  Password
  mypassword

  These values are for the purposes of this example only. If you use other values, record them so that you can set the appropriate values during the task.

- A security identity. Use the **mqsisetdbparms** command to define a security identity called *myidentity* for your user and password details.

  If you want to connect to an FTP server, the security identity must have an `ftp::` prefix, to enable the file nodes to find the identity definition. For example, use the following command:

  ```
  mqsisetdbparms workDir -n ftp::myidentity -u myuserid -p mypassword
  ```

  If you want to connect to an SFTP server, the security identity must have an `sftp::` prefix, as shown in the following example:

  ```
  mqsisetdbparms -w workDir -n sftp::myidentity -u myuserid -p mypassword
  ```

  You can also configure a connection to an SFTP server to use public key authentication, by specifying an SSH identity file and pass phrase, instead of a password. For example:

  ```
  mqsisetdbparms -w workDir -n sftp::myidentity -u myuserid -i identity_file -r passphrase
  ```

  To check what security credentials are already set, use the **mqsireportdbparms** command; see "Checking the password for a resource that is used by an integration server" on page 2630.

  For more information about configuring connections to an SFTP server, see "Transferring files securely by using SFTP" on page 998.
- An input file. To follow this example scenario, create an input file called `test_input1.xml` with the following content:

  ```
  <Message>test1</Message>
  <Message>testtwo</Message>
  <Message>testthree</Message>
  ```

  Each line ends with a line terminator that is suitable for the system on which the FTP or SFTP server is found. Do not put this file in the input directory but, instead, put it in the FTP or SFTP server directory `/ftpfileinput`.
- A message set. This example uses a message set called *xml1*, which uses the XMLNSC parser. Message set *xml1* models messages of the following form:

  ```
  <Message>...</Message>
  ```

About this task

Complete the following steps:

Procedure

1. Set the required node properties on the FileInput node.

   The following table summarizes the FileInput node properties that you must set, the tab on which they are displayed, whether they are mandatory, and the required values.

Tab	Property	Value
Basic	`Input directory`	`C:\FileInput\TestDir` If the input directory does not exist, no files are processed, even if you are processing files over FTP or SFTP.
	`File name or pattern`	`test_input1.xml`
	`Action on successful processing`	`Move to Archive Subdirectory`
	`Replace duplicate archive files`	Selected

Tab	Property	Value
Input Message Parsing	Message domain	XMLNSC
	Message model	xml1
Polling	Polling interval	3
Retry	Action on failing file	Add Time Stamp and Move to Backout Subdirectory
Records and Elements	Record detection	Delimited
	Delimiter	DOS or UNIX Line End
	Delimiter type	Postfix
FTP	Remote transfer	Selected
	Transfer protocol	FTP or SFTP
	Remote server and port	ftpserver.hursley.abc.com
	Security identity	myidentity
	Server directory	/ftpfileinput
	Transfer mode	ASCII (for FTP only)
	Scan delay	45

If you used other values for your FTP or SFTP server resource, enter those values. The settings used here are identical to those used in the example in "Using a local file as input for your message flow" on page 975, except that the Remote transfer property has been selected and there are now properties on the **FTP** tab. If you clear the Remote transfer property, the node operates as it does in the example in "Using a local file as input for your message flow" on page 975; the properties on the **FTP** tab remain set but are ignored.

2. Deploy the message flow to the integration server. See Chapter 7, "Deploying integration solutions," on page 2463.

Results

The following actions occur when you perform these steps:

1. The file test_input1.xml is transferred from the FTP or SFTP server directory (/ftpfileinput) to the local directory (C:\FileInput\TestDir). The file is deleted from the FTP or SFTP server directory.
2. The FileInput node detects records that end with a DOS or UNIX line end and creates a message for each one that it finds, as defined by the properties on the **Records and elements** tab. The node propagates three messages to the message flow that is attached to the Out terminal:
   - Message 1:

     ```
     <Message>test1</Message>
     ```

   - Message 2:

     ```
     <Message>testtwo</Message>
     ```

   - Message 3:

     ```
     <Message>testthree</Message>
     ```

3. If a node is attached to the End of Data terminal, the End of Data message is propagated after the last record in the file has been processed.

4. When processing is complete, the file `test_input1.xml` is moved to the `mqsiarchive` subdirectory `C:\FileInput\TestDir\mqsiarchive`. If a file called `test_input1.xml` exists in the `mqsiarchive` subdirectory, it is overwritten.
5. If the message flow fails, retry processing is attempted according to the values set in the properties of the FileInput node. In this example task, a time stamp is added to the file name and the file is moved to the `mqsibackout` directory. Here is an example of the path to such a file: `C:\FileInput \TestDir\mqsibackout\20070928_150234_171021_test_input1.xml`.

   If an error occurs on the FTP side, stating that access is denied, a 0-byte file is created and moved to the mqsibackout directory. A 0-byte file is created in the mqsibackout directory for every FTP attempt that fails.

Because the `Remote transfer` property is selected, the FTP scan delay of 45 seconds overrides the polling interval of 3 seconds.

What to do next

For more information, see "Controlling how files are separated into records" on page 985, which shows the effects of specifying other combinations of values in the `Record detection`, `Delimiter`, and `Delimiter type` properties of the FileInput node.

Receiving a file by IBM MQ File Transfer Edition
Use the FTEInput node to receive files from an existing IBM MQ File Transfer Edition network.

Before you begin

1. Read about IBM MQ File Transfer Edition.
2. Ensure that IBM MQ is installed on the same machine as IBM App Connect Enterprise. Information about file transfers is held on storage queues that are controlled by IBM MQ, so you must install IBM MQ on the same computer as IBM App Connect Enterprise if you want to use the capabilities that are provided by the FTEInput node.
3. Create the system queues that will store the file transfer information. For more information about creating the system queues, see "Creating the default system queues on an IBM MQ queue manager" on page 99.

About this task

Complete the following steps to create an FTEInput node message flow using the default settings. The task includes some optional steps for additional configuration, but detailed information about configuring the FTEInput node is given on the property panels for the node, in the IBM App Connect Enterprise Toolkit.

Procedure

1. Drag an FTEInput node onto a message flow and wire its Out terminal to an output node of your choice.
2. Optional: To process only a defined subset of files sent to an agent, configure the **Basic panel**.

   This action allows multiple FTEInput nodes in the same integration server to receive specific files, depending on the directory or file filters specified.

   You can also specify whether, after processing, the file should be left in its directory, renamed, or deleted.
3. To change how the node handles a message flow failure, configure the Retry panel.

4. Optional: To change how records are identified in the input file, configure the `Record detection` property on the **Records and Elements** panel.

   For example, you might want to specify that a record is fixed length, and set the record length.

   a) If you set the `Record detection` property to anything other than `Whole File`, drag an additional output node to the flow, such as the MQOutput node. Wire the End of Data terminal on the FTEInput node to the In terminal of the MQOutput node, as shown in the following figure:

   The node connected to the End of Data terminal receives an empty message when the last record in the file is read.

5. Optional: To process the file based on details of the transfer, place a node such as the Route node after the FTEInput node.

   Details of the transfer are stored in the local environment, at `LocalEnvironment.FTE`.

6. Add the flow to a BAR file and deploy the BAR file.
7. Optional: Change the coordination queue manager.

Receiving a file using IBM Sterling Connect:Direct
Use the CDInput node to receive files from an IBM Sterling Connect:Direct network.

Before you begin

1. Read "IBM Sterling Connect:Direct overview and concepts" on page 953.
2. Ensure that IBM MQ is installed on the same machine as IBM App Connect Enterprise. Information about file transfers is held on storage queues that are controlled by IBM MQ, so you must install IBM MQ on the same computer as IBM App Connect Enterprise if you want to use the capabilities that are provided by the CDInput node.
3. Ensure that a queue manager has been specified to own the system queues that store information about the file transfer.
4. Create the system queues that will store the file transfer information. For more information about creating the system queues, see "Creating the default system queues on an IBM MQ queue manager" on page 99.

About this task

Multiple CDInput nodes can be deployed to the same integration server. Multiple CDInput nodes can read files transferred to the same directory without contention. Each file is processed only once, even if the nodes are deployed to separate integration servers.

On z/OS, when the CDInput node receives notification of the arrival of a dataset that it should process, the node copies that dataset into Unix System Services temporarily, before processing.

Complete the following steps to create a CDInput node message flow using the default settings. The task includes some optional steps for additional configuration, but detailed information about configuring the CDInput node is given on the property panels for the node, in the IBM App Connect Enterprise Toolkit. The default settings assume that you have a Connect:Direct server running on the same machine as IBM App Connect Enterprise, and that you are using the default ports.

Procedure

1. Drag a CDInput node onto a message flow and wire its Out terminal to an output node of your choice.
2. Optional: To process only a defined subset of files, configure the **Basic panel**.

   This action allows multiple CDInput nodes in the same integration server to receive specific files, depending on the directory or file filters specified.

   You can also specify whether, after processing, the file is left in its directory, renamed, or deleted.
3. To change how the node handles a message flow failure, configure the Retry panel.
4. Optional: To change how records are identified in the input file, configure the `Record detection` property on the **Records and Elements** panel.

   For example, you might want to specify that a record is fixed length, and set the record length.

   a) If you set the `Record detection` property to anything other than `Whole File`, drag an additional output node to the flow, such as the MQOutput node. Wire the End of Data terminal on the CDInput node to the In terminal of the MQOutput node. The node connected to the End of Data terminal receives an empty message when the last record in the file is read.
5. Optional: To process the file based on details of the transfer, place a node such as the Route node after the CDInput node.

   Details of the transfer are stored in the local environment, at `LocalEnvironment.CD`.
6. Set up the user name and password that are required for the CDInput node to connect to the primary Connect:Direct server by using the command.
7. Add the flow to a BAR file and deploy the BAR file.
8. Use IBM Sterling Connect:Direct to send a file to the local Connect:Direct server.

   The CDInput node processes this file.

Controlling how files are separated into records
Set the `Record detection` and other properties on node **Records and Elements** tabs to read files in different formats.

The following examples are based on the examples described in “Using a local file as input for your message flow” on page 975 and “Reading a file on a remote FTP or SFTP directory” on page 980. In each case, the input file to use, the property settings, and the expected results are described.

The examples, which describe using the FileInput node, can be applied to the FTEInput node, with the following provisos:

- The FTEInput node has no Basic tab.
- FTP and SFTP are not used to transmit files to an FTEInput node.

The examples can also be applied to the FileRead node, with the following provisos:

- The FileRead node propagates only one record from the file and, by default, this record is the first record in the file. The FileRead node can be configured to propagate a specific record. For more information see “Routing or enriching a message based on the contents of a file” on page 976.
- FTP and SFTP are not used to transmit files to an FileRead node.

Example 1. Records are separated by a DOS or UNIX line end

This example is identical to the one described in "Using a local file as input for your message flow" on page 975 or "Reading a file on a remote FTP or SFTP directory" on page 980. Create an input file called `test_input1.xml` with the following content:

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

Each line ends with a line terminator.

The properties to set are:

Tab	Property	Value
Records and Elements	Record detection	Delimited
	Delimiter	DOS or UNIX Line End
	Delimiter type	Postfix

The FileInput node detects records that end with a DOS or UNIX line end and creates a message for each one that it finds.

The result is the propagation of three messages, as follows:

- Message 1:

  ```
  <Message>test1</Message>
  ```

- Message 2:

  ```
  <Message>testtwo</Message>
  ```

- Message 3:

  ```
  <Message>testthree</Message>
  ```

The DOS or UNIX line end is not part of any propagated message.

Example 2. Records are separated by a custom delimiter

Create an input file called `test_input2.xml` with the following content:

```
<Message>test01</Message>,<Message>test001</Message>,<Message>test0001</Message>
```

There must be no line terminator at the end of this file data; the XMLNSC parser ignores the line terminator if it is present.

In addition to the property settings described in "Using a local file as input for your message flow" on page 975 or "Reading a file on a remote FTP or SFTP directory" on page 980, set these properties:

Tab	Property	Value
Basic	File name or pattern	test_input2.xml
Records and Elements	Record detection	Delimited
	Delimiter	Custom Delimiter
	Custom delimiter	2C
	Delimiter type	Infix

The hexadecimal X'2C' represents a comma in ASCII. On other systems, you must use a different hexadecimal code.

The FileInput node detects the comma character and uses it to separate records. Because the value of the `Delimiter type` property is `Infix`, a comma is not required at the end of the file.

The result is the propagation of three messages, as follows:

- Message 1:

```
<Message>test01</Message>
```

- Message 2:

```
<Message>test001</Message>
```

- Message 3:

```
<Message>test0001</Message>
```

The comma character is not part of any propagated message. There are no commas in the bodies of the message in this example; if the message bodies did contain commas, the records would be split at those points resulting in incorrectly formed messages being propagated to the rest of the flow.

Example 3. Records are separated by a fixed number of bytes

Create an input file called `test_input3.xml` with the following content:

```
<Message>123456789</Message><Message>abcdefghi</Message><Message>rstuvwxyz</Message>
```

There must be no line terminator at the end of this file.

In addition to the property settings described in "Using a local file as input for your message flow" on page 975 or "Reading a file on a remote FTP or SFTP directory" on page 980, set these properties:

Tab	Property	Value
Basic	`File name or pattern`	`test_input3.xml`
Records and Elements	`Record detection`	`Fixed Length`
	`Length`	28

The FileInput node splits the input file into records each 28 bytes long.

The result is the propagation of three messages, as follows:

- Message 1:

```
<Message>123456789</Message>
```

- Message 2:

```
<Message>abcdefghi</Message>
```

- Message 3:

```
<Message>rstuvwxyz</Message>
```

Each message is 28 bytes long. If the file contains trailing bytes, for example a carriage return-line feed pair, a further message containing these bytes is propagated; the trailing bytes might or might not be recognized by the message domain, message model, and message type assigned to parse the message.

Example 4. Records are whole files

Create an input file called `test_input4.xml` with the following content:

```
<Message>Text string of a length decided by you, even including line
```

```
terminators, as long as it only contains this tag at the end.</Message>
```

There must be no line terminator at the end of this file; if there is one, it has no effect.

In addition to the property settings described in "Using a local file as input for your message flow" on page 975 or "Reading a file on a remote FTP or SFTP directory" on page 980, set these properties:

Tab	Property	Value
Basic	`File name or pattern`	`test_input4.xml`
Records and Elements	`Record detection`	`Whole File`

The FileInput node does not split the file; it propagates all of the content of the file as a single record to be parsed by the message domain, message model, and message type as specified on the node. In this example, you are using the XMLNSC parser and message set `xml1`, so the message is recognized.

The result is the propagation of one message, as follows:

- Message 1:

```
<Message>Text string of a length decided by you, even including line terminators, as long as
it only contains this tag at the end.</Message>
```

Trailing bytes (for example, line terminators) are included.

Example 5. Records are recognized as separate messages by the parser specified in the `Message domain` property

Create an input file called `test_input5.xml` with the following content:

```
<Message>Text string of a length decided by you  </Message><Message>and another</Message>
<Message>and another on a new line</Message>
```

Line terminators at the end of this file, or at the end of lines, are acceptable.

In addition to the property settings described in "Using a local file as input for your message flow" on page 975 or "Reading a file on a remote FTP or SFTP directory" on page 980, set these properties:

Table 24.

Tab	Property	Value
Basic	`File name or pattern`	`test_input5.xml`
Records and Elements	`Record detection`	`Parsed Record Sequence`

The FileInput node defers to the parser to determine the record boundaries. In this example, message set `xml1` in domain XMLNSC must recognize the complete `<Message>` XML format. XMLNSC absorbs trailing white space (for example, line terminators).

The result is the propagation of three messages, as follows:

- Message 1:

```
<Message>Text string of a length decided by you  </Message>
```

- Message 2:

```
<Message>and another</Message>
```

- Message 3:

```
<Message>and another on a new line</Message>
```

Trailing white space (for example, line terminators) are included in the messages.

Writing a file

Use the FileOutput, CDOutput, and FTEOutput nodes to write files.

About this task

This section contains the following topics:

Writing a file to your local file system

Use a FileOutput node to write a file to a specified directory on your local file system.

Before you begin

This example shows you how one combination of values in the `Record definition`, `Delimiter`, and `Delimiter type` properties result in the creation of a file from multiple messages. The example describes the FileOutput node of a message flow and assumes that the rest of the flow has been developed. It is also assumed that a Windows system is being used. To complete this example task, you must first have added a FileOutput node to a message flow. You must also ensure that the following messages are produced by the flow preceding the FileOutput node:

- Three input messages, which are sent, in this order, to the In terminal of the FileOutput node:
  - Message 1:

    ```
    <Message>test1</Message>
    ```

  - Message 2:

    ```
    <Message>testtwo</Message>
    ```

  - Message 3:

    ```
    <Message>testthree</Message>
    ```

  These messages can be produced, for example, by the XMLNSC domain with a message set which recognizes XML with the following form:

  ```
  <Message>...</Message>
  ```

- A final message, which is sent to the Finish File terminal of the FileOutput node after the first three messages have been sent:

  ```
  <thiscanbe>anything</thiscanbe>
  ```

Complete the following steps:

Procedure

1. Set the required node properties on the FileOutput node.

   The following table summarizes the FileOutput node properties that you must set, on which tab they appear, and the value that you must set in order to follow this example:

Tab	Property	Value
Basic	`Directory`	`C:\FileOutput\TestDir`
	`File name or pattern`	`test_output1.xml`

Tab	Property	Value
	Mode for writing to file	Stage in transit directory and move to output directory on Finish File
	Action if file exists	Time Stamp, Archive and Replace Existing File
	Replace duplicate archive files	Selected
Records and Elements	Record definition	Record is Delimited Data
	Delimiter	Broker System Line End
	Delimiter type	Postfix
FTP	FTP	Cleared

2. Deploy the message flow to the integration node. See Chapter 7, “Deploying integration solutions,” on page 2463.
3. Send the first three messages to the In terminal of the FileOutput node.
4. Send the final message to the Finish File terminal of the FileOutput node.

Results

The following actions occur when you perform these steps:

1. The file is processed. In accordance with the values set in the properties of the FileOutput node, the node generates one record per message with a local file system line terminator after each one. The file contains the following data, each line terminated by a carriage return (X'0D') and line feed (X'0A') pair of characters (on a Windows system):

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

2. Records are accumulated in file `test_output1.xml` in the `C:\FileOutput\TestDir\mqsitransit` directory. When the final message is sent to the Finish File terminal, the file is moved to the output directory, `C:\FileOutput\TestDir` directory.
3. If a file of the same name exists in the output directory, the existing file is renamed and moved to the `mqsiarchive` directory. For example, the following file might be created:

   `C:\FileOutput\TestDir\mqsiarchive\20081124_155346_312030_test_output1.xml`

   If a file of this name exists in this archive directory, it is overwritten in accordance with the `Replace duplicate archive files` property selected on the FileOutput node.

What to do next

See “Setting the Record definition property for the FileOutput and FTEOutput nodes” on page 996 to see the results of running this task with different values set in the `Record definition`, `Delimiter`, and `Delimiter type` properties of the FileOutput node.

You can use the append mode of the FileOutput node to append to a file.

- Appending directly:

  An example is when an application uses the content of the file continually and any changes are seen as they occur. It might be that as soon as the records are seen the application loads the records into a database or a product catalog.

- Staging before appending:

  An example is when an application uses the content of the file during the day, but the application does not want any updates that occur during the day to be seen. IBM App Connect Enterprise batches the new record up in its transit directory and then, at a given time of the day (possibly outside normal working hours) the integration node appends to the file.

If a remote file exists, you can use the append mode of the FileOutput node to append to or replace an existing file. Data is either added to the end of the remote file or, if the file does not exist, the file is created.

Writing a file to a remote FTP or SFTP server
Use a FileOutput node to write a file to a directory on a remote FTP or SFTP server.

Before you begin

This example shows you how one combination of values in the `Record definition`, `Delimiter`, and `Delimiter type` properties result in the creation of a file from multiple messages. The example is an extension of the example described in "Writing a file to your local file system" on page 989, and describes the use of a FileOutput node in a message flow.

These instructions assume that you are using a Windows system, and that you have already created a message flow containing a FileOutput node. You also require the following resources:

- An FTP or SFTP server. Ensure that an FTP or SFTP server exists with the following settings, so that you can follow this example scenario:

  Server
  ftpserver.hursley.abc.com

  Port
  21 (for FTP) or *22* (for SFTP)

  Working directory
  /ftpfileoutput

  User ID
  myuserid

  Password
  mypassword

  These values are for the purposes of this example only. If you use other values, record them so that you can set the appropriate values when you follow the instructions in this task.

- A security identity. Use the **mqsisetdbparms** command to define a security identity called *myidentity* for your user and password details.

  If you want to connect to an FTP server, the security identity must have an `ftp::` prefix, to enable the file nodes to find the identity definition. For example:

  ```
  mqsisetdbparms -w workDir -n ftp::myidentity -u myuserid -p mypassword
  ```

  If you want to connect to an SFTP server, the security identity must have an `sftp::` prefix, as shown in the following example:

  ```
  mqsisetdbparms -w workDir -n sftp::myidentity -u myuserid -p mypassword
  ```

  You can also configure a connection to an SFTP server to use Public Key authentication, by specifying an SSH identity file and pass phrase, instead of a password. For example:

  ```
  mqsisetdbparms -w workDir -n sftp::myidentity -u myuserid -i identity_file -r passphrase
  ```

  To check what security credentials are already set, use the **mqsireportdbparms** command; see "Checking the password for a resource that is used by an integration server" on page 2630.

  For more information about configuring connections to an SFTP server, see "Transferring files securely by using SFTP" on page 998.
- The following messages, which must be produced by the message flow preceding the FileOutput node:
  - Three input messages. These messages are sent, in this order, to the In terminal of the FileOutput node:
    - Message 1:

      ```
      <Message>test1</Message>
      ```

    - Message 2:

      ```
      <Message>testtwo</Message>
      ```

    - Message 3:

      ```
      <Message>testthree</Message>
      ```

    These messages can be produced, for example, by the XMLNSC domain with a message set that recognizes XML, in the following form:

    ```
    <Message>...</Message>
    ```

  - A final message sent to the Finish File terminal of the FileOutput node after the first three messages have been sent:

    ```
    <thiscanbe>anything</thiscanbe>
    ```

Complete the following steps:

Procedure

1. Set the required node properties on the FileOutput node.

   The following table summarizes the FileOutput node properties that you must set, the tabs on which they are displayed, and the values that are used in this example:

Tab	Property	Value
Basic	`Directory`	`C:\FileOutput\TestDir`
	`File name or pattern`	`test_output1.xml`

Tab	Property	Value
	Mode for writing to file	Stage in transit directory and move to output directory on Finish File
	Action if file exists	Time Stamp, Archive and Replace Existing File
	Replace duplicate archive files	Selected
Records and Elements	Record definition	Record is Delimited Data
	Delimiter	Broker System Line End
	Delimiter type	Postfix
FTP	Remote transfer	Selected
	Transfer protocol	FTP or SFTP
	Remote server and port	ftpserver.hursley.abc.com
	Security identity	myidentity
	Server directory	/ftpfileoutput
	Transfer mode	ASCII (for FTP only)
	Action if remote file exists	Replace Existing File or Append to Existing File
	Retain local file after transfer	Selected

If you used other values for your FTP or SFTP server resource, use those values. The settings used here are identical to those settings used in the example in "Writing a file to your local file system" on page 989 except that the Remote transfer property has been selected and there are now properties on the **FTP** tab. If you clear the Remote transfer property, the node operates as it does in the example in "Writing a file to your local file system" on page 989; the properties on the **FTP** tab remain set but are ignored.

You can override the Remote server and port property on the node by setting a value in the local environment. For more information, see Local environment overrides for the remote server on the node.

2. Deploy the message flow to the integration server. See Chapter 7, "Deploying integration solutions," on page 2463.
3. Send the first three messages to the In terminal of the FileOutput node.
4. Send the final message to the Finish File terminal of the FileOutput node.
5. If the remote file exists, the mode for writing to remote file is used to specify if the file transferred replaces an existing file or appends data to the existing file. The transfer happens on the Finish File action. To support the use of Append you might have to update your FTP server configuration.

Results

The following actions occur when you perform these steps:

1. The file is processed. The FileOutput node generates one record per message with a local file system line terminator after each one. The file contains the following data, with each line terminated by a carriage return (X'0D') and line feed (X'0A') pair of characters (on a Windows system):

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

2. Records are accumulated in file `test_output1.xml` in the `C:\FileOutput\TestDir\mqsitransit` directory. When the final message is sent to the Finish File terminal, the file is moved to the remote FTP or SFTP server directory (because the `Remote transfer` property is selected). As a result, the file `/ftpfileoutput/test_output1.xml` is created.
3. If a file with the same name exists in the remote FTP or SFTP server directory, the existing file is overwritten.

   If the remote FTP server is not running on a Windows system and the `Transfer mode` property is set to `ASCII`, the character encoding and line terminator characters might be modified after transfer. For example, on a z/OS FTP server, the ASCII text is typically converted to EBCDIC, and the line terminator character pairs are replaced by EBCDIC new line characters (X'15'). Other FTP servers might treat ASCII transfers differently. If you are using SFTP, the `Transfer mode` property is ignored and files are sent as Binary files.
4. Because the `Retain local file after transfer` property is selected, the local file is not deleted but is moved from the `mqsitransit` subdirectory to the output directory, `C:\FileOutput\TestDir`. If a file with the same name exists in the output directory, the existing file is renamed and moved to the `mqsiarchive` directory. For example, the following file might be created:

   `C:\FileOutput\TestDir\mqsiarchive\20081124_155346_312030_test_output1.xml`

   However, if a file with this name exists in this archive directory, it is overwritten according to the value of the `Replace duplicate archive files` property set on the FileOutput node.

What to do next

For more information, see "Setting the Record definition property for the FileOutput and FTEOutput nodes" on page 996, which shows the results of running this task with different values set in the `Record definition`, `Delimiter`, and `Delimiter type` properties of the FileOutput node.

Sending a file by IBM MQ File Transfer Edition

Send files to an existing IBM MQ File Transfer Edition network.

Before you begin

1. Read about IBM MQ File Transfer Edition.
2. Get the following information from your IBM MQ File Transfer Edition administrator:
   - The name of the remote IBM MQ File Transfer Edition agent to which the file is to be sent.
   - The name of the destination queue manager.
   - The name of the output file.
3. Ensure that IBM MQ is installed on the same machine as IBM App Connect Enterprise. Information about file transfers is held on storage queues that are controlled by IBM MQ, so you must install IBM MQ on the same computer as IBM App Connect Enterprise if you want to use the capabilities that are provided by the FTEOutput node.
4. Ensure that a queue manager has been specified to own the system queues that store information about the file transfer.
5. Create the system queues that will store the file transfer information. For more information about creating the system queues, see "Creating the default system queues on an IBM MQ queue manager" on page 99.
6. Create a message flow that contains an input node.

About this task

Detailed information about configuring the FTEOutput node is given on the property panels for the node, in the IBM App Connect Enterprise Toolkit.

Procedure

1. Drag an FTEOutput node onto the message flow, and wire its In terminal to the input node.
2. On the **Basic** panel, set values for the `Destination agent` and `Destination file name` properties.

   Configuring just these two properties is enough if you want to send all the input message tree as a single record in the output file.
3. Optional: On the **Basic** panel, set a value for the `Destination queue manager` property.
4. Optional: To specify a location in the input message tree for the data to be sent, configure the `Data location` property on the **"Request properties"** panel.
5. Optional: To change how records are placed in the output file, configure the `Record definition` property on the **"Record definition"** panel.

   For example, you might want to specify that a record is fixed length, and set the record length.

   a) If you set the `Record definition` property to anything other than `Record is Whole File`, drag a node such as the MQOutput node to the flow, and wire its Out terminal to the Finish File terminal on the FTEOutput node, as shown in the following figure:

   The node connected to the Finish File terminal must have logic to determine the last record in the file.
6. Optional: To set properties for the transfer dynamically, place a node such as the Compute node or Mapping node before the FTEOutput node.

   You can override the following properties:

   - `Destination agent`
   - `Destination file directory`
   - `Destination file name`
   - `Destination queue manager`
   - `Job name`
   - `Overwrite files on destination`

   Configure the node to write the overrides to the `LocalEnvironment.Destination.FTE` subtree.
7. Add the flow to a BAR file and deploy the BAR file.

Setting the `Record definition` property for the FileOutput and FTEOutput nodes
Set the properties on the**Records and Elements** tab of the node to write files in different formats.

The following examples are based on those described in "Writing a file to your local file system" on page 989 and "Writing a file to a remote FTP or SFTP server" on page 991. The FTEOutput does not archive, and files are transferred using IBM MQ File Transfer Edition, rather than FTP or SFTP. In all examples, it is assumed that the same messages are sent to the FileOutput node; three to the In terminal and one to the Finish File terminal:

- Three input messages which are sent, in this order, to the In terminal of the FileOutput node:
  - Message 1:

    ```
    <Message>test1</Message>
    ```

  - Message 2:

    ```
    <Message>testtwo</Message>
    ```

  - Message 3:

    ```
    <Message>testthree</Message>
    ```

  These messages can be produced, for example, by the XMLNSC domain with a message set which recognizes XML with the following form:

  ```
  <Message>...</Message>
  ```

- A final message which is sent to the Finish File terminal of the FileOutput node after the first three messages have been sent. It does not matter what this message contains.

The following examples describe the contents of the file or files produced; the disposition of the files created is as in the "Writing a file to your local file system" on page 989 and "Writing a file to a remote FTP or SFTP server" on page 991 topics.

Example 1. Records written are separated by a DOS or UNIX line end

This example is identical to the one described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991. Specify the node's properties as described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991.

These properties result in one file being written. The file contains three records each terminated by a local system line terminator. On a Windows system, this is a carriage return (X'0D') line feed (X'0A') pair of characters; on UNIX systems it is X'0A'.

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

Example 2. Records written are separated by a custom delimiter

In addition to the property settings described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991, set these properties on the **Records and Elements** tab:

Property	**Value**
`Record definition`	`Record is Delimited Data`
`Delimiter`	`Custom Delimiter`
`Custom delimiter`	`0D0A`

Property	Value
Delimiter type	Postfix

The hexadecimal X'0D0A' represents a carriage return character followed by a line feed character. On a Windows system, this results in a file identical to the one created in Example 1. On other systems, the result might differ from the result in Example 1; Example 1 uses local system line end characters, whereas Example 2 always puts the X'0D0A' sequence at the end of each line.

Example 3. Records written are padded to a fixed length

In addition to the property settings described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991, set these properties on the **Records and Elements** tab:

Property	Value
Record definition	Record is Fixed Length Data
Length (bytes)	30
Padding bytes (hexadecimal)	2A

The hexadecimal character X'2A' represents an asterisk character in ASCII.

The length of each incoming message is 24 bytes, 26 bytes, and 28 bytes respectively. The required fixed length of each record is 30 bytes. Each record is therefore padded by an extra 6 bytes, 4 bytes, and 2 bytes respectively, using the hexadecimal character X'2A'.

One file is written. It contains a single line:

```
<Message>test1</Message>******<Message>testtwo</Message>****<Message>testthree</Message>**
```

Example 4. Records written are not separated by delimiters or padding

In addition to the property settings described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991, set this property on the **Records and Elements** tab:

Property	Value
Record definition	Record is Unmodified Data

The records are concatenated with no padding or delimiters.

One file is written with the following content:

```
<Message>test1</Message><Message>testtwo</Message><Message>testthree</Message>
```

There are no trailing bytes or line terminators.

Example 5. Records are written as whole files

In addition to the property settings described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991, set this property on the **Records and Elements** tab:

Property	Value
Record definition	Record is Whole File

Three files are created, each containing one record:

- File 1:

```
<Message>test1</Message>
```

- File 2:

```
<Message>testtwo</Message>
```

- File 3:

```
<Message>testthree</Message>
```

Each of these files is created with the same name, one by one, in the mqsitransit directory. If you are following the example in "Writing a file to a remote FTP or SFTP server" on page 991, each file is transferred to the remote FTP server. However, because each file overwrites the previous one, only the third file remains when the task is complete.

After optional transfer, if a copy is retained, each file is moved to the output directory, `C:\FileOutput\TestDir`. In accordance with the properties on the FileOutput node as described in "Writing a file to your local file system" on page 989 or "Writing a file to a remote FTP or SFTP server" on page 991, the second file moved displaces the first file from the output directory which is moved to the mqsiarchive subdirectory with a time stamp added to the file name. When the third file is moved to the output directory, it displaces the second file, causing it to be moved to the mqsiarchive subdirectory and renamed. The final result is files similar to these:

```
C:\FileOutput\TestDir\mqsiarchive\20071101_165346_312030_test_output1.xml
C:\FileOutput\TestDir\mqsiarchive\20071101_165347_312030_test_output1.xml
C:\FileOutput\TestDir\test_output1.xml
```

being File 1, File 2, and File 3 respectively. If FTP processing was enabled, File 3 would also be in the remote FTP server directory and called `test_output1.xml`.

Transferring files securely by using SFTP

You can transfer files securely by using the Secure File Transfer Protocol (SFTP), which enables file transfer by using the Secure Shell (SSH) protocol.

Use the properties on the FTP tab of the FileInput and FileOutput nodes to configure the secure transfer of files.

You can also use the FTP Server policy to configure other SFTP properties, including the cipher to be used for SFTP communication, compression level, and strict known host checking (see FTP Server policy (FtpServer)).

See the following topics for more information about configuring secure file transfer:

- "Configuring SFTP file transfer" on page 998
- "Known host checking" on page 999

Configuring SFTP file transfer

Use an FTP Server policy to specify the Secure File Transfer Protocol (SFTP) settings for a message flow, and to override the SFTP settings that are specified on the FileInput and FileOutput nodes.

About this task

The settings that you specify by using an FTP Server policy are read and validated when the message flow starts, and are used to configure any SFTP connections that are made for the node. The policy can override any or all of the remote transfer properties on the **FTP** tab of the FileInput and FileOutput nodes. For more information about the settings that you can specify with an FTP Server policy, see FTP Server policy (FtpServer).

You can configure strict host key checking and specify your own known hosts file, or you can turn off strict host key checking and use the known hosts files that are created and managed by the integration node.

Multiple policies can specify the same host and port, even with different known hosts files. FTP defaults to port 21 and SFTP defaults to port 22, which is the SSH default port. If you set the port and specify an FTP connection to an SFTP server (or specify an SFTP connection to an FTP server) a connection error occurs and a message is added to the event log.

You can use the FTP Server policy to configure the following SFTP settings:

- Cipher used for SSH/SFTP communication
- Compression level
- Strict known host checking
- Protocol (FTP/SFTP) for nodes to use for remote file transfer
- Location of a known hosts file when strict known host checking is set to **Yes**

Procedure

1. Create an FTP Server policy with the required parameter values by using the Policy editor (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. In the FileInput and FileOutput nodes, specify the name of the FTP Server policy in the **Remote server and port** property on the **FTP** tab.

Known host checking
Use known host checking to control which hosts the integration node can connect to, and to verify the identity of those hosts.

Known host checking enables the integration node to protect the messages in the message flow from unauthorized attempts to intercept the data (sometimes known as *man-in-the-middle attacks*). Known hosts files contain the SSH keys of the hosts to which the integration node can connect. On z/OS systems, known hosts files and SSH identity files are stored in EBCDIC format, and on other operating systems they are stored in ASCII format.

Before it connects to a host to receive or transfer a file (using the FileInput or FileOutput nodes), the integration node checks the host key against the keys that are stored in the known hosts file. If the host key does not match an existing entry for the host in the known hosts file, the connection fails. If the host is new (and has no entry in the known hosts file), the result depends on whether strict known host checking is turned on or off.

You can specify whether strict known host checking is turned on or off by setting the **Strict host key checking** property of the FTP Server policy (see FTP Server policy (FtpServer)).

Strict known host checking

When strict known host checking is turned on (by setting the **Strict host key checking** property to Yes), the integration server connects only to known hosts with valid SSH host keys that are stored in the known hosts file. If you use strict known host checking, you must create your own known hosts file, in OpenSSL PEM format, containing the SSH keys of your trusted hosts. When the integration server attempts to make a connection to a host, it checks the host key against the contents of the known hosts file. If the key is not in the known hosts file, the connection fails and a BIP3371 error occurs.

You can have multiple known hosts files and specify a different one for each policy. The known hosts files that you provide for strict known host checking are not modified by the integration server.

Non-strict known host checking

When strict known host checking is turned off (by setting the **Strict host key checking** property to No) the integration server connects only to known hosts with valid keys or to new hosts to which it has not connected before. If the integration server attempts to connect to a new host (to which it has not connected previously), the integration server makes the connection, accepts the host's SSH key, and stores it in the known hosts file. When the integration server tries to connect to the same host on subsequent occasions, the host key is checked against the key stored in the known hosts file, and, if the

key matches, the connection is made. However, if the host key is different from the one stored in the known hosts file, the connection attempt fails and a BIP3371 error occurs.

When strict known host checking is turned off, the known hosts file is managed by the integration server. One known hosts file exists for each integration server.

BIP3371 error message

The BIP3371 error message might indicate that there has been an unauthorized attempt to intercept a message. However, the connection failure (and resulting BIP3371 error message) might be caused by a change to the host's SSH key at some time following its first connection to the integration server. For example, if the SSH server is reinstalled, it is assigned a new key, which is not found in the known hosts file and is therefore not accepted by the integration server. As a result, the connection fails and the BIP3371 error message is shown.

If you know that the SSH host key has changed (as a result of a recent SSH server reinstallation, for example), you can solve the connection failure by modifying the known hosts file:

1. Stop the message flow.
2. Edit the known hosts file.

   If you have strict known host checking turned off, remove the host's entry from the known hosts file that is managed by the integration server. The known hosts file is in the `\components\`*`BROKERNAME-NAME`*`\`*`EG-UID`*`\config\known_hosts` subdirectory of the directory in which IBM App Connect Enterprise is installed. For example, on Windows the default directory is `C:\ProgramData\IBM\MQSI\components\`*`BROKERNAME-NAME`*`\`*`EG-UID`*`\config\known_hosts`. On UNIX systems the default directory is `/var/mqsi/components/`*`BROKERNAME-NAME`*`/`*`EG-UID`*`/config/known_hosts`.

   When the integration server attempts to reconnect, it adds the new host key to the known hosts file.
3. Restart the message flow.

Managed file transfers using WebSphere MQ File Transfer Edition

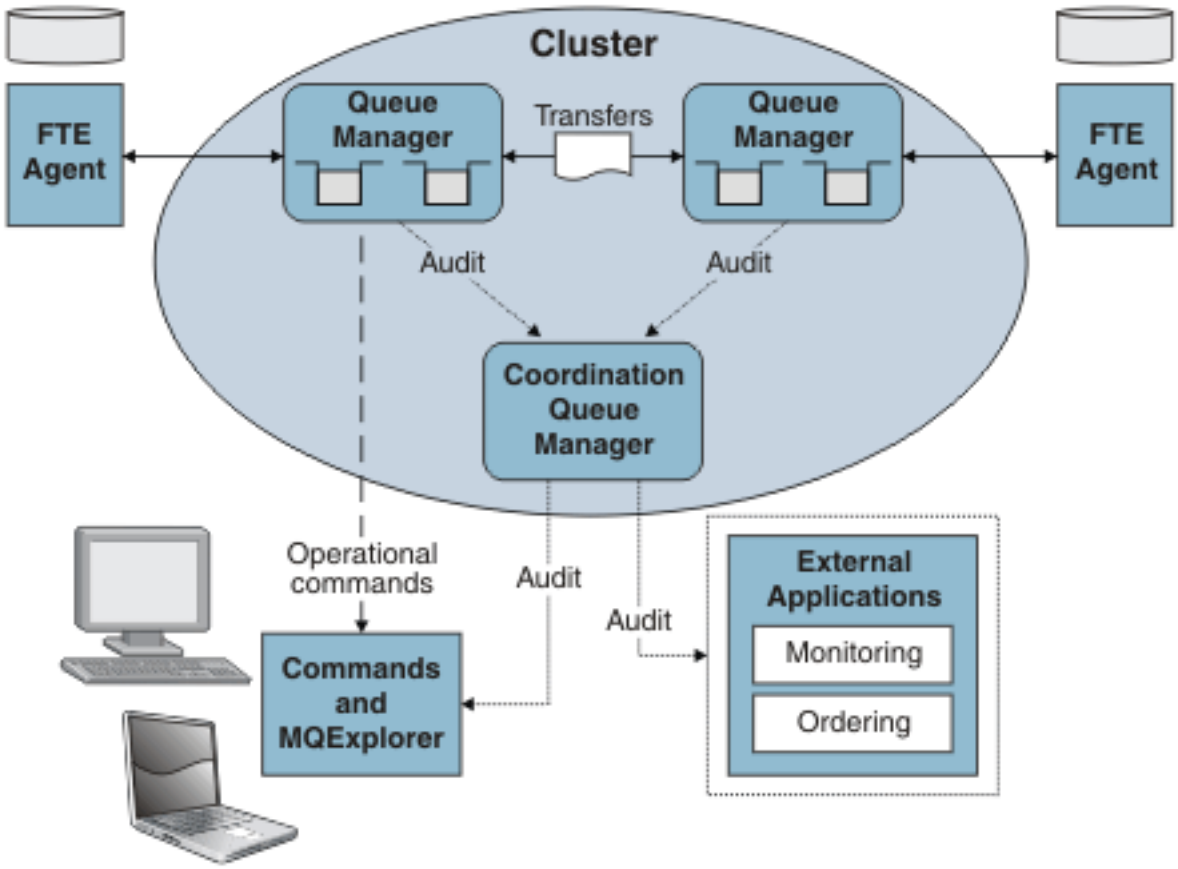
Transfer files, with file transfer metadata, in a timely and reliable manner.

- Transfer metadata is supported, providing more flexible file processing.
- Transfers are timely.
- Resource statistics are available.

About IBM MQ File Transfer Edition

WebSphere MQ File Transfer Edition V7.0 delivers a reliable managed file transfer solution for moving files between IT systems without the need for programming. Files that are larger than the maximum individual WebSphere MQ message size can be moved. A log of file movements demonstrates that business data in files is transferred with integrity from source file system to destination file system.

Using the WebSphere MQ File Transfer Edition nodes offers seamless integration with your existing IBM MQ File Transfer Edition network. The following diagram shows a typical IBM MQ File Transfer Edition network:



The main components and concepts of IBM MQ File Transfer Edition are:

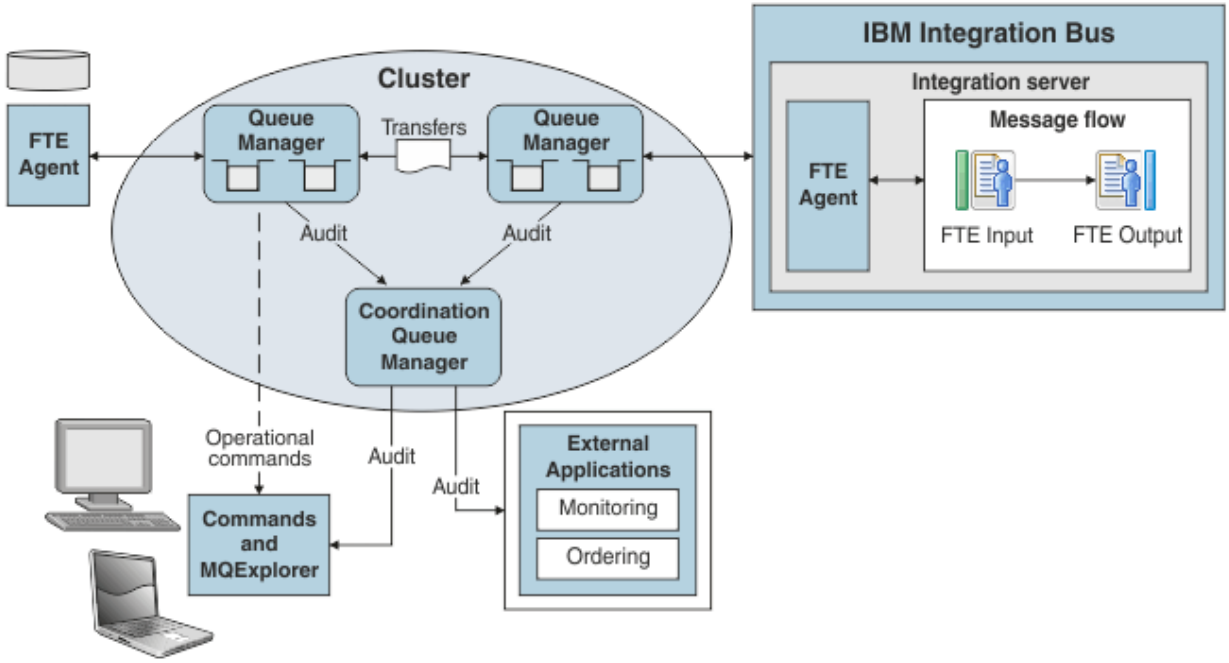
agent
A process that forms the end point of a transfer (source or destination). An agent is an IBM MQ application, and is connected to one queue manager. Many agents can be connected to the same queue manager. Operational commands can be sent to an agent (for example, to request a transfer) by putting an XML message on a particular queue on the agent's queue manager.

coordination queue manager
One queue manager in the topology takes on the responsibility of the coordination queue manager. All agents register with the coordination queue manager and also send audit information about each transfer. The coordination queue manager is responsible for publishing that audit information to external monitoring applications.

transfer
A transfer is a movement of one or more files from one agent to another. The transfer goes direct from one agent's queue manager to the other agent's queue manager, not via the coordination queue manager. The transfer takes place even if the coordination queue manager is not running.

transfer log
The IBM MQ Explorer plug-in tool includes a Transfer Log view that subscribes to the coordination queue manager for the audit information. The view displays information about every transfer that occurs in a given topology.

How IBM App Connect Enterprise fits in



agent

An agent runs in each integration server that has deployed flows containing WebSphere MQ File Transfer Edition nodes. The agent is responsible for receiving and initiating all IBM MQ File Transfer Edition transfers.

You do not need to start or stop this agent; if a flow that contains WebSphere MQ File Transfer Edition nodes is deployed, the agent is running. The agent is stopped only when the integration server is stopped.

transfer

Multiple FTEOutput nodes can be deployed to the same integration server. FTEOutput nodes can send one file per transfer. Each file can have multiple records. Each record can have multiple elements. Transfers from the FTEOutput are non-blocking; an error occurs if another transfer is outstanding with the same file name.

Multiple FTEInput nodes can be deployed to the same integration server. Multiple FTEInput nodes can read files transferred to the same directory without contention. Each file is processed only once, even if the nodes are deployed to separate integration servers.

When sending a file, you can dynamically set the following properties:

- `Destination agent`
- `Destination file directory`
- `Destination file name`
- `Destination queue manager`
- `Job name`
- `Overwrite files on destination`

Put a node such as the Compute node or Mapping node before the FTEOutput node.

When receiving files, you can apply filters. If an integration server has more than one FTEInput node, each node receives only the appropriate files. You can also determine what happens after the file has been processed (the file is left in its existing destination directory, left with a timestamp added, or deleted). See the Basic tab on the node for details.

You can combine the FTEInput and FTEOutput nodes to create a request and reply flow. See the sample for details.

Using elements in the local environment, you can call a program on the destination agent before starting the transfer, or when the transfer is finished. See "LocalEnvironment.Destination.FTE fields" on page 968 for details.

Overview of using WebSphere MQ File Transfer Edition nodes

You do not need to configure the IBM MQ File Transfer Edition code that runs in IBM App Connect Enterprise.The following nodes are provided:

FTEOutput
FTEInput

Take the following steps to use the nodes to send or receive data across an existing IBM MQ File Transfer Edition network:

1. Ensure that IBM MQ is installed on the same machine as IBM App Connect Enterprise. Information about file transfers is held on storage queues that are controlled by IBM MQ, so you must install IBM MQ on the same computer as IBM App Connect Enterprise if you want to use the capabilities that are provided by the FTEInput and FTEOutput nodes.
2. Ensure that a queue manager has been specified to own the system queues that store information about the file transfer.
3. Create the system queues that will store the file transfer information. For more information about creating the system queues, see "Creating the default system queues on an IBM MQ queue manager" on page 99.
4. Create a flow that includes one of the IBM MQ File Transfer Edition nodes.
5. Configure the node.
6. Deploy the flow.

Monitoring the license usage of WebSphere MQ File Transfer Edition in IBM App Connect Enterprise

A message is written to the system log for every integration server that has a IBM MQ File Transfer Edition node deployed.

Initiating a managed file transfer using IBM Sterling Connect:Direct

Use a CDOutput node to send a file from a specified directory on your primary Connect:Direct server (PNODE) to a filename and directory on a secondary Connect:Direct server (SNODE).

Before you begin

1. Ensure that IBM MQ is installed on the same machine as IBM App Connect Enterprise. Information about file transfers is held on storage queues that are controlled by IBM MQ, so you must install IBM MQ on the same computer as IBM App Connect Enterprise if you want to use the capabilities that are provided by the CDOutput node.
2. Ensure that a queue manager has been specified to own the system queues that store information about the file transfer.
3. Create the system queues that will store the file transfer information. For more information about creating the system queues, see "Creating the default system queues on an IBM MQ queue manager" on page 99.
4. Create a message flow containing a CDOutput node; for example, create a simple flow containing an MQInput connected to a CDOutput node.

About this task

Multiple CDOutput nodes can be deployed to the same integration server. CDOutput nodes can send one file per transfer. Each file can have multiple records; each record can have multiple elements. Transfers from the CDOutput node are non-blocking.

Procedure

1. Set the required node properties on the CDOutput node.

   If you set the `Destination file name` only, and leave all the other options at their default values, the file is transferred:

   - From the primary Connect:Direct server (PNODE) back to itself
   - Into the default transfer directory using the default process name.

   Additionally, the file is created if it does not exist, or replaced if it already exists.

   The following table summarizes the CDOutput node properties that you can set, on which tab they appear, and a value that you can select:

Tab	Property	Value
Basic	`Process name`	You can use any name you want for the process. Note, however, that the name must be a maximum of eight characters and cannot contain any spaces.
	`SNODE`	`The secondary` Connect:Direct server to which the file is being transferred.
	`Destination file directory`	`TestDir` on secondary Connect:Direct server (SNODE).
	`Destination file name`	`Filename` on secondary Connect:Direct server (SNODE).
	`Disposition`	`RPL`
	`Transfer mode`	`Text mode`

2. Setup the *username* and *password* that is required for the CDOutput node to connect to the primary Connect:Direct server using the command.
3. Deploy the message flow (see Chapter 7, “Deploying integration solutions,” on page 2463).
4. Send the file to the In terminal of the CDOutput node.

Results

The following actions occur when you perform these steps:

1. The file is constructed in accordance with the values set in the properties of the CDOutput node.
2. The file is staged in the local file system and then a command is sent to the Connect:Direct server to cause the transfer to occur.
3. If a file of the same name exists in the selected directory on the secondary Connect:Direct server, the processing of the existing file is determined by the value of the *Disposition* property; in this example, the file is replaced.

   Once the transfer has completed the local, staged file is deleted.

Note, that when sending a file, you can dynamically set the following properties:

- `Secondary Connect:Direct server (SNODE)`

- Process name
- Accounting data
- Destination file directory
- Destination file name
- Copy from options
- Copy to options

You have complete control of the Copy statements.

For example:

```
LocalEnvironment.Destination.CD.Copy.To.Option.PERMISS = '777'
```

causes IBM Sterling Connect:Direct to set the permissions on the destination file to 777 (or RWX RWX RWX) if the destination file is on a UNIX operating system, or within Unix System Services on z/OS.

However, if you enter an incorrect format, a syntax error is detected when the process script is submitted and this causes an error to be thrown in the node.

For example:

```
LocalEnvironment.Destination.CD.Copy.To.Option.PERMISS = '7xddd'
```

causes a syntax error because '7xddd' is not of the format nnn. When an error occurs the process script is available in the exception thrown and the user trace.

Tip: To help you with problem determination, you can view the script generated by the CDOutput node by turning on user trace.

WebSphere Service Registry and Repository

The WebSphere Service Registry and Repository (WSRR) is a central repository of entities. A wide range of entities can be stored and retrieved, including user-defined concepts and definitions related specifically to web services, such as WSDL services, service interfaces, and associated policies.

You can configure a message flow to dynamically retrieve resources from WSRR at run time, and to use and expose those resources in the message flow. You can therefore defer the decision about which resources you want to use until run time, rather than deciding at deployment time.

WSRR has specific support for many of the document types that are associated with web services, including generic XML documents, WSDL, and SCDL. For example, when you load a WSDL document into WSRR it also identifies and stores its individual logical components, such as the service and port type.

Use the WSRR nodes (the RegistryLookup and EndpointLookup nodes) to create message flows that retrieve data dynamically from WSRR. Data is retrieved according to search criteria defined by node properties, possibly supplemented or overridden by local environment definitions. The retrieved data is placed in the local environment tree, which makes the data available to subsequent nodes. The input message that is received by the node is propagated to the output terminal unchanged.

Use the RegistryLookup node to submit generic queries to WSRR. Entities that are returned by the query are stored in the ServiceRegistry output tree in the local environment. You can also specify that details of the relationships between the returned entities and other entities that they reference are represented in the ServiceRegistry output tree.

Use the EndpointLookup node to submit queries for web service endpoints. This node is tailored to retrieve WSDL port definitions that implement a specified WSDL portType. The details of service endpoints that match the specified criteria are placed in the ServiceRegistry output tree in the local environment. If the node is configured to return a single matching service endpoint, the web service URL destination that is used by the SOAP and HTTP request nodes is also overridden in the local environment. If the node is configured to return all matching service endpoints, the local environment is not set up automatically for the SOAP and HTTP request nodes. In this case, the local environment tree might contain data for multiple service endpoints, and the message flow interprets and uses this information.

Set the configuration parameters for the WSRR nodes to specify how IBM App Connect Enterprise interfaces with your WSRR server.

- Use the **connectionTimeout** parameter to set a system-wide connection timeout for queries that are issued by the EndpointLookup and RegistryLookup nodes. If a query result is not returned from the WSRR server before the connection timeout period expires, the configured error handling is invoked.
- Use the **needCache** parameter to enable the IBM App Connect Enterprise WSRR cache. The cache is used to store results from queries that are issued by the EndpointLookup and RegistryLookup nodes.
- If the IBM App Connect Enterprise WSRR cache is enabled, use the **timeout** parameter to set a system-wide cache timeout. The cache timeout controls how long results from queries that are stored in the cache are used before the query is reissued.

For information about the specific levels of WSRR that are supported by IBM App Connect Enterprise, see IBM App Connect Enterprise system requirements.

The following topics provide further information about working with WSRR:

Configuration parameters for the WebSphere Service Registry and Repository nodes

These parameters affect the integration node configuration when interfacing with WebSphere Service Registry and Repository (WSRR).

To set these parameters, you must edit the `WSRRConnectorProvider` entries in the `ConnectorProviders` section of the `node.conf.yaml` or `server.conf.yaml` configuration file. When you create a new integration node or a new independent integration server, the `.conf.yaml` configuration file contains the following subset of the WSRR parameters. All the other WSRR parameters have default settings which generally do not need to be changed. If you need to change any of the other WSRR parameters, you must add them to the `.conf.yaml` configuration file.

```
ConnectorProviders:
    #WSRRConnectorProvider:    # Requires the optional WSRR component install
    #endpointAddress: 'https://host:9443/WSRR8_0/services/WSRRCoreSDOPort'   # WSRR server
 endpoint url
    #needCache: true                                                        # enable WSRR cache
    #predefinedCacheQueries: ''                                             # semicolon-
separated XPath querys to initialize WSRR cache at start-up
    #enableCacheNotification: false                                         # enable WSRR cache
 notification
    #locationJNDIBinding:  'iiop://host:2809'                               # WSRR cache WAS
 JMS provider JNDI bindings url
```

The following table describes the parameters that are used in the `node.conf.yaml` or `server.conf.yaml` configuration file to configure the WebSphere Service Registry and Repository (WSRR).

Configuration Setting Name	Default value	Description
endpointAddress	For all versions of WSRR: `http://hostname:9080/WSRRCoreSDO/services/WSRRCoreSDOPort`	Endpoint of the WSRR server. Where *hostname:port* is the domain qualified hostname and port of your WSRR server. To connect to a secure WSRR, specify `https://` instead of `http://`. For more information, see "Accessing a secure WebSphere Service Registry and Repository repository" on page 1011. For more information about the specific levels of WSRR that are supported by IBM App Connect Enterprise, see IBM App Connect Enterprise system requirements.
connectionTimeout	180	The WSRR connection timeout period in seconds. The default value is 180 seconds. Set a value that is sufficiently long for complex queries to complete.

For more information about WSRR endpoint addresses, see WSRR web service interface URLs.

The following table describes the parameters for Cache that are configured by updating the `node.conf.yaml` or `server.conf.yaml` configuration file for the relevant integration node or server.

Configuration Setting Name	Default value	Description
needCache	true	Enable IBM App Connect Enterprise WSRR cache.
timeout	100000000	The timeout value for the cache. The cache expiry time in milliseconds. (The default value of 100000000 milliseconds is approximately 27.8 hours).
predefinedCacheQueries	None	A list of semicolon-separated WSRR XPath query expressions with which to initialize the IBM App Connect Enterprise WSRR cache at startup. These WSRR XPath query expressions are defined by the WSRR SOAP interface query expression language, and can include an optional depth specifier extension.

The following table describes the parameters for Cache Notification that are configured by updating the `node.conf.yaml` or `server.conf.yaml` configuration file for the relevant integration node or server.

Configuration Setting Name	Default value	Description
enableCacheNotification	false	Enable IBM App Connect Enterprise WSRR Cache Notification.
refreshQueriesAfterNotification	true	When a notification is received from WSRR, if `refreshQueriesAfterNotification` is set to `true`, the cache is updated with the new version of the object immediately; if `false`, the cache is updated on the next request.

Configuration Setting Name	Default value	Description
connectionFactoryName	jms/SRConnectionFactory	The name of the WSRR WebSphere Application Server JMS provider JMS connection factory for Cache Notification.
initialContextFactory	com.ibm.websphere.naming.WsnInitialContextFactory	The name of the WSRR WebSphere Application Server JMS provider JMS context factory for Cache Notification.
locationJNDIBinding	iiop://*hostname*:2809/	The URL to the WebSphere Application Server JMS provider JNDI bindings, where *hostname* is variable.
secureJNDIPropertiesFiles	C:\SSLPropsFiles	The directory where your sas.client.props and the ssl.client.props files are stored when using secure IIOP for WSRR cache notification.
subscriptionTopic	jms/SuccessTopic	The topic name used to receive WebSphere Application Server JMS provider Cache Notification.

For more information about accessing a secure WSRR server, see "Accessing a secure WebSphere Service Registry and Repository repository" on page 1011.

Changing the configuration parameters for the WebSphere Service Registry and Repository nodes

To change the configuration parameters for the WebSphere Service Registry and Repository nodes, edit the `.conf.yaml` configuration file for the integration node, or integration server.

About this task

Any properties that you set for an integration node in the `node.conf.yaml` file, are inherited by the integration servers that it owns. However, you can change any of the properties of an integration server that is owned by an integration node by modifying them in the appropriate `server.conf.yaml` file. You can change any of the properties of an independent integration server by modifying them in the appropriate `server.conf.yaml` file. For more information about configuring integration servers, see Configuring an integration server by modifying the server.conf.yaml file.

To set the WSRR parameters, you must edit the `WSRRConnectorProvider` entries in the `ConnectorProviders` section of the `node.conf.yaml` or `server.conf.yaml` configuration file. When you migrate your IBM Integration Bus 10.0 integration servers and integration nodes to IBM App Connect Enterprise 12.0 by using the **mqsiextractcomponents** command, the values of the DefaultWSRR configurable service properties are placed in the `ConnectorProviders` section of the `.conf.yaml` file. When you create a new integration node or a new independent integration server, the `.conf.yaml` configuration file contains the following subset of the WSRR parameters. All the other WSRR parameters have default settings, which generally do not need to be changed. If you need to change any of the other WSRR parameters, you must add them to the `.conf.yaml` configuration file.

```
ConnectorProviders:
    #WSRRConnectorProvider:    # Requires the optional WSRR component install
    #endpointAddress: 'https://host:9443/WSRR8_0/services/WSRRCoreSDOPort'   # WSRR server
 endpoint url
    #needCache: true                                                        # enable WSRR cache
    #predefinedCacheQueries: ''                                             # semicolon-
separated XPath querys to initialize WSRR cache at start-up
```

```
   #enableCacheNotification: false                                    # enable WSRR cache
notification
   #locationJNDIBinding:  'iiop://host:2809'                          # WSRR cache WAS
JMS provider JNDI bindings url
```

For more information about configuration parameters that affect WSRR use, see "Configuration parameters for the WebSphere Service Registry and Repository nodes" on page 1006.

Complete the following steps to update the configuration parameters for WSRR:

Procedure

1. Ensure that the integration node or independent integration server is running.

   For more information, see "Starting and stopping an integration node" on page 247 and "Starting an integration server" on page 250.
2. Edit the *connectionFactoryName* parameter in the `.conf.yaml` file to show the name of the WSRR WebSphere Application Server WebSphere® Application Server JMS provider JMS connection factory for Cache Notifications. The default value is `'jms/SRConnectionFactory.connectionFactoryName'`

   ```
   connectionFactoryName: 'jms/SRConnectionFactory' # The name of the WSRR Application Server
    JMS provider JMS connection factory for Cache Notifications. The default value is 'jms/
   SRConnectionFactory'.
   ```
3. Edit the *connectionTimeout* parameter in the `.conf.yaml` file to show the WSRR connection timeout period in seconds. The default value is 180 seconds (3 minutes).

   ```
   connectionTimeout: 180 # The WSRR connection timeout period in seconds. The default value is
    180 seconds (3 minutes).
   ```
4. Set the *enableCacheNotification* parameter in the `.conf.yaml` file to `true` to enable IBM App Connect Enterprise WSRR Cache Notification. The default value is false.

   ```
   enableCacheNotification: true # The default value is false. Select true to enable IBM® App
    Connect Enterprise WSRR Cache Notification.
   ```
5. Edit the *endpointAddress* parameter in the `.conf.yaml` file to show the location or endpoint of the WSRR server.

   ```
   endpointAddress: 'http://fill.in.your.host.here:9080/WSRRCoreSDO/services/WSRRCoreSDOPort'
      #The location or endpoint of the WSRR server. The default value for all versions of WSRR
    is 'http://fill.in.your.host.here:9080/WSRRCoreSDO/services/WSRRCoreSDOPort'
   ```

   The default value for all versions of WSRR is `'http://fill.in.your.host.here:9080/WSRRCoreSDO/services/WSRRCoreSDOPort'`

   For example, to connect to a server that uses WSRR v7.5 compatibility use the following values:

   ```
   'http://fill.in.your.host.here:9080/WSRR7_5/services/WSRRCoreSDOPort'
   ```

   For more information about WSRR endpoint addresses, see WSRR web service interface URLs.

   For more information about the specific levels of WSRR that are supported by IBM App Connect Enterprise, see IBM App Connect Enterprise system requirements web page.
6. Edit the *initialContextFactory* parameter in the `.conf.yaml` file to show the name of the WSRR WebSphere Application Server WebSphere® Application Server JMS provider JMS connection factory for Cache Notifications. The default value is `'com.ibm.websphere.naming.WsnIitialContextFactoryCopy'`

   ```
   initialContextFactory: 'com.ibm.websphere.naming.WsnIitialContextFactoryCopy' # The name
    of the WSRR WebSphere Application Server JMS provider JMS context factory for Cache
    Notifications.

     The default value is 'com.ibm.websphere.naming.WsnIitialContextFactoryCopy'
   ```

7. Edit the *locationJNDIBinding* parameter in the `.conf.yaml` file to show the URL to the WebSphere Application Server JMS provider JNDI bindings. The default value is `'iiop://host_name:2809/'`

```
locationJNDIBinding: 'iiop://host_name:2809/' # The URL to the WebSphere Application Server
 JMS provider JNDI bindings. The default value is 'iiop://host_name:2809/'
```

8. Edit the *secureJNDIPropertiesFiles* parameter in the `.conf.yaml` file to show the directory where your.props files are stored. For example, `'C:\SSLPropsFiles'`

```
secureJNDIPropertiesFiles: 'C:\SSLPropsFiles' # The directory where your .props files are
 stored. For example 'C:\SSLPropsFiles'
```

9. Set the *needCache* parameter in the `.conf.yaml` file to `true` to indicate that the IBM App Connect Enterprise cache is enabled. The default value is `true`

```
needCache: true # The default value is true, indicating that the IBM App Connect Enterprise
 WSRR cache is enabled.
```

10. Edit the *predefinedCacheQueries* parameter in the `.conf.yaml` file to show a list of semicolon-separated WSRR XPath query expressions with which to initialize the IBM App Connect Enterprise cache at start-up.

```
predefinedCacheQueries: "//*[@name='Wss100.wsdl'];/WSRR/WSDLService/ports[binding/
portType[@name='DemoCustomer' and @namespace='http://demo.sr.eis.ibm.com'] and
 @PortProperty1='ValueOfPortProperty1' and exactlyClassifiedByAllOf(., 'http://www.ibm.com/
xmlns/prod/serviceregistry/6/0/governance/DefaultLifecycle#InitialState1','http://
www.ibm.com/xmlns/prod/serviceregistry/6/0/governance/DefaultLifecycle#Approve')]" #  A list
 of semicolon-separated WSRR XPath query expressions with which to initialize the IBM App
 Connect Enterprise WSRR cache at start-up.
```

    These WSRR XPath query expressions are defined by the WSRR SOAP interface query expression language, and might include an optional depth specifier extension. For more information about XPath, see https://www.ibm.com/support/knowledgecenter/en/SSWLGF_8.5.6/com.ibm.sr.doc/twsr_xpath_query.html.

11. Set the *refreshQueriesAfterNotification* parameter in the `.conf.yaml` file to `true` or `false` according to your requirements.

    The default value is `true`. When a notification is received from WSRR, and *refreshQueriesAfterNotification* is set to `true`, the Cache is updated with the new version of the object immediately. If it is set to `false`, the Cache is updated on the next request.

```
refreshQueriesAfter Notification: true # When a notification is received from WSRR, if
 refreshQueriesAfterNotification is set to true, the Cache is updated with the new version
 of the object immediately; if it is set to
                                                    false, the Cache is updated on the next
 request. The default value is true.
```

12. Edit the *subscriptionTopic* parameter in the `.conf.yaml` file to show topic name that is used to receive the WebSphere Application Server JMS provider Cache Notifications. The default value is `'jms/SuccessTopic'`.

```
subscriptionTopic: 'jms/SuccessTopic' # The topic name that is used to receive WebSphere
 Application Server JMS provider Cache Notifications. The default value is 'jms/
SuccessTopic'
```

13. Edit the *timeout* parameter in the `.conf.yaml` file to show the cache expiry time in milliseconds. The default value is `100000000`, which is approximately 27.8 hours.

```
timeout: 100000000 # The cache expiry time in milliseconds. The default value is 100000000,
 which is approximately 27.8 hours.
```

14. Restart the integration node or independent integration server. For more information, see “Starting and stopping an integration node” on page 247, “Starting an integration server” on page 250, and “Stopping an integration server” on page 254.

Accessing a secure WebSphere Service Registry and Repository repository

To access a secure WebSphere Service Registry and Repository repository, edit the parameters in the `.conf.yaml` configuration file for the integration node, or integration server.

About this task

You must connect over HTTPS, not HTTP, which is specified in the `endpointAddress` property of the `WSSRConnectorProvider` entry in the `ConnectorProviders` section of the `node.conf.yaml` or `server.conf.yaml` configuration file. The configuration must specify the domain qualified hostname and port of your WebSphere Service Registry and Repository server and you must define the WebSphere Service Registry and Repository server logon credentials and HTTPS SSL certificates.

For more information about the `endpointAddress` configuration parameter, see "Configuration parameters for the WebSphere Service Registry and Repository nodes" on page 1006.

To access a secure WebSphere Service Registry and Repository from a managed server, enter the following sequence of commands. Any properties that you set for an integration node, in the `node.conf.yaml` file, are inherited by the integration servers that it owns. However, you can change the owned integration server properties by modifying them in the appropriate `server.conf.yaml` file. For an independent integration server, edit the `server.conf.yaml` configuration file to set the properties that would be set by the following commands. For more information about configuring integration servers, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

Procedure

1. Ensure that the integration node is running. If it is not, use the **mqsistart** command to start it.
2. Edit the `.conf.yaml` file to configure the integration node or integration server to use HTTPS to communicate with the WebSphere Service Registry and Repository server.

   ```
   WSRRConnectorProvider:

             # endpointAddress                              # The location or endpoint of the
    WSRR server.
   ```

   The default value for all versions of WebSphere Service Registry and Repository is `https://fill.in.your.host.here:9080/WSRRCoreSDO/services/WSRRCoreSDOPort`

   For more information about the specific levels of WebSphere Service Registry and Repository that are supported by IBM App Connect Enterprise, see IBM App Connect Enterprise system requirements web page.

3. Configure the integration node keystore to contain your WebSphere Service Registry and Repository server certificate keys; for a discussion of digital certificates, see "Digital certificates" on page 2493. Obtain these certificate keys from the installation of the WebSphere Application Server that hosts your WebSphere Service Registry and Repository server. The integration node uses a single keystore. Therefore, if your integration node also implements WS-Security, HTTPS, or SSL-secured IBM MQ, you might need to merge the provided keys into an existing keystore file. Display the current configuration parameters of the integration node by using the following command:

   ```
   mqsireportproperties INODE -o BrokerRegistry -r
   ```

   The parameters in this example represent the following values:

   The **-o** parameter specifies the name of the object (in this case, `BrokerRegistry`)

The **-r** parameter specifies that all property values of the object are displayed, including the child values, if appropriate.

If your WebSphere Service Registry and Repository server uses mutual SSL authentication, configure the integration node keystore to contain a private key. Then, set the `brokerKeystoreFile` configuration parameters for the integration node, by using one of the following options.

- Use the **mqsichangeproperties** command to change configuration parameters for the integration node.

```
mqsichangeproperties INODE -o BrokerRegistry
-n brokerKeystoreFile -v C:\WSRR\SSL\ClientKeyFile.jks
```

  The parameters in this example represent the following values:

  The **-o** parameter specifies the name of the object (in this case, `BrokerRegistry`).
  The **-n** parameter specifies the names of the properties to be changed (in this case, `brokerKeystoreFile`).
  The **-v** parameter specifies the values of properties that are defined by the **-n** parameter (in this case, `C:\WSRR\SSL\ClientKeyFile.jks`).

- Edit the `.conf.yaml` file to change configuration parameters for the integration node.

```
BrokerRegistry:
           brokerKeystoreType: 'JKS'                        # Trust store type
           brokerKeystoreFile: 'C:\devel\ACE11\WSRR
\comics1.fyre.ibm.com.serverKeyFile.jks'      # Location of the broker key store
         # Location of the broker trust key store
```

4. Configure the integration node truststore to contain signer certificates for your WebSphere Service Registry and Repository server. As stated for the keystore, the integration node uses a single truststore. Therefore, you might need to merge certificates into an existing truststore file. The integration node truststore is configured by using the **mqsichangeproperties** command. To change the `brokerTruststoreFile` configuration parameters for the integration node, use the following command:

```
mqsichangeproperties INODE -o BrokerRegistry
-n brokerTruststoreFile -v C:\WSRR\SSL\ClientTrustFile.jks
```

   The parameters in this example represent the following values:

   The **-o** parameter specifies the name of the object (in this case, `BrokerRegistry`).
   The **-n** parameter specifies the names of the properties to be changed (in this case, `brokerTruststoreFile`).
   The **-v** parameter specifies the values of properties that are defined by the **-n** parameter (in this case, `C:\WSRR\SSL\ClientTrustFile.jks`).

5. Stop the integration node by using the **mqsistop** command.

   You must stop the integration node to complete the following step.

6. If you are using the secure credentials vault to store the WebSphere Service Registry and Repository server credentials, complete the following steps:

   Create a vault key for the specified server by running the **mqsivault** command:

```
mqsivault INODE --create --vault-key 12345678
```

   The parameters in this example represent the following values:

   The `--create` parameter creates a vault for the specified server.

The `--vault-key` parameter specifies the vault key to be used for creating the vault. (in this case, 12345678).

Define the WebSphere Service Registry and Repository type default credential-name in the `node.conf.yaml` configuration file by running the following command:

```
mqsicredentials INODE --all-integration-servers --set-as-default --credential-type wsrr  --
credential-name wsrrServerCred
```

For an independent integration server, add the following lines to the `server.conf.yaml` configuration file.

```
Defaults:
  Credentials:
    wsrr: 'wsrrServerCred'
```

7. Set the WebSphere Service Registry and Repository server username and password by using one of the following methods:
   - Set the username and password by running the **mqsisetdbparms** command.

     ```
     mqsisetdbparms INODE -n DefaultWSRR::WSRR -u wasuser -p waspass
     ```

     The parameters in this example represent the following values:

     The **-n** parameter specifies the name of the data source (in this case, `DefaultWSRR::WSRR`).
     The **-u** parameter specifies the user ID to be associated with this data source (in this case, `wasuser`).
     The **-p** parameter specifies the password to be associated with this data source (in this case, `waspass`).
   - Create the username and password by running the **mqsicredentials** command:

     ```
     mqsicredentials INODE --all-integration-servers --vault-key <myvaultkey> --create --
     credential-type wsrr --credential-name wsrrServerCred wsrr --username <wsrr user> --
     password <wsrr password>
     ```

     The parameters in this example represent the following values:

     The **--all-integration-servers** parameter creates a vault for all servers. (use –integration-server for a specified server).
     The **--vault-key** parameter specifies the vault key to be used for creating the vault.
     The **--create** parameter specifies the vault key to be used for creating the vault.
     The **--credential-type** parameter specifies the type of credential (in this example, `wsrr` is used).
     The **--username** parameter specifies the username.
     The **--password** parameter specifies the password.
8. If your WebSphere Service Registry and Repository server uses mutual SSL authentication, set the `brokerKeystore` username and password by using one of the following methods.
   - Set the username and password by running the **mqsisetdbparms** command:

     ```
     mqsisetdbparms INODE -n brokerKeystore::password -u dummy -p WebAS
     ```

     The parameters in this example represent the following values:

     The **-n** parameter specifies the name of the data source (in this case, `brokerKeystore::password`).
     The **-u** parameter specifies the user ID to be associated with this data source (in this case, `dummy`).

The **-p** parameter specifies the password to be associated with this data source (in this case, WebAS).

- Set the brokerKeyStore by running the **mqsicredentials** command:

```
mqsicredentials INODE --all-integration-servers --vault-key <myvaultkey> --create --
credential-type keystore --credential-name password --password changeme
```

The parameters in this example represent the following values:

The **--all-integration-servers** parameter specifies that the command applies to all integration servers on the specified integration node. Alternatively, you can specify a named integration server (`-integration-server IntegrationServerName`).
The **--vault-key** parameter specifies the vault key that was used to create the vault.
The **--create** parameter creates credentials in the vault.
The **--credential-type** parameter specifies the credential type.
The **--credential-name** parameter specifies the name of the credential. In this case, `password` is used. You must update the `node.conf.yaml` to set this name as follows.

```
BrokerRegistry:
brokerTruststorePass: ‘password'
```

The **--password** parameter specifies the password to be associated with this resource.

9. Set the `brokerTrustStore` username and password by using one of the following methods:

- Set the username and password by running the **mqsisetdbparms** command.

```
mqsisetdbparms INODE -n brokerTruststore::password -u dummy
-p WebAS
```

The parameters in this example represent the following values:

The **-n** parameter specifies the name of the data source (in this case, `brokerTruststore::password`).
The **-u** parameter specifies the user ID to be associated with this data source (in this case, `dummy`).
The **-p** parameter specifies the password to be associated with this data source (in this case, `WebAS`).

- Set the `brokerTrustStore` by running the **mqsicredentials** command:

```
mqsicredentials INODE --all-integration-servers --vault-key <myvaultkey> --create --
credential-type truststore --credential-name password --password changeme
```

You must update the `node.conf.yaml` file set the specified credential name as follows.

```
BrokerRegistry:
  brokerTruststorePass: 'password'
```

The parameters in the example represent the following values:

The **--all-integration-servers** parameter specifies that the command applies to all integration servers on the specified integration node. Alternatively, you can specify a named integration server (`-integration-server IntegrationServerName`).
The **--vault-key** parameter specifies the vault key that was used to create the vault.
The **--create** parameter creates credentials in the vault.
The **--credential-type** parameter specifies the credential type.
The **--credential-name** parameter specifies the name of the credential. In this case, `password` is used to match the setting of **BrokerRegistry.brokerKeystorePass** in the `.conf.yaml` configuration file.
The **--password** parameter specifies the password to be associated with this resource.

10. To use cache notification with your secure WebSphere Service Registry and Repository server, follow the instructions in “Setting up cache notification” on page 1016.

11. Restart the integration node by using the **mqsistart** command.

    If you create a vault key, you must specify the **--vault-key** parameter in the **mqsistart** command.

    ```
    mqsistart INODE --vault-key 12345678 -u userid -p password
    ```

Caching artifacts from the WebSphere Service Registry and Repository

IBM App Connect Enterprise saves the data that it retrieves from the WebSphere Service Registry and Repository (WSRR) in a local cache.

The WSRR nodes, EndpointLookup and RegistryLookup, can retrieve data that was stored in the Integration node WSRR cache by a previous query, improving performance and message throughput. The first occurrence of each query is always sent to WSRR. By default, this activity occurs when a WSRR node first issues a specific query, although it is possible to pre-populate the cache, when the integration node or integration server starts, by using the queries described here.

Configuring the WSRR Cache

The cache is configured individually for each integration node or independent integration server by editing the parameters in the `.conf.yaml` configuration file; for more information, see “Configuration parameters for the WebSphere Service Registry and Repository nodes” on page 1006.

You can configure the cache in the following ways:

- **Disabling the cache**

  Disable the cache by setting the `needCache` parameter to `false`. By default, the cache is enabled, but the WSRR nodes can operate without the cache. If the cache is disabled, every query that is issued by the node is sent to WSRR, ensuring that the results of the query always reflect the current contents of the registry. This activity can affect performance.

- **Preloading the cache**

  Preload the cache by setting the `predefinedCacheQueries` parameter. By default, no items are preloaded in the cache and the first occurrence of every query is sent to WSRR. You can specify predefined queries that are executed when the integration node or integration server starts, or when a message flow that contains WSRR flows is first deployed, populating the cache for use by subsequent WSRR nodes. By specifying predefined queries, performance might be affected at startup, rather than on the first occurrence of a query at run time. The predefinedCacheQueries parameter is a list of WSRR XPath query expressions that are separated by semicolons, each with an optional depth specification. The user trace shows the WSRR XPath query expression that is generated by a WSRR node.

- **Changing the cache expiry timeout value**

  Change the cache expiry timeout value by setting the `timeout` parameter. The cached results of a query are discarded after the specified elapses. The next occurrence of the query is sent to WSRR and the new result is entered in the cache. If the contents of the registry are likely to change frequently, you can specify a shorter expiry timeout value so that changes are picked up quicker. This activity affects performance as more queries are sent to WSRR.

- **Enabling cache notification**

  Enable cache notification by setting the `enableCacheNotification` parameter to `true` and by setting the `initialContextFactory` and `locationJNDIBinding` properties for your WSRR server. By default, cache notification is disabled. Cache notification is a more flexible method than expiry timeout for refreshing cached data because it allows individual WSRR entities to be refreshed at the time they are modified in WSRR.

  If cache notification is enabled, the cache subscribes to events that occur in WSRR and is notified when an object is updated or deleted in WSRR. The object is discarded from the cache. If the `refreshQueriesAfterNotification` parameter is set to `true`, the cache is updated with the new version of the object immediately. If the `refreshQueriesAfterNotification` parameter is set to `false`, the cache is updated the next time that a relevant query is issued by a WSRR node.

Setting up cache notification
Edit the `.conf.yaml` configuration file to enable cache notification so that the cache is notified of events that occur in WebSphere Service Registry and Repository (WSRR).

About this task

WSRR publishes notification events by using WebSphere Application Server. Cache notification allows the cache to subscribe to these events.

To set the WSRR parameters, you must edit the `WSRRConnectorProvider` entries in the `ConnectorProviders` section of the `node.conf.yaml` or `server.conf.yaml` configuration file. When you create a new integration node or a new independent integration server, the `.conf.yaml` configuration file contains the following subset of the WSRR parameters. All the other WSRR parameters have default settings which generally do not need to be changed. If you need to change any of the other WSRR parameters, you must add them to the `.conf.yaml` configuration file.

```
ConnectorProviders:
    #WSRRConnectorProvider:    # Requires the optional WSRR component install
    #endpointAddress: 'https://host:9443/WSRR8_0/services/WSRRCoreSDOPort'   # WSRR server
 endpoint url
    #needCache: true                                                        # enable WSRR cache
    #predefinedCacheQueries: ''                                             # semicolon-
separated XPath querys to initialize WSRR cache at start-up
    #enableCacheNotification: false                                         # enable WSRR cache
 notification
    #locationJNDIBinding:  'iiop://host:2809'                               # WSRR cache WAS
 JMS provider JNDI bindings url
```

To enable cache notification, complete the following steps to change the relevant properties in the `.conf.yaml` configuration file, and to add a user ID and password if you are connecting to a secure WebSphere Application Server. Any properties that you set for the integration node, in the `node.conf.yaml` file, are inherited by the integration servers that it owns. However, you can change any of the integration server properties by modifying them in the appropriate `server.conf.yaml` file. For more information about configuring integration servers that are managed by an integration node, see Configuring an integration server by modifying the server.conf.yaml file.

Procedure

1. Set the **enableCacheNotification** property value to `true` in the `.conf.yaml` configuration file:

   ```
   enableCacheNotification: true # The default value is false. Select true to enable IBM® App
    Connect Enterprise WSRR Cache Notification.
   ```

2. Set the **locationJNDIBinding** property to the value that you require for your WSRR server in the `.conf.yaml` configuration file:
   For example:

   ```
   locationJNDIBinding: 'iiop://host_name:2809/' # The URL to the WebSphere Application Server
    JMS provider JNDI bindings. The default value is iiop://host_name:2809/
   ```

3. When you use WebSphere Application Server Version 8.0 or later, the default IIOP secure setting is `SSL-Required`. Therefore, if you connect to your server without changing this option to `SSL-Optional`, you must configure the `sas.client.props` and the `ssl.client.props` files in the following way:

   `sas.client.props`

   ```
   - Set com.ibm.ssl.alias=AnotherSSLSettings
   - Set com.ibm.CORBA.loginSource=properties
   ```

   `ssl.client.proprs`

   ```
   -- Use the AnotherSSLAlias template that is already in the file, but comment ou the
    DefaultAlias Keystore and Truststore information to prevent it affecting the current
    configuration
   ```

```
-- Comment out the KeyStore part of the 'another SSL Alias' because the TrustStore is the
 only one that is required:
- Set com.ibm.ssl.enableSignerExchangePrompt=false in all scenarios
```

4. Set the **secureJNDIPropertiesFiles** property in the `.conf.yaml` file to point to the directory where your `.props` files are stored.
   For example:

```
secureJNDIPropertiesFiles: 'C:\SSLPropsFiles' #  The directory where your .props files are
 stored. For example C:\SSLPropsFiles.
```

If you are connecting to a secure WebSphere Application Server, you must use a user ID and password. To set the user ID and password complete one of the following steps:

5. Optional: Set the user ID and password by using the **mqsisetdbparms** command:
   a) If the integration node is running, stop it by using the **mqsistop** command.
   b) Issue the **mqsisetdbparms** command to set up your user ID and password.
      For example:

```
mqsisetdbparms INODE -n jms::DefaultWSRR@jms/SRConnectionFactory
-u userid -p password
```

      where:

      -n specifies the name of the data source
      (in this case, `jms::DefaultWSRR@jms/SRConnectionFactory` is used.
      You can also use `wsrr`)
      -u specifies the user ID to be associated with this data source
      (in this case, *userid*)
      -p specifies the password to be associated with this data source
      (in this case, *password*)
   c) Restart the integration node by using the **mqsistart** command.
6. Optional: Set the user ID and password by using the **mqsicredentials** command:
   a) If the integration is running, stop it by using the **mqsistop** command.
   b) Issue the **mqsicredentials** command to set up your user ID and password.
      For example:

```
mqsicredentials --work-dir --create --credential-type jms --credential-name wsrr@jms/
SRConnectionFactory --vault-key 12345abcde --username jmsvaultuser --password jmsvaultpwd
-u userid -p password
```

      where:

      --work-dir specifies path to the work directory that is used by an independent integration server.

      --credential-type specifies the resource that requires credentials for access.
      (in this case, *jms*)
      --credential-name specifies the vault key that is used to access the vault where the credential is stored.
      --vault-key specifies the vault key that is used to access the vault where the credential is stored.
      --username specifies the user ID to be associated with this resource.
      --password specifies the password to be associated with this resource.
   c) Restart the integration node by using the **mqsistart** command.

Dynamically defining the search criteria

You can use the RegistryLookup and EndpointLookup nodes to issue WebSphere Service Registry and Repository (WSRR) queries specified in the local environment.

The RegistryLookup and EndpointLookup nodes issue WSRR queries at run time and save the resulting data in the local environment. You can specify the queries at design time by using node properties to

define the search criteria. Both nodes require at least one query property to be defined before you can deploy the message flow. However, you can specify the search criteria at run time in the local environment, either supplementing or overriding the node properties.

The following table defines the local environment overrides for WSRR queries. These fields must be set in OutputLocalEnvironment.ServiceRegistryLookupProperties by a preceding transformation node, such as a Compute node.

Setting	Description
Name	This setting overrides the Name property on the node; for example, with an ESQL Compute node: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Name = 'DemoCustomer';` This setting relates to the PortType Name property on the EndpointLookup node. Therefore, to set the PortType Name property, use the Name setting in the local environment.
Namespace	This setting overrides the Namespace property on the node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Namespace = 'http://mb.sr.eis.ibm.com';` This setting relates to the PortType Namespace property on the EndpointLookup node. Therefore, to set the PortType Namespace property, use the Namespace setting in the local environment.
Version	This setting overrides the Version property on the node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Version = '1.0';` This setting relates to the PortType Version property on the EndpointLookup node. Therefore, to set the PortType Version property, use the Version setting in the local environment.
MatchPolicy	This setting overrides the Match Policy property on the node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.MatchPolicy = 'One';` Valid values are One and All.

Setting	Description
DepthPolicy	This setting overrides the `Depth Policy` property on the RegistryLookup node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.DepthPolicy = 'MatchOnly';` Valid values are: • `MatchOnly` for `Return matched only (Depth = 0)` • `MatchShowRel` for `Return matched showing immediate relationships (For compatibility only)` • `MatchPlusImmediate` for `Return matched plus immediate related entities (Depth = 1)` • `MatchPlusAll` for `Return matched plus all related entities (Depth = -1)` The `MatchShowRel` property provides compatibility with versions of IBM App Connect Enterprise before Version 6.1.0.4, by using the output format that was used in those previous versions. This option is deprecated, and should not be used if you are creating a new message flow. Consider migrating existing message flows to use one of the other options.

UserProperties	This setting overrides the `User Properties` property on the node. You can specify more than one user-defined property in the local environment; for example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.UserProperties.property1 = 'value1';`
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.UserProperties.property2 = 'value2';`
	You can remove a user-defined property from the local environment by setting its value to NULL; for example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.UserProperties.property1 = NULL;`
	You can use the node properties editor at design time to specify ESQL paths or XPath expressions to read the value for a user property at run time from a field in the message tree. However, the override values that you set in the local environment are the string values that are used in the query.

Classification	This setting overrides the `Classification` property on the node; for example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Classification = 'http://www.ibm.com/xmlns/prod/serviceregistry/6/0/governance/DefaultLifecycle#InitialState0';`
	You can specify more than one classification in the local environment. For example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Classification[1] = 'http://www.ibm.com/xmlns/prod/serviceregistry/6/0/governance/DefaultLifecycle#InitialState0';`
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Classification[2] = 'http://www.ibm.com.policy/GovernancePolicyDomain';`

EndpointLookup node output

Use an EndpointLookup node to retrieve the endpoint addresses for WSDL service definitions held in WebSphere Service Registry and Repository (WSRR).

The input message is not changed by the EndpointLookup node. Instead, the local environment is updated to contain details of the endpoints retrieved by the query specified by the node and any local environment overrides.

You can configure the EndpointLookup node to dynamically set the service endpoint address for services that will be invoked by a subsequent SOAP or HTTP request node. The EndpointLookup node sets the destination URL in the local environment overrides for those nodes.

EndpointLookup node output if the `Match Policy` property is set to `One`

If the `Match Policy` property of the node is set to `One`, theEndpointLookup node inserts the endpoint URL retrieved by the query into the local environment in an ITService entry in the local environment under ServiceRegistry, and sets the destination overrides for the SOAP and HTTP request nodes that can be connected directly to its output terminal. The following locations are updated:

- `LocalEnvironment.Destination.SOAP.Request.Transport.HTTP.WebServiceURL`
- `LocalEnvironment.Destination.HTTP.RequestURL`

These settings override the `Web service URL` property of the SOAPRequest, SOAPAsyncRequest, and HTTPRequest nodes, allowing a dynamic call to a web service provider.

The following example shows typical output from the EndpointLookup node when the `Match Policy` is set to `One`. (Other entries might exist in the local environment depending on previous processing in the flow.)

```
<LocalEnvironment>
  <Destination>
    <SOAP>
      <Request>
        <Transport>
          <HTTP>
            <WebServiceURL>http://localhost:9081/DemoCustomerWeb/
              services/DemoCustomer</WebServiceURL>
          </HTTP>
        </Transport>
      </Request>
    </SOAP>
    <HTTP>
      <RequestURL>http://localhost:9081/DemoCustomerWeb/
        services/DemoCustomer
    </RequestURL>
   </HTTP>
  </Destination>
  <ServiceRegistry>
    <ITService>
      <Endpoint>
        <Address>http://localhost:9081/DemoCustomerWeb/
          services/DemoCustomer</Address>
        <PortType>
          <name>DemoCustomer</name>
          <namespace>http://demo.sr.eis.ibm.com</namespace>
          <version>1.0</version>
        </PortType>
        <Property>
          <name>policy</name>
          <value>RM</value>
        </Property>
        <Property>
          <name>country</name>
          <value>China</value>
        </Property>
        <Classification>http://eis.ibm.com/ServiceRegistry/
          GenericObjecttypes#Routing</Classification>
      </Endpoint>
    </ITService>
  </ServiceRegistry>
</LocalEnvironment>
```

EndpointLookup node output if the Match Policy property is set to All

If the Match Policy is set to All the EndpointLookup node writes an ITService entry in the local environment location ServiceRegistry for each endpoint retrieved by the query.

The following example shows typical output from the EndpointLookup node when the Match Policy is set to All. (Other entries might exist in the local environment depending on previous processing in the flow.)

```
<LocalEnvironment>
  <ServiceRegistry>
    <ITService>
      <Endpoint>
        <Address>http://localhost:9081/DemoCustomerWeb/
          services/DemoCustomer</Address>
        <PortType>
          <name>DemoCustomer</name>
          <namespace>http://demo.sr.eis.ibm.com</namespace>
          <version>1.0</version>
        </PortType>
        <Property>
          <name>policy</name>
          <value>RM</value>
        </Property>
        <Property>
          <name>country</name>
          <value>China</value>
        </Property>
        <Classification>http://eis.ibm.com/ServiceRegistry/
          GenericObjecttypes#Routing</Classification>
      </Endpoint>
    </ITService>
    <ITService>
      <Endpoint>
        <Address>http://localhost:9081/DemoCustomerWeb/
          services/DemoCustomer2</Address>
        <PortType>
          <name>DemoCustomer2</name>
          <namespace>http://demo.sr.eis.ibm.com</namespace>
          <version>1.0</version>
        </PortType>
      </Endpoint>
    </ITService>
  </ServiceRegistry>
</LocalEnvironment>
```

RegistryLookup node output

Use the RegistryLookup node to retrieve any type of entity held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. The input message is not modified.

This topic contains the following sections:

Setting the Depth Policy property

The Depth Policy property on the RegistryLookup node specifies how much data is returned for each matched entity. The following table shows the valid values.

Depth Policy property value	Local environment override value	Data returned
Return matched only (Depth = 0)	MatchOnly	Just the matched entities

Depth Policy property value	Local environment override value	Data returned
Return matched showing immediate relationships (For compatibility only)	MatchShowRel	The matched entities and additional references
Return matched plus immediate related entities (Depth = 1)	MatchPlusImmediate	The matched entities and the immediate related child entities
Return matched plus all related entities (Depth = -1)	MatchPlusAll	The matched entities and all the related child entities

Use MatchShowRel for compatibility with versions of WebSphere Message Broker before Version 6.1.0.4. The local environment output for MatchShowRel is shown in Example 1 and follows the format that was used in those previous versions. However, the MatchShowRel option is deprecated, and provided only for compatibility with previous versions. Do not use MatchShowRel if you are creating a new message flow, and consider migrating existing message flows to use one of the other options.

Use the MatchOnly option to retrieve just the individual entities matched by the search criteria. This option is efficient, however the local environment output does not contain any information about entities related to the matched entities.

Use the MatchPlusImmediate option to retrieve the entities matched by the search criteria, and the related child entities. This option offers a useful compromise, allowing you to access the immediate relations of the matched entities, while still restricting the total amount of data retrieved.

Use one of the MatchOnly or MatchPlusImmediate options when migrating a message flow that uses the deprecated MatchShowRel option. If your original message flow used the relationship information in the matched entities, use the MatchPlusImmediate option. See "Migrating a message flow that uses the MatchShowRel option" on page 1024.

Use the MatchPlusAll option to retrieve the entities matched by the search criteria, and all the related child entities. Use this option only if your message flow needs access to more than the immediate relations of the matched entities, because it retrieves considerably more data than the MatchPlusImmediate option, see "Local environment output tree" on page 1022.

Local environment output tree

The local environment output tree has a different format when the deprecated MatchShowRel option of the Depth Policy property is used. The following table describes the differences in the local environment output tree format.

MatchOnly, MatchPlusImmediate, and MatchPlusAll options	MatchShowRel option
The ServiceRegistry folder element is owned by the XMLNSC compiler.	No owning parser on the ServiceRegistry folder element, and each Entity element is owned by the XMLNS parser
The ServiceRegistry tree does not use unnecessary namespaces.	Namespaces are attached to all UserDefined folder elements, meaning that the path specified must declare and use the relevant namespace to access fields within these folders.
The ServiceRegistry tree is optimized through use of the XMLNSC parser.	The output tree contains a number of XML declaration, pcdata, and white space elements that have no business significance.

MatchOnly, MatchPlusImmediate, and MatchPlusAll options	**MatchShowRel option**
In WSRR, binary data is represented as a GenericDocument with a `content` attribute. The `content` attribute is represented in the local environment as XMLNSC type Attribute +base64Binary, (0x03000160). You can access the unencoded binary data directly as `Entity.content`. However, because of the special XMLNSC element type, the data is automatically base64 encoded if the tree is serialized.	Binary content is represented as a base64 encoded character string in the `content` attribute. The message flow must invoke a Java method to decode the value if the original binary data is required.
The retrieved entities are not modified to add any user properties.	The matched Entities appear in the local environment with a user property called `WSRREncoding`. This property has no specific significance to message flow processing. If there is a user property called `WSRREncoding` defined for the entity, the defined value is used, otherwise the `WSRREncoding` property is added with `value="DEFAULT"`.

The `MatchPlusImmediate` and `MatchPlusAll` options result in a graph of entities being returned when WSRR executes the query. Each entity in the graph can refer to other entities. There are two types of relationship that cannot be expressed directly in a hierarchical tree:

- Cyclic references - a graph can contain an entity from which you can follow relationships that arrive back at the same entity.
- Multiple references - a graph can contain an entity that is referenced by multiple entities.

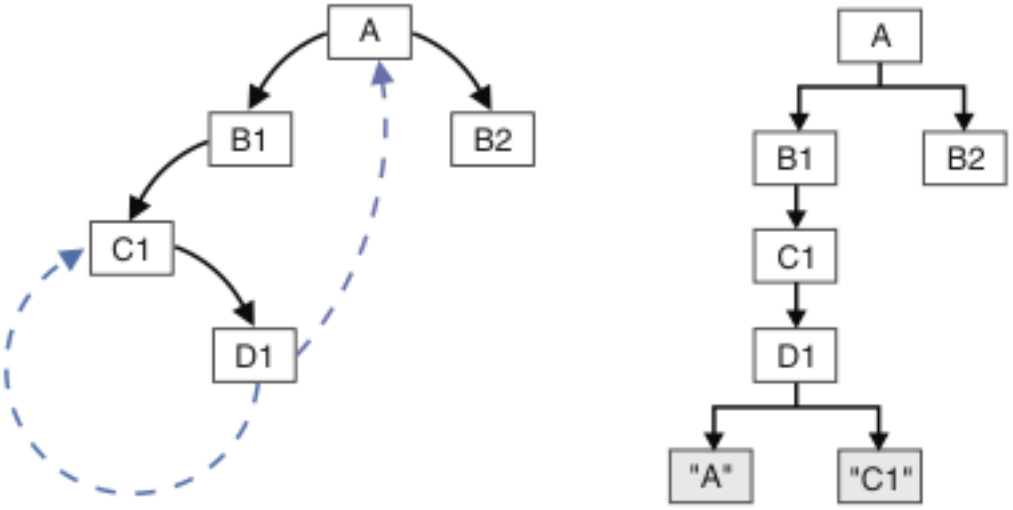
The representation of these relationships in the local environment output tree is described in the following text.

The WSRR graph is represented in the local environment output tree as follows:

- The matched entities that are returned in the WSRR graph are represented as Entity elements as the first children of the LocalEnvironment.ServiceRegistry. The properties of the matched entities are represented as child elements.
- A matched entity can contain references to other entities. If `MatchPlusImmediate` is set, these references are represented as Entity child elements of the matched entity. If `MatchPlusAll` is set, the same rule is applied recursively to these children.
- Cyclic references - if an entity references another entity that is one of its ancestors in the WSRR graph, the referenced entity is represented as an EntityRef element. An EntityRef element does not represent

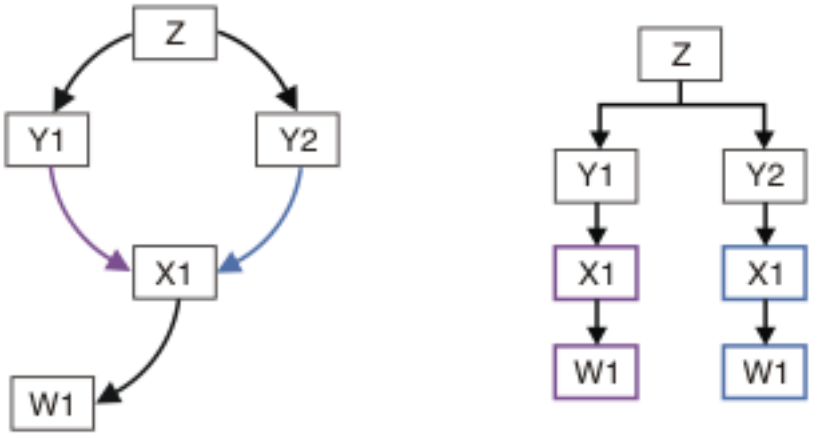
the target entity directly, but provides information to identify it. This prevents the possibility of entering cyclic loops when navigating the tree.

The following diagram shows references from entity D1 in the graph to entities C1 and A that are ancestral; therefore, Entity D1 in the message tree contains EntityRef elements for A and C1.



- Multiple references - if an entity in the WSRR SDO graph is referenced by more than one other entity, it is represented as a separate Entity element in the message tree each time it is referenced. The Entity element is cloned, along with any entities that it refers to.

  The following diagram shows that entity X1 in the graph is referenced by entities Y1 and Y2, so Entity X1 and Entity W1 that it references are modeled twice in the message tree.



Migrating a message flow that uses the `MatchShowRel` option

When you migrate an existing message flow that uses the deprecated `MatchShowRel` option of the `Depth Policy` property, the local environment output tree will have a different format. The table shown earlier describes the differences in the local environment output tree formats, and indicates what you must modify in the message flow to access the data in the updated format; see “Local environment output tree” on page 1022.

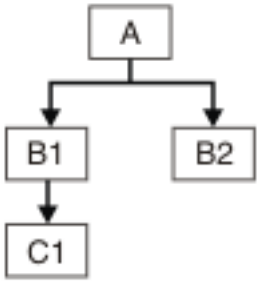
Examples

The following examples show typical output from the RegistryLookup node:

- Example 1 shows the full RegistryLookup node output in two cases for a query that returns two versions of a concept entity. In both cases the `Match Policy` property is set to `All`. In the first case the `Depth Policy` property is set to `Return matched plus immediate related entities (Depth = 1)`, and in the second case the `Depth Policy` property is set to `Return matched only, showing immediate relationships (For compatibility only)`. This example also shows example ESQL to read elements of the output. See "RegistryLookup node output: example 1" on page 1025
- Example 2 shows the structure of RegistryLookup node output for all possible values of the `Depth Policy` property for a query on a concept entity that has a number of user relationships to other concept entities. See "RegistryLookup node output: example 2" on page 1028
- Example 3 shows the structure of RegistryLookup node output for a query on an entity having metadata relationships and user-defined relationships, using a `Depth Policy` property value of `Return matched plus all related entities (Depth = -1)`. See "RegistryLookup node output: example 3" on page 1031.

RegistryLookup node output: example 1
Example showing the full RegistryLookup node output in two cases for a query that returns two versions of a concept entity. In both cases the `Match Policy` property is set to `All`. In the first case the `Depth Policy` property is set to `Return matched plus immediate related entities (Depth = 1)`, and in the second case the `Depth Policy` property is set to `Return matched only, showing immediate relationships (For compatibility only)`. This example also shows example ESQL to read elements of the output.

This example shows the ServiceRegistry message tree that is stored in the LocalEnvironment when an entity called ConceptA1 is retrieved from WebSphere Service Registry and Repository (WSRR). ConceptA1 is defined in WSRR with 2 versions: 1.0 which is deprecated, and 2.0 which is classified as initial state. Additional properties and relationships have been added to the 2.0 version. The following diagram shows the relationships between the elements in the message tree.



The following message trees show the different values of the `Depth Policy` property.

- `Depth Policy` property set to `Return matched plus immediate related entities (Depth = 1)`

  The following ESQL was used to create a serialization of the output of the ServiceRegistry node:

```
SET OutputRoot.XMLNSC.Result.ServiceRegistry =
  InputLocalEnvironment.ServiceRegistry;
```

  The ServiceRegistry folder element is owned by the XMLNSC parser so you can invoke a like parser tree copy to OutputRoot.XMLNSC. The following XML, which has been formatted, is produced when writing this output root tree.

```
<ServiceRegistry>

```

```
          name="ConceptB2"
          namespace="http://www.examples.com/ConceptB2" version="1.0"
          description="Testing" owner="UNAUTHENTICATED"
          lastModified="1227191700812"
          creationTimestamp="1227177334515"
          lastModifiedBy="UNAUTHENTICATED"
          primaryType="" />
      </targetEntities>
    </userDefinedRelationships>
  </Entity>
</ServiceRegistry>
```

The following ESQL shows how to retrieve the values from the ServiceRegistry message tree in the LocalEnvironment when the `Depth Policy` property is set to `Return matched plus immediate related entities (Depth = 1)`.

```
DECLARE c1 CHARACTER;

-- Following sets c1 to "ConceptA1" by indexing the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].name;
-- Following sets c1 to "2.0" by indexing the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].version;
-- Following sets c1 to "property1" by indexing the first
--   userDefinedProperties within the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].
  userDefinedProperties[1].name;
-- Following sets c1 to "value1 for v2" by indexing the first
--   userDefinedProperties within the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].
  userDefinedProperties[1].value;
```

- `Depth Policy` property set to `Return matched showing immediate relationships (For compatibility only)`

  The following ESQL was used to create a serialization of the output of the ServiceRegistry node:

  ```
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputLocalEnvironment.ServiceRegistry.Entity[]);
  WHILE I < J DO
    SET OutputRoot.XMLNS.ServiceRegistry.Entity[I] =
      InputLocalEnvironment.ServiceRegistry.Entity[I];
    SET I = I + 1;
  END WHILE;
  ```

  The ServiceRegistry folder does not have an owning parser so you must navigate to the ""elements and initiate a like-parser-copy to the XMLNS owned output root tree. The following XML is produced when writing this output root tree.

  ```
  <ServiceRegistry>
    <Entity
      xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
      xmlns:sdo="http://www.ibm.com/xmlns/prod/serviceregistry/6/0/sdo"
      xsi:type="sdo:GenericObject"

    </NS6:userDefinedProperties>
  </Entity>
</ServiceRegistry>
```

The following ESQL shows how to retrieve the values from the ServiceRegistry message tree in the LocalEnvironment when the `Depth Policy` property is set to `Return matched showing immediate relationships (For compatibility only)`. Note that in this case it is necessary to use the namespace qualifier.

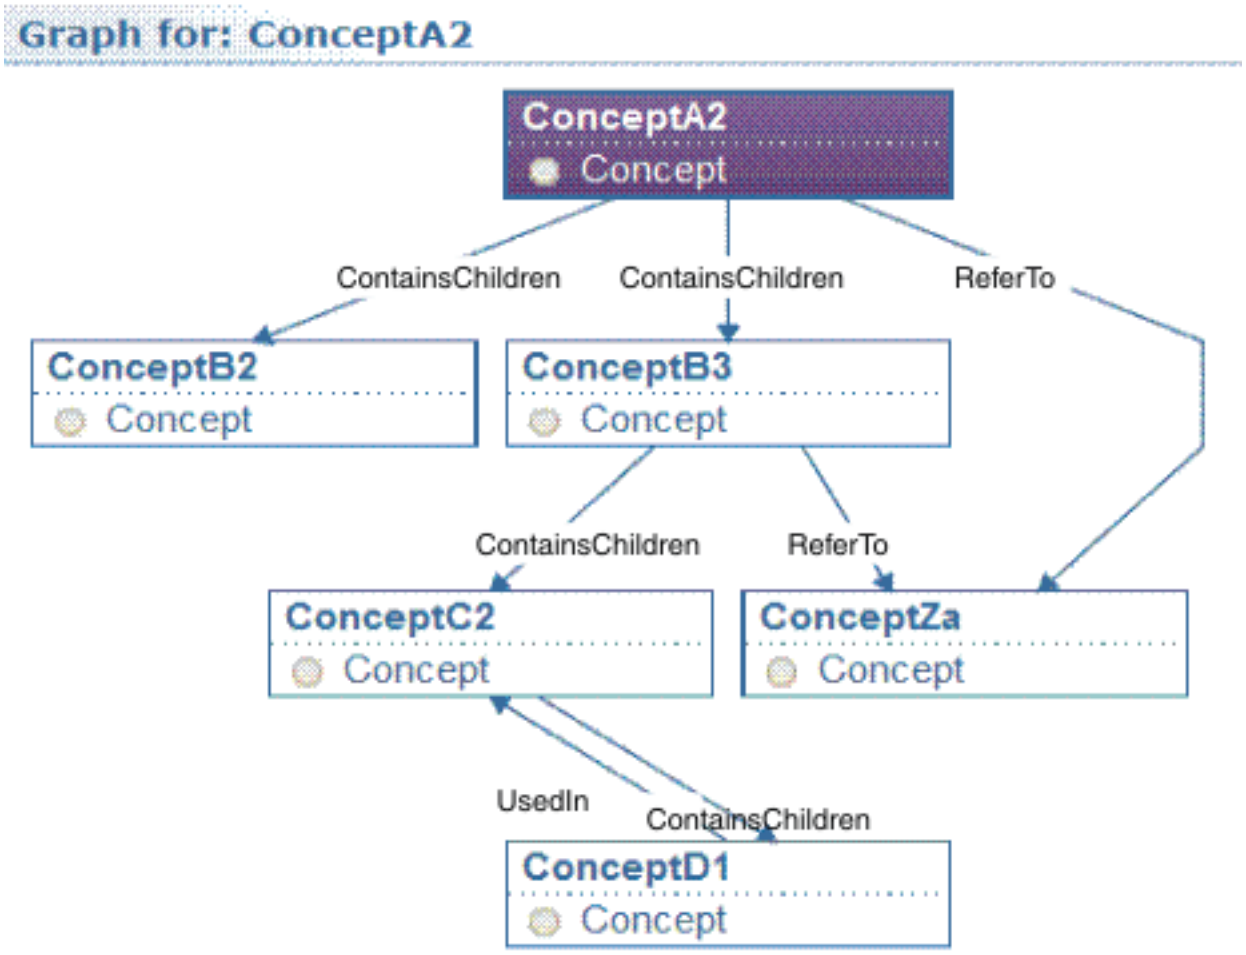
```
DECLARE ns1 NAMESPACE 'http://www.ibm.com/xmlns/prod/serviceregistry/6/0/sdo';
DECLARE c1 CHARACTER;

-- Following sets c1 to "ConceptA1" by indexing the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].name;
-- Following sets c1 to "2.0" by indexing the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].version;
-- Following sets c1 to "property1" by indexing the first
--   userDefinedProperties within the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].ns1:
userDefinedProperties[1].name;
-- Following sets c1 to "value1 for v2" by indexing the first
--   userDefinedProperties within the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].ns1:
userDefinedProperties[1].value;
```

RegistryLookup node output: example 2

Example showing the structure of RegistryLookup node output for all possible values of the `Depth Policy` property for a query on a concept entity that has a number of user relationships to other concept entities.

This example shows the ServiceRegistry message trees that are stored in the LocalEnvironment when the Concepts shown in the following WebSphere Service Registry and Repository graph are retrieved. The graph has been annotated with the relationship names to clarify the elements in the message tree.



The following ServiceRegistry message trees have some elements replaced by `...` to emphasis the structure of the tree. Likewise, the bsrURIs have been truncated.

The following shows the message trees for each possible value of the `Depth Policy` property:

- `Return matched only (Depth = 0)`

```
ServiceRegistry
  Entity
    type   = sdo:GenericObject
    bsrURI = a2e62137a605
    name   = ConceptA2
    ...
```

- `Return matched showing immediate relationships (For compatibility only)`. The entities contain elements showing the details of relationships, but only provide a list of the bsrURIs for the related child entities.

  This value of the `Depth Policy` property is deprecated, so you should use of the other options. The output tree structure produced when using this value is not compatible with those from the other values for the `Depth Policy` property. In particular, note the namespace qualifications.

```
ServiceRegistry
  Entity
    type   = sdo:GenericObject
    bsrURI = a2e62137a605
    name   = ConceptA2
    ...
    ns1:userDefinedRelationships
      name    = ContainsChildren
```

```
      targets = b2f73637f6e8 b3de6036e1af
    ns1:userDefinedRelationships
      name    = ReferTo
      targets = zac084d6b804
```

- `Return matched plus immediate related entities (Depth = 1)`. The entities contain elements showing the details of relationships, and the details of the related child entities.

```
ServiceRegistry
  Entity
    type   = GenericObject
    bsrURI = a2e62137a605
    name   = ConceptA2
    ...
    userDefinedRelationships
      name = ContainsChildren
      targetEntities
        Entity
          bsrURI = b2f73637f6e8
          name   = ConceptB2
          ...
        Entity
          bsrURI = b3de6036e1af
          name   = ConceptB3
          ...
          userDefinedRelationships
            name    = ContainsChildren
            targets = c26e43ac45a
          userDefinedRelationships
            name    = ReferTo
            targets = zac084d6b804
    userDefinedRelationships
      name = ReferTo
      targetEntities
        Entity
          bsrURI = zac084d6b804
          name   = ConceptZa
          ...
```

- `Return matched plus all related entities (Depth = -1)`. The entities contain elements showing the details of relationships, and the details of the all related child entities. ConceptD1 uses an EntityRef element to refer to its ancestor ConceptC2. ConceptZa appears twice in the tree as it is referenced by both ConceptA2 and ConceptB3.

```

Connecting to external REST APIs

IBM App Connect Enterprise provides a set of REST nodes, which enable you to interact either synchronously or asynchronously with external REST APIs.

About this task

The following REST nodes are provided with IBM App Connect Enterprise:

- node
- node
- node

An AppConnectRESTRequest node is also provided, which you can use to interact with an IBM App Connect REST API. For more information about using this node, see “Connecting to an App Connect REST API” on page 1047.

You can use a RESTRequest node in a message flow to issue synchronous requests to external REST APIs. The RESTRequest node issues a request and then waits for a response from the REST API. Alternatively, you can use a pair of RESTAsyncRequest and RESTAsyncResponse nodes to interact with a REST API

asynchronously. The RESTAsyncRequest node sends a REST request, and then returns control to the flow without waiting for a response. The RESTAsyncResponse node, which can be in either the same flow or a separate flow, handles the response from the REST API. A separate thread processes the response, and that thread starts a new transaction to handle the response.

You might want to use asynchronous request-response processing when interacting with a backend server that has a high latency. Using synchronous REST requests can result in multiple outstanding requests that require large numbers of threads to make enough simultaneous connections to the backend server, whereas asynchronous processing allows the response to be decoupled from the request.

For more information about using a RESTRequest node in a message flow, see node. For more information about using the asynchronous REST nodes, see node and node.

Procedure

Complete the steps in one the following tasks to configure interactions with external REST APIs by using REST nodes in a message flow:

- "Calling REST APIs by using the RESTRequest node" on page 1033
- "Interacting asynchronously with REST APIs by using the RESTAsyncRequest and RESTAsyncResponse nodes" on page 1035

Calling REST APIs by using the RESTRequest node

IBM App Connect Enterprise provides a RESTRequest node, which you can use to interact with external REST APIs.

About this task

You can use a RESTRequest node in a message flow to issue synchronous requests to external REST APIs. The RESTRequest node uses an imported Swagger document or an imported OpenAPI 3.0 document in either JSON or YAML format. You can import the document from the toolkit workspace, your file system, or from a URL.

If you created a REST API from scratch in the IBM App Connect Enterprise Toolkit, a Swagger document or an OpenAPI 3.0 document was created. You can import the document and use it with the RESTRequest node.

For more information about creating REST APIs, see "Creating a REST API" on page 2019. For more information about using a RESTRequest node, see node.

Procedure

Import a Swagger document or an OpenAPI 3.0 document and configure a RESTRequest node by completing the following steps:

1. Create a message flow to include your RESTRequest node.

   For more information about creating a message flow, see "Creating a message flow" on page 574.
2. Populate the **REST APIs Catalog**.

   Each project in the Application Development view has a **REST APIs Catalog** folder that contains a list of all the REST APIs that are available in the project for use with RESTRequest and RESTAsyncRequest

nodes. Each REST API folder in the **REST APIs Catalog** contains a list of all the available operations in the REST API. Populate the **REST APIs Catalog** by completing the following steps:

a) Right-click a project or an application in the Application Development view and select **Import**. Alternatively, select **File** > **Import**.

b) Select **RESTAPIs** > **RestAPI definition** to open the **Import a RESTAPI definition** dialog.

c) Select a project from the **Project** menu or click **New** to create a new project.

d) Select **Select an OpenAPI document from the workspace or from a file system** or **Retrieve an OpenAPI document from a URL using HTTP or HTTPS**.

e) Click **Next** to open the **Import a RESTAPI definition** dialog.

f) Depending on the choice you made at substep d, you are prompted to select a file from a file system or a project in the workspace, or specify a URL.

g) Click **Next** to review the details of the RESTAPI that you want to import.

h) If the details of the RESTAPI are correct, click **Next**

The Swagger document or OpenAPI 3.0 document is copied into the **REST APIs Catalog** and the **Other resources** folder for the project that contains the RESTRequest node, and is visible in the Application Development view.

3. Configure the RESTRequest node to use an imported Swagger document or an imported OpenAPI 3.0 document that contains the operation that you want to invoke, by using one of the following methods:

   - Drag an operation from the **REST APIs Catalog** onto the message flow canvas or onto a connection between two existing nodes in the message flow. A RESTRequest node is created automatically and configured to use the selected operation. If the operation is dropped onto a connection between two existing nodes, the RESTRequest is inserted into the flow between the two existing nodes and configured to use the selected operation.
   - Drag a RESTRequest node from the palette onto the message flow canvas or onto a connection between two existing nodes in your message flow. If you drag the RESTRequest node onto the canvas, a configuration wizard opens. If you drag a RESTRequest node from the palette onto a connection between two existing nodes in your message flow, the RESTRequest node is inserted into the flow between the two existing nodes, and the configuration wizard opens.

     You must then use the configuration wizard opens to choose the REST API and the operation that you want to invoke. You can select an operation from the set of operations in the imported Swagger document or imported OpenAPI 3.0 document. You can also specify parameter values as node properties, by using XPath or ESQL expressions to select data from the input message tree.

     a. Use the **Invoke an operation in a REST API** page in the wizard to specify the location of the Swagger document or OpenAPI 3.0 document that contains the operation that you want to use:

        – **Select a Swagger document or an OpenAPI 3.0 document from a referenced project or from a file system**

          Select this option to display a window in which you can specify either a location in your file system, or select a Swagger document or an OpenAPI 3.0 document from a referenced

project. If you select a Swagger document or an OpenAPI 3.0 document from your file system, it is copied into the project that contains your RESTRequest node.

If you want to use a Swagger document or an OpenAPI 3.0 document from a shared library that is not referenced, you must reference the shared library, and then add the RESTRequest node.

- **Retrieve a Swagger document or an OpenAPI 3.0 document from a URL using HTTP or HTTPS**

  Select this option to display a window in which you can specify a URL to a Swagger document or an OpenAPI 3.0 document. This Swagger document or OpenAPI 3.0 document is downloaded and stored in the project that contains the RESTRequest node.

- **Configure the REST request node manually**

  Select this option to close the wizard without changing the RESTRequest node. You can then optionally drag an operation from the **REST APIs Catalog** in the Navigation onto the RESTRequest node in the message flow, and it is configured automatically to use that operation.

b. If you selected either **Select a Swagger document or an OpenAPI 3.0 document from a referenced project or from a file system** or **Retrieve a Swagger document or an OpenAPI 3.0 document from a URL using HTTP or HTTPS** in the previous step, a window is displayed in which you can select an operation to invoke in the REST API. Select the required operation and click **Finish**. The RESTRequest node is automatically configured to use the selected operation.

4. Configure the remaining properties of your RESTRequest node.

   For more information, see node.

5. Configure the security credentials for interacting with the REST API, by using the command command.

   For more information, see “Configuring security credentials for connecting to a REST API” on page 1037.

Interacting asynchronously with REST APIs by using the RESTAsyncRequest and RESTAsyncResponse nodes

You can make REST requests and receive responses asynchronously by using RESTAsyncRequest and RESTAsyncResponse nodes in your message flow.

About this task

You might want to use asynchronous request-response processing with a backend server that has a high latency. Synchronous processing can result in many outstanding requests that require large numbers of threads to make simultaneous connections to the backend server. Asynchronous processing allows the response to be decoupled from the request.

You can use a pair of RESTAsyncRequest and RESTAsyncResponse nodes to interact with a REST API asynchronously. The paired nodes correlate responses against the original requests by using a unique identifier, which is specified on both nodes. Only one pair of nodes in an execution group can have the same unique identifier.

The RESTAsyncRequest node sends a REST request, and then returns control to the flow without waiting for a response. This action frees the request thread to handle further requests, while the response is handled by the paired RESTAsyncResponse node on a different thread and in a new transaction. This asynchronous functionality enables multiple outbound requests to be made almost in parallel because the outbound request is not blocked waiting for the response. The RESTAsyncResponse node can be in either the same flow or a separate flow, but it must be in the same integration server as its paired request node.

You can specify a timeout interval, so that if the whole request-response operation takes longer than the specified duration, the request is propagated to the Failure terminal on one of the paired nodes. The timeout interval applies to the interval that starts with the request being sent by the RESTAsyncRequest node, and ends with the response being completely received by the RESTAsyncResponse node.

For each request that the RESTAsyncRequest node processes, it uses a connection to send the request, and passes the connection to the paired RESTAsyncResponse node for the response. If the timeout interval is specified, the socket is closed if the interval expires. This closure ensures that a request gets only the correct response, and any response data for a request that is timed out is discarded.

The request-response processing is split between the RESTAsyncRequest node and the RESTAsyncResponse node. If a timeout occurs during the request phase of processing, the request and an exception are propagated to the Failure terminal of the RESTAsyncRequest node. Similarly, if a timeout occurs during the response phase of processing, an exception is propagated to the Failure terminal of the RESTAsyncResponse node. In most cases, the timeout would occur when waiting for a server response, in which case the Failure terminal of the RESTAsyncResponse node is used. In rare cases a timeout might occur when the request node sends data to the server. In this case, the Failure terminal of the RESTAsyncRequest node is used.

Procedure

Import a Swagger document or an OpenAPI 3.0 document and configure a RESTAsyncRequest node by completing the following steps:

1. Create a message flow to include your RESTAsyncRequest node.

   For more information about creating a message flow, see “Creating a message flow” on page 574.

2. Optional: If you intend to Configure the REST request node manually at step 3, you must populate the **REST APIs Catalog**.

   Each project in the Application Development view has a **REST APIs Catalog** folder that contains a list of all the REST APIs that are available in the project for use with RESTRequest and RESTAsyncRequest nodes. Each REST API folder in the **REST APIs Catalog** contains a list of all the available operations in the REST API. Populate the **REST APIs Catalog** by completing the following steps:

   a) Right-click a project or an application in the Application Development view and select **Import**. Alternatively, select **File** > **Import**.

   b) Select **RESTAPIs** > **RestAPI definition** to open the **Import a RESTAPI definition** dialog.

   c) Select a project from the **Project** menu or click **New** to create a new project.

   d) Select **Select an OpenAPI document from the workspace or from a file system** or **Retrieve an OpenAPI document from a URL using HTTP or HTTPS**.

   e) Click **Next** to open the **Import a RESTAPI definition** dialog.

   f) Depending on the choice you made at substep d, you are prompted to select a file from a file system or a project in the workspace, or specify a URL.

   g) Click **Next** to review the details of the RESTAPI that you want to import.

   h) If the details of the RESTAPI are correct, click **Next**

   The Swagger document or OpenAPI 3.0 document is copied into the **REST APIs Catalog** and the **Other resources** folder for the project that contains the RESTRequest node, and is visible in the Application Development view.

3. Drag a RESTAsyncRequest node from the palette onto the message flow canvas, and configure it to use an imported Swagger document or an imported OpenAPI 3.0 document that contains the operation that you want to invoke.

   Alternatively, you can drag a RESTAsyncRequest node from the palette onto a connection between two existing nodes in your message flow. The RESTAsyncRequest node is inserted into the flow between the two existing nodes.

   When you place the node onto the canvas, a wizard guides you through choosing the REST API and the operation that you want to invoke. You can select an operation from the set of operations in the

imported Swagger document or the imported OpenAPI 3.0 document, and specify parameter values as node properties, by using XPath or ESQL expressions to select data from the input message tree.

a) Use the **Invoke an operation in a REST API** page in the wizard to specify the location of the Swagger document or OpenAPI 3.0 document that contains the operation that you want to use:

- **Select a Swagger document or an OpenAPI 3.0 document from a referenced project or from a file system**

  Select this option to display a window in which you can specify either a location in your file system, or select a Swagger document or OpenAPI 3.0 document from a referenced project. If you select a Swagger document or an OpenAPI 3.0 document from your file system, it is copied into the project that contains your RESTAsyncRequest node.

  If you want to use a Swagger document or an OpenAPI 3.0 document from a shared library that is not referenced, you must reference the shared library first, and then add the RESTAsyncRequest node.

- **Retrieve a Swagger document or an OpenAPI 3.0 document from a URL using HTTP or HTTPS**

  Select this option to display a window in which you can specify a URL to a Swagger document or an OpenAPI 3.0 document. This Swagger document or OpenAPI 3.0 document is downloaded and stored in the project that contains the RESTAsyncRequest node.

- **Configure the REST request node manually**

  Select this option to close the wizard without changing the RESTAsyncRequest node. You can then optionally drag an operation from the **REST APIs Catalog** in the Navigation onto the RESTAsyncRequest node in the message flow, and it is configured automatically to use that operation.

b) If you selected either **Select a Swagger document or an OpenAPI 3.0 document from a referenced project or from a file system** or **Retrieve a Swagger document or an OpenAPI 3.0 document from a URL using HTTP or HTTPS** in the previous step, a window is displayed in which you can select an operation to invoke in the REST API. Select the required operation and click **Finish**. The RESTAsyncRequest node is automatically configured to use the selected operation.

4. Configure the remaining properties of your RESTAsyncRequest node.

   For more information, see node.

5. Add a RESTAsyncResponse node to handle the response to your REST request. This node can be in either the same flow or a separate flow, but it must be in the same integration server.

   For more information, see node.

6. Configure the security credentials for interacting with the REST API, by using the command command.

   For more information, see “Configuring security credentials for connecting to a REST API” on page 1037.

7. You can share data between the flow containing the RESTAsyncRequest node and the flow containing the RESTAsyncResponse node, by storing and retrieving data in the UserContext folder in the Local Environment. You can store data in the request flow under `OutputLocalEnvironment.Destination.REST.Request.UserContext` and you can retrieve data in the response flow from `LocalEnvironment.REST.Response.UserContext`. For examples, see “Using local environment variables with REST nodes” on page 1039.

Configuring security credentials for connecting to a REST API

Create a security identity by using the **`mqsisetdbparms`** command, and configure a REST request node in a message flow to use that identity for connecting to a secured REST API.

About this task

Follow these steps to configure a connection to a secured REST API:

Procedure

1. Use the **mqsisetdbparms** command to associate a user name, password, and API key with a connection to an external REST API.

   You can specify these values in any one of the following combinations:

   - User ID, password, and API key
   - User ID and password
   - API key only

   You can specify the security credentials by setting the following parameters:

   -n *rest::securityIdentity*
   The name of the security identity that is used to authenticate a connection to a REST API, where *securityIdentity* is the value of the `Security Identity` property in the RESTRequest or RESTAsyncRequest node.

   -u *UserId*
   The user ID to be used for connecting to the REST API.

   -p *Password*
   The password to be used for connecting to the REST API.

   -k *API key*
   The API key to be used for connecting to the REST API.

   The following example shows how to specify a user ID, password, and API key:

   ```
   mqsisetdbparms -w workDir -n rest::myRESTSecurityIdentity -u myRESTUserID -p myRESTPassword -
   k myRESTAPIKey
   ```

   Alternatively, you might choose to specify only the API key, as shown in the following example:

   ```
   mqsisetdbparms -w workDir -n rest::myRESTSecurityIdentity -k myRESTAPIKey
   ```

   For more information about associating security credentials with resources, see command.

   If the configured REST API operation contains multiple "securityDefinitions" each of which requires a different set of credentials, you must create a separate "Security Identity" for each "securityDefinition". This can be achieved only by using LocalEnvironment overrides for "Security Identity" as detailed in “Using local environment variables with REST nodes” on page 1039.

2. In your message flow, specify the name of the security identity that you configured in step 1 (in this example, `myRESTSecurityIdentity`) as the value in the `Security identity` property in the RESTRequest or RESTAsyncRequest node.

   This security identity is used when you connect to the REST API from IBM App Connect Enterprise.

   In order for the REST request nodes to authenticate to a REST API by using a security identity created with the **mqsisetdbparms** command, the REST request nodes require additional information about how to apply that security identity to the REST API. The REST request nodes use the specified security identity only if the operation or API being invoked specifies one or more security requirements in the Swagger document or OpenAPI 3.0 document.

   Security requirements can be specified at the API level, or for a specific operation, by adding Security Requirement Objects to the **security** property of the Swagger Object, the OpenAPI 3.0 object, or the relevant Operation Object. Each Security Requirement Object must refer to a Security Scheme Object in the Security Definitions Object, which is defined through the **securityDefinitions** property of the Swagger object or OpenAPI 3.0 object. IBM App Connect Enterprise supports only Security

Scheme Objects that have a type of `basic` or `apiKey`. Security Scheme Objects with a type of `oauth2` are not supported.

For more information about Swagger, see the following topics:

- Swagger
- Swagger RESTful API Documentation Specification Version 2.0
- “Restrictions on Swagger documents” on page 2018

For more information about OpenAPI 3.0, see the following topics:

- “OpenAPI 3.0” on page 2018
- https://github.com/OAI/OpenAPI-Specification/blob/main/versions/3.0.0.md
- “Restrictions on OpenAPI 3.0 documents” on page 2019

What to do next

You can use the **mqsireportdbparms** command to show information about the security identities that are being used for connecting to a REST API. For example:

- Enter the following command to show the security identity for HTTP Basic Authentication and the API key, for use with a REST request node:

```
mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuthAndApiKey
```

This command returns output similar to the following example:

```
$ mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuthAndApiKey
BIP8180I: The resource name 'rest::myBasicAuthAndApiKey' has userID 'myUserID'.
BIP8214I: The resource name 'rest::myBasicAuthAndApiKey' has API key
 'C664C588-885A-4F07-9390-9CD7A4F8A89F'.
```

- Enter the following command to validate the password for a single security identity for HTTP Basic Authentication, for use with a REST request node:

```
mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuth -u myUserID -p password
```

This command returns output similar to the following example:

```
$ mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuth -u myUserID -p password
BIP8180I: The resource name 'rest::myBasicAuth' has userID 'myUserID'.
BIP8201I: The password you entered, 'password' for resource 'rest::myBasicAuth' and userId
 'myUserID' is correct.

BIP8071I: Successful command completion.
```

For more information about the security credentials that were set on the integration server, see command.

Using local environment variables with REST nodes

The REST request nodes support a number of local environment message tree variables, which you can use to dynamically alter the values that are set in the node properties.

The following table shows elements in the **LocalEnvironment.Destination.REST.Request** message tree, which can be used to override properties in the RESTRequest and RESTAsyncRequest nodes. Any properties that are set by the local environment variables will apply to both the RESTRequest and RESTAsyncRequest nodes.

The table includes examples of how to set the values by using ESQL; however, you can also set them by using transformation nodes, such as the Mapping node. To access the LocalEnvironment from a Mapping node, see Customizing a message map to include a message assembly component.

Table 25. Input local environment properties

Element name	Type	Description
Operation	string	The value is the name of the operation to invoke in the REST API. This environment variable overrides the **Operation** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.Operation = 'updateCustomerByID';`

Parameters.*parameter_name*	string	Specify values to use for the parameters of the operation. The values specified in the LocalEnvironment override any literal values or XPath/ESQL expressions specified in the **Parameters** table on the node. For example:
		`SET OutputLocalEnvironment.Destination.REST.Request.Parameters.max = 10;`
		`SET OutputLocalEnvironment.Destination.REST.Request.Parameters.filter = 'Fred Bloggs';`
		Note: If the values are XPath/ESQL expressions, the values are passed to the remote REST API as string literals (and not evaluated as XPath/ESQL expressions).
		To define the REST parameters and set their values in a message map, use the **Add User Defined** function to add the `parameter_name` element, and then provide a mapping to set its value. For more information, see Configuring the local environment tree Variables folder by using the Add User Defined function.

ContentType	string	The value is the value of the Content-Type header to send in the request to the REST API. This environment variable overrides the **Content-Type** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.ContentType = 'application/vnd.ibm-demo+json';`
Accept	string	The value is the value of the Accept header to send in the request to the REST API. This environment variable overrides the **Accept** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.Accept = 'application/json';`
SecurityIdentity	string	The value must be the name of a security identity defined with the **mqsisetdbparms** command. Do not include the "rest::" prefix. This environment variable overrides the **Security identity** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.SecurityIdentity = 'myApiKey';`

Table 25. Input local environment properties (continued)

Element name	Type	Description
UserID	string	If this environment variable is specified, it overrides all the values that are specified by the `LocalEnvironment.Destination.REST.Request.SecurityIdentity` override and the **Security identity** property on the node. If the `LocalEnvironment.Destination.REST.Request.UserID` environment variable is specified, the `LocalEnvironment.Destination.REST.Request.Password` environment variable is also required.
Password	string	If this environment variable is specified, it overrides all the values that are specified by the `LocalEnvironment.Destination.REST.Request.SecurityIdentity` override and the **Security identity** property on the node. If the `LocalEnvironment.Destination.REST.Request.Password` environment variable is specified, the `LocalEnvironment.Destination.REST.Request.UserID` environment variable is also required.
APIKey	string	If this environment variable is specified, it overrides all the values that are specified by the `LocalEnvironment.Destination.REST.Request.SecurityIdentity` override and the **Security identity** property on the node. The `LocalEnvironment.Destination.REST.Request.APIKey` environment variable can be specified either alone or in conjunction with the `LocalEnvironment.Destination.REST.Request.UserID` and `LocalEnvironment.Destination.REST.Request.Password` environment variables.
Timeout	integer	The time (in seconds) that the node waits for the REST API to process the operation. This environment variable overrides the **Request timeout (sec)** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.Timeout = 300;`
BaseURL	string	This environment variable overrides the **Base URL override** property on the node, and the base URL specified in the Swagger document containing the definitions of the REST API. For example: `SET OutputLocalEnvironment.Destination.REST.Request.BaseURL = 'https://my-prod-server.ibm.com/customerdb/v1';`
ProxyURL	string	This environment variable overrides the **HTTP(S) proxy location** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.ProxyURL = 'http://my-proxy-server.ibm.com';`

Table 25. Input local environment properties (continued)

Element name	Type	Description
FollowRedirection	boolean	This environment variable overrides the **Follow HTTP(S) redirection** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.FollowRedirection = TRUE;`
KeepAlive	boolean	This environment variable overrides the **Enable HTTP 1/1 keep-alive** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.KeepAlive = FALSE;`
Compression	string	This environment variable overrides the **Compression** property on the node. Valid values are: • gzip • zlib-deflate • raw-deflate For example: `SET OutputLocalEnvironment.Destination.REST.Request.Compression = 'zlib-deflate';`
Protocol	string	This environment variable overrides the **Protocol** property on the node. Valid values are: • TLS • TLSv1 • TLSv1.2 • TLSv1.3 • SSL_TLS • SSL_TLSv2 For example: `SET OutputLocalEnvironment.Destination.REST.Request.Protocol = 'TLSv1.2';`
AllowedCiphers	string	This environment variable overrides the **Allowed SSL Ciphers** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.AllowedCiphers = 'SSL_RSA_FIPS_WITH_3DES_EDE_CBC_SHA';`
HostnameChecking	boolean	This environment variable overrides the **Enable SSL certificate hostname checking** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.HostnameChecking = FALSE;`

Table 25. Input local environment properties (continued)

Element name	Type	Description
KeyAlias	string	This environment variable overrides the **SSL client authentication key alias** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.KeyAlias = 'myClientCertificate';`
EnableCRLCheck	boolean	This environment variable overrides the **Enable certificate revocation list checking** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.EnableCRLCheck = TRUE;`
AcceptCompressedResponses	string	This environment variable overrides the **Accept compressed responses by default** property on the node. For example: `SET OutputLocalEnvironment.Destination.REST.Request.AcceptCompressedResponses = TRUE;`
ServicePrincipalName	string	Specifies the Service Principal Name (SPN) to use when the integration node negotiates the Kerberos security protocol. For example: `SET OutputLocalEnvironment.Destination.REST.Request.ServicePrincipalName = 'HTTP/iib.iibservice2.com:7800';`
SecuritySchemes.*security_scheme*.SecurityIdentity	string	Specifies the name of a security identity to use for the specified security scheme. The specified security identity is used only for the specified security scheme. If this environment variable is specified, it overrides the `LocalEnvironment.Destination.REST.Request.SecurityIdentity` override and the **Security identity** property on the node. The name of the security scheme corresponds to the name of a Security Scheme Object in a Security Definitions Object in the Swagger document containing the definitions of the REST API. The value must be the name of a security identity defined with the **mqsisetdbparms** command. Do not include the "rest::" prefix. For example: `SET OutputLocalEnvironment.Destination.REST.Request.SecuritySchemes.petstore_aut = 'myIdentity3'`

Table 25. Input local environment properties (continued)

Element name	Type	Description
SecuritySchemes.*security_scheme*.UserID	string	Specify the user ID to use for the specified security scheme when using HTTP Basic Authentication. The specified user ID is used only for the specified security scheme. If this environment variable is specified, it overrides the user ID specified in a security identity using either the `LocalEnvironment.Destination.REST.Request.SecuritySchemes.secur` or `LocalEnvironment.Destination.REST.Request.SecurityIdentity` overrides, and also the **Security identity** property on the node. The name of the security scheme corresponds to the name of a Security Scheme Object in a Security Definitions Object in the Swagger document containing the definitions of the REST API. For example: `SET OutputLocalEnvironment.Destination.REST.Request.SecuritySchemes.security_sch`
SecuritySchemes.*security_scheme*.Password	string	Specify the password to use for the specified security scheme when using HTTP Basic Authentication. The specified password is used only for the specified security scheme. If this environment variable is specified, it overrides the password specified in a security identity using either the `LocalEnvironment.Destination.REST.Request.SecuritySchemes.secur` or `LocalEnvironment.Destination.REST.Request.SecurityIdentity` overrides, and also the **Security identity** property on the node. The name of the security scheme corresponds to the name of a Security Scheme Object in a Security Definitions Object in the Swagger document containing the definitions of the REST API. For example: `SET OutputLocalEnvironment.Destination.REST.Request.SecuritySchemes.petstore_aut`
SecuritySchemes.*security_scheme*.APIKey	string	Specify the API key to use for the specified security scheme when using HTTP Basic Authentication. The specified API key is used only for the specified security scheme. If this environment variable is specified, it overrides the API key specified in a security identity using either the `LocalEnvironment.Destination.REST.Request.SecuritySchemes.secur` or `LocalEnvironment.Destination.REST.Request.SecurityIdentity` overrides, and also the **Security identity** property on the node. The name of the security scheme corresponds to the name of a Security Scheme Object in a Security Definitions Object in the Swagger document containing the definitions of the REST API. For example: `SET OutputLocalEnvironment.Destination.REST.Request.SecuritySchemes.petstore_aut`

Table 25. Input local environment properties (continued)

Element name	Type	Description

UserContext	mixed content	Specify context data to be stored by the RESTAsyncRequest node. The data can later be accessed by the RESTAsyncResponse node for the matching request.
		
		You can use the user context to specify data that will be passed from the RESTAsyncRequest node to the RESTAsyncResponse node. To store user context data, prior to the RESTAsyncRequest node, either set a value in the `OutputLocalEnvironment.Destination.REST.Request.UserContext` environment variable or create and populate child nodes below it.
		
		For example, to set the values by using an ESQL expression:
		
		`SET OutputLocalEnvironment.Destination.REST.Request.UserContext = 'Some important information';`
		
		`SET OutputLocalEnvironment.Destination.REST.Request.UserContext.Name.FirstName = 'Fred';`
		`SET OutputLocalEnvironment.Destination.REST.Request.UserContext.Name.Surname = 'Bloggs';`
		
		`SET OutputLocalEnvironment.Destination.REST.Request.UserContext.MyData.Binary = CAST('A piece of data' AS BLOB CCSID 1208);`
		
		You can use a Mapping node to set a value, by mapping to the mixed child element `OutputLocalEnvironment.Destination.REST.Request.UserContext.mix` To use a Mapping node to create sub-elements, use user-defined elements or cast `xsd:any` and map to them. For more information, see node.
		
		To access the user context data after a RESTAsyncResponse node, read the value or children of the `LocalEnvironment.REST.Response.UserContext` environment variable.

QueryStringDoNotPercentEncodeChars	String	Specifies those characters in the query string that are not to be percent encoded while the URI is built. For example, to specify that the comma and greater than symbols are not to be percent encoded: `SET OutputLocalEnvironment.Destination.REST.Request.QueryStringDoNotPercentEncod = ',>';` The default set of characters not to be percent encoded is asterisk (*), minus (-), period (.), and underscore (_).

The following table shows the data that is written by the RESTRequest node to the LocalEnvironment when propagating an output message:

Table 26. Output local environment properties generated by the RESTRequest node		
Element	**Type**	**Description**
LocalEnvironment.WrittenDestination.REST.Method	string	The HTTP method used when invoking the operation in the REST API.
LocalEnvironment.WrittenDestination.REST.URL	string	The URL used when invoking the operation in the REST API.
LocalEnvironment.WrittenDestination.REST.RequestHeaderSize	integer	The size of the request headers sent to the REST API.
LocalEnvironment.WrittenDestination.REST.RequestBodySize	integer	The size of the request body sent to the REST API.
LocalEnvironment.WrittenDestination.REST.StatusCode	integer	The HTTP status code in the response from the REST API.
LocalEnvironment.WrittenDestination.REST.ResponseHeaderSize	integer	The size of the response headers received from the REST API.
LocalEnvironment.WrittenDestination.REST.ResponseBodySize	integer	The size of the response body received from the REST API.
LocalEnvironment.WrittenDestination.REST.TotalRequestTime	integer	The total elapsed time invoking the operation in the REST API.

The following table shows the data that is written by the RESTAsyncRequest node when propagating an output message:

Table 27. Output local environment properties generated by the RESTAsyncRequest node:		
Element	**Type**	**Description**
LocalEnvironment.WrittenDestination.REST.Method	string	The HTTP method used when invoking the operation in the REST API.
LocalEnvironment.WrittenDestination.REST.URL	string	The URL used when invoking the operation in the REST API.
LocalEnvironment.WrittenDestination.REST.RequestHeaderSize	integer	The size of the request headers sent to the REST API.
LocalEnvironment.WrittenDestination.REST.RequestBodySize	integer	The size of the request body sent to the REST API.
LocalEnvironment.WrittenDestination.REST.CorrelationID	blob	The correlation ID used to correlate the request and response between the RESTAsyncRequest and RESTAsyncResponse nodes.

The following table shows the data that is written by the RESTAsyncResponse node when propagating an output message:

Table 28. Output local environment properties generated by the RESTAsyncResponse node:		
Element	**Type**	**Description**
LocalEnvironment.REST.Response.CorrelationID	blob	The correlation ID used to correlate the request and response between the RESTAsyncRequest and RESTAsyncResponse nodes.
LocalEnvironment.REST.Response.StatusCode	integer	The HTTP status code in the response from the REST API.
LocalEnvironment.REST.Response.ResponseHeaderSize	integer	The size of the response headers received from the REST API.
LocalEnvironment.REST.Response.ResponseBodySize	integer	The size of the response body received from the REST API.

Table 28. Output local environment properties generated by the RESTAsyncResponse node: (continued)		
Element	**Type**	**Description**
LocalEnvironment.REST.Response.UserContext	mixed content	The information that was stored in the OutputLocalEnvironment.Destination.REST.Request.UserContext can be retrieved by the response thread.

Connecting to an App Connect REST API

IBM App Connect Enterprise provides an AppConnectRESTRequest node, which enables interaction with an IBM App Connect REST API.

About this task

You can use an AppConnectRESTRequest node in a message flow to issue requests to an IBM App Connect REST API. The AppConnectRESTRequest node uses an imported Swagger document or an imported OpenAPI 3.0 document (in either JSON or YAML format), which defines the REST API and the operations that are available. When you download the Swagger document or the OpenAPI 3.0 document, you can import it from your toolkit workspace and select the operations that you want to invoke. For more information, see node.

Alternatively, you can configure a connection to an App Connect API by using an App Connect REST Request pattern, which is available through the Patterns Explorer. For more information about using patterns, see “Developing integration solutions by using patterns” on page 2056.

Procedure

1. From IBM App Connect, download the Swagger document or the OpenAPI 3.0 document for the App Connect API that you want to use, such as the GoogleSheetsAPI. Import the document into the appropriate application folder in the IBM App Connect Enterprise workspace.

   To import the API document, right click the application and select **Import** > **REST APIs** > **REST API definition** to open the **Import a REST API definition** dialog. Then, pick either **select from workspace** or **retrieve from a URL** to import the document.

   When you have imported it, the Swagger document or OpenAPI 3.0 document is visible in the Application Development view in the **REST APIs Catalog** and the **Other resources** folder of your project that contains your application.
2. Create a message flow to include the AppConnectRESTRequest node.

   For more information about creating a message flow, see “Creating a message flow” on page 574.
3. Drag an AppConnectRESTRequest node from the palette onto the message flow canvas.
4. Configure the AppConnectRESTRequest node by setting the following properties in the **Basic** tab of the node:
   a) In the **Definitions file** field, specify the Swagger document or OpenAPI 3.0 document that contains the definitions of the REST API operations that you want to invoke.

      To select the Swagger document or the OpenAPI 3.0 document, click **Browse**, and then select the required file from the list that is displayed in the REST API Definitions File Selection dialog, and click **OK**. (The file is in `*.json` or `*.yaml` format.)

      The operations that are contained in the selected App Connect API (such as `GoogleSheets.create`) are now listed in the **Operation** field of the AppConnectRESTRequest node.
   b) Select the operation that you want to invoke.
5. The **Request** tab automatically lists any parameters that are required for the selected operation. You can enter a literal value, a location in the message tree, or a location in the Local Environment.
6. Configure the remaining properties of your AppConnectRESTRequest node.

   For more information about these properties, see node.

7. Configure the security credentials for interacting with the REST API, by using the command command.

   For more information, see "Configuring security credentials for connecting to an IBM App Connect REST API" on page 1048.

Configuring security credentials for connecting to an IBM App Connect REST API

Create a security identity by using the **mqsisetdbparms** command, and configure an AppConnectRESTRequest node in a message flow to use that identity for connecting to a secured App Connect REST API.

About this task

Follow these steps to configure a connection to a secured App Connect REST API:

Procedure

1. Use the **mqsisetdbparms** command to associate a user name, password, and API key with a connection to an App Connect REST API.

   You can specify these values in any one of the following combinations:

   - User ID, password, and API key
   - User ID and password
   - API key only

   You can specify the security credentials by setting the following parameters:

   -n *rest::securityIdentity*
   The name of the security identity that is used to authenticate a connection to an App Connect REST API, where *securityIdentity* is the value of the `Security Identity` property in the AppConnectRESTRequest node.

   -u *UserId*
   The user ID to be used for connecting to the App Connect REST API.

   -p *Password*
   The password to be used for connecting to the App Connect REST API.

   -k *API key*
   The API key to be used for connecting to the App Connect REST API.

   The following example shows how to specify a user ID, password, and API key:

   ```
   mqsisetdbparms -w workDir -n rest::myRESTSecurityIdentity -u myRESTUserID -p myRESTPassword -
   k myRESTAPIKey
   ```

   Alternatively, you might choose to specify only the API key, as shown in the following example:

   ```
   mqsisetdbparms -w workDir -n rest::myRESTSecurityIdentity -k myRESTAPIKey
   ```

   For more information about associating security credentials with resources, see command.

2. In your message flow, specify the name of the security identity that you configured in step 1 (in this example, `myRESTSecurityIdentity`) as the value in the `Security identity` property in the AppConnectRESTRequest node.

   This security identity will be used when you connect to the App Connect REST API from IBM App Connect Enterprise.

   In order for the AppConnectRESTRequest request node to authenticate to a REST API using a security identity created with the **mqsisetdbparms** command, the AppConnectRESTRequest node requires additional information about how to apply that security identity to the REST API. The AppConnectRESTRequest node uses the specified security identity only if the operation or API being invoked specifies one or more security requirements in the Swagger document.

What to do next

You can use the **mqsireportdbparms** command to show information about the security identities that are being used for connecting to a REST API. For example:

- Enter the following command to show the security identity for HTTP Basic Authentication and the API key, for use with an AppConnectRESTRequest node:

  ```
  mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuthAndApiKey
  ```

  This command returns output similar to the following example:

  ```
  $ mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuthAndApiKey
  BIP8180I: The resource name 'rest::myBasicAuthAndApiKey' has userID 'myUserID'.
  BIP8214I: The resource name 'rest::myBasicAuthAndApiKey' has API key
   'C664C588-885A-4F07-9390-9CD7A4F8A89F'.
  ```

- Enter the following command to validate the password for a single security identity for HTTP Basic Authentication, for use with an AppConnectRESTRequest request node:

  ```
  mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuth -u myUserID -p password
  ```

  This command returns output similar to the following example:

  ```
  $ mqsireportdbparms -w c:\workdir\ACEServ1 -n rest::myBasicAuth -u myUserID -p password
  BIP8180I: The resource name 'rest::myBasicAuth' has userID 'myUserID'.
  BIP8201I: The password you entered, 'password' for resource 'rest::myBasicAuth' and userId
   'myUserID' is correct.

  BIP8071I: Successful command completion.
  ```

For more information about the security credentials that have been set on the integration server, see command.

Connecting to Enterprise Information Systems

Use WebSphere Adapters to communicate with Enterprise Information Systems (EIS) such as SAP, Siebel, PeopleSoft, and JD Edwards.

About this task

This section contains the following concept information:

WebSphere Broker Adapters Transport

WebSphere Broker Adapters Transport is a service that connects applications to Enterprise Information Systems (such as SAP Software, PeopleSoft Enterprise, and Siebel Business Application systems).

You can use the WebSphere Broker Adapters Transport to support the following operations:

- Accept input from an SAP, Siebel, or PeopleSoft application.
- Send requests to an SAP, Siebel, JD Edwards, or PeopleSoft application.
- Send a reply to an SAP synchronous callout.
- Route IDocs to separate message flows.

These operations are implement by the following built-in nodes:

- SAPInput node
- SAPRequest node
- SAPReply node
- SiebelInput node
- SiebelRequest node
- PeopleSoftInput node
- PeopleSoftRequest node
- JDEdwardsRequest node

Use the input nodes to accept input from an EIS, along with a matching reply node if the EIS needs a response. Use the request nodes to send requests to an EIS.

To use the WebSphere Broker Adapters Transport, you must deploy a message flow that contains one or more WebSphere Adapters nodes.

The following topics contain more information about working with WebSphere Adapters:

- “Connecting to Enterprise Information Systems” on page 1049
- “WebSphere Adapters nodes” on page 1050
- “Developing message flows that use WebSphere Adapters” on page 1106

WebSphere Adapters nodes

A WebSphere Adapters node is a message flow node that is used to communicate with Enterprise Information Systems (EIS), such as SAP, Siebel, JD Edwards, and PeopleSoft.

The following terms are associated with WebSphere Adapters:

EIS
: Enterprise information system. This term is used to describe the applications that form an enterprise's existing system for handling company-wide information. An enterprise information system offers a well-defined set of services that are exposed as local or remote interfaces or both. Enterprise Resource Planning (ERP) and Customer Relationship Management (CRM) are typical enterprise information systems.

EMD
: Enterprise Metadata Discovery. A specification that you can use to examine an EIS and get details of business object data structures and APIs. An EMD stores definitions as XML schemas by default,

and builds components that can access the EIS. In IBM App Connect Enterprise you use the Adapter Connection wizard to examine an EIS.

Business object
In a development or production environment, a set of XML schema attributes that represents a business entity (such as an invoice) and the definition of actions that can be performed on those attributes (such as the create and update operations).

The WebSphere Adapters support two modes of communication:

- **Inbound**: An event is generated on the EIS and the adapter responds to the event by sending a message to the integration node. The WebSphere Adapters input nodes support inbound communication. When the EIS sends an event to the adapter, a message is propagated from the WebSphere Adapters input node. For example, use an SAPInput node to accept input from an SAP application.
- **Outbound**: The integration node uses the adapter to send a request to the EIS. The WebSphere Adapters request nodes support outbound communication. When a message is propagated to the WebSphere Adapters request node, the adapter sends a request to the EIS. For example, use an SAPRequest node to send requests to an SAP application.

The WebSphere Adapters nodes need an adapter component to access the EIS. The input nodes need an inbound adapter component, which allows the EIS to invoke the message flow when an event occurs. The request nodes need an outbound adapter component, which is used by the message flow to invoke a service in the EIS.

The WebSphere Adapters nodes also need XML Schema Definitions (XSD) to ensure that the IBM App Connect Enterprise messages that are propagated to and from the nodes reflect the logical structure of the data in the EIS.

SAP, Siebel, JD Edwards, and PeopleSoft adapters are supported by the following message flow nodes in IBM App Connect Enterprise:

- SAPInput node
- SAPRequest node
- SAPReply node
- SiebelInput node
- SiebelRequest node
- PeopleSoftInput node
- PeopleSoftRequest node
- JDEdwardsRequest node
- JDEdwardsInput node

You can configure the WebSphere Adapters nodes by using properties on the nodes, or by using a policy. For example, you can use an SAP Connection policy to specify the connection details for an SAP system. For more information, see Policy properties.

To effectively maintain the pool of connections to the EIS, you can set a connection timeout value on a policy. For more information, see “Configuring EIS connections to expire after a specified time” on page 213.

The SAPRequest node can also use an identity that is present on an input message, and propagate it to SAP, by using the `Propagate` property on the security profile that is defined on the node. For more information, see “Identity and security token propagation” on page 2580.

To maximize performance and avoid unnecessary data conversion, ensure that messages that are passed to a WebSphere Adapters request node contain the correct data types. The DataObject domain is the default domain when parsing messages that are produced by the WebSphere Adapters request node. However, when passing data to the request node (for example, by using an MQInput node), the use of a different domain can improve performance. For example, use the XMLNSC parser with the MQInput node to parse XML messages.

The mode in which your integration node is working can affect the number of integration servers and message flows that you can deploy, and the type of node that you can use. For example, in Remote Adapter Deployment mode, only adapter-related features are enabled, and the types of node that you can use, and the number of integration servers that you can create, are limited. For more information about the available modes of operation, see "Operation modes" on page 3.

For more information about support for adapters on different operating systems, see IBM App Connect Enterprise system requirements.

The following topics provide an overview of the WebSphere Adapters:

- "Overview of WebSphere Adapter for SAP Software" on page 1052
- "Overview of WebSphere Adapter for Siebel Business Applications " on page 1092
- "Overview of WebSphere Adapter for PeopleSoft Enterprise" on page 1098
- "Overview of WebSphere Adapter for JD Edwards EnterpriseOne" on page 1102

Overview of WebSphere Adapter for SAP Software
With WebSphere Adapter for SAP Software you can create integrated processes that include the exchange of information with an SAP server, without special coding.

By using the adapter, an application component (the program or piece of code that performs a specific business function) can send requests to the SAP server (for example, to query a customer record in an SAP table or to update an order document) or receive events from the server (for example, to be notified that a customer record has been updated). The adapter creates a standard interface to the applications and data on the SAP server so that the developer of the application component does not have to understand the lower-level details (the implementation of the application or the data structures) on the SAP server.

WebSphere Adapter for SAP Software complies with the Java Connector Architecture (JCA) 1.5, which standardizes the way in which application components, application servers, and Enterprise Information Systems (EIS), such as an SAP server, interact with each other.

The adapter, which you generate with the Adapter Connection wizard, uses a standard interface and standard data objects. The adapter takes the standard data object sent by the application component and calls the SAP function. The adapter then returns a standard data object to the application component. The application component does not have to deal directly with the SAP function; it is the SAP adapter that calls the function and returns the results.

For example, the application component that requested the list of customers sends a standard business object with the range of customer IDs to the SAP adapter. The application component receives, in return, the results (the list of customers) in the form of a standard business object. The adapter completes all the interactions directly with the SAP function.

Similarly, the message flow might want to know about a change to the data on the SAP server (for example, a change to a particular customer). You can generate an adapter component that listens for such events on the SAP server and notifies message flows with the update. In this case, the interaction begins at the SAP server.

For more information, see "Technical overview of Adapter for SAP Software" on page 1052.

Technical overview of Adapter for SAP Software
WebSphere Adapter for SAP Software provides multiple ways to interact with applications and data on SAP servers. Outbound processing (from an application to the adapter to the SAP server) and inbound processing (from the SAP server to the adapter to an application) are supported.

WebSphere Adapter for SAP Software connects to SAP systems running on SAP Web application servers. The adapter supports Advanced Event Processing (AEP) and Application Link Enabling (ALE) for inbound processing, and the Business Application Programming Interface (BAPI), AEP, ALE, and Query Interface for SAP Systems (QISS) for outbound processing. You set up the adapter to perform outbound and inbound processing by using the Adapter Connection wizard to generate business objects based on the services it discovers on the SAP server.

For outbound processing, the adapter client invokes the adapter operation to create, update, or delete data on the SAP server or to retrieve data from the SAP server.

For inbound processing, an event that occurs on the SAP server is sent from the SAP server to the adapter. The ALE inbound and BAPI inbound interfaces start event listeners that detect the events. Conversely, the Advanced event processing interface polls the SAP server for events. The adapter then delivers the event to an endpoint, which is an application or other consumer of the event from the SAP server.

You configure the adapter to perform outbound and inbound processing by using the Adapter Connection wizard to create a library that includes the interface to the SAP application as well as business objects based on the functions or tables that it discovers on the SAP server.

Overview of the outbound processing interfaces

WebSphere Adapter for SAP Software provides multiple interfaces to the SAP server for outbound processing.

- Through its BAPI interfaces, the adapter issues remote function calls (RFCs) to RFC-enabled functions, such as a Business Application Programming Interface (BAPI) function. These remote function calls create, update, or retrieve data on an SAP server.
  - The BAPI interface works with individual BAPIs (simple BAPIs). For example, you might want to check to see whether specific customer information exists in an SAP database.
  - The BAPI work unit interface works with ordered sets of BAPIs. For example, you might want to update an employee record. To do so, you use three BAPIs:
    1. To lock the record (to prevent any other changes to the record)
    2. To update the record
    3. To have the record approved
  - The BAPI result set interface uses two BAPIs to select multiple rows of data from an SAP database.

  BAPI calls are useful when you need to perform data retrieval or manipulation and a BAPI or RFC function that performs the task already exists.

  Simple BAPIs can be sent through the synchronous RFC, asynchronous transactional RFC, or asynchronous queued RFC protocol.
  - With synchronous RFC, both the adapter and the SAP server must be available when the call is made from the adapter to the SAP server. The adapter sends a request to the SAP server and waits for a response.
  - With asynchronous transactional RFC, a transaction ID is associated with the call from the adapter to the SAP server. The adapter does not wait for a response from the SAP server. Only the transaction ID is returned to the message flow.
  - With asynchronous queued RFC, the call from the adapter is delivered to a predefined queue on the SAP server. As with asynchronous RFC, a transaction ID is associated with the call, and the adapter does not wait for a response from the SAP server.

    This interface is useful when the event sequence must be preserved.
- The Query interface for SAP Software retrieves data from specific SAP application tables. It can return the data or check for the existence of the data. You can use this type of interaction with SAP if you need to retrieve data from an SAP table without using an RFC function or a BAPI.
- With the Application Link Enabling (ALE) interface, you exchange data using SAP Intermediate Data structures (IDocs). For outbound processing, you send an IDoc or a packet of IDocs to the SAP server.

  The ALE interface, which is particularly useful for batch processing of IDocs, provides asynchronous exchange. You can use the queued transactional (qRFC) protocol to send the IDocs to a queue on the SAP server. The qRFC protocol ensures the order in which the IDocs are received. It is often used for system replications or system-to-system transfers.
- With the ALE pass-through IDoc interface, the adapter sends the IDoc to the SAP server with no conversion of the IDoc. The message tree contains a BLOB field that represents the IDoc.

- With the Advanced event processing interface, you send data to the SAP server. The data is then processed by an ABAP handler on the SAP server.

Overview of the inbound processing interfaces

WebSphere Adapter for SAP Software provides the following interfaces to the SAP server for inbound processing.

- Through its BAPI inbound interface, the adapter listens for events and receives notifications of RFC-enabled function calls from the SAP server.
  - With synchronous RFC, both the adapter and the SAP server must be available when the call is made from the SAP server to the adapter. The adapter sends the request to a predefined application and returns the response to the SAP server.
  - With asynchronous transactional RFC, the event is delivered to the adapter even if the adapter is not available when the call is made. The SAP server stores the event on a list of functions to be invoked and continues to attempt to deliver it until the adapter is available.

    You also use asynchronous transaction RFC if you want to deliver the functions from a predefined queue on the SAP server. Delivering the files from a queue ensures the order in which the functions are sent.

    If you select assured once-only delivery, the adapter uses a data source to persist the event data received from the SAP server. Event recovery is provided to track and recover events in case a problem occurs when the adapter attempts to deliver the event to the endpoint.
- With the ALE inbound processing interface, the adapter listens for events and receives one or more IDocs from the SAP server. As with ALE outbound processing, ALE inbound processing provides asynchronous exchange.

  You can use the qRFC interface to receive the IDocs from a queue on the SAP server, which ensures the order in which the IDocs are received.

  If you select assured once-only delivery, the adapter uses a data source to persist the event data, and event recovery is provided to track and recover events in case a problem occurs when the adapter attempts to deliver the event to the endpoint.
- With the ALE pass-through IDoc interface, the SAP server sends the IDoc through the adapter to the endpoint with no conversion of the IDoc. The message tree contains a BLOB field that represents the IDoc.
- The Advanced event processing interface polls the SAP server for events. It discovers events waiting to be processed. It then processes the events and sends them to the endpoint. For more information, see "The Advanced event processing interface" on page 1086.

How the adapter interacts with the SAP server

The adapter uses the SAP Java Connector (SAP JCo) API to communicate with SAP applications. An application sends a request to the adapter, which uses the SAP JCo API to convert the request into a BAPI function call. The SAP system processes the request and sends the results to the adapter. The adapter sends the results in a response message to the calling application.

For more information, see the following topics.

- "The Adapter Connection wizard (SAP)" on page 1055
- "The BAPI interfaces" on page 1055
- "The ALE interfaces" on page 1074
- "Query interface for SAP Software" on page 1084
- "The Advanced event processing interface" on page 1086

The Adapter Connection wizard (SAP)
The Adapter Connection wizard is a tool that you use to create services. The Adapter Connection wizard establishes a connection to the SAP server, discovers services (based on search criteria that you provide), and generates business objects, interfaces, and import or export files, based on the services that are discovered.

By using IBM App Connect Enterprise, you establish a connection to the SAP server to browse the metadata repository on the SAP server. The SAP metadata repository, which is a database of the SAP data, provides a consistent and reliable means of access to that data.

You specify connection information (such as the user name and password needed to access the server), and you specify the interface that you want to use (for example, BAPI). The service metadata that is associated with that interface is displayed. You can then provide search criteria and select the information (for example, you can list all BAPIs that relate to "CUSTOMER" by using the search filter with "BAPI_CUSTOMER*", then select one or more BAPIs).

The result of running the Adapter Connection wizard is an adapter connection project and a library that contain the interfaces and business objects as well as the adapter.

The Adapter Connection wizard also produces an import file (for outbound processing) or an export file (for inbound processing).

- The import file contains the managed connection factory property settings that you provide in the wizard.
- The export file contains the activation specification property settings you provide in the wizard.

The BAPI interfaces
The WebSphere Adapter for SAP Software supports outbound processing for simple BAPIs, BAPI units of work, and BAPI result sets. In outbound processing, message flows call BAPIs and other RFC-enabled functions on the SAP server. The adapter supports inbound processing for simple BAPIs only. In inbound processing, the SAP server sends an RFC-enabled function (such as a BAPI function) through the adapter to an endpoint.

For example, you want to build a service that creates a new customer on the SAP server. You run the Adapter Connection wizard to discover the BAPI_CUSTOMER_CREATEFROMDATA function, and the wizard generates the business-object definition for BAPI_CUSTOMER_CREATEFROMDATA, as well as other Service Component Architecture (SCA) service resources. During BAPI outbound processing, the adapter receives the service request and converts the data into a BAPI invocation.

BAPI interface (simple BAPIs)

A simple BAPI performs a single operation, such as retrieving a list of customers. The adapter supports simple BAPI calls by representing each with a single business object schema.

Simple BAPIs can be used for outbound or inbound processing. You can specify synchronous RFC processing or asynchronous transactional RFC (tRFC) processing when you configure a module for a simple BAPI. In addition, for outbound processing, you can specify asynchronous queued RFC (qRFC) processing, in which BAPIs are delivered to a predefined queue on the SAP server.

- In synchronous RFC processing, the SAP server and the adapter must be available during processing.
  - In outbound processing, the message flow sends a request, then waits for a response from the SAP server.
  - In inbound processing, the SAP server sends a request through the adapter to an endpoint and waits for a response from the adapter.
- In asynchronous tRFC outbound processing, the adapter associates a transaction ID with the function call to the SAP server. The adapter does not wait for a response from the SAP server. If the delivery is unsuccessful, the message flow can use the SAP transaction ID (TID) to make the request again. The TID is a field in your message.

- In asynchronous tRFC inbound processing, the adapter does not have to be available when the SAP server runs the function call. The function call is placed on a list of functions to be invoked, and the call is attempted until it is successful.

  To send function calls from a user-defined outbound queue on the SAP server, you also specify asynchronous tRFC inbound processing.
- In asynchronous qRFC outbound processing, the process is similar to asynchronous tRFC outbound processing. A TID is associated with the function call, and the adapter does not wait for a response from the SAP server. In addition, the BAPIs are delivered to a predefined queue on the SAP server. By sending BAPIs to the predefined queue, you can ensure the order in which they are delivered.

BAPI work unit interface

A BAPI work unit consists of a set of BAPIs that are processed in sequence to complete a task. For example, to update an employee record in the SAP system, the record needs to be locked before being updated. This task is accomplished by calling three BAPIs, in sequence, in the same work unit. The following three BAPIs illustrate the kind of sequence that forms such a unit of work:

- BAPI_ADDRESSEMP_REQUEST
- BAPI_ADDRESSEMP_CHANGE
- BAPI_ADDRESSEMP_APPROVE

The first BAPI locks the employee record, the second updates the record, and the third approves the update. The advantage of using a BAPI unit of work is that the message flow can request the employee record change with a single call, even though the work unit consists of three separate functions. In addition, if SAP requires that the BAPIs be processed in a specific sequence for the business flow to complete correctly, the work unit supports this sequence.

BAPI result set interface

BAPI result sets use the GetList and GetDetail functions to retrieve an array of data from the SAP server. The information that is returned from the GetList function is used as input to the GetDetail function.

For example, if you want to retrieve information on a set of customers, you use BAPI_CUSTOMER_GETLIST, which acts as the query BAPI, and BAPI_CUSTOMER_GETDETAIL, which acts as the result BAPI. The BAPIs perform the following steps:

1. The BAPI_CUSTOMER_GETLIST call returns a list of keys (for example, CustomerNumber).
2. Each key is mapped dynamically to the business object for BAPI_CUSTOMER_GETDETAIL.
3. BAPI_CUSTOMER_GETDETAIL is processed multiple times, so that an array of customer information is returned.

You use the Adapter Connection wizard to discover the BAPI_CUSTOMER_GETLIST and BAPI_CUSTOMER_GETDETAIL functions and build the key relationship between the two BAPIs. The wizard then generates business object definitions for these BAPIs as well as other SCA service resources. At run time, the client sets the values in the BAPI_CUSTOMER_GETLIST business object, and the adapter returns the corresponding set of customer detail records from the SAP server.

For more information, see the following topics.

- "Outbound processing for the BAPI interface" on page 1056
- "Business objects for the BAPI interface" on page 1073

Note: It is recommended that you modify the mapping from the Adapter to the SAP node when you migrate from a previous version of the Adapter for SAP to the current version of the Adapter for SAP. This precaution prevents empty tags in the BAPI response structure for uninitialized table parameters.

Outbound processing for the BAPI interface
In BAPI outbound processing, a message flow sends a request to the SAP server. For BAPI units of work and BAPI result sets, processing is handled synchronously (the message flow waits for a response

from the SAP server). For simple BAPIs, you can request that processing be handled synchronously or asynchronously (the message flow does not wait for a response from the SAP server).

For BAPI units of work and BAPI result sets, the processing is handled as described in "Synchronous RFC" on page 1057. For simple BAPIs, you make a selection, during configuration, about the type of remote RFC call you want to make.

Synchronous RFC

If you select **Synchronous RFC** (the default) during configuration for a simple BAPI, or if you are using BAPI units of work or BAPI result sets, the following processing steps occur:

1. The adapter receives a request from a message flow in the form of a BAPI business object.
2. The adapter converts the BAPI business object to an SAP JCo function call.
3. The adapter uses the Remote Function Call (RFC) interface to process the BAPI or RFC function call in the SAP application.
4. After passing the data to the SAP server, the adapter handles the response from SAP and converts it back into the business object format required by the message flow.
5. The adapter then sends the response back to the message flow.

Asynchronous transactional RFC

If you select **Asynchronous transactional RFC** during configuration, the following processing steps occur:

1. The adapter receives a request from a message flow in the form of a BAPI business object.
2. The adapter checks the business object to see whether the SAP transaction ID attribute has a value assigned. (The SAP transaction ID (TID) is a field in your message.)
   - If the SAP transaction ID attribute has a value, the adapter uses that value during processing.
   - If the attribute does not have a value, the adapter makes a call to the SAP server and gets a transaction ID from the SAP server.
3. The adapter converts the BAPI business object to an SAP JCo function call.
4. The adapter uses the transactional Remote Function Call (tRFC) protocol to make the call to the SAP server.

   The adapter does not wait for a response from the SAP server.
5. After the function data is passed to the SAP application, control returns to the adapter.
   - If the call to the SAP server fails, the SAP server throws an ABAPException.
   - If the call to the SAP server succeeds but contains invalid data, no exception is returned to the adapter. For example, if the adapter sends a request that contains an invalid customer number, the adapter does not respond with an exception indicating that no such customer exists.
6. The request node builds a message tree that contains the transaction ID as one of the fields.

Asynchronous queued RFC

If you select **Asynchronous queued RFC** during configuration, the following processing steps occur:

1. The adapter receives a request from a message flow in the form of a BAPI business object.
2. The adapter checks the business object to see whether the SAP transaction ID attribute has a value assigned. (The SAP transaction ID (TID) is a field in your message.)
   - If the SAP transaction ID attribute has a value, the adapter uses that value during processing.
   - If the attribute does not have a value, the adapter makes a call to the SAP server and gets a transaction ID from the SAP server.
3. The adapter converts the BAPI business object to an SAP JCo function call.

4. The adapter uses the tRFC protocol to make the call to the specified queue on the SAP server.

   The adapter does not wait for a response from the SAP server.
5. After the function data is passed to the SAP application, control returns to the adapter.
   - If the call to the SAP server fails, the SAP server throws an ABAPException.
   - If the call to the SAP server succeeds but contains invalid data, no exception is returned to the adapter. For example, if the adapter sends a request that contains an invalid customer number, the adapter does not respond with an exception indicating that no such customer exists.
6. The request node builds a message tree that contains the transaction ID as one of the fields.

SAP BAPI transaction commit
When the SAP adapter is used with the BAPI interface, you must consider certain factors when you design transactional flows.

You can configure message flows to be transactional so that updates to resources such as databases can be coordinated; changes are committed or rolled back together within the same transaction. This transactional coordination can be extended to external system updates, such as SAP databases, when you use the BAPI interface with SAPRequest nodes.

Information about the state of in-flight transactions is held in IBM MQ queues, which means that IBM App Connect Enterprise must have access to IBM MQ when it is processing these messages. To enable this, ensure that either an IBM MQ client or an IBM MQ server is installed on the same computer as the integration node. By default, the `Transaction mode` property of the SAPInput node is set to `Yes`, and the `Transaction mode` property of the SAPRequest node is set to `Automatic`, which means that it uses the value that is set on the input node that drives the message flow. If you do not require the nodes in the flow to be transactional, you can set the `Transaction mode` property to `No`, in which case access to IBM MQ is not required. For more information about using IBM MQ with IBM App Connect Enterprise, see “Installing IBM MQ” on page 96.

The SAP adapter can control whether it waits for SAP to commit the updates synchronously, or issues a commit and returns while the SAP commit happens asynchronously. You can determine this behavior by using the **`Use wait parameter before calling BAPI commit`** parameter on the **Configure Objects** pane of the Adapter Connection wizard. The adapter relies on the transactionality setting of the message flow to determine whether to issue the commit call.

BAPIs with implicit commit

In earlier releases of SAP, some BAPIs were coded with a commit. From SAP Release 4.0A onwards, it is more effective for BAPIs to issue a separate BAPI_TRANSACTION_COMMIT to force the update, instead of doing commit work. By using this method, BAPI calls can be made before the work is committed as a batched unit of work. To find out if a BAPI is coded with a commit, see the documentation for the BAPI.

Message flow transactionality

When the `Transaction mode` property on the SAPRequest node is set to `Yes`, the adapter is instructed to issue the SAP commit on completion of the message flow in line with other database commits. You can set the **`Use wait parameter before calling BAPI commit`** parameter in the Adapter Connection wizard that determines whether the commit is synchronous or asynchronous.

If the `Transaction mode` property on the SAPRequest node is set to `No`, the adapter does not issue an SAP commit and the parameter that you set on the Adapter Connection wizard has no relevance. However, the commit can still be issued as part of a BAPI work unit COMMIT verb (to which the property on the wizard does apply) or a call to the BAPI_TRANSACTION_COMMIT (to which the property on the wizard does not apply).

The following rules apply when you set the `Transaction mode` property on the SAPRequest node.

- Set `Transaction mode` to `No` if the following conditions apply:
  - The BAPIs already have commits
  - A BAPI_TRANSACTION_COMMIT is called by an SAPRequest node
  - A BAPI work unit includes a BAPI_TRANSACTION_COMMIT or the COMMIT verb is added on the **Configure Objects** pane of the Adapter Connection wizard

  If the BAPIs are coded with commits and you set `Transaction mode` to `Yes`, the BAPI is called as part of the same transaction as those from other SAPRequest nodes in the same flow and using the same adapter. Therefore, any BAPIs that were called previously in this message flow are committed.
- Set `Transaction mode` to `Yes` if the following conditions apply:
  - The BAPI needs to be committed (that is, the BAPI is not coded with a commit)
  - The BAPI work unit needs to be committed and does not include a BAPI_TRANSACTION_COMMIT or the COMMIT verb

  If you set `Transaction mode` to `No`, the BAPI is not committed now or at the end of the message flow; it is not guaranteed ever to be committed.

The following scenarios illustrate the visibility of the updates made to an SAP system, and show how to use the adapter to avoid uncertainty when data is being committed by an external system.

- Scenario 1: Business partner and relationship processing in a single flow
- Scenario 2: Order create and query application processing with two flows

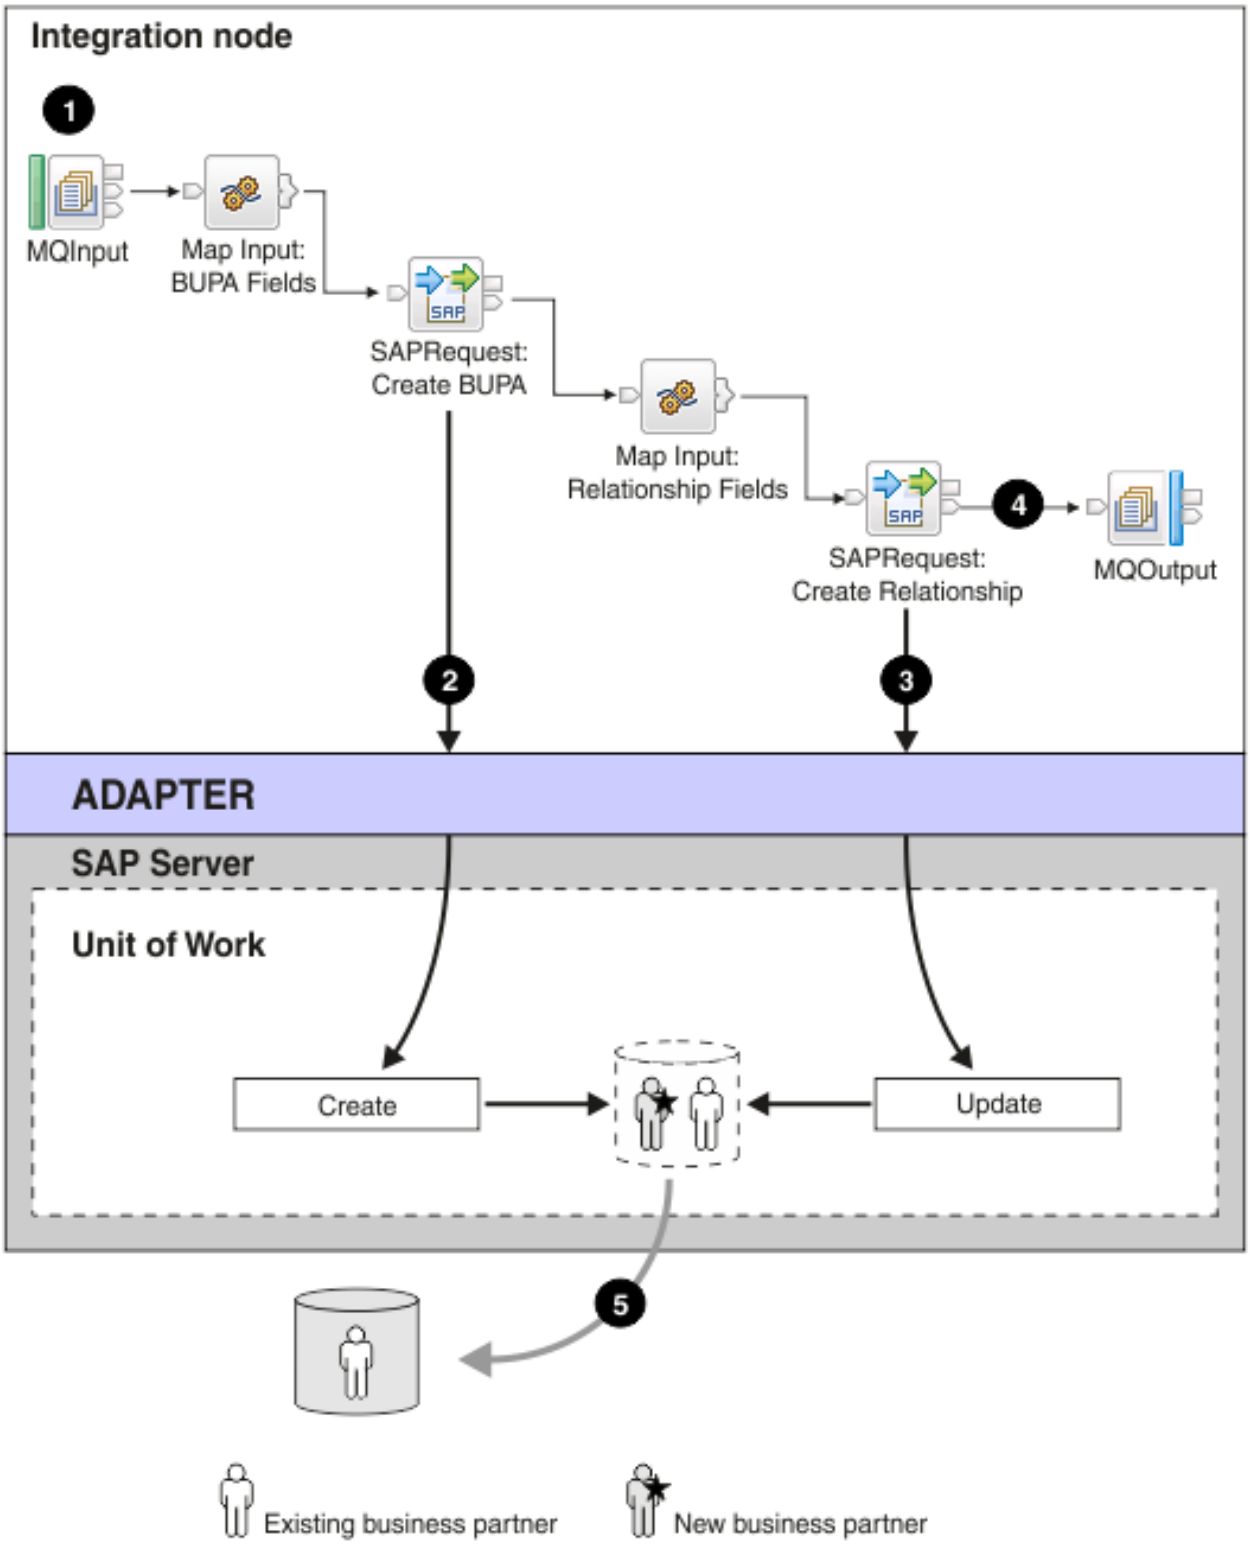
Scenario 1: Business partner and relationship processing in a single flow
You must set the `Transaction mode` property appropriately on an SAPRequest node when you are processing in a single message flow.

This scenario is one of two examples that illustrate the concepts that are described in “SAP BAPI transaction commit” on page 1058; see also “Scenario 2: Order create and query application processing with two flows” on page 1061.

In this scenario, a message flow is used to create a business partner, and a new relationship with an existing partner by using two BAPI calls:

```
BAPI_BUPA_CREATE_FROM_DATA
BAPI_BUPR_RELATIONSHIP_CREATE
```

The message flow consists of two SAPRequest nodes with the `Transaction mode` property set to `Yes` on both nodes to allow commit or rollback in case of exceptions. When the `Transaction mode` property is set to `Yes`, the message flow's final commit takes place at the end of the flow when the adapter requests SAP to commit the order.



1. An application triggers the transactional flow that creates the business partner.
2. The SAPRequest node submits a BUPA creation and returns the business partner number. The commit happens when the message flow completes because the node participates in a message flow level transaction.

3. The second SAPRequest node attempts to create a relationship between an existing business partner and the new business partner; however, SAP has not yet committed the creation of the new business partner to the database.

   If the same adapter is used for both BAPIs, the adapter ensures a single connection to SAP because both nodes have to participate in the same logical work unit. The single connection means that the BUPA creation is visible to the relationship update call (3 in the diagram), even though the flow transactionality has yet to initiate the commit.

   If the `Transaction mode` property were set to `Yes` on the create BUPA call, but `No` on the create relationship call, the adapter would need to use two different connections to SAP; that is, the transactional properties of the connections would be different. The create relationship call would therefore fail because the new business partner would not be visible until the message flow and the transactional commit have completed.
4. The MQOutput node puts an MQ message on the output queue pending transactional commit.
5. The message flow completes and the integration node begins to commit all the resources involved in that flow, including SAP (5 in the diagram). The updates are committed in SAP.

This scenario illustrates the ability of the integration node to use its transactional control of the message flow to provide the necessary information to the SAPRequest nodes to carry out related processing, even though the external SAP system is committing the work asynchronously.

Scenario 2: Order create and query application processing with two flows
You must set the `Transaction mode` property appropriately on an SAPRequest node when you are processing by using separate message flows.

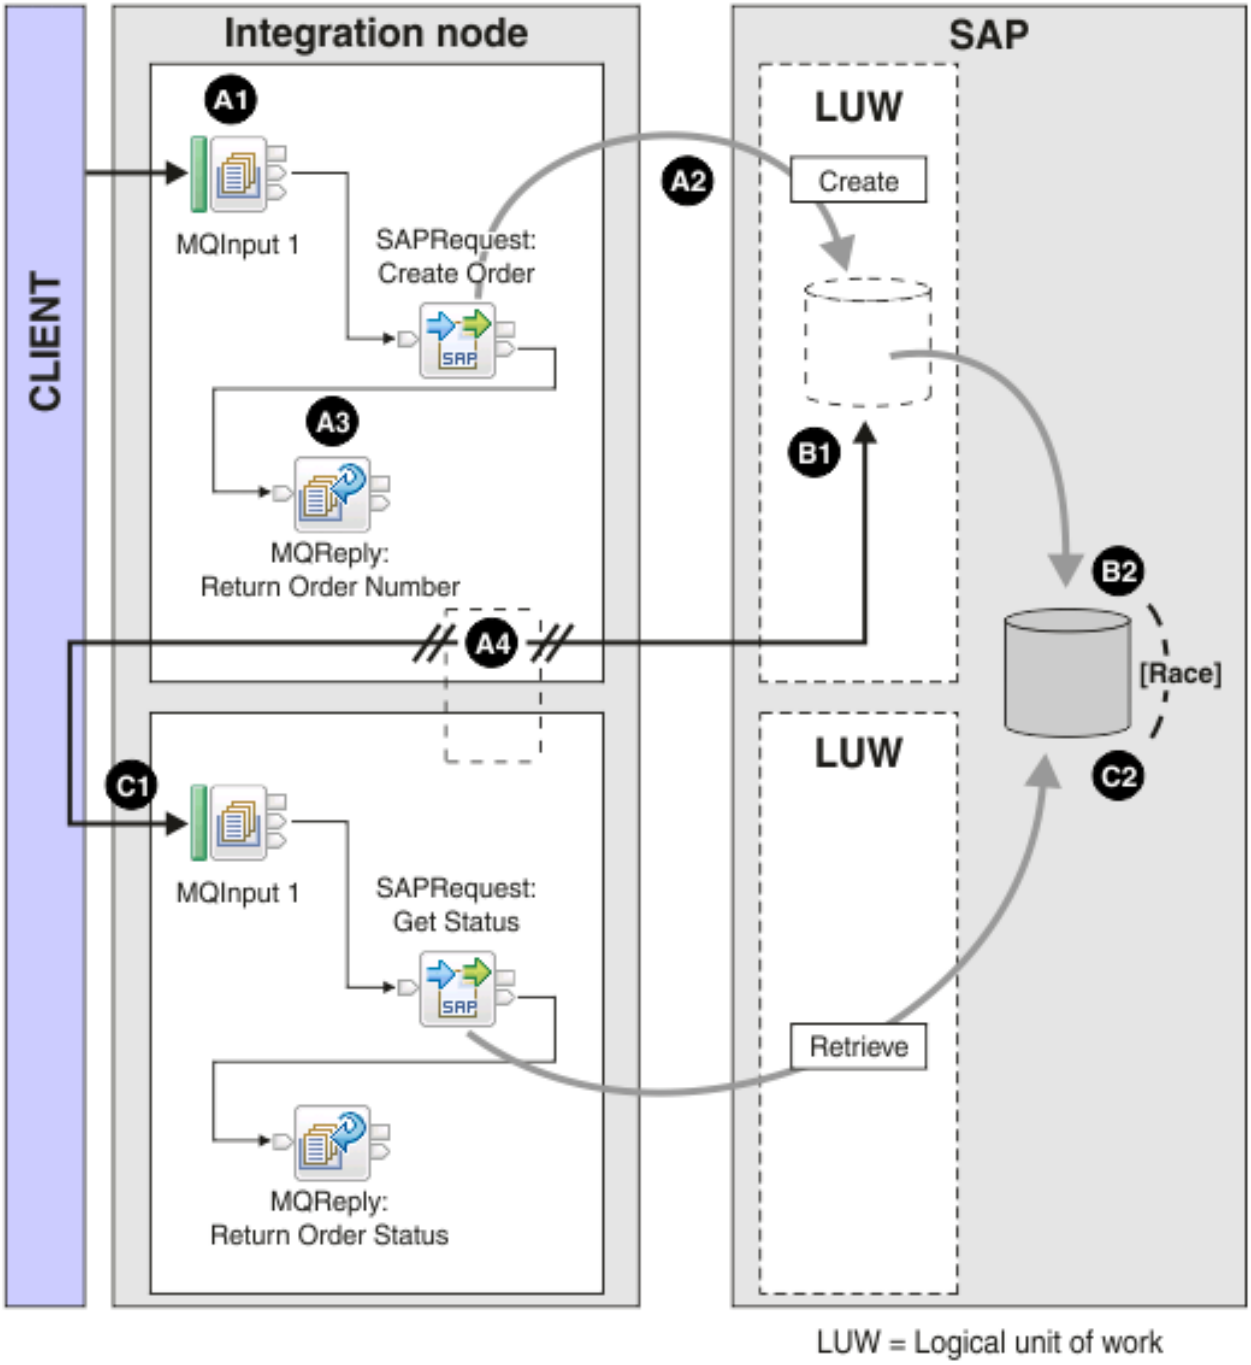
This scenario is one of two examples that illustrate the concepts that are described in “SAP BAPI transaction commit” on page 1058; see also “Scenario 1: Business partner and relationship processing in a single flow” on page 1059.

In this scenario, two message flows are used to issue a sales order create and a subsequent sales order check by using two BAPI calls:

```
BAPI_SALESORDER_CREATEFROMDAT2
BAPI_SALESORDER_GETSTATUS
```

For example, a user queries an order after a purchase has been made by using a Web-based application. The result of the query is closely linked to the asynchronous or synchronous behavior of the order creation steps carried out by the external SAP server.

In the following asynchronous example (the default behavior), the query might fail and the user receives a negative acknowledgment for the order that has been created.



BAPI Create Order message flow

A1. An application triggers the transactional message flow that creates a sales order.

A2. The SAPRequest node submits an order creation and returns the order registration number. The commit happens when the message flow completes because the node participates in a message flow level transaction.

A3. The MQReply node puts an MQ message on the output queue pending transactional commit.

A4. The message flow completes and the integration node begins to commit all the resources involved in that flow, including SAP and the MQReply node call. The order number is available to the user application.

The following two processes occur simultaneously, and effectively race each other to complete.

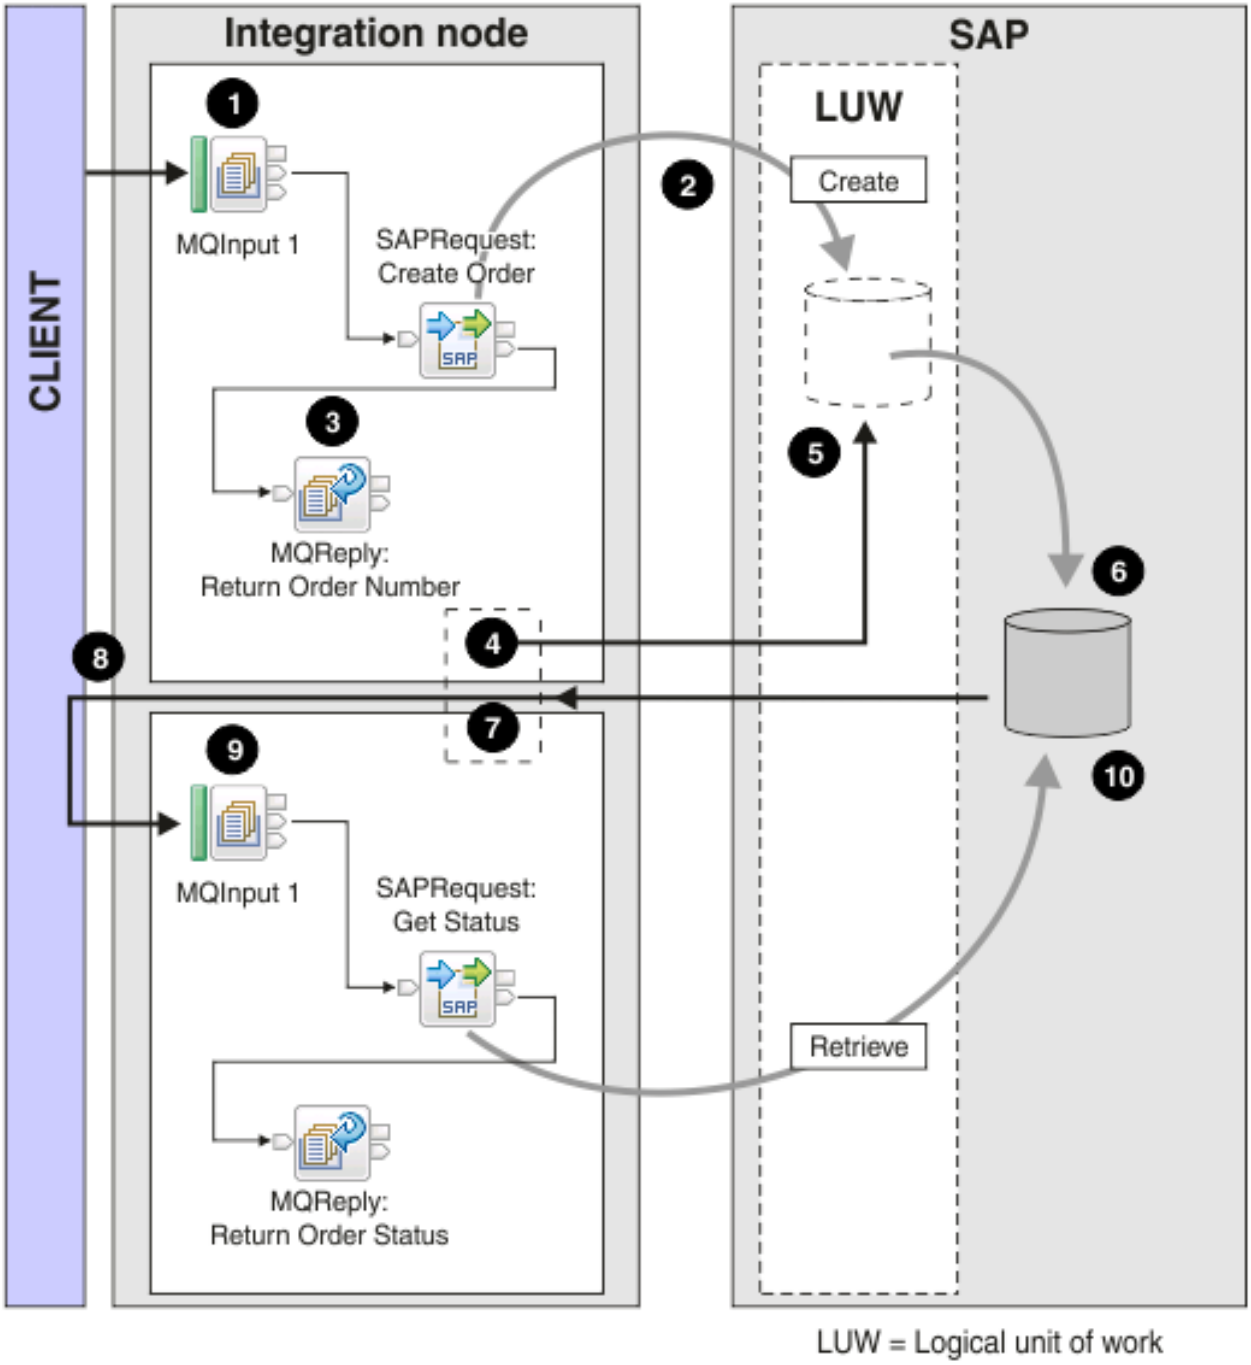
SAP Commits processing asynchronously	BAPI Get Order Status message flow
B1. The SAP commit begins.	**C1.** A request for an order status query is made.
B2. The SAP commit completes.	**C2.** The SAPRequest node requests the order.

Because of the asynchronous commit, two outcomes are possible when the order is queried:

- The order is not found because SAP has not completed the order commit.
- The order is found but only if SAP has committed the order before the query is made.

You can avoid this uncertainty by configuring the adapter to perform the commit synchronously; set the **Use wait parameter before calling BAPI commit** parameter on the adapter connection wizard to `True`, and set the `Transaction mode` property on the SAPRequest node to `Yes`.

In the following synchronous example, the query is successful and the user receives a positive acknowledgment for the order that has been created.



BAPI Create Order message flow

1. An application triggers the transactional message flow that creates the sales order.
2. The SAPRequest node submits an order creation and returns the order registration number. The commit happens when the message flow completes because the node participates in a message flow level transaction.
3. The MQReply node puts an MQ message on the output queue pending transactional commit.
4. The message flow completes and the integration node begins to commit all the resources involved in that flow, including SAP.

SAP Commits processing synchronously

5. The SAP commit begins.
6. The SAP commit completes.
7. The adapter hands control back to the integration node.
8. The MQReply node call is committed, therefore the order number is available to the user application.

BAPI Get Order Status message flow

9. A request for an order status query is made.
10. The SAPRequest node requests the order.

SAP has completed the order commit; therefore, the order query is successful.

Inbound processing for the BAPI interface
The adapter supports inbound processing (from the SAP server to the adapter) for simple BAPIs.

A client application on the SAP server invokes a function through the adapter to an end point.

For more information, see the following topics:

- “Synchronous and asynchronous RFC ” on page 1065
- “Event recovery for the BAPI interface” on page 1066
- “Passing parameters and reporting errors” on page 1066
- “BAPI inbound scenarios” on page 1067
- “SAP adapter scalability and performance” on page 1071

Synchronous and asynchronous RFC
For BAPI inbound and outbound processing, you can specify that the processing be handled synchronously (in which both the message flow and the adapter must be available during processing) or asynchronously (in which the adapter does not have to be available when the message flow makes the function call). In synchronous processing, the message flow waits for a response from the adapter. In asynchronous processing, the SAP application does not wait for a response and the adapter does not have to be available when the SAP application makes the function call.

For diagrams that illustrate synchronous and asynchronous Remote Function Calls (RFC), see “BAPI inbound scenarios” on page 1067.

The BAPI interface has two sets of activation specification properties (one for synchronous RFC and one for asynchronous RFC), which you use to set up inbound processing. You specify values for the properties with the Adapter Connection wizard.

The sequence of processing actions that result from an inbound request differ, depending on the selection you make during configuration from the **SAP Remote Function Call (RFC) type** list.

Synchronous RFC

If you select **Synchronous RFC** (the default) during configuration, the following processing steps occur:

1. The adapter starts event listeners, which listen for an RFC-enabled function event (which you specified with the RFCProgramID property) on the SAP server.
2. The RFC-enabled function event is pushed to the adapter by way of the event listeners.
3. The adapter resolves the operation and business object name using the received RFC-enabled function name.
4. The adapter sends the business object to an endpoint in a synchronous manner.
5. The adapter receives the response business object from the endpoint.

6. The adapter maps the response business object to an RFC-enabled function and returns it to the SAP server.

The adapter does not listen for events until the endpoint is active and available.

Asynchronous transactional RFC

If you select **Asynchronous Transactional/Queued RFC** during configuration, the following processing steps occur:

1. A client on the SAP server invokes an RFC-enabled function call on the adapter.

   Note: To send the RFC-enabled functions from a queue on the SAP server, the client program on the SAP server delivers the events to a user-defined outbound queue.

   A transaction ID is associated with the call.

   The calling program on the SAP server does not wait to see whether the call to the adapter was successful, and no data is returned to the calling program.
2. The RFC-function call is placed on a list of functions to be delivered.

   You can see the event list by entering transaction code SM58 on the SAP server
3. The RFC-function call is invoked on the adapter. If the adapter is not available, the call remains in the list on the SAP server, and the call is repeated at regular intervals until it can be processed by the adapter.

   When the SAP server successfully delivers the call event, it removes the function from the list.
4. If you selected **Ensure once-only event delivery**, the adapter sets the transaction ID in the event persistent table.

   This is to ensure the event is not processed more than once.
5. The adapter resolves the operation and business object name using the received RFC-enabled function name.
6. The adapter sends the business object to an endpoint.

   If you are sending functions from a user-defined queue on the SAP server, the functions are delivered in the order in which they exist on the queue. You can see the contents of the queue by entering transaction code SMQ1 on the SAP server.
7. If the delivery is successful, and if you selected **Ensure once-only event delivery**, the adapter removes the transaction ID from the event persistent table.

   If a failure occurs when the adapter attempts to deliver the business object, the transaction ID remains in the event table. When another event is received from the SAP server, the following processing occurs:

   a. The adapter checks the transaction ID.

   b. If the event matches an ID in the table, the adapter processes the failed event once; it does not send the event with the duplicate ID, thereby ensuring that the event is processed only once.

Event recovery for the BAPI interface
You can configure the adapter for BAPI inbound processing so that it supports event recovery in case a failure occurs while the event is being delivered from the adapter to the endpoint. When event recovery is specified, the adapter persists the event state in an event recovery table that resides on a data source.

Event recovery is not the default; you must specify it by enabling once-only delivery of events during adapter configuration.

Passing parameters and reporting errors
The BAPI interface is defined by its input parameters (IMPORT), output parameters (EXPORT), and tables.

After the Adapter Connection wizard has discovered the BAPI interface, the wizard creates a message set that contains an element and a type for the definition of that interface. Each of the import or export

parameters has a corresponding field, which has an associated type that can be simple or complex. Tables are represented in the message type definition as repeating complex structures (maxOccurs = -1).

BAPIs are also defined by the messages (error, warning, or success) that they can return. These messages are typically returned in an export parameter (for example, BAPIRETURN). Most BAPIs have this parameter in common, although the type of the parameter can vary. For example, its type can be:

- BAPIRETURN
- BAPIRET1
- BAPIRET2

These structures are similar, except for a few fields that have been added in later versions.

To send an error back to the calling SAP program, use the BAPIReturn structure that was specified as one of the export parameters when the BAPI was defined. Messages are returned in the Return export parameter. You can use the transaction code SE91 for message maintenance.

For more information, see Return Parameters (Error Handling) in the BAPI Programming Guide Reference on the SAP Help Portal.

As well as the application level errors, which can be reported by the Return export parameter, system or communication failures also exist, which indicate to SAP that the function could not be called or did not complete.

BAPI inbound scenarios
In SAP, you can call functions in other applications or SAP systems that are registered with SAP as remote function call (RFC) servers. In IBM App Connect Enterprise, you can register the SAP adapter with SAP as an RFC server so that it accepts synchronous and asynchronous calls from SAP.

Integrating SAP with a system with a synchronous interface

In SAP, a BAPI interface is a function call. If a system is connected to SAP as an RFC server, you can use the BAPI interface to define the interface where a program running in SAP can call an external system. The external system is identified in SAP by its RFCDestination value, which is bound to a program ID in SAP administration. The program ID is specified by the external system when it first connects to SAP.

By using the WebSphere Adapter for SAP, a message flow can connect to SAP as an RFC Server by configuring the adapter with the relevant program ID and deploying the message flow to the integration node. After deployment, the message flow can receive synchronous function calls by using the BAPI interface.

The reply identifier

The BAPI import parameters are received by the adapter and propagated from an SAPInput node as a message tree structure. The BAPI export parameters are propagated to an SAPReply node as a message tree structure. The adapter then sends back the export parameters to the calling SAP program. In this case, the SAPReply node is typically in the same flow as the SAPInput node. The SAPInput node provides a unique ID (the reply identifier) for each BAPI call. The reply identifier is propagated to the SAPReply node (in the local environment) to indicate to which BAPI call it is replying.

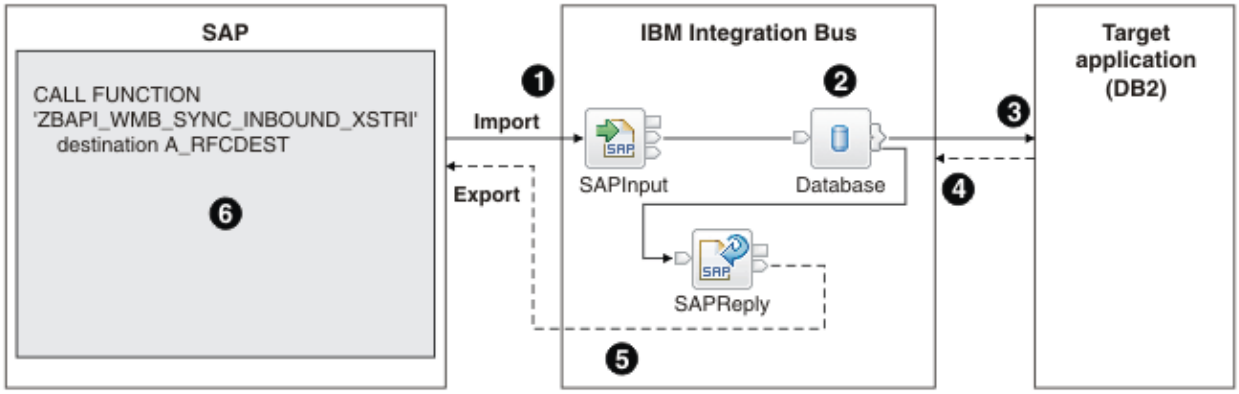
If no reply identifier exists in the local environment, the SAPReply node automatically uses the reply identifier from the SAPInput node that triggered the current execution of the message flow. If the flow is triggered by anything but an SAPInput node, or if a break occurs in the flow, an error is issued. An unhandled exception in the message flow causes a system failure in SAP.

Even if the BAPI does not expect any output parameters, the (empty) message must be propagated to the SAPReply node.

You can process two concurrent callouts from SAP by configuring the message flow with an additional instance.

Scenario 1

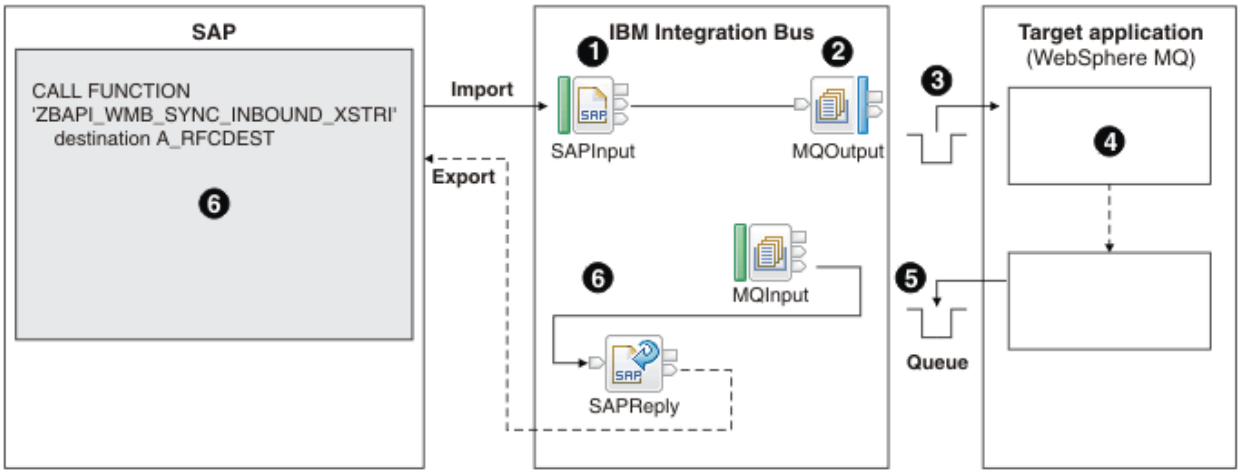
The following diagram represents a message flow where IBM App Connect Enterprise provides a link between SAP and a target application (in this case, DB2) The SAP program requires reply data, therefore it blocks further processing until the call completes.



1. The SAP program makes a BAPI call to IBM App Connect Enterprise.
2. IBM App Connect Enterprise converts the call to an SQL call.
3. IBM App Connect Enterprise passes the call on to DB2.
4. DB2 processes the SQL and returns the result to IBM App Connect Enterprise.
5. IBM App Connect Enterprise converts the SQL result to a BAPI reply and sends the reply to SAP.
6. The SAP program processes the next line of code.

Scenario 2

The following diagram also represents a message flow where the SAP program requires reply data, but in this scenario, calls between IBM App Connect Enterprise and the target application (in this case, IBM MQ) are asynchronous. The SAP system blocks further processing until the call completes. If the value of the SAP **`Maximum client wait time`** property is insufficient, or if it is set to `0`, then a timeout error might be generated. For more information about the **`Maximum client wait time`** property of the SAP Input Node, see Maximum client wait time (secs). When you use the SAPReply node in a different flow from the SAPInput node, deploy the SAPReply node in the same integration server as the SAPInput node.

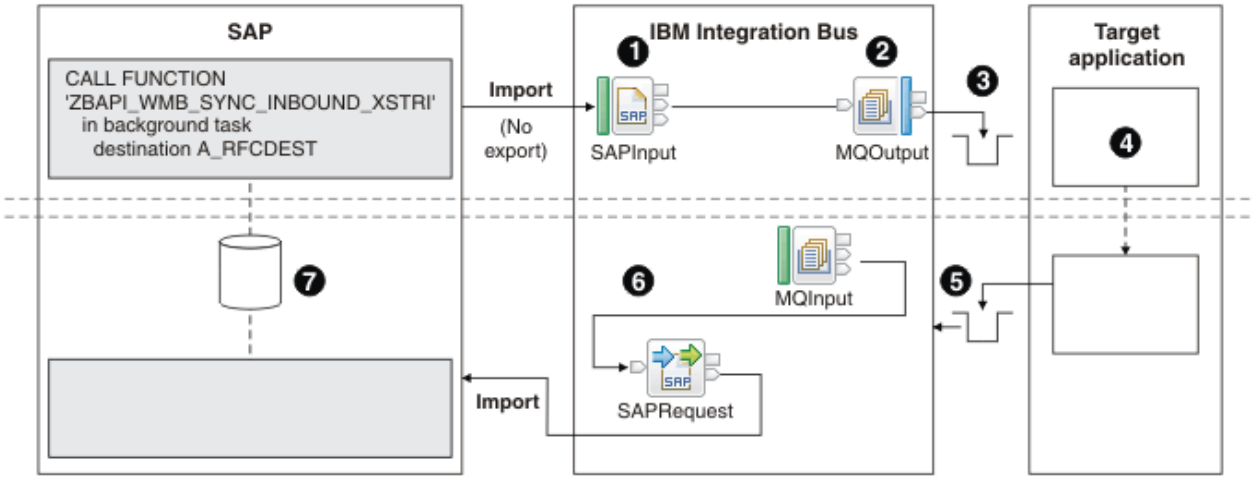


1. The SAP program makes a BAPI call to IBM App Connect Enterprise.
2. IBM App Connect Enterprise converts the import parameters into a message format that is understood by the target application.
3. IBM App Connect Enterprise puts that message on a request queue.

4. The target application gets the request message from the queue, processes it, and puts a reply message on the reply-to queue.
5. IBM App Connect Enterprise gets the reply message from the queue.
6. IBM App Connect Enterprise converts the reply message to BAPI export parameters and sends the reply to SAP.

Scenario 3

The following diagram represents an asynchronous call from SAP to IBM App Connect Enterprise, and an asynchronous call from IBM App Connect Enterprise to a target application. This scenario shows how you can combine the inbound processing that is described in this topic with outbound processing to achieve the same result as in scenarios 1 and 2. For more information about outbound processing, see "Outbound processing for the BAPI interface" on page 1056.



1. The SAP program makes a BAPI call to IBM App Connect Enterprise, stores relevant information in a database table, and continues to process the next line of code.
2. IBM App Connect Enterprise converts the import parameters into a message format that is understood by the target application.
3. IBM App Connect Enterprise puts that message on a request queue.
4. The target application gets the request message from the queue and processes it.
5. IBM App Connect Enterprise gets the reply message from the queue.
6. The SAPRequest node sends the message to the SAP program, requesting an update in SAP.
7. The SAP program refers to the information that is stored in the database table and makes the requested update.

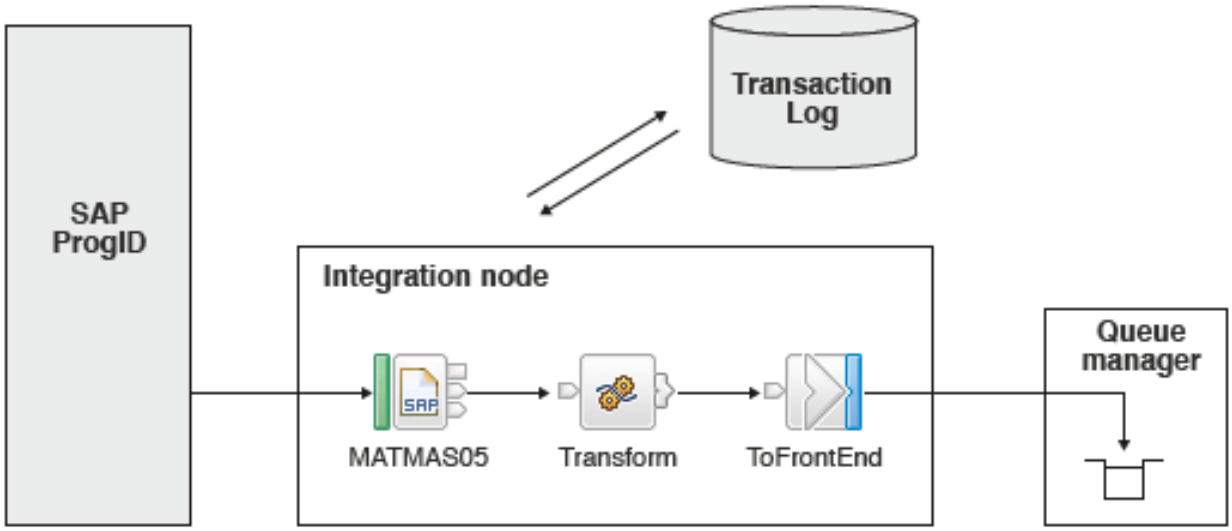
Errors and warnings

- If an SAPReply node is deployed but no SAPInput node is deployed to that integration server, a warning is written to syslog or the Windows Event Viewer.
- If the SAPReply node is provided with a reply identifier that does not correspond to any BAPI call in this integration server, an error is issued.
- If the same reply identifier is sent to two SAPReply nodes, the second node receives an error message.
- If an SAP program tries to call a BAPI that is using the RFCDestination value of the integration node, but that BAPI was not discovered for that adapter, an error is written to syslog or the Windows Event Viewer, and a failure message is sent back to the calling SAP program.

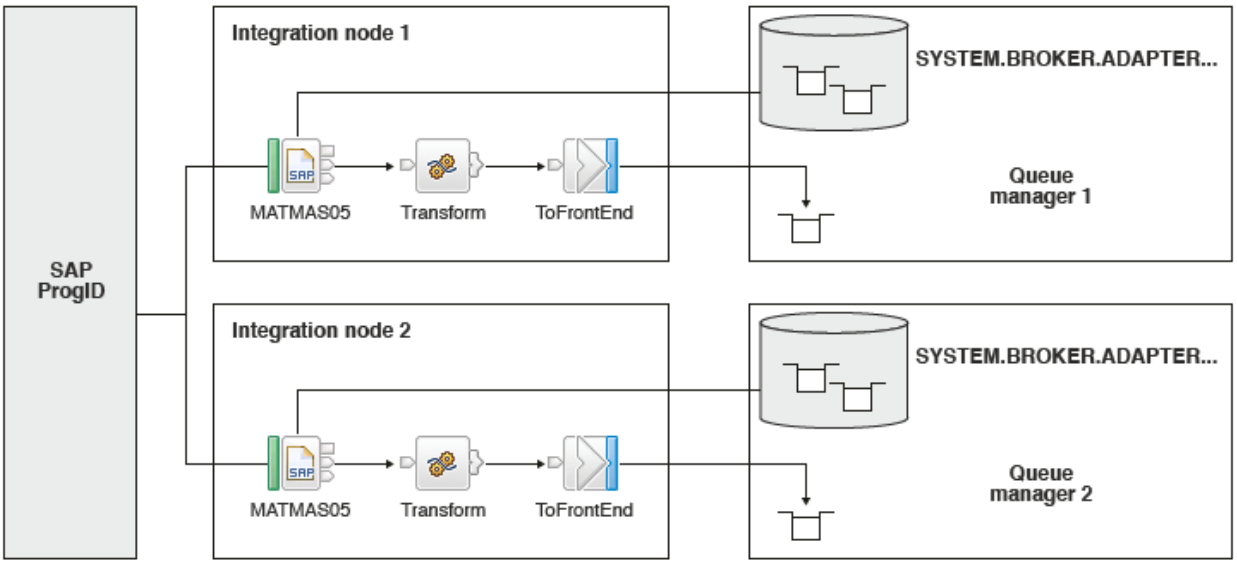
SAP high availability

You can configure IBM App Connect Enterprise to withstand software or hardware failures when working with SAP, so that IBM App Connect Enterprise is available for as much of the time as possible.

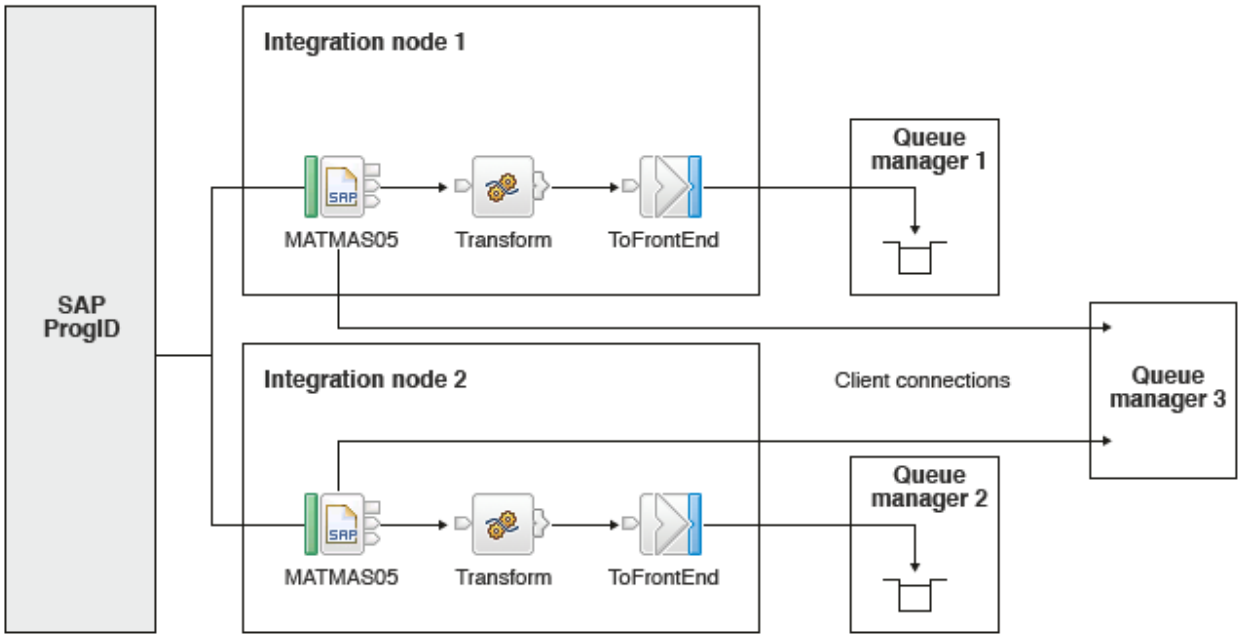
In previous versions of IBM App Connect Enterprise, the tRFC protocol between SAP and IBM App Connect Enterprise (acting as the RFC server) ensures that IDocs and tRFC BAPI calls are delivered exactly once. This behavior is possible because each delivery has an associated transaction ID (TID). IBM App Connect Enterprise monitors the progress of a delivery until SAP confirms a successful delivery. If the connection is lost or IBM App Connect Enterprise fails before that confirmation is issued, SAP attempts to redeliver the message. By keeping a persistent record (in the TID store or transaction log), IBM App Connect Enterprise can ensure integrity and avoid a duplicate delivery.



When two `.inadapter` components, with the same RFC program ID, are deployed to two integration nodes, two connections to the same RFC server are visible to SAP. If the connection is lost to one of the integration nodes, SAP might attempt to redeliver to the other integration node. The integration nodes have separate TID stores, therefore, the second integration node accepts the redelivery, even though the first integration node might have processed some (or all) of the IDocs in the packet.



In IBM App Connect Enterprise, you can now move the TID store to a remote queue manager that can be shared between two integration nodes. To avoid a single point of failure, make this third queue manager an IBM MQ high availability, multi-instance queue manager. For instructions, see “Setting up SAP for high availability” on page 1118.



SAP adapter scalability and performance
You can improve performance by configuring the number of listeners on the adapter and the number of additional instances on the message flow to prevent delays when processing synchronous calls from SAP.

The SAP inbound adapter receives synchronous calls from SAP. The adapter has a property called `Number of listeners`, which controls the maximum number of concurrent calls by configuring the adapter to have a particular number of threads listening to the SAP program ID. The listeners send the input parameters of these calls to the SAPInput node for processing, and the output parameters are sent to the SAPReply node.

When the listener receives a call from SAP, it blocks processing until a message flow instance that contains the SAPInput node is available. When a message flow instance has become available, and has started to process the import parameters, the listener again blocks processing until a message that contains the export parameters is propagated to an SAPReply node.

The amount of time that elapses between the SAPInput node sending the message and the SAPReply node receiving the reply message can be affected by the additional instances property on the message flow. To avoid delays in processing, tune the maximum number of listeners and the number of additional instances for the message flow that contains the SAPInput and SAPReply nodes. You can configure the number of additional instances at message flow level or on the SAPInput node itself.

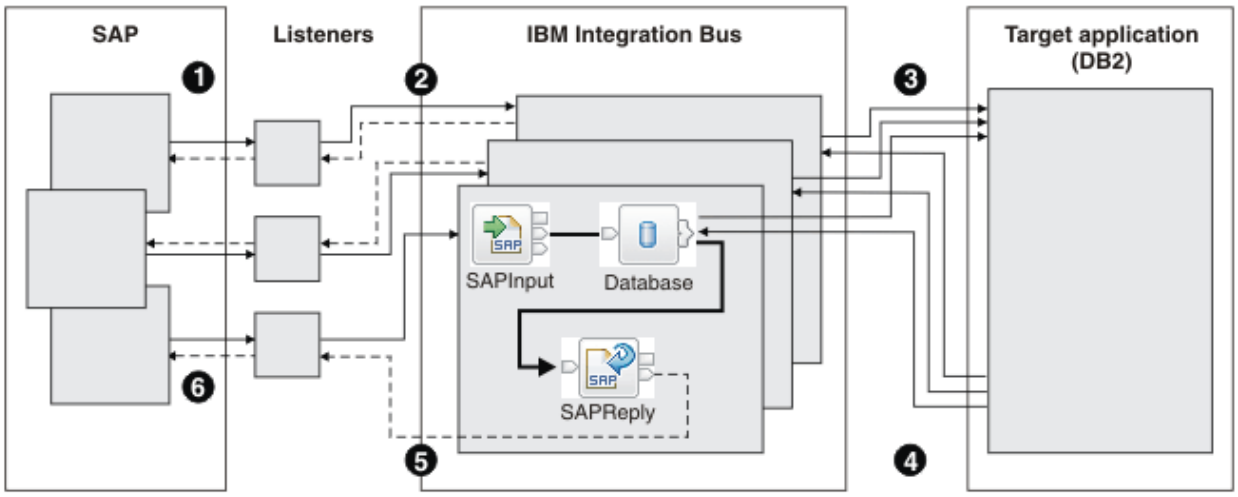
Restrictions

The number of listeners is limited by the SAP configuration. In SAP transaction SMQS, you can view and change the maximum connections property for each RFC destination. Configuring a number of listeners greater than the maximum number of connections has no effect.

For each additional instance of the message flow, extra resources are used by each node in the flow, depending on the types of node in the flow.

Scenarios

The following diagram illustrates a basic scenario, where the number of listeners is equal to the number of additional instances of the message flow; in this case, the scenario has been configured with three listeners and three message flow instances.



1. SAP makes three calls, each of which is received by a listener.
2. Each of the listeners sends the input parameters of each call to the SAPInput node in one of three instances of the message flow.
3. Each message flow instance sends its message to the target application.
4. The target application processes the messages and returns replies to the message flow instances.
5. The SAPReply node in each message flow instance sends the reply message to the listener that received the original call.
6. Each listener returns the reply message to the appropriate SAP program.

The SAPReply node can be in the same message flow as the SAPInput node, as illustrated in the previous example. However, in the following scenario, the SAPReply node is in a different flow from the SAPInput node. The SAPReply node must be deployed in the same integration server as the SAPInput node.

1. SAP makes three calls, each of which is received by a different listener.
2. Each of the listeners sends the input parameters of each call to a message flow that contains an SAPInput node.
3. The message flow puts the message onto a queue for the target application.
4. The target application gets the messages from the queue and processes them.
5. The target application puts the messages onto a queue.
6. A second message flow that contains an SAPReply node gets the messages from the queue and processes them.
7. The SAPReply node sends the reply messages to the appropriate listeners.
8. Each listener returns a reply message to the appropriate SAP program.

In this scenario, the message flow has low latency compared to the time taken by the entire scenario. Therefore, you can limit the resources that are used by the message flow containing the SAPInput node by configuring fewer additional instances for this message flow. One instance of the message flow, as in the example, can service many listeners because the message flow propagates the import parameters quickly for processing.

The following scenarios are also possible.

- A single message flow contains an SAPReply node but it is used to reply to several SAPInput nodes. After the message has been propagated to the SAPReply node, the listener sends the reply back to SAP and is therefore ready to receive another call from SAP. However, the current instance of the message flow is still busy processing the nodes downstream from the SAPReply node. In this case, increase the number of instances on the message flow that contains the SAPReply node.

- After propagating to the SAPReply node, other nodes in the message flow perform extra processing. In this case, increase the number of instances on the message flow that contains the SAPReply node, even when it is the same flow that contains the SAPInput node.

  This scenario might have an undesirable effect on the integrity of your data. If an exception occurs after the SAPReply node, resources that are updated by the message flow (for example, database tables or IBM MQ queues) might be rolled back. However, the reply has been sent back to SAP already and cannot be rolled back. If this behavior is not appropriate, you can improve data integrity by ensuring that the SAPReply node is the final node in the message flow.

Business objects for the BAPI interface
A business object is a structure that consists of data, the action to be performed on the data, and additional instructions for processing the data.

For outbound processing, the integration node uses business objects to send data to SAP or obtain data (through the adapter) from SAP. The integration node sends a business object to the adapter, and the adapter converts the data in the business object to a format that is compatible with an SAP API call. The adapter then runs the SAP API with this data.

For inbound processing, the SAP server sends a BAPI function call through the adapter to an endpoint. The adapter converts the BAPI function call into a business object.

The adapter uses the BAPI metadata that is generated by the Adapter Connection wizard to construct a business-object definition. This metadata contains BAPI-related information such as the operation of the business object, import parameters, export parameters, table parameters, transaction information, and dependent or grouped BAPIs.

The BAPI business-object definition that is generated by the Adapter Connection wizard is modeled on the BAPI function interface in SAP. The business-object definition represents a BAPI function, such as a BAPI_CUSTOMER_GETLIST function call.

If you change the BAPI interface, you must run the Adapter Connection wizard again to rebuild the business object definition.

How business-object definitions are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

Business object structure

The structure of a BAPI business object depends on the interface type (simple BAPI, BAPI work unit, or BAPI result set).

For more information, see the following topics.

- “Business object structure for a simple BAPI” on page 1073
- “Business object structure for a nested BAPI” on page 1074
- “Business object structure for a BAPI work unit” on page 1074
- “Business object structure for a BAPI result set” on page 1074

Business object structure for a simple BAPI
A business object for a simple BAPI call reflects a BAPI method or function call in SAP. Each business object property maps to a BAPI parameter. The metadata of each business-object property indicates the corresponding BAPI parameter. The operation metadata determines the correct BAPI to call.

For a simple BAPI that performs Create, Update, Retrieve, and Delete operations, each operation is represented by a business object, with the business objects being grouped together in a wrapper.

The business object wrapper can be associated with multiple operations, but for a simple BAPI, each business object is associated with only one operation. For example, while a wrapper business object can contain BAPIs for Create and Delete operations, BAPI_CUSTOMER_CREATE is associated with the Create operation, not the Delete operation.

The BAPI business objects are children of the business object wrapper, and, depending on the operation to be performed, only one child object in this wrapper needs to be populated at run time in order to process the simple BAPI call. Only one BAPI, the one that is associated with the operation to be performed, is called at a time.

If you select **Asynchronous Transactional RFC** (for outbound or inbound processing) or **Asynchronous Queued RFC** (for outbound processing) , the BAPI wrapper business object also contains a transaction ID. The transaction ID is used to resend the BAPI call if the receiving system is not available at the time of the initial call.

Business object structure for a nested BAPI
A nested BAPI business object contains structure parameters that can contain one or more other structures as components.

A BAPI business object can contain both simple parameters and structure parameters. A business object that contains structure parameters can in turn contain other structures, such as simple parameters and a business object.

Business object structure for a BAPI work unit
A business object that represents a BAPI work unit (also known as a BAPI transaction) is a wrapper object that contains multiple child BAPI objects. Each child BAPI object in the wrapper object represents a simple BAPI.

The adapter supports a BAPI work unit by using a top-level wrapper business object that consists of multiple child BAPIs, each one representing a simple BAPI in the sequence. The BAPI wrapper object represents the complete work unit, while the child BAPI objects contained in the BAPI wrapper object represent the individual operations that make up the work unit.

Business object structure for a BAPI result set
The top-level business object for a result set is a wrapper that contains a GetDetail business object. The GetDetail business object contains the results of a query for SAP data. The GetDetail business object also contains, as a child object, the query business object. The query business object represents a GetList BAPI. These two BAPIs work together to retrieve information from the SAP server.

The ALE interfaces
The SAP Application Link Enabling (ALE) interface and ALE pass-through IDoc interface enable business process integration and asynchronous data communication between two or more SAP systems or between SAP and external systems. The data is exchanged in the form of Intermediate Documents (IDocs).

The adapter supports outbound and inbound processing by enabling the exchange of data in the form of business objects.

- For inbound processing, SAP pushes the data in IDocs to the SAP adapter. The adapter converts the IDocs to business objects and delivers them to the endpoint.
- For outbound processing, the SAP adapter converts the business object to an IDoc and delivers it to SAP.

To use the ALE interface or ALE pass-through IDoc interface for inbound processing, make sure that your SAP server is properly configured (for example, you must set up a partner profile and register an SAP RCF program ID to listen for events).

Application systems are loosely coupled in an ALE integrated system, and the data is exchanged asynchronously.

IDocs

Intermediate Documents (IDocs) are containers for exchanging data in a predefined (structured ASCII) format across system boundaries. The IDoc type indicates the SAP format that is to be used to transfer the data. An IDoc type can transfer several message types (the logical messages that correspond to different business processes). IDocs can be used for outbound and inbound processing. The SAP adapter supports the basic and extension type of IDocs.

For example, if an application developer wants to be notified when a sales order is created on the SAP server, the developer runs the Adapter Connection wizard to discover the ORDERS05 IDoc on the SAP server. The wizard then generates the business object definition for ORDERS05. The wizard also generates other resources, such as an EIS export component and Service Component Architecture (SCA) interfaces.

IDocs are exchanged for inbound and outbound events, and IDocs can be exchanged either as individual documents or in packets.

The processing of IDoc data depends on whether you are using the ALE interface or the ALE pass-through IDoc interface.

- **ALE interface**

  For outbound processing, the adapter uses the IDoc business object to populate the appropriate RFC-enabled function call made to the SAP server.

  For inbound processing, IDocs can be sent from the SAP server as parsed or unparsed documents

  – For parsed documents, the adapter parses the IDoc and creates a business object that reflects the internal structure of the IDoc.

  – For unparsed IDocs, the adapter processes the IDoc but does not convert the data portion of the IDoc.

- **ALE pass-through IDoc interface**

  For both outbound and inbound processing, the adapter does no conversion of the IDoc, which is useful when the client wants to perform the IDoc parsing.

Transactional RFC processing

The adapter uses transactional RFC (tRFC) to assure delivery and to ensure that each IDoc is exchanged only once with SAP. The tRFC component stores the called RFC function in the database of the SAP system with a unique transaction identifier (TID). The TID is a field in your message.

The message flow must determine how to store the SAP transaction ID and how to relate the SAP transaction ID to the data being sent to the adapter. When the events are successful, the message flow should not resubmit the event associated with this TID again to prevent the processing of duplicate events.

- If the message flow does not send an SAP transaction ID with the business object, the adapter returns one after running the transaction.
- If the message flow has an SAP transaction ID, it must populate the SAP transaction ID property in the business object with that value before running the transaction.

The SAP transaction ID can be used for cross-referencing with a global unique ID that is created for an outbound event. You can create the global unique ID for managing integration scenarios.

Queued RFC processing

The adapter uses qRFC (queued transactional RFC) to ensure that IDocs are delivered in sequence to a queue on the SAP server or are received in sequence from the SAP server. Additional threads can increase the throughput of a message flow but you should consider the potential effect on message order. To maintain message order, ensure that your message flow is single threaded.

For more information about ALE interfaces, see the following topics:

Outbound processing for the ALE interface
The adapter supports outbound processing (from the adapter to the SAP server) for the ALE interface and the ALE pass-through IDoc interface. ALE uses IDocs for data exchange, and the adapter uses business objects to represent the IDocs.

The following list describes the sequence of processing actions that result from an outbound request that uses the ALE interface and ALE pass-through IDoc interface.

The message flow that makes the request uses the interface information that was generated by the Adapter Connection wizard.

1. The adapter receives a request, which includes an IDoc business object, from a message flow.

   For pass-through IDocs, the Message tree contains a BLOB field that represents the IDoc. No separate IDoc business object exists for pass-through IDocs.
2. The adapter uses the IDoc business object to populate the appropriate RFC-enabled function call used by the ALE interface.
3. The adapter establishes an RFC connection to the ALE interface and passes the IDoc data to the SAP system. If you are using the qRFC protocol, the adapter passes the IDoc data in the order specified in the wrapper business object to the specified queue on the SAP server.
4. After passing the data to SAP, the adapter performs one of the following steps:
   - If the call is not managed by a local transaction that uses the integration node's Local Transaction Manager, the adapter releases the connection to SAP and does not return any data to the caller. When no exceptions are raised, the outbound transaction is considered successful. You can verify whether the data is incorporated into the SAP application by inspecting the IDocs that have been generated in SAP.
   - If the call is managed by a local transaction that uses the integration node's Local Transaction Manager, the adapter returns the transaction ID.

     The adapter uses the tRFC protocol to support J2C local transactions.

Inbound processing for the ALE interface
The adapter supports inbound processing (from the SAP server to the adapter) for the ALE interface and the ALE pass-through IDoc interface.

When you are configuring a module for the ALE interface or the ALE pass-through interface, you indicate whether the IDocs are sent as a packet and, for the ALE interface, you can specify whether they are sent parsed or unparsed. You make these selections in the Adapter Connection wizard. When you use the ALE pass-through IDoc interface, the Message tree contains a BLOB field that represents the IDoc. No separate IDoc business object exists for pass-through IDocs.

The following list describes the sequence of processing actions that result from an inbound request using the ALE interface.

1. The adapter starts event listeners to the SAP server.
2. Whenever an event occurs in SAP, the event is sent to the adapter through the event listeners.
3. The adapter converts the event into a business object before sending it to the endpoint.

The adapter uses the event recovery mechanism to track and recover events in case of abrupt termination. The event recovery mechanism uses a data source for persisting the event state.

The following table provides an overview of the differences between the ALE interface and the ALE pass-through IDoc interface for inbound processing.

Interface	When to use	SplitIDoc = true	SplitIDoc = false	Parsed IDoc = true
ALE inbound	This interface converts the raw incoming IDocs to business objects, which are readily consumable by the client at the endpoint.	On receiving the IDoc packet from SAP, the adapter converts the IDocs to business objects, one by one, before sending each one to the endpoint.	On receiving the IDoc packet from SAP, the adapter converts the IDocs in the packet as one business object before sending it to the endpoint.	The incoming IDoc is only partially parsed (the control record of the IDoc is parsed but the data record is not). The client at the endpoint is responsible for parsing the data record.
ALE pass-through IDoc	This interface wraps the raw incoming IDoc in a business object before delivering it to the client at the endpoint. The client is responsible for parsing the raw IDoc.	On receiving the IDoc packet from SAP, the adapter wraps each raw IDoc in a business object before sending the objects, one by one, to the endpoint.	On receiving the IDoc packet from SAP, the adapter wraps the raw IDoc packet in a business object before sending it to the endpoint.	This attribute is not applicable to the ALE pass- through IDoc interface. (Neither the control record nor the data record of the IDoc is parsed.)

For more information, see the following topics.

- "Event error handling" on page 1077
- "Event recovery for the ALE interface" on page 1078
- "Event processing for parsed IDoc packets" on page 1078
- "Event processing for unparsed IDocs" on page 1079
- "IDoc status updates" on page 1080

Event error handling
WebSphere Adapter for SAP Software provides error handling for inbound ALE events by logging the errors and attempting to restart the event listener.

When the adapter detects an error condition, it performs the following actions:

1. The adapter logs the error information in the syslog (on Linux and UNIX systems), Windows Event Viewer, or user trace log.
2. The adapter attempts to restart the existing event listeners.

   The adapter uses the activation specification values for RetryLimit and RetryInterval.

   - If the SAP application is not active, the adapter attempts to restart the listeners for the number of times configured in the RetryLimit property.
   - The adapter waits for the time specified in the RetryInterval parameter before attempting to restart the event listeners.
3. If the attempt to restart the event listeners fails, the adapter performs the following actions:

   - The adapter logs the error condition in the syslog (on Linux and UNIX systems), Windows Event Viewer, or user trace log.
   - The adapter cleans up the existing ALE event listeners.
   - The adapter starts new event listeners.

   The adapter uses the values of the RetryLimit and RetryInterval properties when starting the new event listeners.

4. If all the retry attempts fail, the adapter logs the relevant message and CEI events and stops trying to recover the ALE event listener.

   You must restart the adapter or Service Component Architecture (SCA) application in this case.

Event recovery for the ALE interface
You can configure the adapter for ALE inbound processing so that it supports event recovery in case of abrupt termination.

When event recovery is specified, the adapter persists the event state in an event recovery table that resides on a data source. Event recovery is not the default behavior; you must specify it by enabling once-only delivery of events during adapter configuration.

Event processing for parsed IDoc packets
An inbound event can contain a single IDoc or multiple IDocs, with each IDoc corresponding to a single business object. The multiple IDocs are sent by the SAP server to the adapter in the form of an IDoc packet. You can specify, during adapter configuration, whether the packet can be split into individual IDocs or whether it must be sent as one object (non-split).

Event processing begins when the SAP server sends a transaction ID to the adapter. The following sequence occurs.

1. The adapter checks the status of the event and takes one of the following actions:
   - If this is a new event, the adapter stores an EVNTID (which corresponds to the transaction ID) along with a status of `0` (Created) in the event recovery table.
   - If the event status is `-1` (Rollback), the adapter updates the status to `0` (Created).
   - If the event status is `1` (Executed), the adapter returns an indication of success to the SAP system.
2. The SAP system sends the IDoc to the adapter.
3. The adapter converts the IDoc to a business object and sends it to the endpoint.

   For single IDocs and non-split IDoc packets, the adapter can deliver objects to endpoints that support transactions as well as to endpoints that do not support transactions.

   - For endpoints that support transactions, the adapter delivers the object as part of a unique XA transaction. When the endpoint processes the event and the transaction is committed, the status of the event is updated to `1` (Executed).

     The endpoint must be configured to support XA transactions.
   - For endpoints that do not support transactions, the adapter delivers the object to the endpoint and updates the status of the event to `1` (Executed). The adapter delivers the business object without the quality of service (QOS) that guarantees once-only delivery.
4. For split packets only, the adapter performs the following tasks:
   a. The adapter updates the BQTOTAL column (or table field) in the event recovery table to the number of IDocs in the packet. This number is used for audit and recovery purposes.
   b. The adapter sends the business objects to the message endpoint, one after the other, and updates the BQPROC property to the sequence number of the IDoc it is working on. The adapter delivers

the objects to the appropriate endpoint as part of a unique XA transaction (a two-phase commit transaction) controlled by the application server.

c. When the endpoint receives the event and the transaction is committed, the adapter increments the number in the BQPROC property.

The message endpoint must be configured to support XA transactions.

If the adapter encounters an error while processing a split IDoc packet, it can behave in one of two ways, depending on the IgnoreIDocPacketErrors configuration property:

- If the IgnoreIDocPacketErrors property is set to `false`, the adapter stops processing any additional IDocs in the packet and reports errors to the SAP system.
- If the IgnoreIDocPacketErrors property is set to `true`, the adapter logs an error and continues processing the rest of the IDocs in the packet. The status of the transaction is marked 3 (InProgress). In this case, the adapter log shows the IDoc numbers that failed, and you must resubmit those individual IDocs separately. You must also manually maintain these records in the event recovery table.

This property is not used for single IDocs and for non-split IDoc packets.

d. The SAP system sends a COMMIT call to the adapter.

e. After the adapter delivers all the business objects in the IDoc packet to the message endpoint, it updates the event status to 1 (Executed).

f. In case of abrupt interruptions during IDoc packet processing, the adapter resumes processing the IDocs from the current sequence number. The adapter continues updating the BQPROC property, even if IgnoreIDocPacketErrors is set to `true`. The adapter continues the processing in case you terminate the adapter manually while the adapter is processing an IDoc packet.

5. If an exception occurs either while the adapter is processing the event or if the endpoint generates an exception, the event status is updated to `-1` (Rollback).
6. If no exception occurs, the SAP server sends a CONFIRM call to the adapter.
7. The adapter deletes the records with a 1 (Executed) status and logs a common event infrastructure (CEI) event that can be used for tracking and auditing purposes.

Event processing for unparsed IDocs
Unparsed IDocs are passed through, with no conversion of the data (that is, the adapter does not parse the data part of the IDoc). The direct exchange of IDocs in the adapter enables high-performance, asynchronous interaction with SAP, because the parsing and serializing of the IDoc occurs outside the adapter. The consumer of the IDoc parses the IDoc.

The adapter processes the data based on whether the packet IDoc is split or non-split and whether the data needs to be parsed.

- The adapter can process packet IDocs as a packet or as individual IDocs. When an IDoc is received by the adapter from SAP as a packet IDoc, it is either split and processed as individual IDocs, or it is processed as a packet. The value of the SplitIDocPacket metadata at the business-object level determines how the IDoc is processed.

  For split IDocs, the wrapper contains only a single, unparsed IDoc object.
- The Type metadata specifies whether the data should be parsed. For unparsed IDocs, this value is `UNPARSEDIDOC`; for parsed IDocs, the value is `IDOC`. This value is set by the Adapter Connection wizard.

Unparsed data format

In the fixed-width format of an unparsed IDoc, the segment data of the IDoc is set in the IDocData field of the business object. It is a byte array of fixed-length data.

The entire segment length might not be used. The adapter pads spaces to the fields that have data; the rest of the fields are ignored, and an end of segment is set. The end of segment is denoted by a null value.

The following figure shows a segment with fields demarcated by the '|' symbol for reference.

Figure 1. Example of a segment before processing

When the adapter processes this segment into unparsed data, it takes into account only those fields that have data in them. It maintains the field width for each segment field. When it finds the last field with data, it appends a null value to mark the end of segment.

Figure 2. Example of a segment after processing

The next segment data processed as unparsed data would be appended after the null value.

Limitations

The unparsed event feature introduces certain limitations on the enterprise application for a particular IDoc type.

- The enterprise application supports either parsed or unparsed business-object format for an IDoc type or message type.
- For an IDoc type, if you select unparsed business-object format for inbound, you cannot have inbound and outbound interfaces in the same EAR file, because outbound is based on parsed business objects.
- The DummyKey feature is not supported for unparsed IDocs.

IDoc status updates
To monitor IDoc processing, you can configure the adapter to update the IDoc status.

When the adapter configuration property UpdateStatus is set to `true` (indicating that an audit trail is required for all message types), the adapter updates the IDoc status of ALE business objects that are retrieved from the SAP server. After the event is sent to the message endpoint, the adapter updates the status of the IDoc in SAP to indicate whether the processing succeeded or failed. Monitoring of IDocs applies only to inbound processing (when the IDoc is sent from the SAP server to the adapter).

The adapter updates a status IDoc (ALEAUD) and sends it to the SAP server.

An IDoc that is not successfully sent to the endpoint is considered a failure, and the IDoc status is updated by the adapter. Similarly, an IDoc that reaches the endpoint is considered successfully processed, and the status of the IDoc is updated.

The status codes and their associated text are configurable properties of the adapter, as specified in the activation specification properties and shown in the following list:

- SuccessCode
- FailureCode
- SuccessText
- FailureText

Perform the following tasks to ensure that the adapter updates the standard SAP status code after it retrieves an IDoc:

- Set the UpdateStatus configuration property to `true` and set values for the SuccessCode and FailureCode configuration properties.
- Configure the inbound parameters of the partner profile of the logical system in SAP to receive the ALEAUD message type. Set the following properties to the specified values:

Table 29. Inbound properties of the logical system partner profile	
SAP property	**Value**
Basic Type	ALEAUD01
Logical Message Type	ALEAUD
Function module	IDOC_INPUT_ALEAUD
Process Code	AUD1

Pass-through support for IDocs, and MQSeries link for R/3 link migration
Both the inbound and outbound SAP adapters support a pass-through mode for IDocs.

In this mode, the bit stream for the IDoc is provided without any form of parsing. The bit stream can then be used directly in a message flow, and parsed by other parsers, or sent unchanged over transports.

Use the Adapter Connection wizard to select pass-through support: on the Configure settings for adapter pane, select `ALE pass-through IDoc` as the interface type.

A business object is created that contains one field, which is the bit stream of the IDoc. You can transform this business object in a Compute node to an MQSeries® link for R/3 format message, as shown in the following example.

```
DECLARE ns NAMESPACE
'http://www.ibm.com/xmlns/prod/websphere/j2ca/sap/sapmatmas05';

CREATE COMPUTE MODULE test4_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  CALL CopyMessageHeaders();
  -- CALL CopyEntireMessage();
  set OutputRoot.MQSAPH.SystemNumber = '00';
  set OutputRoot.BLOB.BLOB =
InputRoot.DataObject.ns:SapMatmas05.IDocStreamData;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;

 CREATE PROCEDURE CopyEntireMessage() BEGIN
  SET OutputRoot = InputRoot;
 END;
END MODULE;
```

You can also create a request business object from an MQSeries link for R/3 message, as shown in the following example.

```
CREATE COMPUTE MODULE test4_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  set
OutputRoot.DataObject.ns:SapMatmas05.IDocStreamData =
InputRoot.BLOB.BLOB;
  RETURN TRUE;
 END;
END MODULE;
```

The name of the SapMatmas05 element depends on selections that you make when you run the Adapter Connection wizard.

ALE pass-through IDoc business object structure
During ALE processing, the adapter exchanges business objects with the SAP application.

The message tree contains a BLOB field that represents the IDoc. The BLOB field is modelled as a HexBinary type in the XSD file. The message tree contains the stream data (the BLOB field), which is the entire data of the IDoc. The transaction ID, iDoc type, and queue name fields contain information about that data and how it has been transferred.

The transaction ID (SAPTransactionID) is used to ensure once-only delivery of business objects, and the queue name (qRFCQueueName) specifies the name of the queue on the SAP server to which the IDocs should be delivered. If you are not using transaction IDs or queues, these properties are blank.

To parse the IDoc control record, select **Parse the IDoc Control Record** when you run the Adapter Connection wizard.

Generic IDoc routing
By using the SAPInput node in passthrough mode, IBM App Connect Enterprise can receive any IDoc and route it according to IDoc type.

The message definition for a generic IDoc in ALE passthrough mode contains four fields. Three of these fields are control information:

- The transaction ID
- The queue name (if qRFC is used)
- The name of the IDoc type

The fourth field is a hexBinary field that contains the entire IDoc in a raw, unparsed format. You can use the DataObject parser to parse this raw format to a full logical structure of a specific IDoc if you provide a library that contains the definition for that IDoc type. To parse raw IDocs, you must use an MQInput node with the `Message domain` property set to `DataObject`, and the `Message format` property set to `SAP ALE IDoc`.

When passthrough mode is not used, the library contains a fully parsed IDoc structure. These structures are specific to each IDoc, therefore the library must have a type defined for every IDoc that could be received by the `.inadapter` component. This library is determined by the RFC Program ID that is configured on the adapter and the ALE or RFC configuration on the SAP side. This behavior can affect how message models are managed.

Whenever you need to develop message flows in isolation, where each flow is to handle a different type of IDoc, the ALE parsed mode is not appropriate because all flows have a common denominator (the library), which needs to be changed whenever a new IDoc type is added.

By using the generic passthrough mode, you can create a routing message flow that uses the IDoc type field of the generic IDoc model to separate IBM MQ queues, for example. You can create message flows that deal with each different IDoc type. If the set of discovered IDocs is extended, you can create a message flow and a library (which contains just the new IDoc), then deploy them, without the need to change existing message flows or libraries.

By using this method, you can also use a single RFC program ID to receive all IDoc types, while still allowing individual IDoc processing.

ALE business objects
A business object is a structure that consists of data, the action to be performed on the data, and additional instructions for processing the data. The adapter client uses business objects to send data to SAP or to obtain data (through the adapter) from SAP.

The adapter uses the IDoc metadata that is generated by the Adapter Connection wizard to construct a business-object definition. This metadata contains ALE-related information such as segment information, field names, and an indication of whether the business object handles a single IDoc or an IDoc packet.

The Message tree contains a BLOB field that represents the IDoc.

How business-object definitions are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

For more information, see the following topics.

- "ALE business object structure" on page 1083
- "Transaction ID support" on page 1084

ALE business object structure
During ALE processing, the adapter exchanges business objects with the SAP application. The business object represents an individual IDoc or an IDoc packet. This business object is a top-level wrapper object that contains one or more IDoc child objects, each one corresponding to a single IDoc. The same business object format is used for inbound and outbound processing.

Wrapper business object

The wrapper business object contains a transaction ID, a queue name, and one or more IDoc business objects. The transaction ID (SAPTransactionID) is used to ensure once-only delivery of business objects, and the queue name (qRFCQueueName) specifies the name of the queue on the SAP server to which the IDocs should be delivered. If you are not using transaction IDs or queues, these properties are blank.

For individual IDocs, the wrapper business object contains only one instance of an IDoc business object. For IDoc packets, the wrapper business object contains multiple instances of an IDoc business object.

Note that the transaction ID and queue name attributes are present in the business object even if you are not using the tRFC or qRFC features.

You can generate business object names to match the SAP XI standard by selecting `Generate business objects according to SAP naming conventions`. For more information, see SAP connection properties for the Adapter Connection wizard.

IDoc business object

The IDoc business object contains the following objects:

Control record
The control record business object contains the metadata required by the adapter to process the business object.

The control record can be generated from SAP field names or from SAP field descriptions. While configuring the properties for the control record you can specify if you want the control record to be generated from SAP field names or from SAP field descriptions. If you want the control record generated from field names, select the check box to use SAP field names to generate attribute names.

Data record
The data record business object contains the business object data to be processed by the SAP application and the metadata required for the adapter to convert it to an IDoc structure for the RFC call.

The data record business object is generated for a parsed IDoc. The data record business object contains all the segments of the IDoc. Each segment in turn has a child business object. The segment attributes can also be generated by using SAP field names or field descriptions. You can use SAP field names to generate attribute names.

Dummy keys are not used in IBM App Connect Enterprise.

Unparsed IDocs

For an unparsed IDoc, in which the data part of the IDoc is not parsed by the adapter, the IDoc business object contains a dummy key, a control record, and the IDoc data. The IDoc data is of hexBinary type and represents the whole data record containing segments in binary content.

Transaction ID support
An SAP transaction ID (TID) is contained in the ALE wrapper business object and is therefore available as a field in the message tree. You can use transaction ID support to ensure once-only delivery of ALE objects.

The most common reason for using transaction ID support is to ensure once and only once delivery of data. The SAP transaction ID property is always generated by the Adapter Connection wizard.

The message flow must determine how to store the SAP transaction ID and how to relate the SAP transaction ID to the data being sent to the adapter. When the events are successful, the message flow should not resubmit the event associated with this TID again to prevent the processing of duplicate events.

- If the message flow does not send an SAP transaction ID with the business object, the adapter returns one after executing the transaction.
- If the message flow has an SAP transaction ID, it needs to populate the SAP transaction ID property with that value before executing the transaction.

The SAP transaction ID can be used for cross-referencing with a global unique ID that is created for an outbound event. The global unique ID is something you can create for managing integration scenarios.

Query interface for SAP Software
The Query interface for SAP Software (QISS) provides you with the means to retrieve data from application tables on an SAP server or to query SAP application tables for the existence of data. The adapter can perform hierarchical data retrieval from the SAP application tables.

Query interface for SAP Software supports outbound interactions for read operations (RetrieveAll and Exists) only. You can use this interface in local transactions to look up records before write operations (Create, Update, or Delete). For example, you can use the interface as part of a local transaction to do an existence check on a customer before creating a sales order. You can also use the interface in non-transaction scenarios.

Query interface for SAP Software supports data retrieval from SAP application tables, including hierarchical data retrieval from multiple tables. The interface supports static as well as dynamic specification of `where` clauses for the queries.

The Adapter Connection wizard finds the application data tables in SAP, interprets the hierarchical relationship between tables, and constructs a representation of the tables and their relationship in the form of a business object. The wizard also builds a default `where` clause for the query.

You can control the depth of the data retrieval, as well as the amount of information, by using the maxRow and rowsSkip properties.

Query interface for SAP software (QISS) supports hierarchical data retrieval from the SAP application tables. By using this interface, the adapter can determine the existence of data in SAP application tables, or retrieve all the data in SAP application tables. For example, to check if customer Bob exists in SAP system, the Adapter Connection wizard can be run to discover the SAP application table KNA1. The wizard then generates the business object for KNA1 along with other SCA service artifacts. At run time, the SAPRequest node passes the KNA1 business object to the adapter to call the QISS interface, the adapter retrieves the table data from SAP, and returns the result to the node.

For more information, see the following topics.

- "Outbound processing for the query interface for SAP Software" on page 1085
- "Business objects for the query interface for SAP Software" on page 1085

Outbound processing for the query interface for SAP Software
You use the Query interface for SAP Software for outbound processing only.

The message flow that makes the request uses the interface information that was generated by the Adapter Connection wizard.

The following list describes the sequence of processing actions that result from an outbound request that uses the query interface for SAP Software.

1. The adapter receives a request, which includes a table object, from a message flow.

   The query business object can be in a container business object, or it can be received as a table business object.
2. The adapter determines, from the table object sent with the query, the name of the table to examine.
3. The adapter determines the columns to retrieve or examine.
4. The adapter determines the rows to retrieve or examine.
5. The adapter responds.
   - For a RetreiveAll operation, the adapter returns a result set in the form of a container of query business objects, which represent the data for each row retrieved from the table. If the query is received as a table business object (not inside a container), the rows are returned one at a time, as they are retrieved.
   - For the Exists operation, the adapter returns an indication of whether the data exists in the SAP table.
   - If no data exists, the adapter generates an exception.

Business objects for the query interface for SAP Software
A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The input to the Query interface for SAP Software is a table business object. The table business object represents the columns in a table on the SAP server. The adapter uses the table business object to obtain data from tables on the SAP server.

How data is represented in business objects

The adapter uses metadata that is generated by the Adapter Connection wizard to construct a business-object definition.

The data in the business object represents the columns of the associated table in SAP.

How business objects are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

Business object structure

The table business object can be part of a container.

The table business object contains columns selected from the specified SAP table.

In addition to column information, the table business object also contains a query business object as the last parameter.

The properties of the query business object are sapWhereClause, sapRowsSkip, and sapMaxRows:

- The sapWhereClause property retrieves information from SAP tables. The default value is populated by the Adapter Connection wizard. The space character is used as the delimiter to parse the sapWhereClause.

- The sapMaxRows property is the maximum number of rows to be returned. The default value is 100.
- The sapRowsSkip property is the number of rows to skip before retrieving data. The default value is 0.

The tables can be modeled as hierarchical business objects. You specify the parent-child relationship of the tables in the Adapter Connection wizard.

Tables are linked by a foreign key to form parent-child relationships. The child table business object has a foreign key that references a property in the parent query business object.

In the KNA1 business object, notice the reference to SapAdrc, a child business object. The SapAdrc table object has a column named AddressNumber. This column has an associated property (ForeignKey) that contains a reference to the parent business object.

The return from the Query interface for SAP Software call for a RetrieveAll operation is a container of table objects.

The Advanced event processing interface
The Advanced event processing interface of the WebSphere Adapter for SAP Software is used for both inbound and outbound processing.

For inbound processing, it polls for events in SAP, converts them into business objects, and sends the event data as business objects to IBM App Connect Enterprise.

For outbound processing, the adapter processes events sent from an application to retrieve data from or update data in the SAP server.

For more information, see the following topics.

- "Outbound processing for the AEP interface" on page 1086
- "Inbound processing for the AEP interface" on page 1089
- "Business objects for the Advanced Event Processing (AEP) interface" on page 1092

Outbound processing for the AEP interface
During outbound processing, business object data is converted into an ABAP handler function, which is called on the SAP server. When the data is returned by the ABAP handler function, the data is converted to a business object, and the business object is returned as a response.

The following list describes the sequence of processing actions that result from an outbound request that uses the Advanced event processing interface.

1. The adapter receives the Advanced event processing record, which contains business data along with the metadata.
2. The Advanced event processing interface of the adapter uses the metadata of the business object to obtain the type of IDoc specified and to reformat the business object data into the structure of that IDoc.
3. After it reformats the data, the adapter passes the business object data to an object-specific ABAP handler (based on the operation), which handles the integration with an SAP native API.
4. After the object-specific ABAP handler finishes processing the business object data, it returns the response data in IDoc format to the adapter, which converts it to the business object.
5. The adapter returns the results to the caller.

For more information, see the following topics.

- "ABAP handler overview" on page 1087
- "ABAP handler creation" on page 1087
- "Call Transaction Recorder wizard" on page 1088

ABAP handler overview
An ABAP handler is a function module that gets data into and out of the SAP application database. For each business object definition that you develop, you must support it by developing a custom ABAP handler.

ABAP handlers are in the SAP application as ABAP function modules. ABAP handlers are responsible for adding business-object data into the SAP application database (for Create, Update, and Delete operations) or for using the business-object data as the keys to retrieving data from the SAP application database (for the Retrieve operation).

You must develop operation-specific ABAP handlers for each hierarchical business object that must be supported. If you change the business object definition, you must also change the ABAP handler.

An ABAP handler can use any of the SAP native APIs for handling the data. The following list contains some of the native APIs.

- Call Transaction

  Call Transaction is the SAP-provided mechanism for entering data into an SAP system. Call Transaction guarantees that the data adheres to the SAP data model by using the same screens an online user sees in a transaction. This process is commonly referred to as *screen scraping*.

- Batch data communication (BDC)

  Batch Data Communication (BDC) is an instruction set that SAP can follow to process a transaction without user intervention. The instructions specify the sequence in which the screens in a transaction are processed and which fields are populated with data on which screens. All of the elements of an SAP transaction that are exposed to an online user have identifications that can be used in a BDC.

- ABAP SQL

  ABAP SQL is the SAP proprietary version of SQL. It is database-independent and platform-independent, so that whatever SQL code you write, you can run it on any database and platform combination that SAP supports. ABAP SQL is similar in syntax to other versions of SQL and supports all of the basic database table commands such as update, insert, modify, select, and delete. For a complete description of ABAP SQL, see your SAP documentation.

  By using ABAP SQL, an ABAP handler can modify SAP database tables with business-object data for create, update, and delete operations. It can also use the business-object data in the where clause of an ABAP select statement as the keys.

  Do not use ABAP SQL to modify SAP tables, because it might corrupt the integrity of the database. Use ABAP SQL only to retrieve data.

- ABAP Function Modules and Subroutines

  From the ABAP handler, you can call ABAP function modules or subroutines that implement the required function.

The adapter provides the following tools to help in the development process:

- The adapter includes the Call Transaction Recorder wizard to assist you in developing the ABAP handlers that use call transactions or BDC sessions.
- The Adapter Connection wizard generates the required business objects and other resources for Advanced event processing. The business objects are based on IDocs, which can be custom or standard.
- The adapter provides samples that you can refer to for an understanding of the Advanced event processing implementation.

ABAP handler creation
For each IDoc object definition that you develop, you must support it by developing a custom ABAP handler.

You can use either standard IDocs or custom IDocs for the Advanced event processing interface. After defining the custom IDoc for an integration scenario, create an ABAP handler (function module) for each operation of the business object that must be supported.

Each function should have the following interface to ensure that adapter can call it:

```
*" IMPORTING
*" VALUE(OBJECT_KEY_IN) LIKE /CWLD/LOG_HEADER-OBJ_KEY OPTIONAL
*" VALUE(INPUT_METHOD) LIKE BDWFAP_PAR-INPUTMETHD OPTIONAL
*" VALUE(LOG_NUMBER) LIKE /CWLD/LOG_HEADER-LOG_NR OPTIONAL
*" EXPORTING
*" VALUE(OBJECT_KEY_OUT) LIKE /CWLD/LOG_HEADER-OBJ_KEY
*" VALUE(RETURN_CODE) LIKE /CWLD/RFCRC_STRU-RFCRC
*" VALUE(RETURN_TEXT) LIKE /CWLD/LOG_HEADER-OBJ_KEY
*" TABLES
*" IDOC_DATA STRUCTURE EDID4
*" LOG_INFO STRUCTURE /CWLD/EVENT_INFO
```

The following table provides information about the parameters:

Table 30. Interface parameters

Parameter	Description
OBJECT_KEY_IN	Should be no value.
INPUT_METHOD	Indicates whether the IDoc should be processed in a dialog (that is, through Call Transaction). Possible values are: " " - Background (no dialog) "A" - Show all screens "E" - Start the dialog on the screen where the error occurred "N" Default
LOG_NUMBER	Log Number.
OBJECT_KEY_OUT	Customer ID returned from the calling transaction.
RETURN_CODE	0 - Successful. 1 - Failed to retrieve. 2 - Failed to create, update, or delete.
RETURN_TEXT	Message describing the return code.
IDOC_DATA	Table containing one entry for each IDoc data segment. The following fields are relevant to the inbound function module: Docnum - The IDoc number. Segnam - The segment name. Sdata - The segment data.
LOG_INFO	Table containing details regarding events processed with either a success or error message.

Call Transaction Recorder wizard

The adapter provides the Call Transaction Recorder wizard to assist you in developing the ABAP handlers that use call transactions or BDC sessions.

The Call Transaction Recorder wizard enables you to generate sample code for call transactions to facilitate development. It generates sample code stubs for each screen that is modified during the recording phase.

To access this wizard, enter the /CWLD/HOME transaction in the SAP GUI.

The following example is sample code that is generated by the wizard. You can adopt this code in the ABAP Handler.

```
* Customer master: request screen chnge/displ cent.
perform dynpro_new using 'SAPMF02D' '0101' .

* Customer account number
perform dynpro_set using 'RF02D-KUNNR' '1' .

* Function Command
perform dynpro_set using 'BDC_OKCODE' '/00' .

* Function Command
perform dynpro_set using 'BDC_OKCODE' '/00' .

* Customer master: General data, CAM address, communication
perform dynpro_new using 'SAPMF02D' '0111' .

* Title
perform dynpro_set using 'SZA1_D0100-TITLE_MEDI' 'Mr.' .

* Function Command
perform dynpro_set using 'BDC_OKCODE' '=UPDA' .

* Call Transaction
Call Transaction 'XD02' using bdcdata
    mode input_mode
   update 'S'
  messages into bdc_messages.
```

The wizard does not generate the required business object. You use the Adapter Connection wizard to generate the business object.

Inbound processing for the AEP interface
The adapter uses the Advanced event processing interface to poll for events on the SAP server, to process the events, and to send them to an endpoint.

The following list describes the sequence of processing actions that result from an inbound request that uses the Advanced event processing interface.

1. A triggered event enters the event table with an initial status of prequeued.
2. When the adapter polls for events, the status of the event changes from prequeued to queued if there are no database locks for the combination of the user who created the event and the event key.
3. After the event is retrieved from the event table, the status of the event is updated to InProgress.

   If locks exist, the status of the event is set to locked and the event is requeued into the queue. Every event with a prequeued or locked status is updated with every poll. You can configure the polling frequency by using the Poll Frequency property.
4. After preprocessing all prequeued events, the adapter selects the events.

   The property Poll Quantity determines the maximum number of events returned for a single poll call.
5. For each event, the adapter uses the remote function specified for the Retrieve operation to retrieve the data and send it to the endpoint.

   If the AssuredOnceDelivery property is set to true, an XID value is set for each event in the event store. After each event is picked up for processing, the XID value for that event is updated in the event table.

   If, before the event is delivered to the endpoint, the SAP connection is lost or the application is stopped, and the event is consequently not processed completely, the XID column ensures that the event is reprocessed and sent to the endpoint. After the SAP connection is reestablished or the adapter starts up again, it first checks for events in the event table that have a value in the XID column. It then processes these events first and then polls the other events during the poll cycles.
6. After each event is processed, it is updated or archived in the SAP application.

   When the event is processed successfully, it is archived and then deleted from the event table.

   The adapter can also filter the events to be processed by business object type. The filter is set in the Event Filter Type property. This property has a comma-delimited list of business object types, and only the types specified in the property are picked for processing. If no value is specified for the property, no filter is applied and all the events are picked up for processing.

For more information, see the following topics.

- "Event detection" on page 1090
- "Event triggers" on page 1091

Event detection
Event detection refers to the collection of processes that notify the adapter of SAP application object events. Notification includes, but is not limited to, the type of the event (object and operation) and the data key required for the external system to retrieve the associated data.

Event detection is the process of identifying that an event was generated in the SAP application. Typically, adapters use database triggers to detect an event. However, because the SAP application is tightly integrated with the SAP database, SAP allows very limited access for direct modifications to its database. Therefore, the event-detection mechanisms are implemented in the application transaction layer above the database.

Adapter-supported event detection mechanisms

The four event-detection mechanisms that are supported by the adapter are described in the following list:

- Custom Triggers, which are implemented for a business process (normally a single SAP transaction) by inserting event detection code at an appropriate point in the SAP transaction
- Batch programs, which involve developing an ABAP program containing the criteria for detecting an event
- Business workflows, which use the object-oriented event detection capabilities of SAP
- Change pointers, a variation of business workflows, which use the concept of change documents to detect changes for a business process

All these event-detection mechanisms support real-time triggering and retrieval of objects. In addition, custom triggers and batch programs provide the ability to delay the retrieval of events. An event whose retrieval is delayed is called a future event.

Each event detection mechanism has advantages and disadvantages that need to be considered when designing and developing a business object trigger. Keep in mind that these are only a few examples of event detection mechanisms. There are many different ways to detect events.

After you determine the business process to support (for example, sales quotes or sales orders) and determine the preferred event-detection mechanism, implement the mechanism for your business process.

When implementing an event detection mechanism, it is a good idea to support all of the functions for a business process in one mechanism. This limits the effect in the SAP application and makes event detection easier to manage.

Event table

Events that are detected are stored in an SAP application table. This event table is delivered as part of the ABAP component. The event table structure is as follows.

Table 31. Event table fields

Name	Type	Description
event_id	NUMBER	Unique event ID that is a. primary key for the table
object_name	STRING	Business object name.
object_key	STRING	Delimited string that. contains the keys for the business object

Table 31. Event table fields (continued)

Name	Type	Description
object_function	STRING	Operation corresponding to. the event (Delete, Create, or Update)
event_priority	NUMBER	Any positive integer to. denote the priority of the event
event_time	DATE	Date and time when the. event was generated
event_status	NUMBER	
Xid	STRING	Unique XID (transaction. ID) value for assured-once delivery
event_user	STRING	User who created the event.
event_comment	STRING	Description of the event.

Event triggers
After an event is identified by one of the event-detection mechanisms, it is triggered by one of the adapter-delivered event triggers. Event triggers can cause events to be processed immediately or in the future.

The function modules that trigger events are described in the following list.

- /CWLD/ADD_TO_QUEUE

  This function module triggers events to the current event table for immediate processing.
- /CWLD/ADD_TO_QUEUE_IN_FUTURE

  This function module triggers events to the future event table to be processed at a later time.

Both functions are for real-time triggering.

Current event table

If the event will be triggered in real-time, /CWLD/ADD_TO_QUEUE_AEP commits the event to the current event table (/CWLD/EVT_CUR_AEP). Specifically, it adds a row of data for the object name, verb, and key that represents the event.

Future event table

If an event needs to be processed at a future date, the processing that is described in the following list occurs.

1. A custom ABAP handler calls /CWLD/ADD_TO_QUEUE_IN_FUTURE_AEP with the event.
2. The /CWLD/ADD_TO_QUEUE_IN_FUTURE_AEP module commits the event to the future event table (/CWLD/EVT_FUT_AEP). Specifically, it adds a row of data for the object name, verb, and key that represents the event. In addition, it adds a Date row
3. The adapter-delivered batch program /CWLD/SUBMIT_FUTURE_EVENTS_AEP reads the future event table.
4. If scheduled to do so, the batch program retrieves events from the future event table.
5. After it retrieves an event, the batch program calls /CWLD/ADD_TO_QUEUE_AEP.
6. The /CWLD/ADD_TO_QUEUE_AEP module triggers the event to the current event table.

/CWLD/ADD_TO_QUEUE_IN_FUTURE_AEP uses the system date as the current date when it populates the Date row of the future event table.

Business objects for the Advanced Event Processing (AEP) interface
During advanced event processing, the adapter exchanges business objects with the SAP application.

How data is represented in business objects

Advanced event processing business objects are based on custom IDocs, standard IDocs, or extension IDocs available in the SAP system.

How business-object definitions are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

For custom interfaces that you want to support, you must first define the custom IDoc in the SAP system. You can then use the Adapter Connection wizard to discover this custom IDoc and build the required resources, including the business-object definition.

Overview of WebSphere Adapter for Siebel Business Applications
With WebSphere Adapter for Siebel Business Applications , you can create integrated processes that exchange information with a Siebel application, without special coding.

Use the WebSphere Adapter for Siebel Business Applications to create integrated processes that exchange information with a Siebel application. With the adapter, an application can send requests to the Siebel Business Applications server or receive notifications of changes from the server.

The adapter creates a standard interface to the applications and data on the Siebel Business Applications server, so that the application developer does not need to understand the lower-level details (the implementation of the application or the data structures) on the Siebel Business Applications server. An application, for example, can send a request to the Siebel Business Applications server, to query or update an Account record, represented by a Siebel business component instance. It can also receive events from the server; for example, to be notified that a customer record has been updated. This behavior provides you with improved business workflow and processes to help manage your customer relations.

WebSphere Adapter for Siebel Business Applications complies with the Java Connector Architecture (JCA). JCA standardizes the way application components, application servers, and Siebel applications, such as Siebel Business Applications server, interact with each other.

The adapter configuration, which you generate with the Adapter Connection wizard, uses a standard interface and standard data objects. The adapter takes the standard data object sent by the application component and calls the Siebel Business Applications function. The adapter then returns a standard data object to the application component. The application component does not have to deal directly with the Siebel Business Applications function; it is the Siebel Business Applications adapter that calls the function and returns the results.

For example, the application component that needs the list of customers sends a standard business object with the range of customer IDs to Adapter for Siebel Business Applications. In return, the application component receives the results (the list of customers) in the form of a standard business object. The application component does not need to know how the function worked or how the data was structured. The adapter completes all the interactions with the Siebel Business Applications function.

Similarly, the message flow might want to know about a change to the data on the Siebel Business Applications server (for example, a change to a particular customer). You can generate an adapter component that polls for such events on the Siebel Business Applications server and notifies message flows of the update. In this case, the interaction begins at the Siebel Business Applications server.

Technical overview of the Adapter for Siebel Business Applications
WebSphere Adapter for Siebel Business Applications supports the exchange of information between your existing applications and Siebel Business Applications. The adapter supports Siebel entities, including business objects, business components, and business services. This enables you to create business processes that exchange data.

The adapter supports outbound processing (requests for data or services from an application to the Siebel application) and inbound processing (event notification from a Siebel application server to an application).

With Adapter for Siebel Business Applications, you can use existing or newly-created applications that run in a supported runtime environment to send requests for data and services to Siebel Business Applications.

You can also add event-generation triggers to Siebel business objects to have notifications of events, such as the creation, update, and deletion of a record, sent to one or more of your applications.

For more information, see the following topics.

- "Outbound processing for Siebel Business Applications" on page 1093
- "Inbound processing for Siebel Business Applications" on page 1094
- "Business objects for Siebel Business Applications" on page 1097
- "Adapter Connection wizard (Siebel)" on page 1097

Outbound processing for Siebel Business Applications
WebSphere Adapter for Siebel Business Applications supports synchronous outbound processing. This means that when the component sends a request in the form of a WebSphere business object hierarchy to the adapter, the adapter processes the request and returns a WebSphere business object hierarchy that represents the result of the operation.

When the adapter receives a WebSphere business object hierarchy, the adapter processes it as follows:

1. The adapter extracts metadata from the WebSphere business object hierarchy.
2. It identifies the appropriate Siebel objects to access (for example, Siebel business objects and business components, or Siebel business services, integrations objects, and integration components) depending on the objects against which the artifacts were generated.
3. The adapter extracts the outbound operation to perform from the WebSphere business object hierarchy.
4. After accessing the required Siebel objects, the adapter retrieves, updates, deletes, or creates a Siebel business component hierarchy or performs the corresponding business service method on the integration component hierarchy.
5. If there are updates (Create, Update, Delete), the adapter populates that Siebel object (business or integration component hierarchy) with data from the hierarchy of WebSphere business objects.

Supported Outbound Operations

WebSphere Adapter for Siebel Business Applications supports the outbound operations shown in the following table.

Table 32. Supported outbound operations

Operation	Description
Create	Creates the business component.
Delete	Deletes the business component and its children.
Exists	Checks for the existence of incoming business objects. The output business object, "ExistsResult" will be returned with the boolean value populated.
Retrieve	Specifies the value of the business component.

Table 32. Supported outbound operations (continued)	
Operation	**Description**
RetrieveAll	Retrieves multiple instances of the same business component and populates it as the container object.
Update	Updates the Siebel application with the incoming business object.

Inbound processing for Siebel Business Applications
WebSphere Adapter for Siebel Business Applications supports asynchronous inbound processing, which means that the adapter polls the Siebel Business Applications at specified intervals for events. When the adapter detects an event, it converts the event data into a business object and sends it to the component.

Before inbound processing can occur, a Siebel event business component must be created in the Siebel application (IBM2 for Siebel version 7.x and IBM_EVENT for Siebel version 8) and its name specified against the corresponding property in the adapter activation specification.

When the adapter detects an event for Siebel event business components or integration components, it processes the event by retrieving the updated data for the Siebel event business component or integration component and converting it into a business object. The adapter then sends the business object to the event business component. For example, if an event business component (an account) is updated, an event trigger adds an event record to the event business component. The adapter polls the event business component, retrieves the event record, and processes it.

When the adapter finds an event for a Siebel event business component, it processes the event in the following way:

1. The adapter retrieves the event information from the Siebel event business component.
2. The adapter retrieves the corresponding event business component instance hierarchy.
3. The adapter populates the associated WebSphere business object or business graph (if it was generated) with the values that it retrieves from the event business component.
4. The adapter sends a notification to each registered application.

If an inbound event in the event table fails or is invalid, the event status is updated to `-1`, which indicates an error in processing the event, and a resource exception message is issued that explains the reason for the error.

Event store for Siebel Business Applications
The event store is a persistent cache where event records are saved until the polling adapter can process them. To keep track of inbound events as they make their way through the system, the adapter uses an event store.

The creation, update, or deletion of an event record in the Siebel business application is an 'event'. Each time a business object is created, updated, or deleted, the adapter updates the status of the event in an event store.

For example, if you have a customer component and a new customer has just been added to it, this signals an update. If the adapter is configured to receive the events about the new update, there are triggers attached to the Siebel end and connected to the customer component. The triggers add a record to the event business component. The record contains information about the new customer, such as the customer ID. This information is stored in the object key. The object key is the unique identifier that provides the key name and value of the event business component that was updated (for example, `Id=1-20RT`). The object name is the WebSphere business-object name that represents the customer component (for example, `Account`). The adapter retrieves this event and the new customer information that relates to it. It then processes the event and delivers it to the export component.

During inbound processing, the adapter polls the event business components from the event store at regular intervals. Each time it polls, a number of events are processed by the adapter. Events are processed in ascending order of priority and ascending order of the event time stamp. In each poll cycle, new events are picked up. The adapter retrieves the value set in the object key field for the event

and loads the business object that corresponds to it. The business object is created from the retrieved information and is delivered to the export components.

If you set the activation specification property AssuredOnceDelivery to `true`, a transaction ID (XID) value is set for each event in the event store. After the event is retrieved for processing, the XID value for it is updated in the event store and displayed in the XID column in the event business component. The event is then delivered to its corresponding export component, and the status is updated to show that the event has been successfully delivered. If the application is stopped or the event is not processed completely, the XID column is filled with a value. This ensures that the event is reprocessed and sent to the export component. After the connection is reestablished or the adapter starts again, the adapter checks for events in the event store that have a value in the XID column. The adapter processes these events first, then polls the other events during the poll cycles.

The adapter can either process all events or process events filtered by business-object type. You set the filter through the activation specification property, EventTypeFilter. This property contains a comma-delimited list of business-object types. Only the types specified in the property are processed. If the EventTypeFilter property is not set, all of the events are processed. If the FilterFutureEvents property is set to `true`, the adapter filters events based on the time stamp. The adapter compares the system time in each poll cycle to the time stamp on each event. If an event is set to occur in the future, it is not processed until that time.

After an event is successfully posted and delivered to the export component, the entry is deleted from the event store. Failed events (posting and delivery to the export component is unsuccessful), remain in the event store and are marked `-1`. This prevents duplicate processing.

Event store structure for Siebel business objects and business components

The `IBM2` event business component stores information about the event. The information stored is used by the resource adapter during event subscription to build the corresponding business object and send it to the registered export components. The information that is stored, and the structure of the event store used by the adapter, are shown in the following table.

Table 33. Event store structure for `IBM2` Siebel event business objects and business components

Field	Description	Example
Description	Any comment associated with the event.	Account Create Event
Event ID	The ID of the event row.	Automatically generated unique ID in Siebel (for example: `1-XYZ`)
Event timestamp	The time stamp for the event. The format is in *mm/dd/yyyy hh:mm:ss*	*02/24/2007 11:37:56*
Event type	The type of event.	Create, Update, or Delete
Object key	A unique identifier of the business-object row for which the event was created. It is a name-value pair consisting of the name of the property (key name) and value.	`ID=1-20RT`
Object name	The name of the business object for which the event was detected.	`IOAccountPRMANIICAccount`
Priority	The event priority.	1

Table 33. Event store structure for IBM2 Siebel event business objects and business components (continued)		
Field	**Description**	**Example**
Status	The event status. This is initially set to the value for a new event and updated by the adapter as it processes the event. The status can have one of the following values: • 0: Identifies a new event. • 1: Identifies an event that has been delivered to an export component. • -1: An error occurred while processing the event. This column cannot contain a null value.	0
XID	The transaction ID. This is to ensure assured once-only delivery.	None
CONNECTOR ID	The ID set for the adapter.	Siebel001

Event store structure for Siebel business services

The event is retrieved from the IBM2 event business component and the information is used to retrieve the event business component.

Table 34. Event store structure for IBM2 Siebel business services		
Field	**Description**	**Example**
Description	Any comment associated with the event.	Account PRM ANI Event
Event ID	The ID of the event row.	Automatically generated unique ID in Siebel (for example: 1-XYZ)
Event timestamp	The time stamp for the event. The format is in *mm/dd/yyyy hh:mm:ss*	*02/24/2007 11:37:56*
Event type	The type of event.	Create, Update, or Delete
Object key	A unique identifier of the business-object row for which the event was created. It is a name value pair consisting of the name of the property (key name) and value.	Name=TestName;Location=BGM, where 'Name' and 'Location' are the keys in the integration component. 'TestName' and 'BGM' are the values specified, and ; is the event key delimiter.
Object name	The name of the business object for which the event was detected.	IOAccountPRMANIICAccount
Priority	The event priority.	1

Table 34. Event store structure for IBM2 Siebel business services (continued)		
Field	**Description**	**Example**
Status	The event status. This is initially set to the value for a new event and updated by the adapter as it processes the event. The status can have one of the following values: • 0: Identifies a new event. • 1: Identifies an event that has been delivered to an export component. • -1: An error occurred while processing the event. This column cannot contain a null value.	0
XID	The transaction ID. This is to ensure 'assured once delivery'.	None

Business objects for Siebel Business Applications
To send data or obtain data from Siebel Business Applications, the adapter uses business objects. A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The data can represent either a business entity, such as an invoice or an employee record, or unstructured text.

How business objects are created

You create business objects by using the Adapter Connection wizard, which connects to the application, discovers data structures in the application, and generates business objects to represent them. It also generates other resources that are needed by the adapter.

The Siebel business objects are created with long names by default. To generate business objects with shorter names, select **Generate business objects with shorter names** on the **Configure Objects** screen of the Adapter Connection wizard. For more information, see Naming conventions for business objects representing Siebel business services.

Business object structure

The adapter supports business objects that are hierarchically structured. The top-level business object must have a one-to-one correspondence with the Siebel business component, and collections that occur in the top-level object are children of it. Information about the processed object is stored in the application-specific information for the object and each of its attributes.

Adapter Connection wizard (Siebel)
The Adapter Connection wizard is a tool that you use to configure your adapter. The wizard establishes a connection to the Siebel server, discovers business objects and services (based on search criteria you provide), and generates business objects based on the services discovered.

By using the Adapter Connection wizard, you establish a connection to the Siebel server to browse the metadata repository on the Siebel server. You also specify connection information, such as the Connection URL, user name, and password needed to access the server.

The result of running the wizard is a library that contains the Siebel business objects and services along with the adapter.

Overview of WebSphere Adapter for PeopleSoft Enterprise
With the adapter for PeopleSoft Enterprise you can create integrated processes that exchange information with PeopleSoft Enterprise through a standard interface. This interface shields the message flow developer from having to understand the lower level details about implementation of the application or data structures used on the PeopleSoft Enterprise server.

With the adapter, a message flow can send a request, for example to a PeopleSoft Enterprise database to query a record in an HR table, or it can receive events from the server, such as notification that an employee record has been updated.

WebSphere Adapter for PeopleSoft Enterprise complies with the Java Connector Architecture (JCA), which standardizes the way application components, application servers, and enterprise information systems, such as a PeopleSoft Enterprise server, interact with each other.

The adapter component, which you generate with the Adapter Connection wizard uses a standard interface and standard data objects. The adapter component takes the standard data object sent by the message flow and calls the PeopleSoft function. It then returns a standard data object to the message flow. The message flow does not have to deal directly with the PeopleSoft function; it is the adapter component that calls the function and returns the results.

For example, the message flow that requested the list of employees sends a standard business object with the range of skill codes to the PeopleSoft adapter component. The message flow receives, in return, the results (the list of employees) in the form of a standard business object. The adapter component completes all the interactions directly with the PeopleSoft function.

Similarly, the message flow might need to be notified about a change to the data on the PeopleSoft Enterprise server (for example, a change to the skills set of a particular employee). You can generate an adapter component that listens for such events on the PeopleSoft Enterprise server and notifies message flows with the update. In this case, the interaction begins at the PeopleSoft Enterprise server.

For more information, see "Technical overview of the WebSphere Adapter for PeopleSoft Enterprise" on page 1098.

Technical overview of the WebSphere Adapter for PeopleSoft Enterprise
The adapter supports the exchange of business data between the PeopleSoft Enterprise server and IBM App Connect Enterprise. It does so by connecting to two layers of PeopleTools application programming interface classes that reveal the underlying business data for integration.

The Adapter for PeopleSoft Enterprise establishes bidirectional connectivity with the PeopleSoft Enterprise server by connecting to two PeopleTools application programming interfaces as follows:

1. The adapter accesses the primary API layer to create a session instance and to connect to the application server through the Jolt port.
2. The adapter then accesses the PeopleSoft Component Interface API, which reveals underlying business objects, logic, and functions.

In PeopleSoft, a component is a set of pages grouped together for a business purpose (such as an employee profile), and a component interface is an API that provides synchronous access to a component from an external application. After the adapter connects to the component interface, the following entities are exposed to the adapter and available for integration:

- All business objects in the component interface definition
- PeopleCode methods associated with the underlying components
- Records, except searches and menu-specific processing options

For more information, see the following topics.

- "Outbound processing for PeopleSoft Enterprise" on page 1099
- "Inbound processing for PeopleSoft Enterprise" on page 1099
- "Business objects for PeopleSoft Enterprise" on page 1101

Outbound processing for PeopleSoft Enterprise
The Adapter for PeopleSoft Enterprise supports synchronous outbound request processing. Synchronous outbound processing means that when the message flow sends a request in the form of a business object to the adapter, the adapter processes the request and returns a business object representing the result of the operation to the message flow.

When the adapter receives a WebSphere business object hierarchy, adapter processes it as follows:

1. The adapter extracts metadata from the WebSphere business object hierarchy that identifies the appropriate PeopleSoft component interface to access.
2. The adapter extracts the outbound operation to perform from the WebSphere business object hierarchy.
3. After the adapter accesses the component interface, it sets the keys from values specified in the business objects. If key values are not generated, for example with a create operation, the PeopleSoft application generates key fields.
4. After it retrieves the PeopleSoft objects, the adapter instantiates an existing component interface to delete, retrieve, update, or create a component interface.
5. If there are updates (Create, Update), the adapter populates the component interface with data from the WebSphere business object hierarchy. If there are Deletes, the adapter populates the component interface only with StatusColumnName and value information.

For Create and Update operations, the adapter processes attributes in the order defined in the business object. For example, if there is a complex attribute between two simple attributes, the adapter processes the simple attribute at the first position, the complex attribute followed by the simple attribute. After the changes are made, the component interface is saved to commit the data to the PeopleSoft database.

Supported outbound operations

WebSphere Adapter for PeopleSoft Enterprise supports the following outbound operations:

Table 35. Supported outbound operations

Operation	Description
Create	Creates the business object.
Delete	Deletes the business object and its children. Because the adapter supports only logical deletes, objects are marked as deleted but not removed.
Exists	Checks for the existence of incoming business objects.
Retrieve	Retrieves the PeopleSoft component, and maps component data onto the business object hierarchy.
RetrieveAll	Retrieves multiple instances of the PeopleSoft component, and maps component data onto the business object hierarchy.
Update	Updates the corresponding PeopleSoft component with the incoming business object.

Inbound processing for PeopleSoft Enterprise
The WebSphere Adapter for PeopleSoft Enterprise supports inbound event processing.

Inbound event processing means that the adapter polls the PeopleSoft Enterprise server at specified intervals for events. When the adapter detects an event, it converts the event data into a business object and sends it to the message flow.

To use inbound event processing, you must create a custom event project in PeopleSoft, as described in "Creating a custom event project in PeopleTools" on page 1127.

For more information, see "Event store for PeopleSoft Enterprise" on page 1100.

Event store for PeopleSoft Enterprise
The event store is a table that holds events that represent data changes until the polling adapter can process them. The adapter uses the event store to keep track of event entities.

To use inbound processing, you must use PeopleTools Application Designer to create a custom project for event notification. The custom project uses two PeopleCode functions that determine the way future events are processed, and the custom project creates the event store the adapter needs for inbound processing. Each time a business object is created, updated, or deleted, the PeopleCode function used in the project and then added to the component interface inserts a new record in the event store, with the appropriate object name, keys, and status value.

With inbound processing, the adapter polls the event entities from the event store at configured poll intervals. In each poll call, a configured number of events are processed by the adapter. The order of event processing is based on the ascending order of priority and the ascending order of the event time stamp. The events with the status, Ready for poll (0), are picked up for polling in each poll cycle. The adapter uses the object name and object key to retrieve the corresponding business object.

If you set the activation specification property AssuredOnceDelivery to `true`, an XID (transaction ID) value is set for each event in the event store, and it is used to ensure that an event is delivered only once to the target application. After an event is obtained for processing, the XID value for that event is updated in the event store. The event is then delivered to its corresponding export component, and its status is updated to show that event delivery has been completed. If the application is stopped before the event can be delivered to the export component or if delivery has failed, the event might not be processed completely. In this case, the XID value represents in-progress status, and the XID column ensures that the event is reprocessed and sent to the export component. Once the database connection is re-established or the adapter starts again, the adapter checks for events in the event table that have a value in the XID column of Ready for Poll (0). The adapter processes these events first, and then polls the other events during the poll cycles.

The adapter uses special processing for events that have status code (99), which indicates that they will occur in the future. During a poll cycle, when the adapter retrieves events with a future status, the adapter compares the system time with the time stamp on each event. If the event time is earlier than or equal to the system time, the adapter processes the event and changes the event status to Ready for Poll (0).

If you want to the adapter to process future status events in the present time, use the function `IBM_PUBLISH_EVENT` instead of `IBM_FUTURE_PUBLISH_EVENT`. Doing so means that the event is identified as Ready to Poll (0) instead of Future (99).

As events are retrieved and processed from the event store, the status of the event changes to reflect the cycle, as shown in the following table:

Table 36. Event status values

Status short name	Description	Event table value
Error processing event	An error. occurred during event processing	-1
Ready for poll	The event has. The event is not yet beenready to be picked up by thepicked up. adapter	0
Success	The event has. been delivered to the event manager	1

Table 36. Event status values (continued)		
Status short name	**Description**	**Event table value**
Deleted	The event has. been processed successfully and is removed from the event store	4
Future Events	These events. should be processed at a future date	99

Business objects for PeopleSoft Enterprise
To send data or obtain data from PeopleSoft Enterprise, the adapter uses business objects. A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The data can represent either a business entity, such as an invoice or an employee record, or unstructured text.

How business objects are created

You create business objects by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business objects to represent them. It also generates other resources that are needed by the adapter.

Business object structure

The adapter supports business objects that are hierarchically structured. The top-level business object must have a one-to-one correspondence with the PeopleSoft component interface, and collections that occur in the top-level object are children of it. Information about the processed object is stored in the application-specific information for the object and each of its attributes.

The following table describes the attributes that form a business object.

Attribute property	**Description**
Name	Indicates the name of the business object attribute.
Type	Indicates the type of the Business Object attribute. The adapter uses character mapping between PeopleSoft component property types and the generated business object attribute types. PeopleSoft component property types map to generated attribute types in the following manner: CHAR maps to attribute type String NUMBER maps to attribute type BigDecimal LONG maps to attribute type Long SIGN maps to attribute type BigDecimal DATE maps to attribute type Date TIME maps to attribute type Time DTTM maps to attribute type DateTime
Key	Child business objects have their own keys that have the primary key application-specific information. They also inherit keys from their parent business object.

Attribute property	Description
Cardinality	Single cardinality for simple attributes; multiple cardinality for container attributes.

Overview of WebSphere Adapter for JD Edwards EnterpriseOne
With the WebSphere Adapter for JD Edwards EnterpriseOne, you can create integrated processes that include the exchange of information with a JD Edwards EnterpriseOne server, without special coding.

The adapter provides a standard interface that eliminates the need for the component to understand the lower-level implementation details or data structures of the application. By using the adapter, a component (the program or piece of code that performs a specific business function) can send requests to the JD Edwards EnterpriseOne server (for example, to query a customer record in a table or to update an order document).

WebSphere Adapter for JD Edwards EnterpriseOne complies with the Java Platform, Enterprise Edition (Java EE) Connector Architecture (JCA). JCA standardizes the way in which application components, application servers, and Enterprise Information Systems (EIS), such as a JD Edwards EnterpriseOne server, interact with each other. WebSphere Adapter for JD Edwards EnterpriseOne makes it possible for JCA-compliant application servers to connect to and interact with the JD Edwards EnterpriseOne server. Clients running on the JCA-compliant server can then communicate with the JD Edwards EnterpriseOne server in a standard way (by using business objects or JavaBeans).

Suppose a medium-sized retail company uses JD Edwards EnterpriseOne to coordinate most of its business operations. JD Edwards EnterpriseOne includes a business function that can return a real-time list of inventory items for its 100 stores located across the United States. An application component might be able to use this business function as part of an overall business process. For example, an employee of a retail company can access the real-time list of available inventory items, therefore providing correct, real-time information to a customer.

For more information, see "Technical overview of the WebSphere Adapter for JD Edwards EnterpriseOne" on page 1102.

Technical overview of the WebSphere Adapter for JD Edwards EnterpriseOne
The IBM WebSphere Adapter for JD Edwards EnterpriseOne provides a way for applications to interact with data on JD Edwards EnterpriseOne applications.

The adapter processes requests using one of two types of business objects: business functions and XML Lists. A business function is a business object container that can contain one or many business objects that can be processed as a single transaction. An XML List is a single business object that can query a table and return multiple records.

You create business objects by using the Adapter Connection wizard. The business objects that are generated by the Adapter Connection wizard have predefined business object definitions.

For more information, see the following topics:

- "Outbound processing (JD Edwards)" on page 1102
- "Inbound processing for JD Edwards EnterpriseOne" on page 1103
- "Business objects for JD Edwards EnterpriseOne" on page 1105
- "The Adapter Connection wizard (JD Edwards)" on page 1105

Outbound processing (JD Edwards)
The WebSphere Adapter for JD Edwards EnterpriseOne supports synchronous outbound request processing. When the adapter receives a request from the module, in the form of a business object, the adapter processes the request and returns the result, when applicable, in a business object.

The adapter processes requests by using one of two types of business object: business functions and XML Lists. A business function is a business object container that can contain one or many business objects, which can be processed as a single transaction. An XML List is a single business object that can query a table and return multiple records. The component sends a request in the form of a WebSphere business

object hierarchy to the adapter, the adapter processes the request, and returns a WebSphere business object hierarchy that represents the result of the operation.

When the adapter receives a WebSphere business object hierarchy, the adapter processes it in the following way.

1. The adapter extracts metadata from the WebSphere business object hierarchy.
2. The adapter identifies the appropriate JD Edwards EnterpriseOne objects to access (for example, JD Edwards EnterpriseOne business objects and business components, or JD Edwards EnterpriseOne business function, or JD Edwards EnterpriseOne XML List) depending on the objects against which the artifacts were generated.
3. The adapter extracts the outbound operation to complete from the WebSphere business object hierarchy.
4. After accessing the required JD Edwards EnterpriseOne objects, the adapter retrieves the data for XML List, or completes the corresponding business function method.
5. If updates are involved (Create, Update, Delete), the adapter populates that JD Edwards EnterpriseOne object (business function or XML List hierarchy) with data from the hierarchy of WebSphere business objects.

Supported outbound operations

When the adapter receives a request, it processes the request by using the JD Edwards EnterpriseOne Dynamic Java connector to call either a business function or an XML List.

Business functions support the following types of operation:

- Create
- Delete
- Execute
- Retrieve
- Update

XML Lists support the retrieveAll operation

Operations	Description
Create	Creates the business object.
Delete	Deletes the business object and its children. The adapter supports only logical deletes, therefore objects are marked as deleted but not removed.
Exists	Checks for the existence of incoming business objects.
Retrieve	Retrieves the JD Edwards EnterpriseOne component, and maps component data onto the business object.
RetrieveAll	Retrieves multiple instances of the JD Edwards EnterpriseOne component, and maps component data onto the business object.
Update	Updates the corresponding JD Edwards EnterpriseOne component with the incoming business object.

Inbound processing for JD Edwards EnterpriseOne
The WebSphere Adapter for JD Edwards EnterpriseOne supports asynchronous inbound processing. The adapter polls the JD Edwards EnterpriseOne server at specified intervals for events. When the adapter receives an event, it converts the event data into a business object and sends the business object to the component.

The WebSphere Adapter for JD Edwards EnterpriseOne supports real-time events. A real-time event is a business transaction that provides information from the JD Edwards EnterpriseOne server that can be

used to interoperate with a third-party system. Real-time events can be generated wherever business functions run, such as HTML, WIN32, and enterprise servers. Real-time events are useful for producing notifications in real time. The adapter supports both single and container real-time events.

When the adapter gets a real-time event from the JD Edwards EnterpriseOne transaction server by calling the JD Edwards EnterpriseOne Dynamic Java Connector API, it parses the content of this real-time event and converts it into a business object. The adapter then sends the business object to the event endpoints. For example, if a company is updated, the JD Edwards EnterpriseOne server captures this change immediately, and one real-time event is generated by the JD Edwards EnterpriseOne transaction server. The adapter then communicates with the JD Edwards EnterpriseOne transaction server, retrieves this real-time event, and processes it. After converting it into a business object, the adapter delivers this business object to the event endpoint.

WebSphere Adapter for JD Edwards EnterpriseOne processes events in the following way.

1. The adapter calls the JD Edwards EnterpriseOne Dynamic Java Connector API to get a real-time event.
2. The adapter parses the content of this real-time event.
3. The adapter populates the associated business object with the values that it retrieves from the payload of this real-time event.
4. The adapter sends the generated business object to each registered application.

Before inbound processing can occur, the JD Edwards EnterpriseOne server must be configured to support real-time events.

Event persistence (JD Edwards)
The WebSphere Adapter for JD Edwards EnterpriseOne supports event persistence for inbound processing in case of abrupt termination. Event persistence (or assured-once delivery) is a way to make sure that events are delivered once, and only once, to the endpoint in the case of a failure.

During event processing, the adapter persists the event state in an event store located on the data source. You must set up this data source before you can create the event store. To use the recovery feature, set the `AssuredOnceDelivery` property in the activation specification to `True`. This recovery feature is set to `True` by default.

When a failed event occurs, the adapter tries to deliver the event once more only. If the event fails again, its status is marked as FAILED and the event remains in the event store until it is either deleted manually or has its status changed. If the adapter fails or stops before the event is marked as FAILED, when it recovers, the adapter retrieves the event from the event store with the stored data and attempts to redeliver the event, marking its status as FAILED only after the default retry limit of one has been exceeded again.

Event store (JD Edwards)
The event store is a persistent cache where event records are saved until the polling adapter can process them. The adapter uses event stores to record inbound events as they make their way through the system.

Each time a real-time event is received, the adapter updates the status of the event in an event store. The status of each event is continually updated by the adapter for recovery purposes until the events are delivered to the endpoint. If the adapter detects that no event store exists for the inbound module in IBM App Connect Enterprise, it creates one automatically when the application is deployed to the run time. Each event store that is created by the adapter is associated with a specific inbound module. The adapter does not support multiple adapter modules pointing to the same event store.

When the adapter polls the JD Edwards EnterpriseOne transaction server and receives a real-time event, it creates an entry in the event store for each event that matches the search criteria specified in the activation specification properties. The adapter records the status of each new entry as NEW.

If a real-time event is successfully delivered, the corresponding event store entries are deleted. For failed events, the entries remain in the event store.

Assured once delivery

The JD Edwards EnterpriseOne transaction server provides guaranteed event delivery quality of service. All the real-time events to which the adapter subscribes are delivered to the adapter without any loss. The JD Edwards EnterpriseOne transaction server can send duplicate real-time events to the adapter, therefore the adapter provides assured once event delivery; each event is delivered once and only once. To enable assured once delivery, you must set the `AssuredOnceDelivery` activation specification property to `True`.

When you set the `AssuredOnceDelivery` activation specification property to `True`, the `AutoAcknowledge` activation specification property is set to `False` automatically.

When a real-time event is obtained, it is processed in the following way.

1. The event is delivered to its corresponding endpoint.
2. The event entry is deleted from the event store.
3. An acknowledgment is issued to the JD Edwards EnterpriseOne transaction server.

Business objects for JD Edwards EnterpriseOne
A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The data can represent either a business entity, such as an invoice or an employee record, or unstructured text. The adapter uses business objects to send data to or obtain data from the JD Edwards EnterpriseOne server.

How the adapter uses business objects

The WebSphere Adapter for JD Edwards EnterpriseOne uses the JD Edwards EnterpriseOne Dynamic Java Connector APIs to communicate with the JD Edwards EnterpriseOne server. The adapter exchanges information with JD Edwards EnterpriseOne through business functions, XML List calls, and the real-time event mechanism.

How business objects are created

You create business objects by using the Adapter Connection wizard, which connects to the application, discovers data structures in the application, and generates business objects to represent them. It also generates other resources needed by the adapter.

Business object structure

The adapter supports processing of hierarchical business objects. A container business object representing a JD Edwards EnterpriseOne operation is a wrapper object that contains single or multiple child business function objects, also called simple business function objects. Each business function object represents a specific function call in the JD Edwards EnterpriseOne application.

The Adapter Connection wizard (JD Edwards)
The Adapter Connection wizard is a tool that you use to create services. The Adapter Connection wizard establishes a connection to the JD Edwards EnterpriseOne server, discovers services (based on search criteria that you provide), and generates business objects, interfaces, and import or export files, based on the services that are discovered.

See the WebSphere Adapter for JD Edwards EnterpriseOne product documentation online for further information.

By using IBM App Connect Enterprise, you establish a connection to the JD Edwards EnterpriseOne server to browse the metadata repository on the JD Edwards EnterpriseOne server.

You specify connection information (such as the user name and password needed to access the server), and you specify the method of operation that you want to use for an outbound or inbound request:

- For an outbound request, you specify either a business function or an XML List.
- For an inbound request, you specify real-time events.

You can then provide search criteria and select the information (for example, by using the search filter with libraries for business functions, or by selecting tables for XML Lists).

The result of running the Adapter Connection wizard is an adapter connection project and a library that contain the interfaces and business objects as well as the adapter.

The Adapter Connection wizard also produces an import file (for outbound processing) or an export file (for inbound processing).

- The import file contains the managed connection factory property settings that you provide in the wizard.
- The export file contains the activation specification property settings you provide in the wizard.

Developing message flows that use WebSphere Adapters

For information about how to develop message flows that use WebSphere Adapters, see the following topics.

About this task

- “Preparing your system to use WebSphere Adapters nodes” on page 1106
- “Activating IBM License Metric Tool for WebSphere Adapters” on page 1108
- “Connecting to an EIS by using the Adapter Connection wizard” on page 1108
- “Configuring WebSphere Adapters nodes for secondary adapters” on page 1110
- “Calling new services from a WebSphere Adapters request node without changing existing deployed resources” on page 1111
- “Handling new event types from a Websphere Adapters input node without changing existing deployed resources” on page 1112
- “Interacting with an SAP application” on page 1112
- “Interacting with a Siebel application” on page 1122
- “Interacting with a PeopleSoft application” on page 1126
- “Interacting with a JD Edwards application” on page 1129

Preparing your system to use WebSphere Adapters nodes

Before you can connect to an Enterprise Information System (EIS), you must prepare your system by adding external software dependencies and configuring the EIS to work with the WebSphere Adapter.

Before you begin

- For general background information, read “WebSphere Adapters nodes” on page 1050
- Check for the latest information about WebSphere Adapters at WebSphere Adapters technotes.
- Check for the latest information about support for adapters on different operating systems at IBM App Connect Enterprise system requirements.
- Enable the WebSphere Adapters nodes in the IBM App Connect Enterprise runtime environment; see “Preparing the environment for WebSphere Adapters nodes” on page 209.
- If you want to use the IBM Tivoli License Manager (ITLM), perform the steps in “Activating IBM License Metric Tool for WebSphere Adapters” on page 1108.

About this task

Perform the following steps, in the order shown, to prepare your system to use WebSphere Adapter nodes.

Procedure

- **SAP**
  1. Follow the instructions in "Adding external software dependencies for SAP" on page 1113.
  2. Follow the instructions in "Configuring the SAP server to work with the adapter" on page 1115.
- **Siebel**
  1. Follow the instructions in "Creating the event store manually" on page 1123.
- **PeopleSoft**
  1. Follow the instructions in "Creating a custom event project in PeopleTools" on page 1127.

What to do next

After you have prepared your system, connect to an EIS by following the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.

Preparing the environment for WebSphere Adapters nodes

Before you can use the WebSphere Adapters nodes, you must set up the IBM App Connect Enterprise runtime environment so that you can access the Enterprise Information System (EIS).

Before you begin

Read "WebSphere Adapters nodes" on page 1050.

About this task

To enable the WebSphere Adapters nodes in the IBM App Connect Enterprise runtime environment, configure the integration server with the location of the EIS provider JAR files and native libraries. (On Windows, the location of the JAR files cannot be a mapped network drive on a remote Windows computer; the directory must be local or on a Storage Area Network (SAN) disk.)

The integration server configuration file (`server.conf.yaml`) contains a section for connector providers, which defines the location of the required JAR files and native libraries, as you can see in the following example:

```
ConnectorProviders:
  SAPConnectorProvider:
    jarsURL: default_Path     # Set to the absolute path containing the SAP JCo JARs
    nativeLibs: default_Path  # Set to the absolute path containing the SAP JCo libraries
```

By default, the location is set to `default_Path`, which indicates that the JAR files and libraries can be found in the integration server's shared-classes directory.

Procedure

To configure the integration server with the location of required JAR files and libraries, complete the following steps.

1. The WebSphere Adapters nodes require libraries from the EIS vendors. For more information on how to obtain and use these libraries, see "Developing message flows that use WebSphere Adapters" on page 1106.
2. Use a YAML editor to open the `server.conf.yaml` file, then find the `ConnectorProviders` section.

   For more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.
3. Set the `jarsURL` property to the absolute path where the JAR files are stored.
4. Set the `nativeLibs` property to the absolute path where the native libraries are stored.
5. Save the `server.conf.yaml` file.

What to do next

When you have set up the environment for the WebSphere Adapters nodes, you can perform the preparatory tasks that are listed in "Developing message flows that use WebSphere Adapters" on page 1106.

Activating IBM License Metric Tool for WebSphere Adapters

If you want to use IBM License Metric Tool (ILMT), you must activate it for each of the WebSphere Adapters.

About this task

ITLM enables you to monitor the usage of IBM (and other) software products. For more information, see the IBM License Metric Tool website.

The following steps describe how to activate the ILMT file for each of the adapters.

Procedure

1. Locate the ILMT directory for the adapter.
   - For SAP: *install_dir*/itlm/SAP
   - For Siebel: *install_dir*/itlm/Siebel
   - For PeopleSoft: *install_dir*/itlm/PeopleSoft
   - For JD Edwards: *install_dir*/itlm/JDE
2. Remove the inactive file extension from the file in the ILMT directory so that it ends with `.sys2`.

Results

After you have performed these steps, when you run ILMT, the adapter is visible.

Connecting to an EIS by using the Adapter Connection wizard

Use the Adapter Connection wizard to create the resources that enable the WebSphere Adapters to connect to an Enterprise Information System (EIS).

Before you begin

- Complete the preparatory tasks listed in "Developing message flows that use WebSphere Adapters" on page 1106.
- Before you run the Adapter Connection wizard, gather the information that you need from the system administrator. You need information to connect to the EIS, and information to discover objects. For a list of the information that you might need to gather for each EIS, see the appropriate topic:
  - "Interacting with an SAP application" on page 1112
  - "Interacting with a Siebel application" on page 1122
  - "Interacting with a PeopleSoft application" on page 1126
  - "Interacting with a JD Edwards application" on page 1129

About this task

A message flow that uses one of the WebSphere Adapters requires the following resources:

- One or more message flows that contain one or more WebSphere Adapters nodes
- An XML Schema Definition (XSD) for each business object in the Enterprise Information System (EIS)
- An adapter component file for the WebSphere Adapter that is being used
- A library or application to contain these resources

The Adapter Connection wizard creates these resources automatically.

You can take an adapter component that was created by using the Adapter Connection wizard, and update it with newly discovered objects from the EIS by running the Adapter Connection - Iterative Discovery wizard. This facility is known as *iterative discovery*. You can either add the new objects without modifying existing objects, or replace existing objects. For more information, see "Enhancing existing adapters with newly discovered objects" on page 1120.

The following steps describe how to connect to an EIS.

Procedure

1. Click **File** > **New** > **Adapter Connection**.

   Alternatively, click **Quick Starts**, then click **Start from adapter connection**.

   The Adapter Connection wizard opens.
2. Follow the instructions in the wizard. To see a description of each field within the wizard, hold the mouse pointer over the field.

   Ensure that inbound and outbound SAP IDocs have different names if they are stored in the same library.

   When you have completed the steps in the wizard, the specified library contains a message type for each business object that is to be used.

   When the Adapter Connection wizard completes, the IBM App Connect Enterprise Toolkit displays a message that prompts you to drag the adapter component onto the message flow canvas.
3. Ensure that a message flow is open in the Message Flow editor so that the message flow canvas is available.
4. In the Application Development view, expand the folders beneath the library until you see the adapter component, which has a suffix of inadapter or outadapter.
5. Drag the adapter component onto the message flow canvas.

   The component appears as a message flow node.
6. Configure the node, as described in "Configuring a message flow node" on page 624.
7. When you have developed and saved your message flow, deploy it by following the instructions in "WebSphere Adapters resources" on page 2475.

What to do next

Using policies for WebSphere Adapters nodes

WebSphere Adapters nodes can get connection details from either the adapter component or a policy. By using policies, you can change the connection details for adapters without the need to redeploy the adapters. For more details about using policies with WebSphere Adapters nodes, see the appropriate topic:

- "Changing connection details for SAP adapters" on page 209

Configuring EIS connections to expire after a specified time
You can configure connections to SAP, Siebel, and PeopleSoft to expire after a specified time by using a policy.

About this task

You can use the `Connection idle timeout` property on a policy to control the number of connections to SAP, Siebel and PeopleSoft by closing connections that have not been used for a specified time.

Procedure

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create a policy and select an appropriate policy type, such as **SAP Connection** (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).

2. Ensure that the name of the policy is the same as the name that is specified by the `Primary adapter component` property on the message flow node that you want to override.

   Specify the name of the policy project and the policy on the message flow node in the format *{policyProjectName}:PolicyName*.
3. Set the `Connection idle timeout` property on the policy to the number of seconds for which the connection can be idle before it is closed.

   The default value for this property is 0 (zero) seconds, indicating that no timeout occurs. Note that new connections to SAP are opened with different user IDs; therefore do not set this property to zero if you are using identity propagation.
4. Deploy this policy before you start the associated message flow.

Configuring WebSphere Adapters nodes for secondary adapters
You can deploy the resources that are required to support new methods in an Enterprise Information System (EIS), without affecting any resources that are already deployed, by using primary and secondary adapters. You must configure the WebSphere Adapters nodes in your message flows to use the secondary adapters.

Before you begin

- Read the concept topic, "WebSphere Adapters resources" on page 2475.
- Complete the steps in "Preparing your system to use WebSphere Adapters nodes" on page 1106.

About this task

The primary adapter for a WebSphere Adapters node contains its connection information and part of its interface; the secondary adapters contain the rest of the interface. The primary library contains message model metadata for the parts of the interfaces that are supported by the node; the secondary libraries define the rest of the model.

Complete the following steps to configure a message flow so that it can be extended by secondary adapters and libraries.

Procedure

1. To create a primary adapter and library, run the **Adapter Connection** wizard by following the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.
2. When the wizard has finished, create a message flow that contains one or more WebSphere Adapters nodes.
3. In the Application Development view, expand the folders beneath the library until you see the adapter component, which has a suffix of `.inadapter` or `.outadapter`.
4. Drag the adapter component onto the WebSphere Adapters node in your message flow.
5. On the Basic properties tab of the WebSphere Adapters node, set the `Secondary adapter mode` to `All adapters in application`.
6. Save the message flow.

What to do next

Add the library to a BAR file, then deploy the BAR file to the integration server. For more information, see "Including WebSphere Adapters resources in a BAR file" on page 2475.

You have created a message flow that you can enhance in the future when you need to call new services or handle new event types in an EIS. For instructions about how to enhance your message flow, see the following topics:

- "Calling new services from a WebSphere Adapters request node without changing existing deployed resources" on page 1111

- "Handling new event types from a Websphere Adapters input node without changing existing deployed resources" on page 1112

Calling new services from a WebSphere Adapters request node without changing existing deployed resources
If your message flow acts as a gateway to an Enterprise Information System (EIS), you can use it to call new services that did not exist when you developed the flow. Therefore, if a new service is provided by the EIS, you do not have to modify and retest the message flow.

Before you begin

- Read the concept topic "WebSphere Adapters resources" on page 2475.
- Ensure that you have created and deployed a message flow that is configured to use secondary adapters, as described in "Configuring WebSphere Adapters nodes for secondary adapters" on page 1110.

About this task

To use iterative deployment, you can configure an SAPRequest, SiebelRequest, PeopleSoftRequest, or JDEdwardsRequest node to look for a specified operation in all relevant `.outadapter` components that are deployed to the integration server.

Procedure

1. Run the **Adapter Connection** wizard to create an `.outadapter` component and a library for the new EIS services.

   You do not need to rediscover existing services. For more information about running the Adapter Connection wizard, see "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.
2. Ensure that method names are unique across all primary and secondary adapters that are used by the request node. If they are not unique, edit them by clicking **Edit Operations** on the **Service Generation and Deployment Configuration** panel of the **Adapter Connection** wizard.

   The method names correspond to the Service Operation names, which are configured by the **Adapter Connection** wizard. In most cases, the names are based on the name of the service that is being discovered (for example, the BAPI name in SAP, or the business object and operation name in Siebel). However, in some cases, you must edit them to avoid a clash.

   You can set the method name dynamically in the message flow by setting the local environment field `$LocalEnvironment/Adapter/MethodName`.
3. Avoid duplicate method names by using user trace in the following way.
   a) Start user trace by following the instructions in "User trace example" on page 3030.
   b) Stop and restart the message flow.
   c) Read user trace. Message BIP3432 identifies which methods are already defined by currently deployed adapters.

   Alternatively, you can identify the methods that are defined by the adapter by looking at the `Default method` property of the request node. If you have a `.outadapter` component in your workspace, you can drop it onto a message flow to create a request node for the `.outadapter` component. The request node has that adapter set as its primary adapter, and the list of methods that are defined by that adapter are visible in the `Default method` property of the request node.
4. Ensure that the library that is created does not contain any types that share the same name and namespace of existing libraries. You can change the namespaces of the types on the **Adapter Connection** wizard by using the Business Object Namespace control.

   Use different namespaces for different libraries. The use of different namespaces is important when working with BAPIs because the BAPI return field typically has the same name for all BAPIs, and its type definition can change depending on the age of the BAPI.

Handling new event types from a Websphere Adapters input node without changing existing deployed resources

You can create an event handler to an Enterprise Information System (EIS) to handle new event types that did not exist when you first developed your message flow. Therefore, if a new event is provided by the EIS, you do not have to modify and retest the message flow.

Before you begin

- Read the concept topic "WebSphere Adapters resources" on page 2475.
- Ensure that you have created and deployed a message flow that is configured to use secondary adapters, as described in "Configuring WebSphere Adapters nodes for secondary adapters" on page 1110.

About this task

To implement an event handler that you can enhance iteratively with new event types (that is, deploy new event types to the event handler), configure an SAPInput node to use secondary adapters. The set of secondary adapters can be extended at operational time without affecting any existing adapters.

Procedure

1. Run the **Adapter Connection** wizard to create a new `.inadapter` component and a new message set for the new EIS events.

   You do not need to rediscover existing events. For more information about running the Adapter Connection wizard, see "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.
2. Ensure that the method names are unique.

   The method names correspond to the Service Operation names. Therefore, when you are choosing or editing the Service Operation names, make sure that they do not clash with those names defined in other adapters that are being used by that node.
3. Avoid duplicate method names by using user trace in the following way.
   a) Start user trace by following the instructions in "User trace example" on page 3030.
   b) Stop and restart the message flow.
   c) Read user trace. Message BIP3432 identifies which methods are already defined by currently deployed adapters.
4. Ensure that the message set that is created does not contain any types that share the same name and namespace of existing message sets. You can change the namespaces of the types on the **Adapter Connection** wizard by using the Business Object Namespace control.

   Use different namespaces for different message sets. The use of different namespaces is important when working with BAPIs because the BAPI return field typically has the same name for all BAPIs, and its type definition can change depending on the age of the BAPI.

Interacting with an SAP application

To interact with an SAP application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

About this task

To connect to an SAP application, the SAP adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the SAP application, then deploy the relevant resources.

Procedure

1. To obtain software dependencies, follow the instructions in "Adding external software dependencies for SAP" on page 1113.

   If you require your message flow to use transactional processing (which is specified by default on the SAPInput node), ensure that IBM MQ is installed on the same computer as IBM App Connect Enterprise. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.
2. Optional: If you are using Application Link Enabling (ALE) processing, register a Remote Function Call (RFC) destination on the SAP server and configure the SAP server, as described in "Configuring the SAP server to work with the adapter" on page 1115.
3. Before you run the Adapter Connection wizard, gather the following information from your SAP administrator:

   - SAP system user name
   - SAP system password
   - SAP host name or IP address
   - SAP Client ID (for example, 001)
   - SAP system number (for example, 00)
   - Language code (for example, EN)

   You might also need to gather some specific information from your SAP administrator about the items that you are discovering. For example, if you are discovering IDocs, you need the appropriate information to complete the following fields:

   - IDoc name
   - Version
   - SAP outbound
   - Verbs (create, update, delete)
   - Partner number
   - Message type

   For more information, see SAP connection properties for the Adapter Connection wizard.
4. To connect to SAP by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.
5. Develop your message flow to define the interaction with the SAP application.
6. Optional: To propagate security credentials to an SAP request, see "Propagating security credentials to Siebel and SAP requests" on page 1121.
7. Deploy the appropriate resources, as described in "Including WebSphere Adapters resources in a BAR file" on page 2475.
8. Optional: To enhance existing adapters with newly discovered objects, see "Enhancing existing adapters with newly discovered objects" on page 1120.

Adding external software dependencies for SAP
Before you can develop message flows that use WebSphere Adapters nodes, you must add prerequisite files to the runtime environment.

Before you begin

- If you require transactional support for SAP nodes, ensure that an IBM MQ client or server is installed on the same computer as the integration server. If you do not require the nodes in the flow to be transactional, you can set the **Transaction mode** property of the SAP node to No, and access to IBM MQ will not be required. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

- Ensure that you have the relevant prerequisite files for your SAP system. (For information about the versions of files that IBM App Connect Enterprise supports, see IBM App Connect Enterprise system requirements.)
  - `sapidoc3.jar`
  - `sapjco3.jar`
  - Windows On Windows:

    - `sapjco3.dll`
  - Linux UNIX On Linux and UNIX:

    - `libsapjco3.so`

  Note: You can download these files for your operating system from the external SAP Web site, SAP Support Portal, and save them to a directory, such as `C:\SAP_LIB`. (On Windows, the directory cannot be a mapped network drive on a remote Windows computer; the directory must be local or on a Storage Area Network (SAN) disk.) You must have an SAPNet account to be able to access this Web site.
  - Windows On Windows, download the `.dll` files that come with the SAP JCo download.
  - Linux UNIX On Linux and UNIX, download the `.so` and `.o` files that come with the SAP JCo download.

Locating the SAP support files in the runtime environment

About this task

The integration server configuration file (`server.conf.yaml`) contains a section for connector providers, which defines the location of the required JAR files and native libraries, as you can see in the following example:

```
ConnectorProviders:
  SAPConnectorProvider:
    jarsURL: default_Path     # Set to the absolute path containing the SAP JCo JARs
    nativeLibs: default_Path  # Set to the absolute path containing the SAP JCo libraries
```

By default, the location is set to `default_Path`, which indicates that the JAR files and libraries can be found in the integration server's shared-classes directory.

To specify a location for the SAP prerequisite files, complete the following steps.

Procedure

- Linux Windows UNIX

  On Windows, Linux, and UNIX:

  a) Use a YAML editor to open the `server.conf.yaml` file, then find the `ConnectorProviders` section.

  For more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.

  b) Set the `jarsURL` property to the absolute path where the JAR files are stored.

  c) Set the `nativeLibs` property to the absolute path where the native libraries are stored.

  d) Save the `server.conf.yaml` file, then restart the integration server.

Locating the SAP support files through the IBM App Connect Enterprise Toolkit

About this task

To add the SAP prerequisite files through the IBM App Connect Enterprise Toolkit, take the following steps.

Procedure

- Windows

  On Windows: When you run the Adapter Connection wizard, you are prompted to specify the paths to the required libraries.

- Linux

  On Linux: Append the directory that contains the SAP libraries to the LD_LIBRARY_PATH environment variable:

  ```
  LD_LIBRARY_PATH=DIRECTORY_CONTAINING_SAP_LIBRARIES:${LD_LIBRARY_PATH}
  export LD_LIBRARY_PATH
  ```

  You must set this variable either for the whole system, or in the same shell or environment from which the IBM App Connect Enterprise Toolkit is launched.

What to do next

Configure the SAP system to work with the adapter

Configuring the SAP server to work with the adapter

Before you configure the WebSphere Adapter for SAP Software for Application Link Enabling (ALE) processing, you must register a Remote Function Call (RFC) destination on the SAP server, and configure a receiver port, logical system, distribution model, and partner profile on the SAP server. Ask your system administrator if these items have been configured.

Before you begin

Add the required external software dependencies for SAP.

About this task

Complete the following steps on the SAP server by using the SAP graphical user interface.

Procedure

1. Register an RFC program ID:
   a) Open transaction **SM59** (Display and Maintain RFC Destinations).
   b) Click **Create**.
   c) Type a name for the RFC destination.
   d) In the **Connection Type** field, select **T**.
   e) In the **Activation Type** field, select **Registered Server Program**.
   f) Type a Program ID.

      You use this program ID when you configure the adapter. This value indicates to the SAP gateway which RFC-enabled functions the program ID listens for.
   g) Enter a description in **Description 1**, such as `RFC for Test Sample`.
   h) Enter a description in **Description 2**, such as your name.
   i) Click **MDMP & Unicode**, and set the RFC destination to **Unicode** or **non-Unicode**, depending on the communication type of the target system.

      To avoid errors when you use multiple language settings, set the RFC destination to **Unicode**.
   j) Save your entry.
2. Set up a receiver port:
   a) Open transaction **WE21** (Ports in IDoc processing).
   b) Select **Transactional RFC**, click **Ports**, and click the **Create** icon.
   c) Type a name for the port and click **OK**.
   d) Type the name of the destination that you created in the previous task (or select it from the list).
   e) Save your entry.
3. Specify a logical system:
   a) Open transaction **BD54** (Change View Logical Systems).
   b) Click **New Entries**.
   c) Type a name for the logical system and click the **Save** icon.
   d) If you see the Prompts for Workbench request, click the **New Request** icon. Then enter a short description and click **Save**.
   e) Click the **Continue** icon.
4. Configure a distribution model:
   a) Open transaction **BD64** (Maintenance of Distribution Model).
   b) Click **Distribution Model** > **Switch processing model**.
   c) Click **Create model view**.
   d) Type a name for the model view and click the **Continue** icon.
   e) Select the distribution model that you created and click **Add message type**.
   f) For outbound processing, type the logical system name that you created in the previous task as **Sender**, and type the logical name of the SAP server as **Receiver**, then select a message type (for example, **MATMAS**) and click the **Continue** icon.
   g) Select the distribution model again and click **Add message type**.
   h) For inbound processing, type the logical name of the SAP server as **Sender**, and the logical system name that you created in the previous task as **Receiver**, then select a message type (for example, **MATMAS**) and click the **Continue** icon.
   i) Save your entry.

5. Set up a partner profile:
   a) Open transaction **WE20** (Partner Profiles).
   b) Click the **Create** icon.
   c) Type the name of the logical system that you created in the earlier task and, for **Partner Type**, select **LS**.
   d) For **Post Processing: permitted agent**, type US and your user ID.
   e) Click the **Save** icon.
   f) In the Outbound parameters section, click the **Create outbound parameter** icon.
   g) In the **Outbound parameters** window, type a message type (for example, MATMAS05), select the receiver port that you created in the earlier task, and select **Transfer IDoc immed**.
   h) Click the **Save** icon.
   i) Press **F3** to return to the Partner Profiles view.
   j) In the Inbound parameters section, click the **Create inbound parameter** icon.
   k) In the **Inbound parameters** window, type a message type (for example, MATMAS), and a process code (for example, MATM).
   l) Click the **Save** icon.
   m) Press **F3** to return to the Partner Profiles view.
   n) In the Inbound parameters section, click the **Create inbound parameter** icon.
   o) In the **Inbound parameters** window, type the following values: ALEAUD for **Message Type**, and AUD1 for **Process Code**.
   p) Click the **Save** icon.
   q) Press **F3** to return to the Partner Profiles view.
   r) Click the **Save** icon.

What to do next

connect to an EIS using the Adapter Connection wizard.

Changing connection details for SAP adapters

SAP nodes can get SAP connection details from either the adapter component or a policy. By using a policy, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a policy is created or modified, you must restart the integration server where the adapter is deployed.

Before you begin

- Read “WebSphere Adapters nodes” on page 1050 and “Overriding properties at run time with policies” on page 324 for background information.

About this task

Use the SAP Connection policy to change connection details for an SAP adapter. The SAP node reads all connection properties from the adapter component that it is configured to use. If a SAP Connection policy exists with the same name as the node's **`Primary adapter component`** property, the node uses the values that are defined in that policy to override the corresponding properties from the adapter. If any properties on the policy are set to an empty string, the values that are configured in the `.inadapter` or `.outadapter` file are used. The properties of the SAP policy are described in SAP Connection policy (SAPConnection).

Procedure

To use a policy to change connection details at run time, complete the following steps:

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create a policy and select **SAP Connection** as the policy type (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. Ensure that the name of the policy is the same as the name that is specified by the `Primary adapter component` property on the SAPInput or SAPRequest node (without the `.inadapter` or `.outadapter` suffix).
3. Set the appropriate properties in the policy for the settings that you want to use at run time.

   The default value for most properties in the policy is an empty string, which indicates that behavior is controlled by the `.inadapter` or `.outadapter` file for those properties. For more information, see SAP Connection policy (SAPConnection).
4. Deploy this policy in the default policy project for the integration server before you start the associated message flow.

   For information about configuring a default policy project, see "Configuring a default policy project" on page 329.

Setting up SAP for high availability
You can configure IBM App Connect Enterprise to withstand software or hardware failures when working with SAP by moving the transaction ID (TID) store to a client queue manager that can be shared between two integration nodes. To avoid a single point of failure, make this queue manager an IBM MQ high availability, multi-instance queue manager.

Before you begin

- Read the concept topic about "SAP high availability" on page 1070.
- Ensure that either an IBM MQ client or an IBM MQ server is installed on the same computer as the integration node. For more information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

About this task

The following topic describes how to set up an IBM MQ shared queue:

Procedure

- "Setting up a shared queue for the SAP adapter event store" on page 1118

Setting up a shared queue for the SAP adapter event store
To achieve high availability when processing SAP messages on distributed systems, you can set up a shared queue for the SAP adapter event store.

About this task

On distributed systems, you can configure the integration node to use a client connection to a remote IBM MQ queue manager to persist the transaction ID (TID) store for SAP transactional RFC (tRFC) data. By using this configuration, two adapters that are deployed to two integration nodes can share the same TID, and can therefore operate as a single RFC server. This configuration is essential if the adapters have been configured with the same RFC Program ID. For important information about using IBM MQ with IBM App Connect Enterprise, see "Installing IBM MQ" on page 96.

Before the integration node can use a remote queue manager as the TID store, you must complete some administration tasks on that queue manager.

1. You must first create the queue for the integration node to use as the TID store.

2. Then you must define two channels for the integration node to use to connect to that queue manager: define the server channel on the queue manager, and define a client channel in a file, which you must make available to the integration node.

   You can use the Run WebSphere MQ Commands (runmqsc) command or IBM MQ Explorer to create this client channel definition file on any queue manager. After you have created the file, you must move it from the queue manager to a file system that is accessible to the integration node.

To set up a shared queue for the SAP adapter event store, complete the following steps.

Procedure

1. Create the queue SYSTEM.BROKER.ADAPTER.PROCESSED.

   You can create the queue either by using IBM MQ Explorer or by running the following command in IBM MQ **runmqsc**:

   ```
   DEFINE QLOCAL('SYSTEM.BROKER.ADAPTER.PROCESSED')
   ```

2. Create the server channel.

   a) On the computer that hosts the shared queue manager, create a server channel by running the IBM MQ **runmqsc** command and entering the following parameters, where *WSADAPTERS.SAP* is an example of the channel name.

   ```
   DEFINE CHANNEL ('WSADAPTERS.SAP') CHLTYPE (SVRCONN) TRPTYPE(TCP)
   ```

   b) After you have created the channel, start it by using the following command in **runmqsc**:

   ```
   START CHANNEL ('WSADAPTERS.SAP')
   ```

3. Create the client definition file.

   On any queue manager, create a client definition file by running the **runmqsc** command and entering the following parameters, where the following criteria apply:

   - *WSADAPTERS.SAP* is an example of the channel name.
   - *myhost.ibm.com* is an example of the host name of the computer where the queue manager is running. This queue manager is the one on which you created the queue in step 1 and the server channel in step 2. This name is used by the integration node to connect to the queue manager, therefore do not use *localhost*.
   - *1414* is an example of the port number where the listener is running on that queue manager.
   - *QMGR* is an example of the queue manager name.
   - You can use any name for the server and client channels, but they must match.
   - Set the CONNAME parameter to the host name or IP address of the computer that hosts the shared queue manager, and the port number of the MQ Listener that is running on that computer. 1414 is the default listener port.

   ```
   DEFINE CHANNEL ('WSADAPTERS.SAP') CHLTYPE (CLNTCONN) CONNAME('myhost.ibm.com(1414)')
    TRPTYPE(TCP) QMNAME(QMGR)
   ```

   If the queue manager is running in multi-instance mode, define two channels, one for each instance of the queue manager

4. Move the client definition file to a file system that is accessible by the integration node.

   - Linux UNIX On Linux and UNIX, you can find this file at `/var/mqm/qmgrs/QMGR_NAME/@ipcc/AMQCLCHL.TAB`.
   - Windows On Windows, you can find this file at `C:\Program Files\IBM\IBM MQ\Qmgrs\QMGR_NAME\@ipcc\AMQCLCHL.TAB`.

5. Configure the integration node.
   a) Create an SAP Connection policy for the `.inadapter` component and ensure that the name of the policy matches the name of the adapter component (see “Creating policies with the IBM App Connect Enterprise Toolkit” on page 327).
   b) Set the `Shared TID store client definition file` property of the policy to the path of the file that you created in step 3 and moved in step 4.
   c) Set the `Shared TID store queue manager` parameter to the name of the queue manager for which you created the queue in step 1 and the server channel in step 2.

   For more information about these parameters, see SAP Connection policy (SAPConnection).
6. Deploy the SAP Connection policy.
7. Verify the setup.

   After you have completed these steps, you can verify that the integration node is using the queue on the remote queue manager by inspecting user trace. If the setup is successful, message BIP3470 is issued, specifying which queue manager the integration node is using as the TID store.

Enhancing existing adapters with newly discovered objects
In WebSphere Message Broker Version 8.0, you can take an adapter component that was created by using the Adapter Connection wizard, and update it with newly discovered objects from the Enterprise Information System (EIS). This facility is known as *iterative discovery*. You can either add the new objects without modifying existing objects, or replace existing objects.

Before you begin

The following instructions assume that you have already run the Adapter Connection wizard to discover a set of objects, as described in “Connecting to an EIS by using the Adapter Connection wizard” on page 1108. You can run iterative discovery only on projects that were created in WebSphere Message Broker Version 7.0 or later versions.

About this task

Procedure

1. From the Application Development view, expand the appropriate message set project folders until you see the .inadapter or .outadapter component.
2. Right-click the adapter component, then click **Iterative discovery**.

   The Adapter Connection - Iterative Discovery wizard opens. The fields in the wizard are populated with the values that you specified when you ran it previously. You can modify these values if anything has changed, such as a password.
3. On the **Find and Discover Services** page, the objects that you previously discovered and selected for import are shown in the **Objects to be imported** pane. You can discover and select new objects to import from the **Objects discovered by query** pane.

4. On the final page of the Adapter Connection - Iterative Discovery wizard, choose from the following options.
   - To add only the new objects that you discovered, select **Add XSDs for new objects and replace .wsdl, .import/.export**. When you click **Finish**, the following results occur:
     – XSD files for the additional objects are added to the adapter component. These files are shown in the **New files** pane.
     – Updated .wsdl and .import or .export files replace the files already in the adapter component.
     – The XSD files that are being added to the adapter component are also imported into the message set that is associated with the adapter component.

     If you have discovered objects by using the SAP Wrapper or SAP Work Unit options, the XSD files that correspond to the SAP wrapper objects are replaced in the adapter component. These XSD files are also imported into the message set, replacing any files that have the same name. This behavior is because the wrapper objects contain references to the new objects.
   - To replace all existing objects with the objects that you have discovered, select **Replace the contents of .in/.outAdapter with the newly discovered files**. When you click **Finish**, the following results occur:
     – The contents of the .inadapter or .outadapter file in the adapter component are replaced.
     – All discovered XSD files are imported into the message set, replacing any files that have the same name.

   Note:

   Select the **Replace the contents of .in/.outAdapter with the newly discovered files** option if you have changed any of the configuration options during rediscovery, or if the interfaces or data structure of objects that you are discovering have changed since the previous discovery.

   If you have discovered objects by using the BAPI result set option, the **Add XSDs for new objects and replace .wsdl, .import/.export** option is not available and you see the message: `Incremental discovery is not applicable for the selected option`.

   For options that are used in rediscovering SAP objects, and the corresponding restrictions, see SAP options for rediscovery.
5. Click **Finish**.

Propagating security credentials to Siebel and SAP requests
The SAPRequest and SiebelRequest nodes can use an identity that is present in the Properties folder of the message tree structure for the security credentials in a request. The nodes must use the `Propagate` property on the security profile that is defined on the node to propagate the security credentials.

About this task

If an SAPRequest node is configured with a security profile, it extracts security tokens from the input message at run time, and propagates an identity to SAP. Similarly, if a SiebelRequest node is configured with a security profile, it extracts tokens from the input message at run time, and propagates an identity to Siebel.

Procedure

To propagate an identity to be used for the Siebel or SAP request security credentials, complete the following steps.

1. Ensure that an appropriate security profile exists for the SAPRequest node, or create a security profile, by following the instructions in “Creating a security profile” on page 2584.
2. Use the BAR editor to select a security profile for the SAPRequest node that has identity propagation enabled.

   For detailed instructions, see “Configuring a message flow for identity propagation” on page 2613.

Interacting with a Siebel application
To interact with a Siebel application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

About this task

To connect to a Siebel application, the Siebel adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the Siebel application, then deploy the relevant resources.

Procedure

1. To configure the Siebel application to work with the adapter, create an event table and a Siebel business object, as described in "Configuring the Siebel application to work with the adapter" on page 1122.
2. Before you run the Adapter Connection wizard, gather the following information from your Siebel administrator:
   - Siebel user name
   - Siebel password
   - Siebel host name or IP address
   - Language code

   For more information, see Siebel connection properties for the Adapter Connection wizard.
3. To connect to Siebel by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.
4. Develop your message flow to define the interaction with the Siebel application.
5. Optional: To propagate security credentials to a Siebel request, see "Propagating security credentials to Siebel and SAP requests" on page 1121.
6. Deploy the appropriate resources, as described in "Including WebSphere Adapters resources in a BAR file" on page 2475.

Configuring the Siebel application to work with the adapter
To configure the Siebel application, create an event table and a Siebel business object.

Before you begin

1. Before you configure the Siebel application to work with WebSphere Adapter for Siebel Business Applications, you must create a user name and password so that the Adapter Connection wizard can connect to Siebel Business Applications to perform outbound operations, and retrieve Siebel business objects and services.

   You perform this task on the Siebel server, therefore ensure that you are familiar with the Siebel tools that are required to complete it. For information about using Siebel tools, refer to the Siebel tools documentation.

   To open Siebel Sales Enterprise on your local database, you must have administrative privileges.

About this task

To configure the Siebel application, you must create an event table and a Siebel business object. IBM App Connect Enterprise contains resources that help you to create the event components and triggers. This topic describes how to use those resources. You can also create the event table and Siebel business object manually; for more information, see "Creating the event store manually" on page 1123.

Procedure

1. Locate the Scripts folder at *install_dir*/tools/ResourceAdapters/Siebel_*version*/Scripts.

   The Scripts folder contains two folders: Siebel7.x.x and Siebel8.0. Each version has an Event_pkg folder, which contains a `.sif` file and a number of `.js` scripts. You use the `.sif` file to create the event components; it can add business objects, views, and all other Siebel objects to the Siebel repository. The `.js` scripts help you to create Siebel triggers.
2. To use the `.sif` file:
   a) Open Siebel tools and click **Tools** > **Import**.
   b) Import the `.sif` file.
   c) Merge the differences between the `.sif` file and the Siebel repository.
   d) Recompile the repository into a Siebel repository file (`.srf` file).
3. Use the `.js` scripts to create Siebel triggers.

   The provided samples show how to create entries in the inbound table when new Account objects are created.

Creating the event store manually
To configure the Siebel application, create an event table and a Siebel business object.

About this task

"Configuring the Siebel application to work with the adapter" on page 1122 describes how to use the samples that are supplied with WebSphere IBM Integration to configure the Siebel application. This topic describes how to create the event store manually.

The following steps describe how to create the event store to be used for inbound operations in the Siebel application. You can substitute all references to Siebel Sales Enterprise with the name of the Siebel application that you are using.

Procedure

1. Create a project called IBM, and lock the project with Siebel tools.
2. Using the object wizard, create an event table called CX_IBM_EVENT in which to store the events.
   a) In the event table, create the columns that are shown in the following table.

Column Name	Type	Length	Data Type	Required	Nullable	Status
DESCRIPTION	Data (public)	255	Varchar	No	Yes	Active
EVENT_ID	Data (public)	30	Varchar	Yes	No	Active
EVENT_TYPE	Data (public)	20	Varchar	Yes	No	Active
OBJECT_KEY	Data (public)	255	Varchar	Yes	No	Active
OBJECT_NAME	Data (public)	255	Varchar	Yes	No	Active
PRIORITY	Data (public)	10	Varchar	No	Yes	Active
STATUS	Data (public)	20	Varchar	Yes	No	Active

Column Name	Type	Length	Data Type	Required	Nullable	Status
XID	Data (public)	255	Varchar	Yes	No	Active

   b) Create a new business component called IBM Event.
   c) Create a new time stamp called Field Event, and map it to the CREATED column from CX_IBM_EVENT. Make the Type of this field DTYPE_UTCDATETIME.
   d) Create a new business object called IBM Event.
   e) Associate the IBM event business component to the IBM Event business object.
   f) Create an applet called IBM Event List Applet, and base it on the IBM Event business component that you have created.
   g) Create a view called IBM Event List View, and base it on the IBM Event business object that you have created.
   h) Create a screen called IBM Event Screen, and associate it with the IBM Event List View in the Siebel tools.
3. Create a page tab.
   a) Click **Start Application** > **Siebel Sales Enterprise**.
   b) Right-click the **Page** tab, and click **New Record**.
   c) Specify IBM Event as the screen name, and IBM Event for the **Text - String Override** field.
   d) Leave the **Inactive** field blank.
4. Create a new business object called Schema Version for your IBM project and associate it with the Schema Version business component.
   a) Apply the physical schema for the new tables to your local database by querying for the new table, CX_IBM_EVENT_Q and selecting the current query to create a physical schema. Leave the table space and index space blank.
   b) Click **Activate** to activate the new schema.
5. Add or modify the Siebel VB or e-scripts for the business component that corresponds to the business objects that are used at your site. Siebel scripts trigger event notification for business objects. Samples are located in the Samples folder in your adapter installation.
6. Create a new Siebel repository file by compiling the updated and locked projects on your local database. The new repository file has an extension of `.srf`.
7. Create and populate a new responsibility.
   a) Open Siebel Sales Enterprise on your local database.
   b) Create a new responsibility called IBM Responsibility for IBM Event List View.
   c) Add the employees or teams who are responsible for reviewing events to the newly created IBM Responsibility.
   d) Create a user name called IBMCONN (or another user name to be used by the adapter later). Add the user name to the newly created IBM Responsibility and also to the Administrative Responsibility.
8. Test the application in your local environment to ensure that you can see the IBM Event List View. An event is generated in the view after you create a record in the supported object. As part of the test, create a new Account business component instance in Siebel. Confirm that a new Account event is shown in the IBM Event List View (assuming that you have added the e-script trigger to the Account business component). If a new Account event is not displayed in the view, check for an error and fix it. For more information on the errors that might be generated, check either the Siebel support site or Siebel documentation.
9. When the test that you perform in Step 8 is successful, add your new and updated projects to your development server.
10. Activate the new table in the development server.
11. Compile a new Siebel repository (`.srf`) file on the server.

12. Back up the original repository file on the server.
13. Stop the Siebel server and replace the original repository file with the newly created one.
14. Restart the Siebel server.

Changing connection details for Siebel adapters
Siebel nodes can get Siebel connection details from either the adapter component or a policy. By using a policy, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a policy is created or modified, you must restart the integration server where the adapter is deployed.

Before you begin

- Read "WebSphere Adapters nodes" on page 1050 and "Overriding properties at run time with policies" on page 324 for background information.

About this task

Use the Siebel Connection policy to change connection details for a Siebel adapter. The Siebel node reads all connection properties from the adapter component that it is configured to use. If a Siebel Connection policy exists with the same name as the node's **`Primary adapter component`** property, the node uses the values that are defined in that policy to override the corresponding properties from the adapter. If any properties on the policy are set to an empty string, the values that are configured in the `.inadapter` or `.outadapter` file are used. The properties of the Siebel policy are described in Siebel Connection policy (SiebelConnection).

You can also connect to different versions of Siebel by creating an EIS Siebel Providers policy and setting the location of the appropriate library files (see "Connecting to different versions of Siebel" on page 1125).

Procedure

To use a policy to change connection details at run time, complete the following steps:

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create a policy and select **Siebel Connection** as the policy type (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. Ensure that the name of the policy is the same as the name that is specified by the `Primary adapter component` property on the SiebelInput or SiebelRequest node (without the `.inadapter` or `.outadapter` suffix).
3. Set the appropriate properties in the policy for the settings that you want to use at run time.

   The default value for most properties in the policy is an empty string, which indicates that behavior is controlled by the `.inadapter` or `.outadapter` file for those properties. For more information, see Siebel Connection policy (SiebelConnection).
4. Deploy this policy in the default policy project for the integration server before you start the associated message flow.

   For information about configuring a default policy project, see "Configuring a default policy project" on page 329.

Connecting to different versions of Siebel
You can access multiple versions of Siebel from a single integration node by using different versions of the client libraries.

About this task

You can connect to different versions of Siebel by configuring integration servers to use different library files. You can then connect to different versions of a Siebel server from two different integration servers.

The integration server configuration file (`server.conf.yaml`) contains a section for connector providers, which defines the location of the required JAR files and native libraries, as you can see in the following example:

```
ConnectorProviders:
  SiebelConnectorProvider:
    jarsURL: default_Path      # Set to the absolute path containing the Siebel JAR files
    siebelPropertiesURL: ''    # Set to the absolute path containing the Siebel properties file
    nativeLibs: default_Path   # Set to the absolute path containing the Siebel libraries
```

By default, the location is set to `default_Path`, which indicates that the JAR files and libraries can be found in the integration server's shared-classes directory.

Procedure

To configure integration servers with the locations of required JAR files and libraries, complete the following steps:

1. Use a YAML editor to open the `server.conf.yaml` file, then find the `ConnectorProviders` section.

   For more information, see "Configuring an integration server by modifying the server.conf.yaml file" on page 172.
2. For the Siebel connector provider, set the `jarsURL` property to the absolute path where the JAR files are stored.
3. Set the `nativeLibs` property to the absolute path where the native libraries are stored.
4. Save the `server.conf.yaml` file.
5. Repeat these steps to specify the file locations for an alternative version of the Siebel server on a second integration server.
6. Restart the integration servers.
7. Deploy the message flows that contain Siebel nodes to the appropriate integration server.

Interacting with a PeopleSoft application

To interact with a PeopleSoft application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

About this task

To connect to a PeopleSoft application, the PeopleSoft adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the PeopleSoft application, then deploy the relevant resources.

Procedure

1. To configure the PeopleSoft application to work with the adapter, create a custom event project, as described in "Creating a custom event project in PeopleTools" on page 1127.
2. Before you run the Adapter Connection wizard, gather the following information from your PeopleSoft administrator:

   - PeopleSoft user name
   - PeopleSoft password
   - PeopleSoft host name or IP address
   - Port number (for example, 9000)
   - Language code (for example, ENG)

   For more information, see PeopleSoft connection properties for the Adapter Connection wizard.
3. To connect to PeopleSoft by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.

4. Develop your message flow to define the interaction with the PeopleSoft application.
5. Deploy the appropriate resources, as described in "Including WebSphere Adapters resources in a BAR file" on page 2475.

Creating a custom event project in PeopleTools
The WebSphere Adapter requires an event project in PeopleSoft to perform asynchronous inbound event processing. Use PeopleTools to create the custom event project.

About this task

If your environment requires inbound event support, you must use a custom event project in PeopleSoft. A sample event project, IBM_EVENT_V600, is provided with the adapter. You can modify and use and the sample project, or you can create your own project by using PeopleTools. If you create your own project, make sure that you complete the following steps.

Procedure

1. Use PeopleTools Application Designer to create and name a new project.
2. Create the fields for the new project as described in the following table:

Field name	Field description
IBM_EVENT_ID	A numeric value that is retrieved from IBM_FETCH_ID record. This value is a unique ID for the event.
IBM_OBJECT_NAME	The name of the corresponding business graph.
IBM_OBJECT_KEYS	The get key property names in the Component Interface, followed by the key values in name-value pairs. This information is used for the component's retrieval from the EIS.
IBM_EVENT_STATUS	If the event is ready to be polled, the status is set to 0 and the IBMPublishEvent function is called.
IBM_OBJECT_VERB	The verb that is set on the business object graph that contains the retrieved business object.
IBM_EVENT_DTTM	The date on which the event is created. For a future dated event, this is the effective date.
IBM_NEXT_EVENT_ID	The field that has the latest event ID under the record IBM_FETCH_ ID. This field is incremented for each event that is added to the IBM_EVENT_TBL, and it populates the IBM_EVENT_ID field in that table.
IBM_XID	The transaction ID that is needed to provide assured event delivery.

3. Create a record named IBM_EVENT_TBL and add to it all the fields that you have just created, except IBM_NEXT_EVENT_ID.
4. Create a record named IBM_FETCH_ID and add to it only the IBM_NEXT_EVENT_ID field.
5. Open the IBM_FETCH_ID record, select the IBM_NEXT_EVENT_ID field, view the PeopleCode, and select **fieldformula.**
6. Copy the PeopleCode for a custom event project from PeopleCode for a custom event project to the project that you are creating.
7. Create a page under your project that contains the fields of the IBM_EVENT_TBL record at level 0. The page can have any name.

8. Create a component under your project that contains the page that you have just created. The component can have any name.
9. Create a Component Interface against this component and give it any name. Confirm that you want to default the properties that are based on the underlying component definition.
10. Build the entire project, selecting all create options.
11. Test and confirm that the Component Interface works, by using the Component Interface tester.
12. Generate the Java APIs for the Component Interface, then add the generated classes to the adapter classpath.

    For complete information about building a PeopleTools project and testing the PeopleSoft Component Interface, refer to PeopleSoft documentation.

Changing connection details for PeopleSoft adapters
PeopleSoft nodes can get PeopleSoft connection details from either the adapter component or a policy. By using a policy, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a policy is created or modified, you must restart the integration server where the adapter is deployed.

Before you begin

- Read "WebSphere Adapters nodes" on page 1050 and "Overriding properties at run time with policies" on page 324 for background information.

About this task

Use the PeopleSoft Connection policy to change connection details for a PeopleSoft adapter. The PeopleSoft node reads all connection properties from the adapter component that it is configured to use. If a PeopleSoft Connection policy exists with the same name as the node's **`Primary adapter component`** property, the node uses the values that are defined in that policy to override the corresponding properties from the adapter. If any properties on the policy are set to an empty string, the values that are configured in the `.inadapter` or `.outadapter` file are used. The properties of the PeopleSoft policy are described in PeopleSoft Connection policy (PeopleSoftConnection).

Procedure

To use a policy to change connection details at run time, complete the following steps:

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create a policy and select **PeopleSoft Connection** as the policy type (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. Ensure that the name of the policy is the same as the name that is specified by the `Primary adapter component` property on the PeopleSoftInput or PeopleSoftRequest node (without the `.inadapter` or `.outadapter` suffix).
3. Set the appropriate properties in the policy for the settings that you want to use at run time.

   The default value for most properties in the policy is an empty string, which indicates that behavior is controlled by the `.inadapter` or `.outadapter` file for those properties. For more information, see PeopleSoft Connection policy (PeopleSoftConnection).
4. Deploy this policy in the default policy project for the integration server before you start the associated message flow.

   For information about configuring a default policy project, see "Configuring a default policy project" on page 329.

Interacting with a JD Edwards application
To interact with a JD Edwards application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

Before you begin

Gather the following information from your JD Edwards administrator; you will need this information when you run the Adapter Connection wizard.

- JD Edwards EnterpriseOne environment name
- JD Edwards user name
- JD Edwards password
- The role that is associated with the user name

To find objects in the JD Edwards system, you use the Adapter Connection wizard to run a query to discover business functions or XML lists. Ask your JD Edwards administrator about the available business function libraries or XML list tables. To complete the wizard, you need to know the table type and the attributes to specify in the query. For more information, see JD Edwards connection properties for the Adapter Connection wizard.

You need the following information to complete the system connection information in the Adapter Connection wizard. You can find this information in the `jdbj.ini` file that is included with the external JD Edwards resource files.

```
[JDBj-BOOTSTRAP SESSION]
user=user
password=***
environment=JDEenv
role=*ALL
```

Connecting to a DB2 database

If you are connecting to a DB2 database, the JDBC driver file that is required for DB2 can be found in the JDBC driver files table. The `jdbj.ini` file contains the following example entries, which have been configured by the JD Edwards administrator:

```
[JDBj-BOOTSTRAP DATA SOURCE]

databaseType=W

[JDBj-JDBC DRIVERS]

UDB=COM.ibm.db2.jdbc.app.DB2Driver
```

Connecting to an Oracle database

If you are Connecting to an Oracle database, the JDBC driver files that are required for Oracle can be found in the JDBC driver files table. The `jdbj.ini` file contains the following example entries, which have been configured by the JD Edwards administrator:

```
[JDBj-JDBC DRIVERS]
ORACLE=oracle.jdbc.driver.OracleDriver

[JDBj-ORACLE]
tns=tnsnames.ora
```

About this task

To connect to a JD Edwards application, the JD Edwards adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the JD Edwards application, then deploy the relevant resources.

Procedure

1. To connect to JD Edwards by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 1108.
2. Develop your message flow to define the interaction with the JD Edwards application.
3. Deploy the appropriate resources, as described in "Including WebSphere Adapters resources in a BAR file" on page 2475.

Changing connection details for JD Edwards adapters
JDEdwards nodes can get JD Edwards EnterpriseOne connection details from either the adapter component or a policy. By using a policy, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a policy is created or modified, you must restart the integration server where the adapter is deployed.

Before you begin

- Read "WebSphere Adapters nodes" on page 1050 and "Overriding properties at run time with policies" on page 324 for background information.

About this task

Use the JDEdwards Connection policy to change connection details for a JD Edwards adapter. The JD Edwards node reads all connection properties from the adapter component that it is configured to use. If a JDEdwards Connection policy exists with the same name as the node's **`Primary adapter component`** property, the node uses the values that are defined in that policy to override the corresponding properties from the adapter. If any properties on the policy are set to an empty string, the values that are configured in the `.inadapter` or `.outadapter` file are used. The properties of the JD Edwards policy are described in JDEdwards Connection policy (JDEdwardsConnection).

Procedure

To use a policy to change connection details at run time, complete the following steps:

1. Use the Policy editor in the IBM App Connect Enterprise Toolkit to create a policy and select **JD Edwards Connection** as the policy type (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
2. Ensure that the name of the policy is the same as the name that is specified by the `Primary adapter component` property on the JDEdwardsInput or JDEdwardsRequest node (without the `.inadapter` or `.outadapter` suffix).
3. Set the appropriate properties in the policy for the settings that you want to use at run time.

   The default value for most properties in the policy is an empty string, which indicates that behavior is controlled by the `.inadapter` or `.outadapter` file for those properties. For more information, see JDEdwards Connection policy (JDEdwardsConnection).
4. Deploy this policy in the default policy project for the integration server before you start the associated message flow.

   For information about configuring a default policy project, see "Configuring a default policy project" on page 329.

Working with databases

Create and configure databases to use with your message flows.

About this task

- "Databases overview" on page 1131
- "Accessing databases from message flows" on page 1134
- "Accessing databases from ESQL" on page 1135

- “Event-based database integration” on page 1136
- “Configuring a DatabaseInput node” on page 1140

Databases overview

The integration server can manipulate business data that is stored in databases. If you have databases, you must configure them before you can access them from your message flow.

IBM App Connect Enterprise supports the databases that are listed in IBM App Connect Enterprise system requirements. If you configure your message flows to access databases, you cannot access some of the data types that are supported by these databases. The supported data types are defined in Data types of values from external databases.

Additional local and remote database managers might also be supported for your computer. For more information, see IBM App Connect Enterprise system requirements.

You must set up connections to the databases so that the integration node can access the databases on behalf of its deployed message flows. Both ODBC and JDBC connections are supported; some restrictions apply on some platforms, as described in the topics in this section. ODBC drivers are supplied and installed with IBM App Connect Enterprise. JDBC drivers are not supplied by IBM App Connect Enterprise; you must obtain these files from your database vendor.

For information about connections to databases, see “Database connections” on page 1131.

Database connections

Databases contain business data that is written and accessed by deployed message flows. You must create connections from the integration node to the database by using ODBC or JDBC.

A database connection is a configuration file where you specify a database's physical details such as database type and version, and parameters to enable a JDBC connection from IBM App Connect Enterprise Toolkit to the database.

ODBC connections to databases are managed internally by the integration node, and therefore any configurable connection pooling options that are available on the ODBC driver should not be used.

The integration node requires a database connection for each data source name (DSN) that is referenced in the message flow, even if different DSNs resolve to the same physical database. If the message flow is operating in coordinated mode, then a separate XA connection to each DSN participating in the globally coordinated flow is also required.

The number of connections to a database that an integration node requires depends on the actions of the message flows that access the database. For each message flow thread, an integration node that accesses a database makes one connection for each data source name (DSN). If a different node on the same thread uses the same DSN, the same connection is used, unless a different transaction mode is used, in which case another connection is required. For further information about transactions, see Database connections for coordinated message flows.

Normally, the integration node makes the connections when it needs to use them in the message flow. However, in the case of connections to ESQL-based data sources, you can make the initial connection before a flow receives a message, and so remove any connection latency from the message processing. Set this option by selecting **`Connect before flow starts`** property on the data source node.

If the message flow contains a DatabaseInput node, at least one database connection remains open while the message flow is running.

On Linux, UNIX, and Windows systems, database connections are released under the following circumstances:

Database connections that have been started with the **`Connect before flow starts`** option selected are not released when the message flow becomes idle. These types of connections are only released in the following circumstances:

- An error occurs, while accessing the database, that requires a new connection to be made.
- The message flow is stopped.

- The integration node is stopped.

All other database connections remain open until one of the following events occurs:

- An error occurs, while accessing the database, that requires a new connection to be made.
- The message flow has been idle for 1 minute.
- The message flow is stopped.
- The integration node is stopped.

z/OS On z/OS, database connections are released if the database has not been accessed for 1 minute.

To change the default time of 1 minute after which a database connection for an idle message flow is released, use the following command:

```
mqsichangeproperties integration_node -e integration_server -o ComIbmDatabaseConnectionManager -
n maxConnectionAge -v newValue
```

or the following command, to change the default time for all integration servers:

```
mqsichangeproperties integration_node -o ComIbmDatabaseConnectionManager -n maxConnectionAge -
v newValue
```

where *maxConnectionAge* is specified in seconds. If *maxConnectionAge* is set to option -1, database connections are never released until the integration server or integration node is stopped.

If you are using DB2 for your database, the default action is to limit the number of concurrent connections to a database to the value of the **maxappls** configuration parameter. The default for **maxappls** is 40. If you believe that the connections that the integration node might require exceeds the value for **maxappls**, increase this parameter and the associated **maxagents** parameter to new values based on your calculations.

For z/OS, the number of connections does not change when you use ODBC CAF (Call Attachment Facility) connections or RRSAF (Recoverable Resource Services Attachment Facility).

Use the **maxConnectionUseCount** configuration parameter to release an ODBC connection to the database after a specified number of transactions on a thread is reached. To activate this function, set **maxConnectionUseCount** to a value that is greater than zero.

maxConnectionUseCount is monitored on a per thread basis. For example, if you have additional instances of a message flow, meaning that you have multiple threads running in parallel, the connection to the database is released only on those threads that reach the value specified in **maxConnectionUseCount**.

For an integration server that is managed by an integration node, you can set the value of **maxConnectionUseCount** by using the **mqsichangeproperties** command. For example, to reset the ODBC connection after every 100 transactions, including commit and rollback processes, for each datasource connection on a thread, issue the following command:

```
mqsichangeproperties integration_node -e integration_server -o ComIbmDatabaseConnectionManager -
n maxConnectionUseCount -v 100
```

Restart the integration server for the update to take effect.

Use the **mqsireportproperties** command to discover the current number of completed transactions on each datasource connection. This value is reported in the **transactionCount** field. For example:

```
mqsireportproperties integration_node -e integration_server -o ComIbmDatabaseConnectionManager -
r

ComIbmDatabaseConnectionManager
  name='DatabaseConnectionManager'
  identifier='ComIbmDatabaseConnectionManager'
  type='resourceManager'
  enableODBCTraceBridge='true'
```

```
  expireXAConnections='false'
  maxConnectionAge='60'
  maxConnectionUseCount='100'
  maxStatementAge='600'
  statementCacheSize='40'
  useDefaultSchemaForStoredProcedures='true'
  active
    activityLogUri='/apiv2/servers/default/resource-managers/activity-log-manager?
log_type=RM&resource_manager=ODBC'
    expireXAConnections='false'
    maxConnectionAge='60'
    serverRestartRequired='false'
    detailed
      databaseContexts
        databaseContext
          threadNumber='27546'
          ODBC_Version_3
            envHandle='139789946390048'
            dataSources
              dataSource
                connectionAge='34'
                coordinated='false'
                name='TESTDB'
                state='2'
                timeoutEnabled='true'
                transactionCount='2'
                managedStatements
                  managedStatement
                    createTime='2020-08-11 04:50:15.285704 (1599799815)'
                    executeCount='2'
                    lastExecuteTime='2020-08-11 04:50:40.404019 (1599799840)'
                    text='INSERT INTO TEST VALUES (?)'
                statements
```

For an independent integration server, you can update the value of **maxConnectionUseCount** in the **ResourceManagers** section of the `server.conf.yaml` file. For example:

```
ResourceManagers:
  DatabaseConnectionManager:
     maxConnectionUseCount: '100'
```

Restart the integration server for the update to take effect.

When the release function that is activated when **maxConnectionUseCount** is set to a value greater than zero, connection release is prompted when whichever of the values in **maxConnectionAge** or **maxConnectionUseCount** is reached first. To serve as an example, consider a scenario where **maxConnectionUseCount** is set to 100, and **maxConnectionAge** is set to 60. In such a scenario:

- If 100 transactions are processed within 30 seconds of the creation of an ODBC connection, the ODBC connection is released immediately after the number of transactions reaches 100. A new ODBC connection will be established on the next message.
- If 10, say, transactions are processed within 30 seconds of the creation of an ODBC connection, and for next 60 seconds, or more, no messages are processed on this ODBC connection, the value specified in **maxConnectionAge** is reached and the connection is released.
- If 10, say, transactions are processed every 30 seconds, and the connection is never idle for more than 60 seconds, the ODBC connection is released after the total transaction count reaches 100, which, in this example, is after 300 seconds.

Note: The **connectionAge** field that is returned as part of the output from the **mqsireportproperties** command is not a configurable property; it is a runtime metric that indicates the age of the connection. There is no relationship between **connectionAge** and **maxConnectionAge**. The value in **connectionAge** can exceed the value in **maxConnectionAge** as seen in the example scenario description above where **connectionAge** would be 300 and **maxConnectionAge** is 60.

If you are using another database, check the database documentation for information about connections and the limits or restrictions that might apply.

When a message flow is idle, the integration server periodically releases database connections that have not been started with the **Connect before flow starts** option. Therefore, connections held by the integration node reflect its current use of these resources. This situation allows the integration node

to respond when a database quiesces, if the database manager supports quiescing. Not all databases support the quiesce function, and not all databases quiesce in the same way. Check your database documentation for information about database quiescing.

Accessing databases from message flows

Create and configure message flows to access databases.

Before you begin

Complete the following tasks:

- "Creating a message flow" on page 574
- "Working with databases" on page 1130

Read the following concept topic:

- "Message flow nodes" on page 484

Check which databases are supported on which platform, and if any restrictions apply:

- IBM App Connect Enterprise system requirements

About this task

You can access a database from a message flow in two ways:

- You can design a message flow that responds to events generated by the database.
- After a flow has already started, you can access the database to read or update information in it. Information from the database can be used to enhance or influence the operation of the message flow.

You can access a database from a message flow by using the following nodes:

- Compute
- Database
- DatabaseInput
- DatabaseRetrieve
- DatabaseRoute
- Filter
- JavaCompute
- Mapping

For more details about these nodes, and how to configure them in message flows, see Built-in nodes.

To access a database from a message flow:

Procedure

1. Identify the database that you want to access.
2. Define a connection to the data source name (DSN) to enable a connection to the database, if one does not exist:
   - Define a JDBC connection if you want to interact with a database directly from a Java application, or from a Mapping node. You can code Java in both a JavaCompute node and in a Java user-defined node.
   - Define an ODBC connection if you want to interact with a database in a node that supports ESQL, including a JavaCompute node in which you use the `MbSQLStatement` interface.

3. Authorize the integration node to access the database.

   Access to a database from within a message flow is controlled by user ID and password.

   - Linux UNIX Use the **mqsisetdbparms** command to specify a user ID and password for a specific database, or to set up a default user ID and password.
   - Windows Use the **mqsisetdbparms** command to specify a user ID and password for a specific database, or to set up a default user ID and password. If Windows integrated authentication is being used for SQL Server database access, then the service user ID under which the broker process runs are used by Windows to access the SQL Server database. That is, it ignores any user ID and password credentials that were set using the **mqsisetdbparms** command.
   - To check existing accesses, use the **mqsireportdbparms** command.

Accessing databases from ESQL

Configure your integration server and your database to support connections from message flows.

Before you begin

- Run the **mqsicreateworkdir** command to create an integration server work directory.

About this task

You must configure your integration server and your databases to support read, write, and update operations in your message flows.

For details of the ESQL statements and functions that you can use to access databases, see "Interaction with databases using ESQL" on page 1666.

Procedure

- Set the `Data Source` property of each message flow node to the name (that is, the ODBC DSN) of the database that you want to access.

You can access more than one database by using the `FROM` clause in your ESQL statement, but all databases that are accessed from the same message flow node must have the same ODBC functions as the database that is specified on the `Data Source` property on that node. This requirement is always satisfied if the databases are of the same type (for example, DB2 or Oracle), at the same release level (for example, release 9.1), and on the same platform. Other database combinations might have the same ODBC functions. If a message flow node tries to access a database that does not have the same ODBC functions as the database specified on the `Data Source` property on that message flow node, the integration node generates an error message.

- Configure the integration server to be able to connect to the database:
  a) Create ODBC data source connections on the system on which the integration server is running.
  b) Define a user ID and password to be used by the integration server to connect to the database by using any of the following options:
     - To set a user ID and password for a particular database, use the **mqsisetdbparms** command.
     - To define default values for user ID and password for the integration server to use for all data source names for which you have not set specific values, use the **mqsisetdbparms** command to specify `dsn::DSN`.
     - Windows On Windows, if Windows integrated authentication is being used for SQL Server database access, then the service user ID under which the broker process runs is used by

Windows to access the SQL Server database. That is, it ignores any user ID and password credentials that were set using the **mqsisetdbparms** command

  - If you have not set up a default user ID and password:
    - On Windows, the service user ID and password are used to connect to the database.
    - On other platforms, connection to the database fails.
  - If you have set a specific user ID and password and want to check what the values are, use the **mqsireportdbparms** command.
- Set up the authorization for the user ID to access the database by using the administration facilities that are provided by the database vendor.

  If you do not do so, the integration server generates an error when the message flow runs.

What to do next

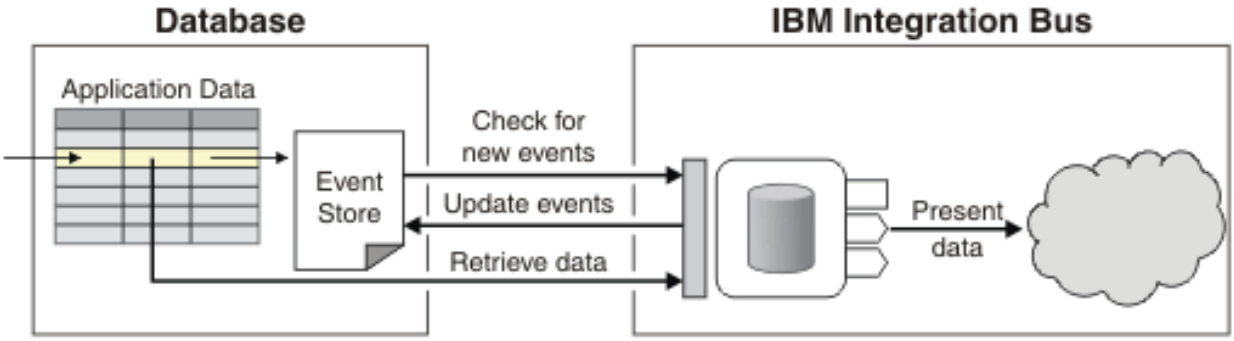
Note: With a single `SELECT FROM` clause, you can access only tables that exist in a single database.

If you access database columns that have names that are composed of only numeric characters, you must enclose the names in double quotation marks; for example, "0001". Because of this restriction, you cannot use a `SELECT *` statement, which returns the names without quotation marks; the names are therefore invalid and the integration server raises an exception.

Event-based database integration

Use a DatabaseInput node to respond to events in a database. For example, the integration node can keep an external system synchronized with a database by sending updates to the target system whenever data is changed in the database.

The database must record the fact that data has changed in an *event store*, which is typically a database table. The event store is not the same as the application data. The following diagram shows the interaction between the database, event store, and the integration node.



1. A database application changes a database table.
2. The database management system (DBMS) records the change in the event store.
3. The integration node polls the event store after the interval specified in the `Polling interval` configuration setting.
4. IBM App Connect Enterprise retrieves the new or changed data, and updates the event store, so that the data is processed only once.
5. IBM App Connect Enterprise processes the data, and ultimately presents it to the target application, for example SAP, web services, or CICS Transaction Server for z/OS. The data can be presented in a different logical and physical format, if required.

Implementing

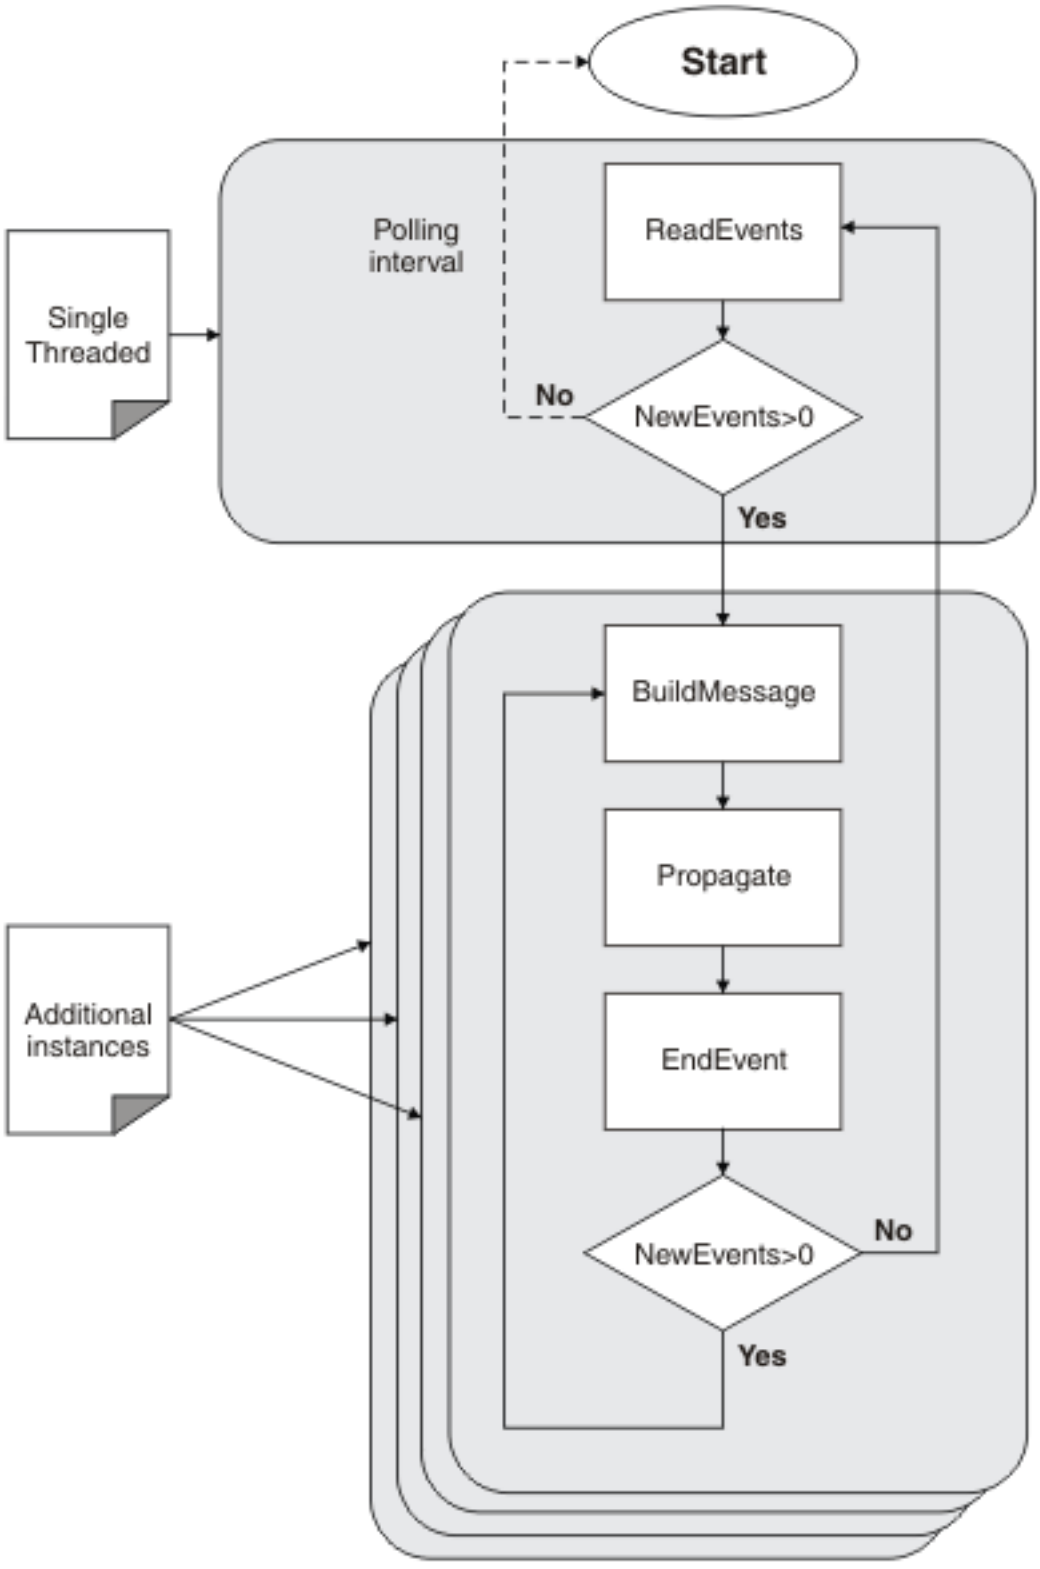
Implementing this scenario involves the following steps:

1. Configuring the database to record events.

2. Determining the format in which the target system must receive the data from these new events.
3. Configuring the integration node to detect these events by using the DatabaseInput node. To configure the DatabaseInput node, see “Configuring a DatabaseInput node” on page 1140.
4. Configuring the rest of the message flow to present the data to your target system in the correct format.

The DatabaseInput node

The following diagram shows how the DatabaseInput node works.



When the process starts, ReadEvents checks the event store for new events, which are then used by BuildMessage to build the message. This message is propagated to the message flow and then EndEvent updates the event store to ensure that the event cannot be processed again. When all events have been processed, the integration node calls ReadEvents to retrieve any events that have been added since the previous check. If the event store is empty, the integration node waits until the polling interval has expired, and then calls ReadEvents again. To avoid contention, the check of the event store is single-threaded.

For each event that is read by ReadEvents, BuildMessage builds the message that is propagated to the message flow. Building the message typically uses the event data to look up data in the application table. The data from the application table is then used to construct the message. When BuildMessage ends, the message is automatically propagated to the message flow. When the message is propagated, the integration node starts any downstream nodes that are required to process the message.

After the message has been propagated to the message flow, EndEvent updates the event store to ensure that the event that has just been processed cannot be processed again.

The detailed operation of ReadEvents, BuildMessage, and EndEvent is controlled by ESQL code. The DatabaseInput node contains an ESQL module with sample code and comments, which you must modify to suit your requirements. ReadEvents populates a NewEvents structure with event data that is read from the event table. Each event data row that is generated has a `Key` and a `Usr` field name; `NewEvents.Event[].Key` and `NewEvents.Event[].Usr`. The `Key` field contains a unique key for an event, and is used to prevent duplicate event processing. The `Usr` field is typically a subtree that contains user-defined data that is associated with an event. For information about modifying the ESQL, see “Configuring a DatabaseInput node” on page 1140.

Transactions and Scaling

The processes that are completed by the DatabaseInput node are split across separate transactions. A new transaction is started when ReadEvents starts. When ReadEvents ends, this transaction is committed and new events are marked for processing. By committing this transaction, any locks put on the database by ESQL code that is run from ReadEvents are released. Then, for each event received by BuildMessage, a new transaction is started. This new transaction is committed after EndEvent finishes.

To scale a DatabaseInput node for many events, change the `Additional instances` property on the **Instances** tab from its default value of `0` to the number of instances that you require. If you are using additional instances, the database must be configured so that multiple applications can read different rows from the application table at the same time. ReadEvents always runs in single-threaded mode to avoid database contention, even if you use additional instances. To improve performance, ReadEvents can read multiple events each time it runs, and these events can be processed at the same time by multiple instances of BuildMessage. The event store must have a primary key, which ReadEvents uses to identify events that are currently being processed. You do not have to write the ESQL in ReadEvents to filter out events that are currently being processed by the message flow.

Failures and retry mechanism

- If an error occurs during ReadEvents, an error is logged to the system log. It will retry after the polling interval next expires. No message is propagated to the Failure terminal.
- If an error occurs during BuildMessage processing, the exception is propagated to the Failure terminal if attached. If exceptions are not handled on the failure terminal (that is, it is not wired or an exception is thrown from the failure terminal), then the transaction is rolled back. Otherwise, the transaction is committed. In either case, whether the exception is handled or not, the message is not propagated to the Out terminal and EndEvent is not invoked.
- If an exception is thrown downstream from the Out terminal, any exceptions not handled by the Catch terminal will cause the transaction to be rolled back and EndEvent is not invoked. If exceptions are handled on the Catch terminal, then the EndEvent is invoked and the transaction is committed.

Retry processing allows the application developer to cope with transient errors that occur in downstream nodes that have not been successfully handled by catch processing. The input node can be configured with one of three retry mechanisms:

1. `Failure`
2. `Short retry then failure`
3. `Short then long retry`

If '`Failure`' is selected, the event is moved to the '`Failed`' state and the transaction is rolled back. Failed events are detected and dealt with before dispatching any Ready events. The failed event is propagated to the Failure terminal, if wired, with an exception list.

For 'Short retry then failure', the message flow performs a number of retries equal to the **Retry Threshold** property, propagating the message down the Out terminal with an interval between each retry equal to the 'Short retry interval'. If the retry threshold is met without successful completion of the transaction, the message is then propagated to the Failure terminal.

For 'Short then long retry', the retry logic is the same as 'short retry then failure' up to the point that the retry threshold has been met. Then, instead of ending the retry attempts and propagating to the failure terminal, it will continue to retry indefinitely but now with a delay between each retry equal to the 'Long retry interval'.

The EndEvent operation is not automatically invoked if the transaction has been rolled back, or if the message has been propagated to the failure terminal. In these circumstances it is up to the user to remove or update the event in the event store if they wish to prevent it from being re-processed.

The EndEvent operation is automatically invoked if the transaction completes successfully, including when an exception has occurred downstream of the Database Input node but that exception has been handled successfully down a Catch terminal.

Configuring a DatabaseInput node
Create and configure message flows that respond to events in a database.

Before you begin

Read the following topics:

- "Event-based database integration" on page 1136
- "Responding to database updates" on page 1142

Check which databases are supported on which platform, and if any restrictions apply:

- IBM App Connect Enterprise system requirements

Ensure that your database is configured to record events (uses an event table), and that you know how to query those events.

z/OS If you use DB2 on z/OS, your user ID (or your user group) requires permission to perform a SELECT on SYSIBM.SYSJAROBJECTS.

Complete the following tasks:

- Add a database definition to the IBM App Connect Enterprise Toolkit.

About this task

When you drag a DatabaseInput node onto the canvas, IBM App Connect Enterprise creates an ESQL module that contains boilerplate text. To configure the DatabaseInput node, modify the statements in that module to suit your requirements.

When you double-click the node to modify the ESQL code, the editor displays the **Database Event Design** tab for the module. Complete the mandatory fields and then click **Generate query**. To view or modify the code, click the **Source** tab. Code that has been generated is clearly marked by color-coded `--@!{` and `--@!}` comments. Any changes that you make within these comments are lost if you regenerate the code.

Procedure

1. In the IBM App Connect Enterprise Toolkit, drag a DatabaseInput node onto the canvas, and double-click the node.

   The **Database Event Design** tab is displayed. Ensure that the correct module is selected.

2. Complete the **Event Table** section.
   a) Optional: Complete the `Database schema` property.
      Leave it blank to use the default runtime schema.
   b) Complete the `Table` property.
      This property represents the database table used as your event store.
   c) Complete the `Primary key` property.
      This property represents the primary key of the database table used as the event store.
   d) Complete the `Foreign key to application table` property.
      This property represents the column in the event table that references the row in the application table containing the changed data to be processed by the DatabaseInput node. This is typically the primary key of the application table.
   e) Optional: Complete the `Status column` property.
      This property represents the name of a column, if you update a column in the event table to indicate that the event has been processed. Leave blank if you delete events from the event table after processing.
   f) Optional: Complete the `New event status value` property.
      This property represents the value written to the status column when the event is first added. Enclose character values in single quotation marks, for example 'Y'. Enter numbers without quotation marks. For a null value, enter NULL. Check the trigger setting in your database for appropriate values.
   g) Optional: Complete the `Processed event status value` property.
      This property represents the value written to the status column after the event has been processed. Enclose character values in single quotation marks, for example 'Y'. Enter numbers without quotation marks. For a null value, enter NULL. Check the trigger setting in your database for appropriate values.
3. Complete the **Application Table** section.
   a) Complete the `Table` property.
      This property represents the table that includes the changed data to be processed by the DatabaseInput node.
   b) Complete the `Primary key` property.
      This property represents the primary key of the database table used as the application table.
   c) Complete the `Output message element` property.
      This property represents the output message that will be propagated to the flow.
4. Click **Generate query**.
5. Optional: Click the **Source** tab to view the code, or add customized code.
6. On the **Basic** tab of the DatabaseInput node, specify the data source. This data source is the ODBC data source name of the database that contains the tables that you refer to in the ESQL module.
7. On the **Basic** tab, ensure that the `ESQL module` property refers to the correct module.
8. Optionally, change values on the other tabs of the node.
9. Configure the rest of the flow to use the message from this node.

What to do next

Configure your target system to receive the message.

Changing the default color of auto-generated text

Procedure

1. Click **Window** > **Preferences**.

2. In the tree on the left, navigate to **Integration Development** > **ESQL** > **ESQL Editor**.
3. On the **Colors** tab, select **Auto-generated**, and select the color.

Responding to database updates
Implement a message flow that responds to database updates, and presents the data to another application.

Before you begin

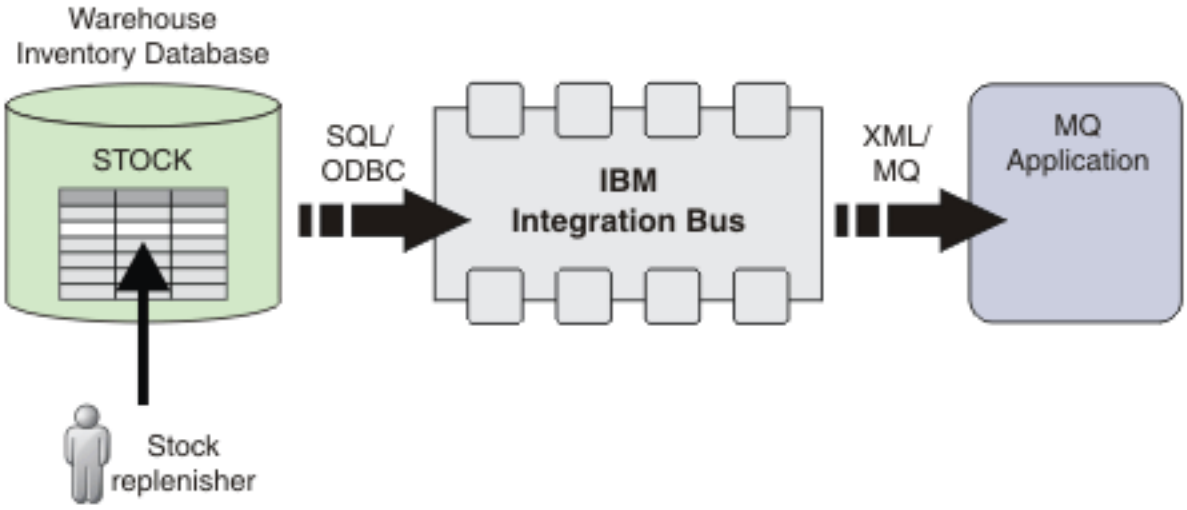
- Create an event table (a database table that serves as a transient store for event data).
- Create a trigger on the application data table. The trigger inserts a row into the event store whenever the application data is changed.
- Configure the IBM App Connect Enterprise runtime component to connect to the database.

z/OS If you use DB2 on z/OS, your user ID (or your user group) requires permission to perform a SELECT on SYSIBM.SYSJAROBJECTS.

You do not need experience of ESQL to complete this task.

About this task

Scenario: A retail company uses a relational database to manage its stock inventory. Since a recent acquisition, a new set of applications based on XML and IBM MQ are added to the environment. The applications notify interested parties of any changes to the stock levels. The applications have a predefined XSD schema model that describes the input message.



IBM App Connect Enterprise is used to respond to database updates, and to notify the IBM MQ application of these changes.

1. A DatabaseInput node retrieves the data.
2. A transformation node, such as a Compute node or a Mapping node, transforms the data to the target format.
3. An output or request node, such as an MQOutput node, sends the transformed message to the target system.

You will complete the following actions:

1. “Discover the database model” on page 1143
2. “Create a new message model for the database input” on page 1143
3. “Create the message flow” on page 1143
4. “Test the flow” on page 1144

Discover the database model
Create a `.dbm` file that you will use to create the message model. You create a data design project, and use a wizard to give IBM App Connect Enterprise details of your database event store and data table.

Procedure

1. Click **File** > **New** > **DataBase Definition**.
2. Click **New** to create a new data design project, or select an existing data design project from the drop down list.
3. Select the appropriate database type and version, and then click **Next**.
4. Select an existing JDBC connection, or create a connection to your database. If you create a connection, test the connection.
5. Select the database schema that you will use to create the message definition.
6. Select the database elements that you need for the model. You require `Tables` and `Triggers`.

   The data model is created, and you can see details of the database tables that are described in the chosen schema.

Create a new message model for the database input
Create a new message schema model file from the discovered data definition if you require a model of the data structure that the database input will present. You need a model if you want to graphically map this input. The model also enables content assistance auto-completion of paths in the ESQL editor if you are transforming the data in ESQL.

Procedure

1. Click **File** > **New** > **Message model**
2. In the **Other** section, select `Database record`, and then click **Next**.
3. Select `Create an XML schema file from a database definition`, and then click **Next**.
4. Navigate to and select the Database definition `.dbm` file that you created during discovery, and then click **Next**.
5. Ensure that the database tables that will be used are selected.
6. Click **Next** and then **Finish**.

Results

The New Message model wizard creates an XML schema message model file in your selected location.

Create the message flow
Create and configure a flow that consists of a DatabaseInput node, a Mapping node, and an MQOutput node. You will use the schema file that describes the input message to create a message definition file.

Procedure

1. Create an integration project that references both the data design project, and the message set project, that you created earlier.
2. Create a message flow, and drag a DatabaseInput node onto the canvas.
3. Configure the node as follows:
   a) Set the **`Data source`** to the ODBC connection that you created earlier.
   b) Follow the instructions in "Configuring a DatabaseInput node" on page 1140 to configure the ESQL procedures to provide details of the event store and application data.
4. To enable graphical mapping from the database data to the output message format, in addition to Creating the new message model for the database input as above, you also require a message model for the target message. This can be a DFDL or XML schema message model as appropriate to your scenario.

5. Drag a Mapping node onto the flow, and configure it.
   a) Set the map source to the message that you defined in "Create a new message model for the database input" on page 1143.
   b) Set the map target to the TARGET message that you just defined.

   You can use other methods to transform the message; see "Transforming and enriching messages" on page 1249.
6. Drag an MQOutput node onto the canvas, and set the queue manager name and queue name.

Test the flow
Use the debugger to test the flow.

Procedure

1. Start the debugger, and then add breakpoints to the flow.
2. Deploy the flow.
3. Change the data source, for example by adding a new row.

   You can change data from within the IBM App Connect Enterprise Toolkit. Under **Data Source Explorer**, right-click the table and choose **Data** > **Edit**.
4. Use the debugger to check that the flow is working correctly.

Event tables
An event table stores information about changes to application tables.

The event table is a database table created by the user, generally within the same schema as the application table for which it stores events. The event table describes the type of change made to an application table, and also contains an identifier for the changed row.

To populate an event table, one or more *triggers* must be created. A trigger is a database construct that can run an SQL script when a predefined action occurs. For example, a trigger can insert a row in the event table when an update in the application table occurs.

The following table shows some typical columns in an event table, and the reasons for including them.

Column name	Column function	Example value
EVENT_ID	Required. The primary key, which identifies the event being processed.	`1`
OBJECT_KEY	Required. The identifying element of the changed row in the application table, typically the element of the row in the primary key column.	`cust1`
OBJECT_VERB	Optional. The change performed, typically one of CREATE, UPDATE, or DELETE. This event is used to distinguish a DELETE event, where the application table contains no row to retrieve when the message for the flow is built.	`CREATE`
OBJECT_NAME	Optional. The name of the application table that has changed. This column is required if the DatabaseInput node is being used to support updates to more than one application table.	`customer`
EVENT_PRIORITY	Optional. The priority of the event. For example, you can ensure that high value transactions are computed first.	`1`
EVENT_TIME	Optional. The time at which the operation was performed. Generally used for logging or performance monitoring of the flow.	`2010-10-19T17:10:00`

Column name	Column function	Example value
EVENT_STATUS	Optional. Used to determine if the event has already been processed. Required if the events are not to be deleted or archived after processing.	`0`
EVENT_COMMENT	Optional. Free-form field, for example, it can be used to store the outcome of the message processing if the event was not deleted after processing.	`Processed with exceptions`

The column names are examples only. You can use other names. If you have a high-throughput application table, a single row might be changed multiple times between retrieving events from the event table. In this case, only the details of the latest change are picked up by the flow. If a record of intermediate changes is required, include more details in the event table. Also ensure that your event table has enough information about events generated by DELETE operations. Here, because the row in the application table no longer exists, all information required to successfully process the event must be present in the event table.

For example, if a new customer with primary key `cust1` is created in the application table, a row is added to the event table:

EVENT_ID	OBJECT_KEY	OBJECT_VERB
1	cust1	Create

The DatabaseInput node responds to the change, and processes the new row in a message flow.

Processing options on completion

When the message flow has processed an event, the flow can handle the event in the following ways:

- Delete the event. Use this option if you do not want to store the event for future reference.
- Update the status column. Use this option if you want to keep a record of processed events. Your event table must have a status column.
- Archive the event to a separate event table. Use this option if you want to keep a record of events while keeping the event table to a minimal size.

Working with IMS

You can use the IMSRequest node to connect to IMS, a message-based transaction manager and hierarchical-database manager for z/OS.

About this task

This section contains the following concept information:

- "IBM Information Management System (IMS)" on page 1146
- "IMS nodes" on page 1147
- "IMS transactions and programs" on page 1148
- "Response models" on page 1149
- "IMS message structure" on page 1150
- "IMS connections" on page 1151

This section contains the following tasks:

- "Preparing the environment for IMS nodes" on page 215
- "Propagating security credentials to IMS" on page 1152

IBM Information Management System (IMS)

IMS is a message-based transaction manager and hierarchical-database manager for z/OS. External applications can use transactions to interact with applications that run inside IMS.

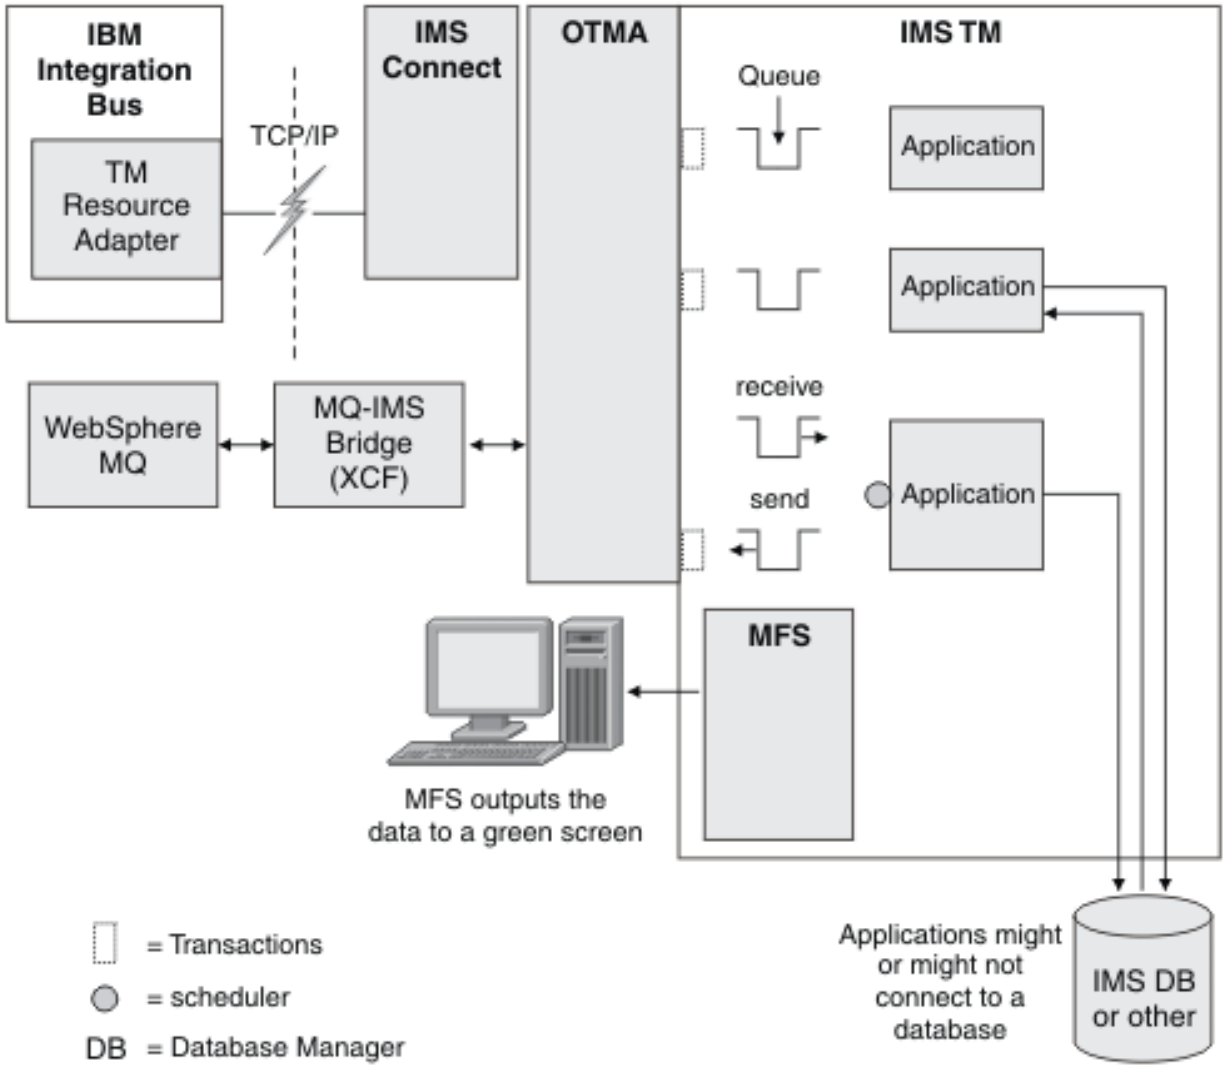
IMS includes two components:

IMS Database Manager (IMS DB)
A database management system for defining database structure, organizing business data, performing queries against the data, and performing database transactions.

IMS Transaction Manager (IMS TM)
A message-based transaction manager for processing input and output messages. IMS TM manages message queuing, security, scheduling, formatting, logging, and recovery.

In addition to these components, IMS Connect manages communications for IMS, connecting one or more clients with one or more IMS systems. IMS Connect also handles workload balancing, and supports the IBM supplied client, the IMS TM resource adapter.

The following diagram shows the layers of communication between IBM App Connect Enterprise and IMS.



You can also use the following methods to connect to an IMS system:

- **The IBM MQ-IMS bridge**

  The WebSphere MQ-IMS bridge is a component of IBM MQ for z/OS. You can use it to access applications on your IMS system from IBM MQ applications. For more information about the IBM MQ-IMS bridge, see IBM MQ product documentation online.

- **The IMS SOAP Gateway**

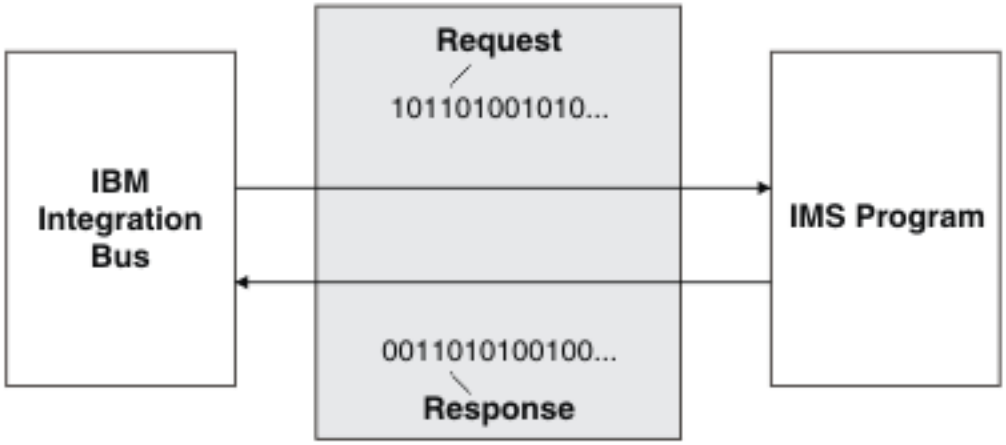
  The IMS SOAP Gateway is a web service solution that integrates IMS assets in a Service-Oriented Architecture (SOA) environment. For more information, see IMS SOAP Gateway web page.

For more details about how IMS works with IBM App Connect Enterprise, see “IMS nodes” on page 1147.

For further information about IMS and its components, see the IBM Information Management Software Library web page, which contains links to the IMS information center and associated IBM Redbooks® publications.

IMS nodes
IBM App Connect Enterprise message flows use IMS nodes to call programs that are running in IMS.

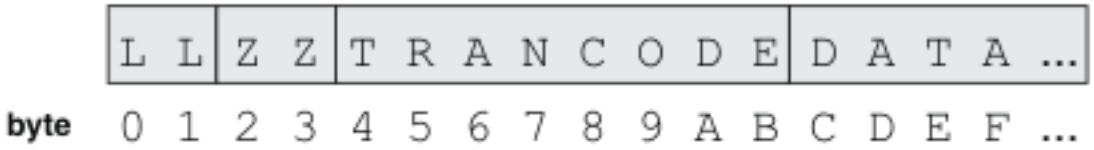
The IMS node sends a bit stream to IMS, which schedules one of its programs to process the message. The program generates a message, which IMS sends back to the IMS node, as illustrated in the following diagram.



The bit stream contains the routing information that IMS needs so that it can schedule a program to receive that bit stream. The structure of the bit stream varies depending on whether it is a request or response bit stream. The structure of the different bit streams are described in the following sections.

Request bit stream

The structure of the request bit stream is illustrated by the following diagram.

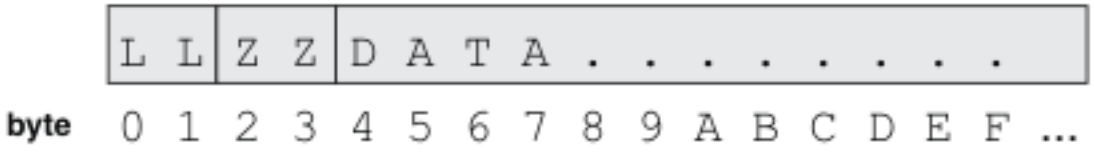


- *LLZZ* is a four-byte field. The first two bytes indicate the length of the bit stream, and the other two bytes are reserved for use by IMS.
- The transaction code can contain up to eight characters. If the code contains less than eight characters, the transaction code must be delimited by a space. When the transaction code is less than eight bytes, IMS reads only the transaction code and one space. The response segments do not need to have the transaction name, but an IMS program can add it.
- The rest of the bit stream comprises the data that the IMS program needs.

IMS reads the first twelve bytes of the bit stream, but it passes the entire bit stream to the IMS program.

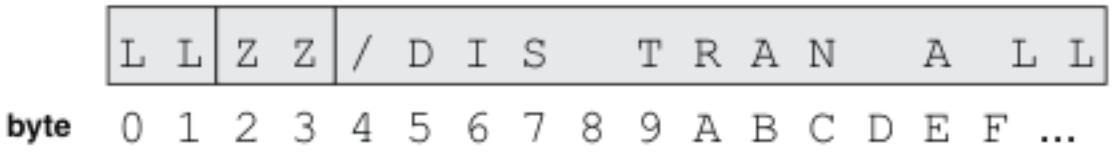
Response bit stream

The structure of the response bit stream is illustrated by the following diagram.



Commands

You can also use bit streams to run commands. The structure of the response bit stream is illustrated by the following diagram.

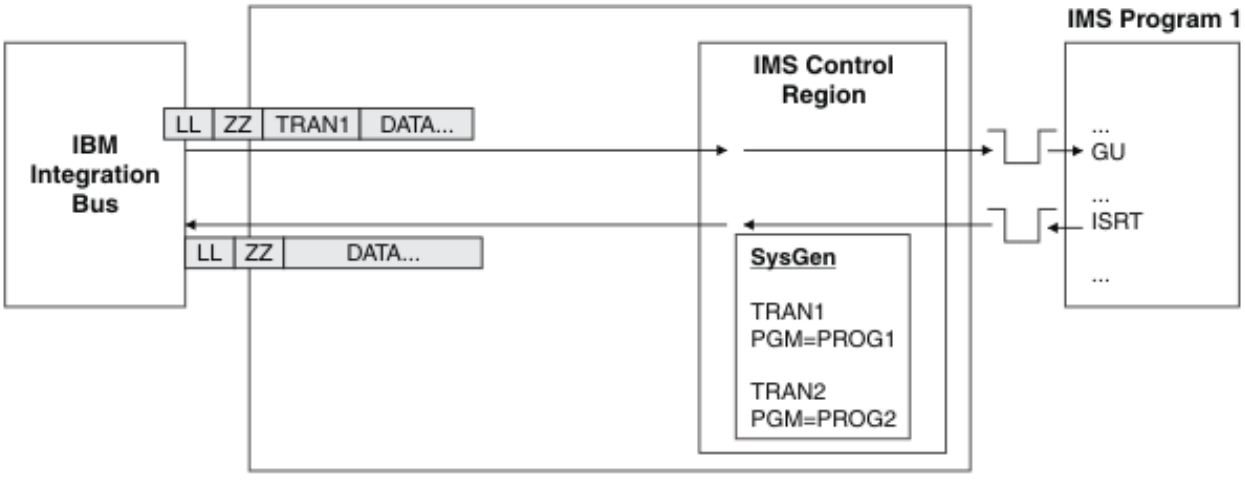


The first character after LLZZ is the slash (/) character, which is followed by the command verb and any arguments. For commands, the response bit stream has the same format as the response bit stream for transactions: LLZZ is followed by the response data.

For more information about IMS concepts, see the following topics:

- "IMS transactions and programs" on page 1148
- "Response models" on page 1149
- "IMS message structure" on page 1150
- "IMS connections" on page 1151

IMS transactions and programs
The IMS system administrator defines the transactions. For each transaction that is defined, a program name is specified. When you invoke a transaction by using an IMS node, the IMS Control Region determines which program is configured for that transaction, and queues the data for retrieval by that program.



After the program has prepared the response data for the IMS node in the message flow, it inserts that data onto another queue. This output queue is tied to the socket to which IBM App Connect Enterprise is connected. Therefore, multiple concurrent message flows that are calling the same transaction each have a separate queue to receive the responses.

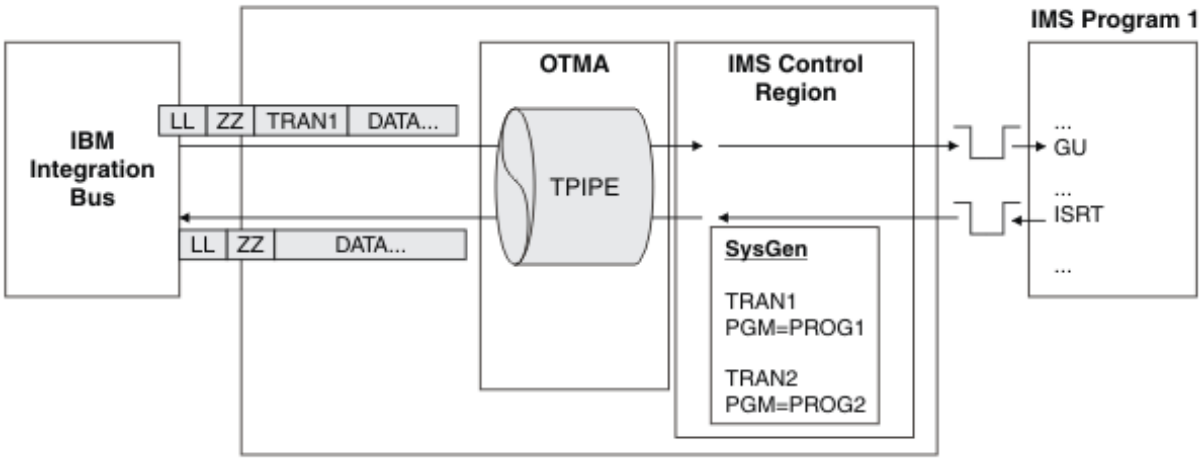
The IMS program gets messages by issuing a GU (GetUnique) call and it produces messages by issuing an ISRT (Insert) call. These calls are known as *DL/1 calls*. DL/1 is the programming interface to IMS. Other common DL/1 calls are PURG (purge) and GN (GetNext).

Response models
The synchronous request and response model is associated with IMS.

Synchronous request and response

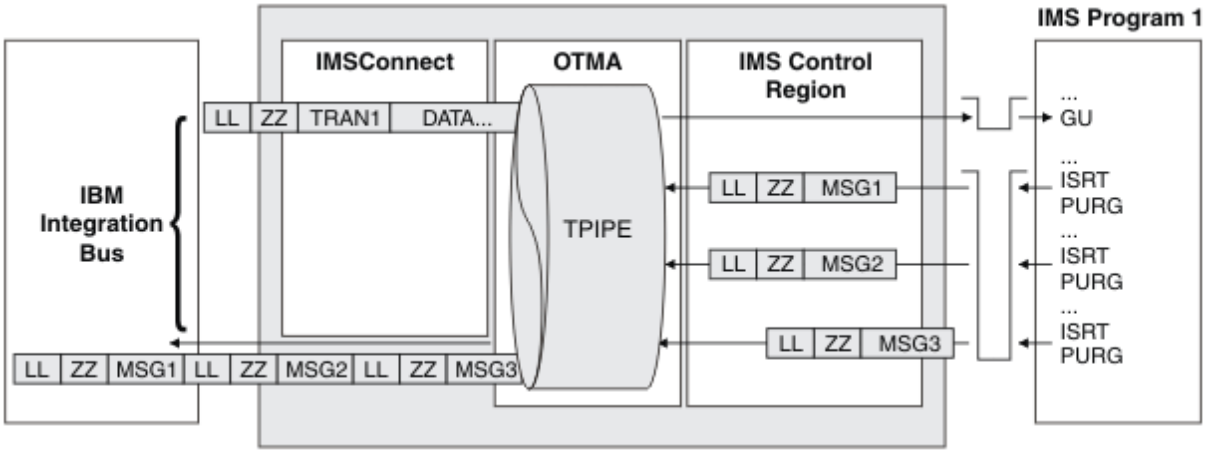
In the synchronous request and response model, the entire transmission is returned to the IMS node synchronously.

After the IMS program has prepared the response data for the IBM App Connect Enterprise message flow, it inserts that data onto a queue. IBM App Connect Enterprise uses Open Transaction Manager Access (OTMA) to communicate with the IMS program. OTMA helps to correlate the input to the IMS program with the output from the IMS program by using a transaction pipe (TPIPE). Therefore, multiple concurrent message flows that are calling the same transaction each receive the relevant response.



The TPIPE is created automatically. It is not necessary for the name of the TPIPE to be known to IBM App Connect Enterprise because it uses a mode of operation known as *sharable persistent sockets*, whereby a TPIPE is created automatically for every TCP/IP connection.

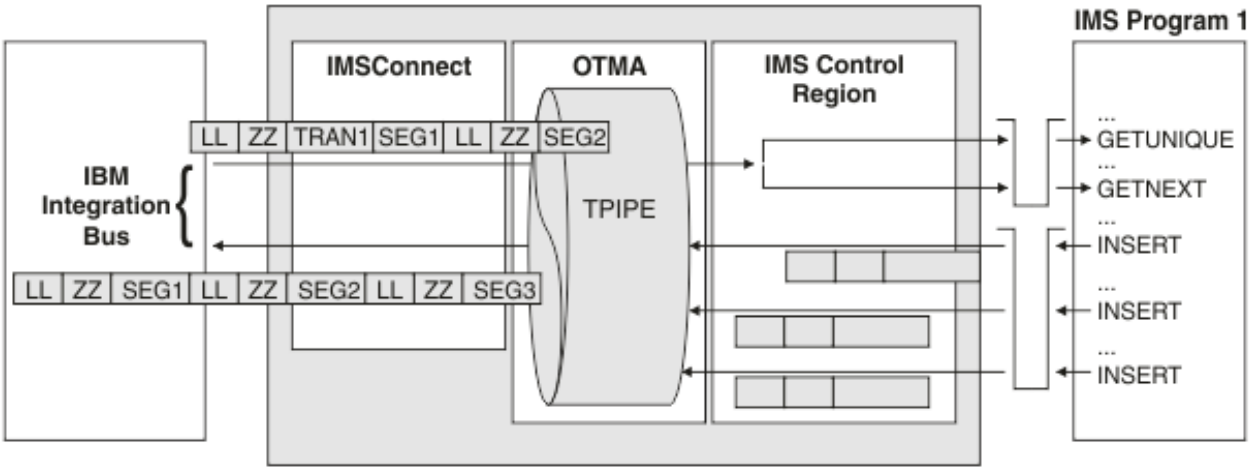
The output of a transaction can contain multiple messages. The IMS program inserts then purges each message, as shown in the following diagram. (For multi-segment output, the IMS program inserts multiple messages without purging them.) If the IMS program inserts multiple messages in a single sync point, OTMA correlates all of those messages to the input message and returns them all to the message flow as a single transmission.



IMS message structure
Each message that is sent to and from IMS can consist of one or more segments. IMS messages often contain multiple segments.

The bit stream that flows between IBM App Connect Enterprise and the IMS program (also known as the *transmission*) can contain multiple segments. Each segment begins with the LLZZ and Transaction code fields that are described in "IMS nodes" on page 1147. The transmission can contain multiple messages, each one containing multiple segments. The IMS program gets the segments one at a time and typically inserts the output data onto the queue one segment at a time. The IMS program purges the end of a message before it sends the first segment of the next message.

For input messages, each segment includes the LLZZ field. Only the first segment contains the transaction code (Trancode) field. For output messages, each segment includes the LLZZ field. The IMS program gets the segments one at a time. It makes a GetUnique (GU) call to read the first segment of the next message, and a GetNext (GN) call to read the next segment of the current message. The IMS program typically inserts the output data to the queue one segment at a time, and purges the end of a message before it sends the first segment of the next message, as shown in the following diagram.



A COBOL IMS program typically includes a copybook with the data structure definition of each segment. The program logic indicates the order in which the segments are retrieved and emitted by the program. The IBM App Connect Enterprise application has two ways to implement this information:

- Model the entire message in MRM.
- Model each segment in MRM but configure the message flow to reflect the application logic in determining the order of these segments.

An IMS transaction's response can have various structures:

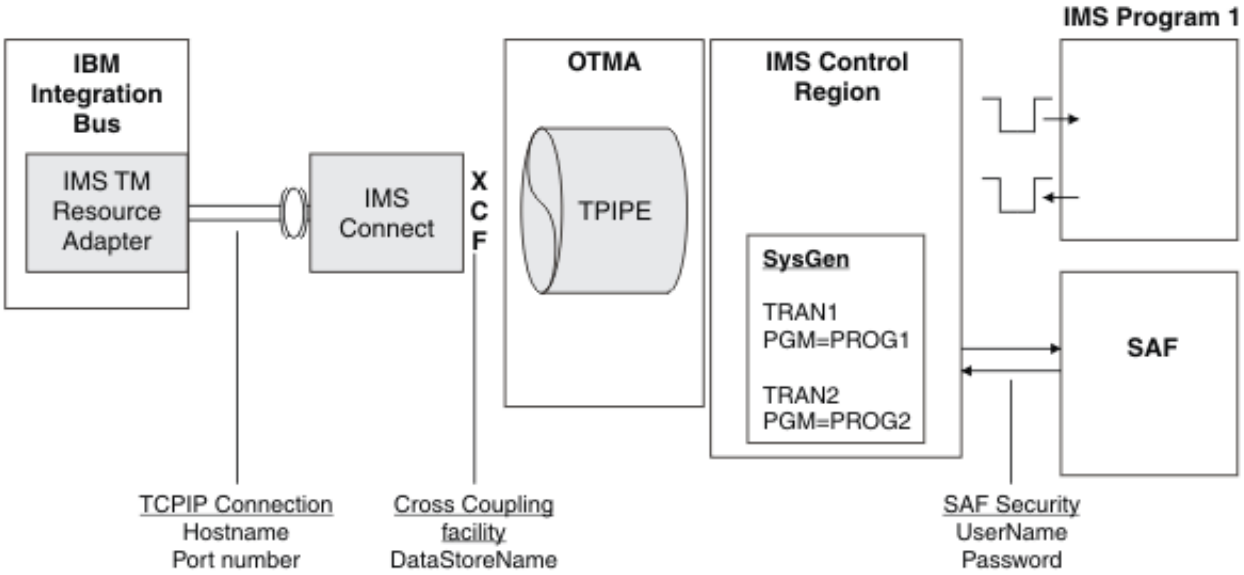
- An MRM-CWF structure, such as a message definition that is derived from a COBOL copybook
- An MRM-TDS structure when the output is 3270-based, such as a list of name=value strings
- Another structure, such as XML output from a Java program that is running in an IMS Java Processing Region (JPR)

If the message definition is derived from a COBOL copybook, a message is a sequence of segments, each of which has a model built by importing its copybook. If the output is 3270-based, each segment is a line of output with an MRM-TDS model built by understanding the IMS transaction program's output.

IMS presents program output as one or more messages (typically, one output message per input message), each of which comprises one or more segments. The IMSRequest node presents the message as a single BLOB. You can parse the message into segments and use Filter or Compute nodes to test the shape of the response to determine how to re-parse the segments with ResetContentDescriptor nodes.

You must set the LL and ZZ values on output. The LL value is the entire length of the segment, including the four-byte LLZZ prefix. Therefore, the message flow typically requires an ESQL expression to calculate the LL value. The LLZZ field must use a big-endian encoding 785.

IMS connections
Open Transaction Manager Access (OTMA) is used to provide access to IMS from IBM App Connect Enterprise.



OTMA uses the z/OS Cross Coupling Facility (XCF) to provide access to IMS from an OTMA client. To access a service through XCF, you must specify a data store name on the IMS node.

IMS Connect is an OTMA client that exposes a TCP/IP interface. IBM App Connect Enterprise uses the IMS TM Resource Adapter, which connects to IMS through IMS Connect. To connect to IMS Connect, you must specify a host name and port number. If the IMS system is configured to authenticate users by using a System Authorization Facility (SAF) product, such as RACF®, you must specify a user ID and password. . For detailed information about how to configure IMS Connect for security, see the *IMS Connect Security Support* topic in the IBM Information Management Software for z/OS Solutions product documentation online.

The IMSRequest node can use an identity that is present on an input message, and propagate it to IMS, by using the `Propagate` property on the security profile that is defined for the node. For more information, see "Propagating security credentials to IMS" on page 1152.

Some restrictions exist for the OTMA environment that affect the range of IMS applications with which IBM App Connect Enterprise can interact. For example, OTMA cannot update the IMS main storage database (MSDB) because it has read only access to the database. For detailed information about the restrictions for the OTMA environment, see the *OTMA restrictions* topic in the IBM Information Management Software for z/OS Solutions product documentation online.

Preparing the environment for IMS nodes

Before you can use the IMS nodes, you must set up the runtime environment so that you can access the IMS system.

Before you begin

Read "IBM Information Management System (IMS)" on page 1146.

About this task

Complete the following steps to ensure that IBM App Connect Enterprise can connect to the IMS system.

Procedure

1. Ensure that IMS Connect is installed and started on the IMS system.
2. Use the **mqsisetdbparms** command to set security details in the integration server store.

   For example, to associate a user ID and password pair with an IMS Connect connection, run the **mqsisetdbparms** command as shown:

```
mqsisetdbparms -w c:\workdir\ACEServ1 -n ims::mySecurityIdentity -u myuserid -p mypassword
```

Propagating security credentials to IMS

The IMSRequest node can use an identity that is present in the Properties folder of the message tree structure for the security credentials in a request, by using the `Propagate` property on the security profile that is defined for the node.

About this task

If an IMSRequest node is configured with a security profile, it extracts security tokens from the input message at run time, and propagates an identity to IMS.

Procedure

To propagate an identity to be used for the IMS request security credentials, complete the following steps.

1. Ensure that an appropriate security profile exists for the IMSRequest node, or create a security profile, by following the instructions in “Creating a security profile” on page 2584.
2. Use the BAR editor to select a security profile for the IMSRequest node that has identity propagation enabled.

   For detailed instructions, see “Configuring a message flow for identity propagation” on page 2613.

Working with CORBA

Use CORBA nodes to connect to CORBA Internet Inter-Orb Protocol (IIOP) applications.

About this task

This section contains the following concept information:

This section contains the following tasks:

Common Object Request Broker Architecture (CORBA)

The Common Object Request Broker Architecture (CORBA) is a standard defined by the Object Management Group (OMG) that enables software components written in multiple computer languages and running on multiple computers to work together.

CORBA is a standard for distributing objects across networks so that operations on those objects can be called remotely. CORBA is not associated with a particular programming language, and any language with a CORBA binding can be used to call and implement CORBA objects. Objects are described in a syntax called Interface Definition Language (IDL).

CORBA includes four components:

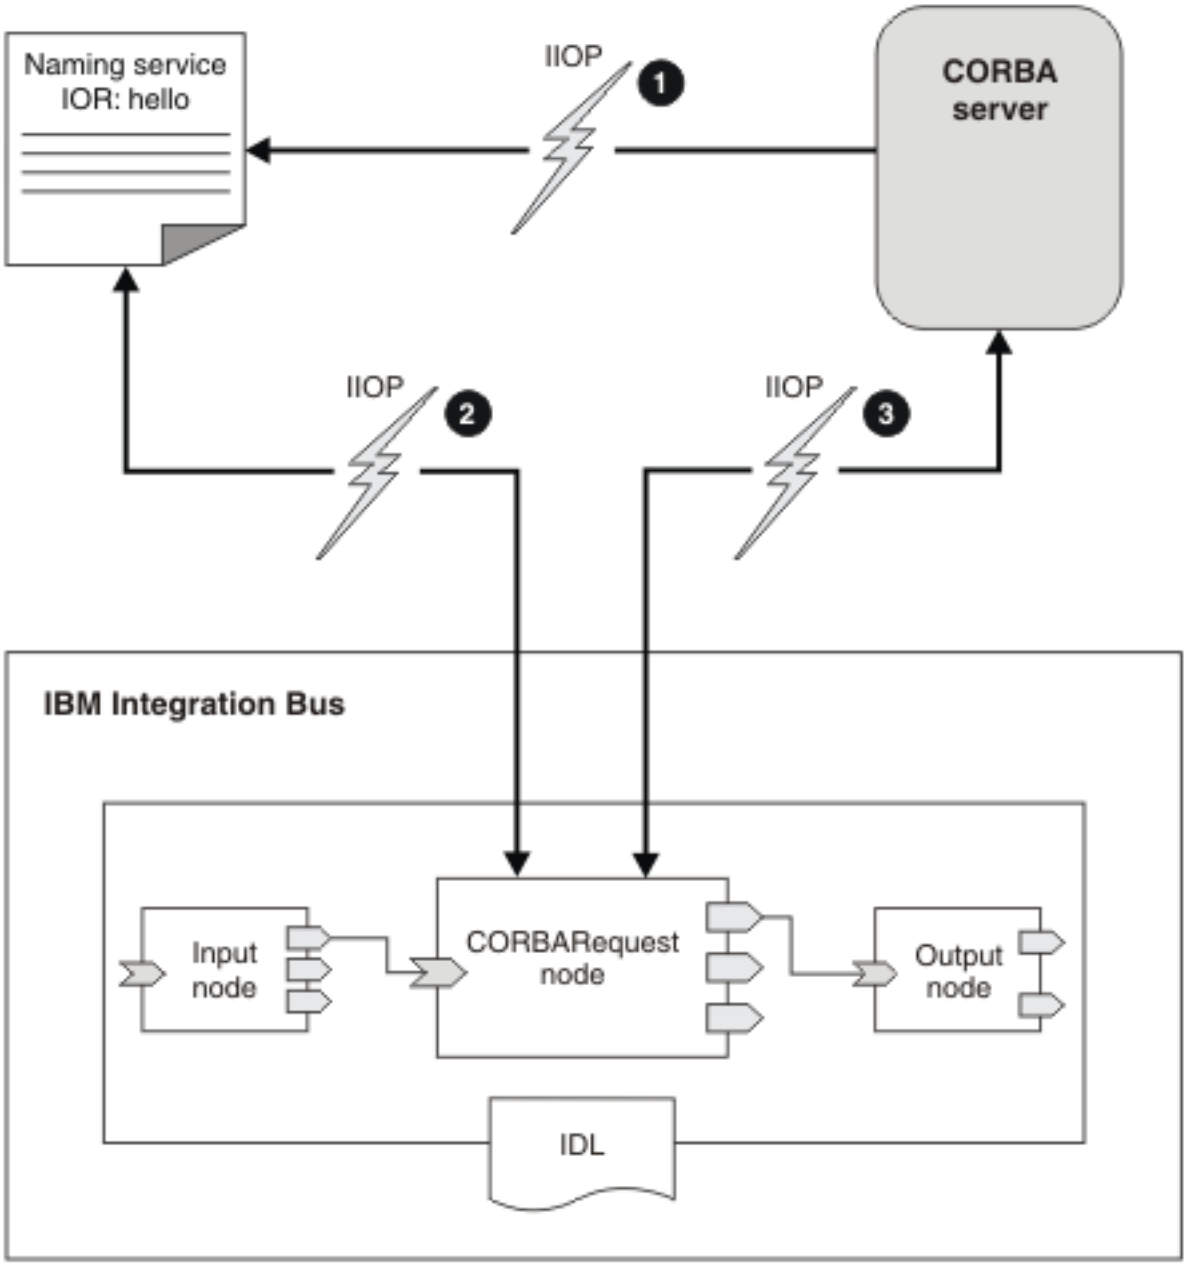
Object Request Integration node (ORB)
: The Object Request Integration node (ORB) handles the communication, marshaling, and unmarshaling of parameters so that the parameter handling is transparent for a CORBA server and client applications.

CORBA server
: The CORBA server creates CORBA objects and initializes them with an ORB. The server places references to the CORBA objects inside a naming service so that clients can access them.

Naming service
: The naming service holds references to CORBA objects.

CORBARequest node
: The CORBARequest node acts as a CORBA client.

The following diagram shows the layers of communication between IBM App Connect Enterprise and CORBA.



The diagram illustrates the following steps.

1. CORBA server applications create CORBA objects and put object references in a naming service so that clients can call them.
2. At deployment time, the node contacts a naming service to get an object reference.
3. When a message arrives, the node uses the object reference to call an operation on an object in the CORBA server.

For more details about how CORBA works with IBM App Connect Enterprise, see “CORBA nodes” on page 1154.

CORBA nodes

Use CORBA nodes to connect IBM App Connect Enterprise with CORBA Internet Inter-Orb Protocol (IIOP) applications.

CORBA is a standard for distributing objects across networks so that operations on those objects can be called remotely. CORBA objects are described in Interface Definition Language (IDL) files, and these IDL

files are used to configure the CORBA message flow nodes. The IDL file is stored in a message set project, in a folder called CORBA IDLs.

An IDL importer imports the IDL file into the message set project and creates the message definition file (`.mxsd`) in the message set. This message definition file is used for mid-flow validation, ESQL content assist, and the Mapping node.

For each IDL file, a single message definition is created. In the message definition, two messages are created for each operation in the IDL file: one message for the request, and one for the response. The request has a child element for each in and inout parameter; the response has a child element for each inout and out parameter, and a child element named "_return" for the return type of the operation.

The name of these elements is based on the interface name and operation name; for example, for the operation *sayHello* in the Interface *Hello*, the request element is called *Hello.sayHello*, and the response element is called *Hello.sayHelloResponse*. If the interface is contained in a module, the request and response element names are qualified with the names of the modules. For example, if the operation *sayHello* in the Interface *Hello* is contained in *ModuleB*, which in turn is contained in ModuleA, the response element would be called *ModuleA.ModuleB.Hello.sayHelloResponse*.

When you add a message flow that contains CORBA nodes to a BAR file, all the IDL files that are used by the nodes are added to the BAR file automatically.

The main scenario for connecting IBM App Connect Enterprise with CORBA applications is described in the following section.

IBM App Connect Enterprise calls a CORBA server

By using a message flow that includes a CORBARequest node, you can give existing CORBA applications a new external interface; for example, a SOAP interface. The message flow uses the IDL file to configure which operation is called on which interface.

After you have deployed the BAR file, you can start the message flow. A CORBA request is sent by using values from the message tree in the DataObject domain as input parameters. If a response is received, the return type and output parameters are propagated to the Out terminal of the CORBARequest node. You can use the data that is returned from the CORBA application to verify the result from the CORBARequest node.

CORBA support
The CORBA nodes in IBM App Connect Enterprise support a set of types and operations in imported IDL files.

IBM App Connect Enterprise supports the CORBA 2.3.1 specification and uses the Java 7 JRE ORB, and is therefore compatible with any CORBA vendor that is compatible with the JRE ORB.

IBM App Connect Enterprise currently supports the following CORBA types and operations.

- All primitive types, except bounded strings
- Two-way operations with in, inout, and out parameters
- User-defined exceptions
- Enums
- Modules
- Sequences (sequences must have associated typedefs; anonymous sequences are not supported)
- Structs
- Typedefs
- Comments

- The following preprocessing tokens:
  - #ifndef
  - #endif
  - #define
  - #include

  Other preprocessing tokens are ignored.

When you import an IDL file, supported and unsupported operations are listed. You can import and deploy IDL files that contain unsupported types and operations, but if you try to call one of these unsupported operations, you see an error message.

You cannot import an IDL file that is not valid. During the importing process, if you select an IDL file that is not valid, you see an error message and cannot complete the wizard.

Abstract interfaces and interfaces that contain inheritance are not supported. IDL pragma directives are not supported, but you can include the following pragmas in your IDL file (these pragmas are ignored):

- cpponly
- ID
- init
- localonly
- localonly abstract
- Prefix
- version

IDL data types
When you use the DataObject domain with CORBA, you need to know how XML schema and ESQL types correspond to the types in the IDL file.

Primitive IDL types

The following table shows the mapping between IDL types, XML schema simple types, and ESQL types.

IDL	XML schema	ESQL
boolean	xsd:boolean	BOOLEAN
char	<xsd:simpleType name="char"> <xsd:restriction base="xsd:string"> <xsd:length value="1" fixed="true/> </xsd:restriction> </simpleType>	CHARACTER
wchar	<xsd:simpleType name= "wchar"> <xsd:restriction base="xsd:string"/> </xsd:simpleType>	CHARACTER
double	xsd:double	FLOAT
float	xsd:float	FLOAT
octet	xsd:unsignedByte	INTEGER
long	xsd:int	INTEGER
Long long	xsd:long	INTEGER
short	xsd:short	INTEGER

IDL	XML schema	ESQL
string	xsd:string	CHARACTER
wstring	xsd:string	CHARACTER
Unsigned short	xsd:unsignedShort	INTEGER
Unsigned long	xsd:unsignedInt	INTEGER
Unsigned long long	xsd:unsignedLong	DECIMAL

Complex IDL types

IBM App Connect Enterprise supports the following complex IDL types:

- Enums
- Typedefs
- Sequences
- Structures

Each complex type is supported in the following places:

- Return types for operations
- In parameters
- Inout parameters
- Out parameters
- Inside exceptions
- Inside structures
- Inside sequences
- Inside typedefs

The following examples show the mapping between IDL types, XML schema, and XML.

Enums

IDL Enums are mapped to enumerations in XML schema. Enums inside the tree are of type string.

Here is an example IDL file:

```
enum myEnum {A, B, C};
interface example {
 void myoperation(in myEnum input1);
};
```

Here is an example XML schema:

```
<xsd:simpleType name="myEnum">
 <xsd:restriction base="xsd:string">
  <xsd:enumeration value="A"/>
  <xsd:enumeration value="B"/>
  <xsd:enumeration value="C"/>
 </xsd:restriction>
</xsd:simpleType>
```

Here is an XML example:

```
<example.myoperation>
 <input1>A</input1>
</example.myoperation>
```

Sequences and typedefs

IDL typedefs are mapped to XML schema type restrictions. IDL sequences are mapped to XML schema sequence complex types. Sequences can be used only within typedefs.

Here is an example IDL file:

```
Typedef long myLong;
typedef sequence<long> longSeq;
interface example {
 void myoperation(in longSeq input1, inout myLong input2);
};
```

Here is an example XML schema:

```
<xsd:complexType name="longSeq">
 <xsd:sequence>
  <xsd:element name="item" minOccurs="0" maxOccurs="unbounded" type="xsd:int"/>
 </xsd:sequence>
</xsd.complexType>
```

A sequence can be bounded with the syntax sequence<long, 10>, which puts a bound in the XSD file.

Here is an XML example:

```
<example.myoperation>
 <input1>
  <item>10</item>
  <item>11</item>
  <item>12</item>
 </input1>
</example.myoperation>
```

Structures

IDL structures are mapped to XML schema complexType definitions.

Here is an example IDL file:

```
struct myStruct {
 char c;
 string str;
 octet o;
 short s;
 unsigned long long ull;
 float f;
 double d;
};
interface example {
 void myoperation(in myStruct input1);
};
```

Here is an example XML schema:

```
<xsd:complexType name="myStruct">
 <xsd:sequence>
  <xsd:element name="c" type="xsd:string" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="str" type="xsd:string" nillable="true" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="o" type="xsd:byte" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="s" type="xsd:short" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="ull" type="xsd:unsignedLong" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="f" type="xsd:float" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="d" type="xsd:double" maxOccurs="1" minOccurs="1"/>
 </xsd:sequence>
</xsd:complexType>
```

Here is an XML example:

```
<example.myoperation>
 <input1>
  <c>c</c>
  <str>hello</str>
  <o>12</o>
  <s>10</s>
  <ull>110</ull>
  <f>12.0</f>
  <d>12.1</d>
 </input1>
</example.myoperation>
```

Modules

In CORBA, modules provide scope. If an interface is contained in a module in the IDL file, the interface name is qualified with the module name in the following format:

ModuleName.*InterfaceName*.*OperationName*

The following example shows a module in an IDL file.

```
Module one {
 Interface OneAInterface {
 };
};
```

The fully qualified name of the interface called OneAInterface is `one.OneAInterface`. In an IDL file, modules can be nested in other modules. In this case, the fully qualified name of the interface can include more than one module name, starting from the root module; for example:

ModuleNameA.*ModuleNameB*.*InterfaceName*.*OperationName*

An IDL file can contain more than one operation with the same name provided that the operations are in different modules.

CORBA naming service
A CORBA naming service holds CORBA object references.

A CORBA server puts references to CORBA objects inside a naming service so that clients can query the naming service and obtain the object reference, then call operations on the CORBA objects. Typically, a client queries the naming service once, then caches the object reference.

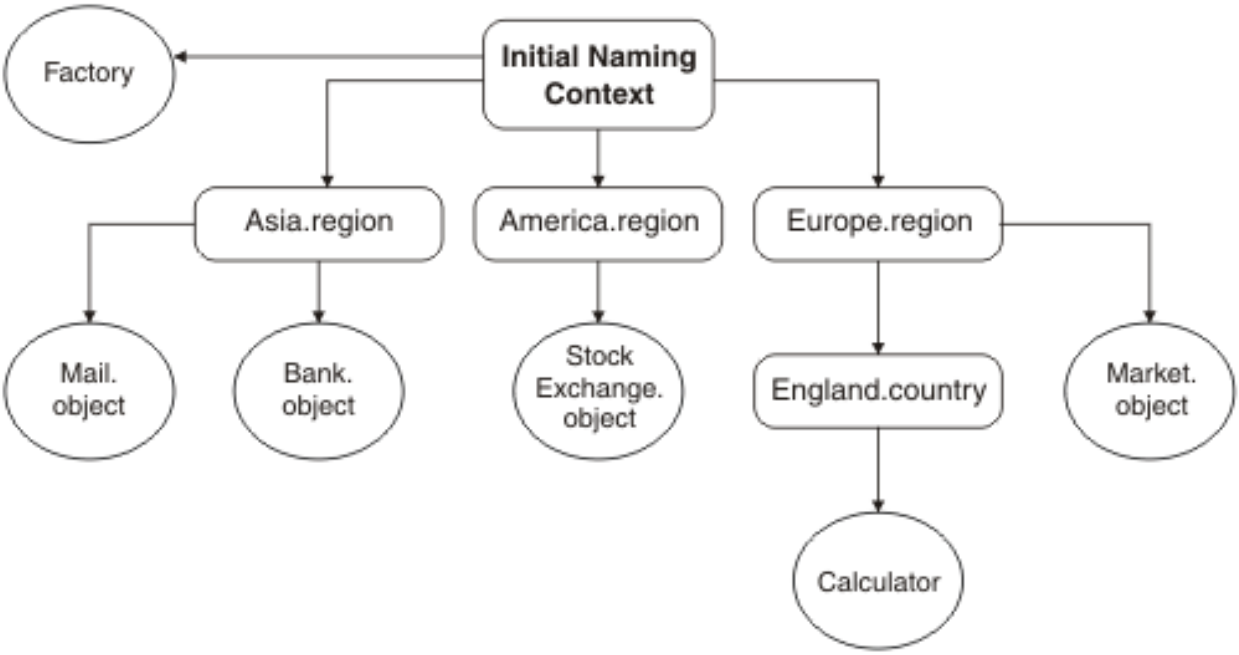
A CORBARequest node is a CORBA client; therefore, when it is deployed, the node contacts a naming service to obtain an object reference. If the object reference is not in the naming service at deployment time, or the naming service that is configured on the node is unavailable, the CORBARequest node issues a warning, and attempts to contact the naming service to get the object reference when it receives a message. If an object reference cannot be acquired from the naming service when the node receives a message, an error is issued. You can specify the location of an object reference by using the properties on the CORBARequest node. For more information, see node.

Identifying an object reference in a naming service

Each object in a naming service has a unique name. You must use this name when you configure the `Object reference name` property on the CORBARequest node.

Naming services are typically arranged in a hierarchy so that names can be given context or scope. The initial naming context is at the top of the hierarchy. Object references can be added to the initial naming context, and additional contexts can exist below it. The number of levels in the hierarchy is unlimited.

Object references and contexts can be assigned a *kind* to facilitate grouping. The kind is appended to the context in the format *context.kind*. If you are using IBM App Connect Enterprise to access an external CORBA application, you need to know the location of the naming service and the name of the object reference in the naming service. The following example shows how to determine the exact string representation of the name.



In the diagram, contexts are represented by squares, and object references are represented by circles.

- An object called Factory is directly attached to the initial naming context.
- Three contexts, with kind *region*, are also attached to the initial naming context.
- These three contexts each have one or more object references attached to them.
- The Europe context has an England context attached to it, of kind *country*, which has an object attached to it (*Calculator*).

The name that you specify when you configure the `Object reference name` property on the CORBARequest node reflects the position of the object in the hierarchy. The following table shows how to refer to the specific objects in the diagram.

Object	**Object reference name**
Factory	Factory
Bank	Asia.region/Bank.object
Mail	Asia.region/Mail.object
StockExchange	America.region/StrockExchange.object
Market	Europe.region/Market.object
Calculator	Europe.region/England.country/Calculator

All objects in the naming service can be connected directly to the initial naming context; in which case, their names would be in the same format as the Factory object in this example.

CORBA operation parameters
CORBA operations can have parameters that can be modified by the server.

CORBA operations can have in, out, and inout parameters. In and inout parameters dictate the appearance of the tree under the DataObject domain when going into a CORBARequest node. The return type, inout and out parameters dictate the appearance of the tree when leaving a CORBARequest node.

The inbound message is contained in the element *interfaceName.operationName* and needs an element for every in or inout parameter. If the interface is contained in a module, the name is qualified with the name of the module. If the module is nested in other modules, all module names are stated; for example: *moduleNameA.moduleNameB.interfaceName.operationName*. Out parameters are not required because

the client does not send a value for out parameters. These elements must be in the same order as the parameters in the IDL file.

The output message from the CORBARequest node is contained in the element *interfaceName.operationName*Response. If the interface is contained in a module, the name is qualified with the module name. The outbound message has an element for the return type, named *_return*, and an element for every inout and out parameter.

Here is an example of an IDL file:

```
interface exampleInterface {
 string outsideModuleOperation(in string one, out string two, inout string three);

};
```

The input message might look like the following example:

```
<exampleInterface.outsideModuleOperation>
 <one>something</one>
 <three>something</three>
</exampleInterface.outsideModuleOperation>
```

The output message might look like the following example:

```
<exampleInterface.outsideModuleOperationResponse>
 <_return>something</_return>
 <two>something</two>
 <three>something</three>
</exampleInterface.outsideModuleOperationResponse>
```

The input message requires all in and inout parameters, therefore one and three are specified. The output has the following elements:

- A *_return* element (because the operation has a return type of string)
- An element called *two* (because *two* is an out parameter)
- An element called *three* (because *three* is an inout parameter)

User-defined exceptions

Exceptions are propagated to the Error terminal under the DataObject domain; the structure of the message depends on the exception.

The following example shows how a user-defined exception is defined in an IDL file.

```
exception BadRecord {
    string why;
  };

  interface SomeInterface {
    long bar(in float pi) raises (BadRecord);
  };
```

The operation *bar* can issue the exception *BadRecord*. If this exception is issued, the following message is propagated to the Error terminal.

```
<BadRecord>
 <why>Reason text</why>
</BadRecord>
```

Edge cases

Two identified edge cases exist for reading a tree and producing a tree:

- No input parameters exist.
- A void function has no inout or out parameters

The following sample IDL file illustrates two examples.

```
interface exampleInterface {
 string exampleOne();
void exampleTwo(in string one);
};
```

- **Example 1 - no input parameters exist**

  Input message: The input message is irrelevant because the CORBARequest node does not look at the body of the message.

  Output message:

  ```
  <exampleInterface.exampleOneResponse>
   <_return>something</_return>
  </exampleInterface.exampleOneResponse>
  ```

- **Example 2 - A void function has no inout or out parameters**

  Input message:

  ```
  <exampleInterface.exampleTwo>
   <one>something</one>
  </exampleInterface.exampleTwo>
  ```

  Output message:

  ```
  <exampleInterface.exampleTwoResponse>
  </exampleInterface.exampleTwoResponse>
  ```

Connecting to an external CORBA application

Connecting to an external CORBA application involves importing an IDL file, creating a message flow, building a message, and processing the response from the CORBARequest node.

Before you begin

An IDL file is used to configure the CORBARequest node. Ensure that you have a valid IDL file that contains elements that are supported by IBM App Connect Enterprise. The CORBA IDL file must contain at least one interface that has one operation. For more information, see “CORBA support” on page 1155.

About this task

To connect to an external CORBA application, complete the following steps.

Procedure

1. Create an integration project.
2. Import an IDL file into the IBM App Connect Enterprise Toolkit, as described in “Message Sets: Importing an IDL file” on page 2309.
3. Develop a message flow that contains a CORBARequest node, as described in “Developing a message flow with a CORBARequest node” on page 1163.
4. Build a message to send to the CORBARequest node, as described in “Building a message for the CORBARequest node” on page 1164.
5. Process the response from the CORBARequest node, as described in “Processing responses from a CORBARequest node” on page 1167.

Developing a message flow with a CORBARequest node
To connect to an external CORBA application, create a message flow that contains a CORBARequest node.

Before you begin

Ensure that you have created an integration project and message set project, and that you have imported an IDL file, as described in "Connecting to an external CORBA application" on page 1162.

About this task

You can create and configure a message flow manually, or you can create a message flow by dragging an imported IDL file onto the canvas.

Creating a message flow from an imported IDL file

Procedure

1. Drag an IDL file from the `CORBA IDLs` folder in the Application Development view to an empty canvas.

   (If you have imported an IDL file that contains includes, drag the top-level IDL file onto the canvas.)

   A CORBARequest node is created. The `IDL file`, `Interface name`, and `Operation name` properties are set according to the IDL file.
2. If the IDL file contains more than one interface or operation, select an interface and operation from the dialog box.
3. Configure the following properties on the CORBARequest node:
   - `Naming service`: Specify the host name and port of the naming service.

     The format of this value is host:port, where port is optional; for example, localhost:2809. You can obtain this value from the administrator of the CORBA application that you are calling.
   - `Object reference name`: Specify the name of the object reference in the naming service.

     You can obtain this value from the CORBA server that you are calling. For more information about how to specify the object reference name, see "CORBA naming service" on page 1159.
4. Add to the message flow other nodes that build the incoming and outgoing messages.

   You can use an XML message for the CORBARequest node, or you can build a message by using a Compute, or JavaCompute node. If the incoming message has a message model, you can use a Mapping node to build the message that is sent to the CORBARequest node.

   If the message that the CORBARequest node produces has a message model, you can use a Mapping node to build the outgoing message.
5. Build a message for the CORBARequest node by using the examples in "Building a message for the CORBARequest node" on page 1164.
6. Save the message flow.
7. Deploy the message flow.

   (If you have used an IDL file that contains includes, ensure that all the IDL files are deployed with the message flow.)

What to do next

You can also drag an IDL file onto an existing CORBARequest node. The existing `IDL file`, `Interface name`, and `Operation name` properties are replaced with values from the new IDL file, and the `Naming service` and `Object reference name` properties are cleared. If the IDL file contains more than one interface or operation, the `Interface name` property is set to the first interface in the IDL file, and the `Operation name` property is set to the first operation in that interface.

Creating a message flow manually

Procedure

1. Create a message flow.
2. Add a CORBARequest node to the message flow.
3. Configure the following properties on the CORBARequest node:
   - `Naming service`: Specify the host name and port of the naming service.

     The format of this value is host:port, where port is optional; for example, localhost:2809. You can obtain this value from the administrator of the CORBA application that you are calling.
   - `Object reference name`: Specify the name of the object reference in the naming service.

     You can obtain this value from the CORBA server that you are calling. For more information about how to specify the object reference name, see "CORBA naming service" on page 1159.
   - `IDL file`: Click **Browse** and select the IDL file from the message set project. If you have imported an IDL file that contains includes, select the top-level IDL file.
   - `Interface name`: Specify the name of the interface in the IDL file that the node calls.
   - `Operation name`: Specify the name of the operation from the interface that you select in the IDL file.

     You can override this property in the local environment by specifying a value in the following location:

     ```
     $LocalEnvironment/Destination/CORBA/Request/OperationName
     ```
4. Add to the message flow other nodes that build the incoming and outgoing messages.

   You can use an XML message for the CORBARequest node, or you can build a message by using a Compute, or JavaCompute node. If the incoming message has a message model, you can use a Mapping node to build the message that is sent to the CORBARequest node.

   If the message that the CORBARequest node produces has a message model, you can use a Mapping node to build the outgoing message.
5. Build a message for the CORBARequest node by using the examples in "Building a message for the CORBARequest node" on page 1164.
6. Save the message flow.
7. Deploy the message flow.

   (If you have used an IDL file that contains includes, ensure that all the IDL files are deployed with the message flow.)

What to do next

After you have deployed the message flow, learn how calls are processed by the CORBARequest node; see "Processing responses from a CORBARequest node" on page 1167.

Building a message for the CORBARequest node

You can use an XML message for the CORBARequest node, or you can build a message by using another message flow node.

Before you begin

Ensure that you have created and configured a message flow with a CORBARequest node, as described in "Developing a message flow with a CORBARequest node" on page 1163.

About this task

The CORBARequest node requires an input message. The node can use an XML message from another node, or you can build a message by using a Compute or JavaCompute node. If the incoming message has

a message model, you can use a Mapping node to build the message to send to the CORBARequest node. The incoming message tree must be in the DataObject domain, and the elements in the tree must match the IDL interface that you are calling. The physical representation of a message in the DataObject domain is XML; therefore, your application constructs message bodies like the following examples.

You can specify the location in the incoming message tree from which data is retrieved to form the request that is sent by the CORBARequest node. Specify this location by using the `Data location` property on the Request tab. The default value is `$Body`.

Procedure

1. Find out what data needs to be in the body of the message to send to the CORBARequest node.
2. Specify the top-level element (interface.operationName) for the message that you need to send to the CORBARequest node.
3. Specify a child for each in and inout parameter. You do not have to pass in a value for out parameters.

Example

The following examples show the XML and ESQL that could be received by a message flow.

A mixture of in inout and out parameters

Here is an example IDL file:

```
interface

ExampleOne {
 enum completion{YES, NO, MAYBE};
  typedef sequence<string> stringlist;
 struct stringobject {string member;};

 string exampleOneOperation(in string inparamA, inout string inoutparamA, out string outparamA);
 completion exampleOneOperationB(in stringlist inparamB, inout stringobject inoutparamB, out
 completion outparamB);
}
```

This IDL file contains an interface with two operations, which have an in parameter, an inout parameter, and an out parameter.

For the first operation, *exampleOneOperationA*, you must pass in the parameters *inparamA* and *inoutparamA* under the top-level type *ExampleOne.exampleOneOperationA*. You do not need to pass in the *outparamA* parameter.

Here is an XML example:

```
<ExampleOne.exampleOneOperationA>
 <inparamA>your value</inparamA>
 <inoutparamA>your value</inoutparamA>
</ExampleOne.exampleOneOperationA>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationA".inparamA = 'yourvalue';

SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationA".inoutparamA = 'yourvalue';
```

For the second operation, *exampleOneOperationB*, you must pass in the parameters *inparamB* and *inoutparamB* under the top-level type *ExampleOne.exampleOneOperationB*. You do not need to pass in the *outparamB* parameter.

Here is an XML example:

```
<ExampleOne.exampleOneOperationB>
 <inparamB><item>your value</item></inparamB>
 <inoutparamB><member>your value</member></inoutparamB>
</ExampleOne.exampleOneOperationB>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationB".inparamB.item = 'your value';

SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationB".inoutparamB.member = 'your value'
```

In and inout parameters only

Here is an example IDL file:

```
interface

ExampleTwo {
 enum completion{YES, NO, MAYBE};
 typedef sequence<string> stringlist;
 struct stringobject {string member;};

 string exampleTwoOperationA(in string inparamA, inout string inoutparamA);
 completion exampleTwoOperationB(in stringlist inparamB, inout stringobject inoutparamB);

}
```

This IDL file contains two operations with an in and inout parameter only. The removal of the out parameter and the existence of only in and inout parameters does not change the parameters that you need to pass in.

To call the first operation, *exampleTwoOperationA*, pass in *inparamA* and *inoutparamA* under the top-level type *ExampleTwo.exampleTwoOperationA*.

Here is an XML example:

```
<ExampleTwo.exampleTwoOperationA>
 <inparamA>your value</inparamA>
 <inoutparamA>your value</inoutparamA>
</ExampleTwo.exampleTwoOperationA>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationA".inparamA = 'yourvalue';

SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationA".inoutparamA = 'yourvalue';
```

To call the second operation, *exampleTwoOperationB*, pass in *inparamB* and *inoutparamB* under the top-level type *ExampleTwo.exampleTwoOperationB*.

Here is an XML example:

```
<ExampleTwo.exampleTwoOperationB>
 <inparamB><item>your value</item></inparamB>
 <inoutparamB><member>your value</member></inoutparamB>
</ExampleTwo.exampleTwoOperationB>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationB".inparamB.item = 'your value';

SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationB".inoutparamB.member = 'your value';
```

No parameters or out parameters only

If the operation contains no parameters, or out parameters only, you do not need to put anything in the body of the message. The CORBARequest node does not look at the incoming message.

What to do next

Process the responses from the CORBARequest, as described in "Processing responses from a CORBARequest node" on page 1167.

Processing responses from a CORBARequest node

Configure the CORBARequest node to define the location to which responses are sent.

Before you begin

Complete the tasks that are described in the following topics:

- "Developing a message flow with a CORBARequest node" on page 1163
- "Building a message for the CORBARequest node" on page 1164

About this task

The CORBARequest node has three output terminals:

- Out: For a successful invocation of the operation.
- Error: If a CORBA system exception or user-defined exception is issued.
- Failure: If a failure occurs in the node; for example, if the node cannot communicate with the naming service or it receives an incorrect message.

You can select the location to which to send the response by configuring the `Output data location` property on the **Result** tab. This property specifies the message tree location to which the CORBARequest node puts output. The output is put under the DataObject domain. For more information, see "Combining a result message with an input message when fetching data from external systems" on page 1811.

Procedure

- **Processing successful calls**

  When a call is successful, the resulting message is propagated to the Out terminal. Inside the tree is a top-level element named *InterfaceName.OperationName*Response. Under this type is the return type of the operation (named _return) and every inout or out parameter. In parameters are not propagated because they do not change.

  A mixture of in inout and out parameters

  Here is an example IDL file:

  ```
  interface

  ExampleOne {
     string exampleOneOperation(in string inparam, out string outparam, inout string
   inoutparam);

  }
  ```

  You receive the parameters *outparam* and *inoutparam* under the top-level element `ExampleOne.exampleOneOperationResponse`.

  Here is an XML example:

  ```
  <ExampleOne.exampleOneOperationResponse>
   <_return>The operation return value</_return>
   <outparam>value from corba app</outparam>
   </inoutparam>your value changed by the corba app<inoutparam>
  </ExampleOne.exampleOneOperationResponse>
  ```

  Out and inout parameters

  Here is an example IDL file:

  ```
  interface
  ```

```
ExampleTwo {
   string exampleTwoOperation(out string outparam, inout string inoutparam);

}
```

The removal of the in parameter makes no difference to the message that is propagated from a CORBARequest node because in parameters are not propagated.

Here is an XML example:

```
<ExampleTwo.exampleTwoOperationResponse>
 <_return>The operation return value</_return>
 <outparam>value from corba app</outparam>
 </inoutparam>your value changed by the corba app<inoutparam>
</ExampleTwo.exampleTwoOperationResponse>
```

In parameters only or no parameters

If the operation contains no parameters, or in parameters only, you receive the _return value under the top-level element.

Here is an example IDL file:

```
interface

ExampleThree {
   string exampleThreeOperation(in string inparam);

}
```

Here is an XML example:

```
<ExampleThree.exampleThreeOperationResponse>
 <_return>The operation return value</_return>
</ExampleThree.exampleThreeOperationResponse>
```

No return type (void) and no inout or out parameters

If the operation that you are calling has no return type (void) and no inout or out parameters, no values are returned from the CORBA application to put in the tree. In this case, only the top-level element is created.

Here is an example IDL file:

```
interface

ExampleFour {
   void exampleFourOperation(in string inparam);

}
```

Here is an XML example:

```
<ExampleFour.exampleFourOperationResponse>
</ExampleFour.exampleFourOperationResponse>
```

- **Processing user-defined exceptions and CORBA system exceptions**

  When a CORBA user-defined exception or a CORBA system exception occurs, a message is propagated to the Error terminal. CORBA system exceptions have a standard shape and look like this:

  In the IDL file:

```
exception SystemException { // descriptive of error

 unsigned long;      // more detail about error
 CompletionStatus;   // yes, no, maybe
}
```

  In the tree:

```
<SystemException>
```

```
 <minor>10</minor>
 <completed>maybe</completed>
</SystemException>
```

The top-level element is the name of the CORBA system exception that is issued. The structure of a user-defined exception is based on the IDL for the exception. Here is an example:

In the IDL file:

```
  exception BadRecord {
 string why;

};
```

In the message:

```
<BadRecord>
 <why>reason text</why>
</BadRecord>
```

As you can see from this example, the structure of the message is based on the exception, and is not qualified by the operation that was being called.

- **Handling failures in the node**

  Any failures are propagated to the Failure terminal. Possible failures include:

  – Inability to communicate with the CORBA server
  – Inability to communicate with the CORBA naming service
  – Invalid body (including the wrong top-level element or missing parameters)

Defining where the CORBARequest node gets the object reference
You can specify an object reference name either on the CORBARequest node or by using a policy.

Before you begin

- Read “Common Object Request Broker Architecture (CORBA)” on page 1153 for background information.

About this task

By using policies, you can specify the location from which the CORBARequest node gets the object reference without the need to redeploy the message flow. You can also use the policy to specify this location for multiple CORBARequest nodes.

Creating and changing policies

Procedure

- To create or update a policy, use the Policy editor in the IBM App Connect Enterprise Toolkit (see “Creating policies with the IBM App Connect Enterprise Toolkit” on page 327).

Working with CICS Transaction Server for z/OS

Use the CICSRequest node to connect to CICS Transaction Server for z/OS applications.

About this task

This section contains the following concept information:

- “CICS Transaction Server for z/OS overview” on page 1170
- “CICS Transaction Server for z/OS connectivity” on page 1175
- “CICS Transaction Server for z/OS two-tier connectivity” on page 1177

- “CICS Transaction Server for z/OS three-tier connectivity” on page 1181
- “COMMAREA or channel data structures” on page 1171
- “CICS Transaction Server for z/OS mirror transactions” on page 1183
- “Local environment overrides for the CICSRequest node” on page 1185

This section contains the following tasks:

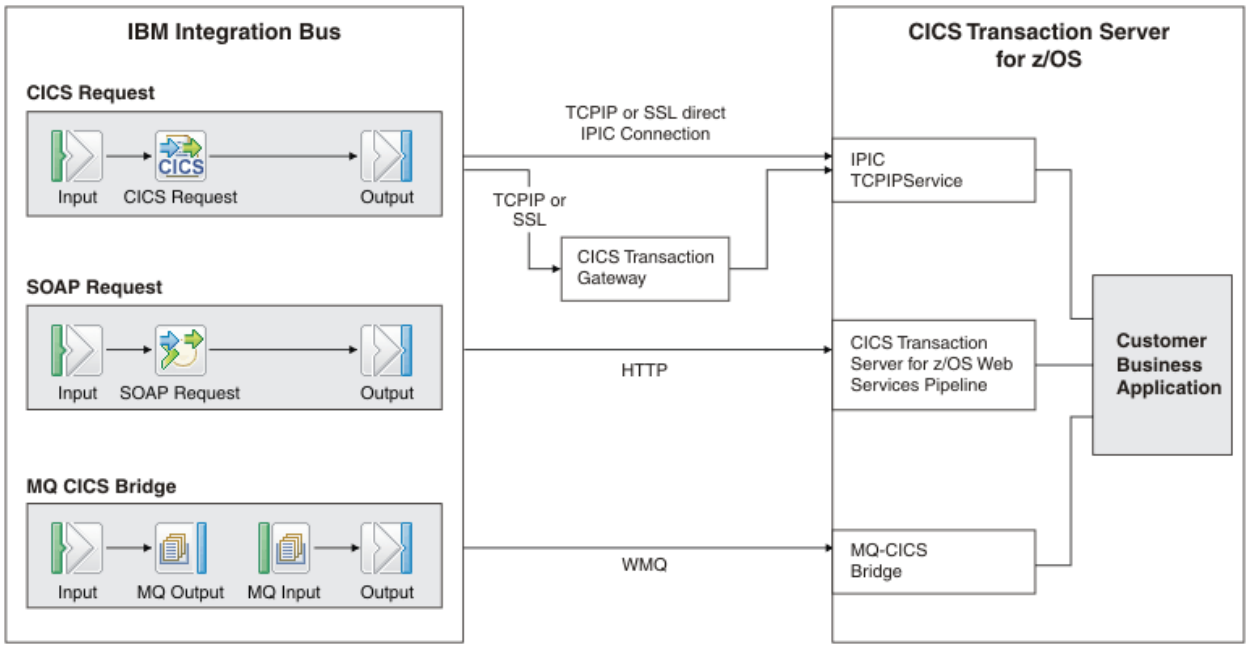
- “Connecting to a CICS Transaction Server for z/OS application” on page 1186
- “Defining a CICS Transaction Server for z/OS data structure” on page 1186
- “Preparing the environment for the CICSRequest node” on page 1187
- “Securing the connection to CICS Transaction Server for z/OS by using SSL” on page 1182
- “Developing a message flow with a CICSRequest node” on page 1188
- “Building a message for the CICSRequest node” on page 1191
- “Processing responses from a CICSRequest node” on page 1193
- “Changing connection information for the CICSRequest node” on page 1194
- “Propagating security credentials to CICS Transaction Server for z/OS” on page 1195

CICS Transaction Server for z/OS overview

CICS Transaction Server for z/OS provides general-purpose transaction processing software for z/OS. CICS is a powerful application server that meets the transaction-processing needs of both large and small enterprises.

By using the CICS support that is provided in IBM App Connect Enterprise you can deploy CICS applications into a service-oriented architecture (SOA). This support keeps your business logic intact and requires little or no change to CICS and CICS applications.

The following diagram shows the layers of communication between IBM App Connect Enterprise and CICS.



You can use the following methods to connect to CICS:

- **CICSRequest node support**

  IBM App Connect Enterprise includes a CICSRequest node that supports connectivity to CICS by using the IP InterCommunications (IPIC) protocol, which is available in CICS Transaction Server for z/OS.

To review the latest supported version of CICS Transaction Server for z/OS, see IBM App Connect Enterprise system requirements

Support includes the following connection methods:

– A direct connection to CICS (two-tier).

– A connection to CICS through CICS Transaction Gateway (three-tier).

- **CICS TG**

  CICS TG is a high-performing, secure, and scalable solution that provides workload management and high-availability options for access to CICS. By using standards-based interfaces, CICS TG deliver access to new and existing CICS applications.

For further information about the CICSRequest node, see CICSRequest node.

- **CICS web services support**

  You can use the web services support in IBM App Connect Enterprise to connect to CICS applications. For further information about web services, see “Processing web service messages” on page 805.

- **CICS-IBM MQ Integration**

  CICS has several components that support integration with IBM MQ. These components are:

  – The CICS-IBM MQ adapter, also known as the CICS-MQ attach (including the CKTI trigger monitor or task initiator). The term CICS-MQ adapter is used to refer to the CICS-IBM MQ adapter.

  – The CICS-IBM MQ bridge, also known as the CICS 3270 and DPL bridges. The term CICS-MQ bridge is used to refer to the CICS-IBM MQ bridge.

For further information about how to use the CICSRequest node to connect IBM App Connect Enterprise to CICS applications, see “CICS Transaction Server for z/OS connectivity” on page 1175.

For further information about CICS, see the CICS Library web page, which contains links to the CICS Information Center and associated IBM Redbooks publications.

COMMAREA or channel data structures

CICS Transaction Server for z/OS programs can be linked to by using either a COMMAREA data structure or a channel data structure as input, which return the same data structure as output. The CICSRequest node supports interaction with CICS through COMMAREA or channel data structures.

Channels are a modern alternative for COMMAREAs, providing relief from the COMMAREA maximum size of 32766 bytes, and allowing greater flexibility in input/output data structures.

- “COMMAREAs” on page 1171
- “Channels” on page 1172

COMMAREAs

If using a COMMAREA as the input data structure for communicating with CICS, the CICSRequest node takes a portion of the Input Body, as defined in the CICSRequest node Request properties, and sends it to CICS as the COMMAREA.

The returning COMMAREA is then put into the Output tree and replaces the existing Body at the location that is defined in the CICSRequest node Result properties. The COMMAREA can then be configured for parsing by using the CICSRequest node Response Message Parsing properties.

When defining a COMMAREA data structure as input, you must ensure that the CICSRequest node `Commarea length` property value is large enough to contain the input request data, or the output response data, but that it does not exceed the maximum value of 32767 bytes. If the `Commarea length` value is not large enough to be used for the response data, or the request data, a memory leak occurs in CICS. The size of the COMMAREA cannot be changed by the CICS program. If the serialized request data is larger than the `Commarea length`, the data is truncated to the `Commarea length`. You can obtain the `Commarea length` value from the CICS administrator or developer.

The default value for the CICSRequest node `data structure` basic property is `Commarea`.

If using direct two-tier connection, CICS looks at the JVM `file.encoding` property to determine the code page of the COMMAREA. This can cause code page conversion errors in the CICS program. If the property is not set, a default value of 437 is used. For more information, see the CICS documentation about code pages.

For more information about using a COMMAREA data structure as input, see "Defining a CICS Transaction Server for z/OS data structure" on page 1186, "Developing a message flow with a CICSRequest node" on page 1188, and "Building a message for the CICSRequest node" on page 1191.

Channels

CICS channels hold a number of structures called containers. Containers hold the business information that is accessed by the target CICS program. Each container can hold up to 2 GB of data, and channels can have as many containers within them as required, which provides flexibility in terms of the size and layout of data. Each container has a 16-character maximum alphanumeric container name, which is unique within the channel, and is used as the mechanism to retrieve the contents of the container from the channel.

There are two types of container; `character` or `binary`. The type of container can affect the data conversion between IBM App Connect Enterprise and CICS, however the container type does not have any impact on the format of the information that can be put into the container.

Character containers

Character containers are more likely to be individual strings or discrete data items, but can also be mapped structures, however it is important to remember that data conversion is applied to the data in the container. When a character container is constructed, the source coded character set ID (CCSID) information about the container is sent to CICS as metadata. The CICS program uses the `GET CONTAINER` application programming interface (API) call to convert the metadata to the default CCSID of the region, unless another CCSID is provided. The CICS program then places the container back into the channel, and the data is converted ready for the IBM App Connect Enterprise application to retrieve and use.

Binary containers

Binary containers can be mapped by using a COBOL copybook structure or they might be discrete values. Data conversion is not applied to the data in a binary container, therefore the data in a binary container is sent to CICS and retrieved from CICS in original form only.

Unlike COMMAREA structures, the size of the response channel does not need to resemble the request, whereas COMMAREAs must allow for the size of the response in the request.

Channels and containers in CICS

In the following example diagram, the CICS channel has two containers; `CustomerName` and `Order`.

Channel Name:		MyChannel		
CustomerName	CHAR	'Joe Bloggs'		
Order	BIN	100	Apples	0.39
...	...	...		

`CustomerName` is a character (CHAR) container that contains a single character string; `Joe Bloggs`. Because `CustomerName` is a character container, data conversion can be applied to the data in the container. `Order` is a binary (BIN) container that might be created by using a COBOL copybook structure or C header file, which you can then import to populate your message set with message definitions. The following example copybook describes the binary layout of the data that the CICS program expects to receive:

```
01 ORDER_STRUCTURE.
          03 QTY                  COMP-1.
          03 ITEM                 PIC X(10).
```

```
           03 PRICE                PIC S9(9).
```

The target CICS program can retrieve both of these containers from the channel by providing the name of the container when using the GET CONTAINER API. When the data is provided to the CICS program, the program processes the data however it chooses. For example, the program can place other containers into the channel to provide a response to the called container by using the PUT CONTAINER API.

Channels and containers in IBM App Connect Enterprise

In IBM App Connect Enterprise, a CICS channel is represented as a message collection structure. A message collection can hold child messages, each treated as a container by the CICSRequest node. A message collection structure is used as both input and output to the CICSRequest node when using a channel data structure. For more information about message collections, see "Message collections" on page 1841, and for information about creating a message collection, see "Creating a message collection by using ESQL" on page 1843.

The message collection name is used to name the channel. The name of the child message in the message collection is used as the name of the container in the channel, and must be unique. If the child message name in the message collection is not unique, the request is rejected in CICS.

The following table shows the channel and container to message collection and child message mapping:

CICS	IBM App Connect Enterprise
Channel name	Message collection name
Container name (must be unique to the parent channel)	Child message name (must be unique to the message collection)

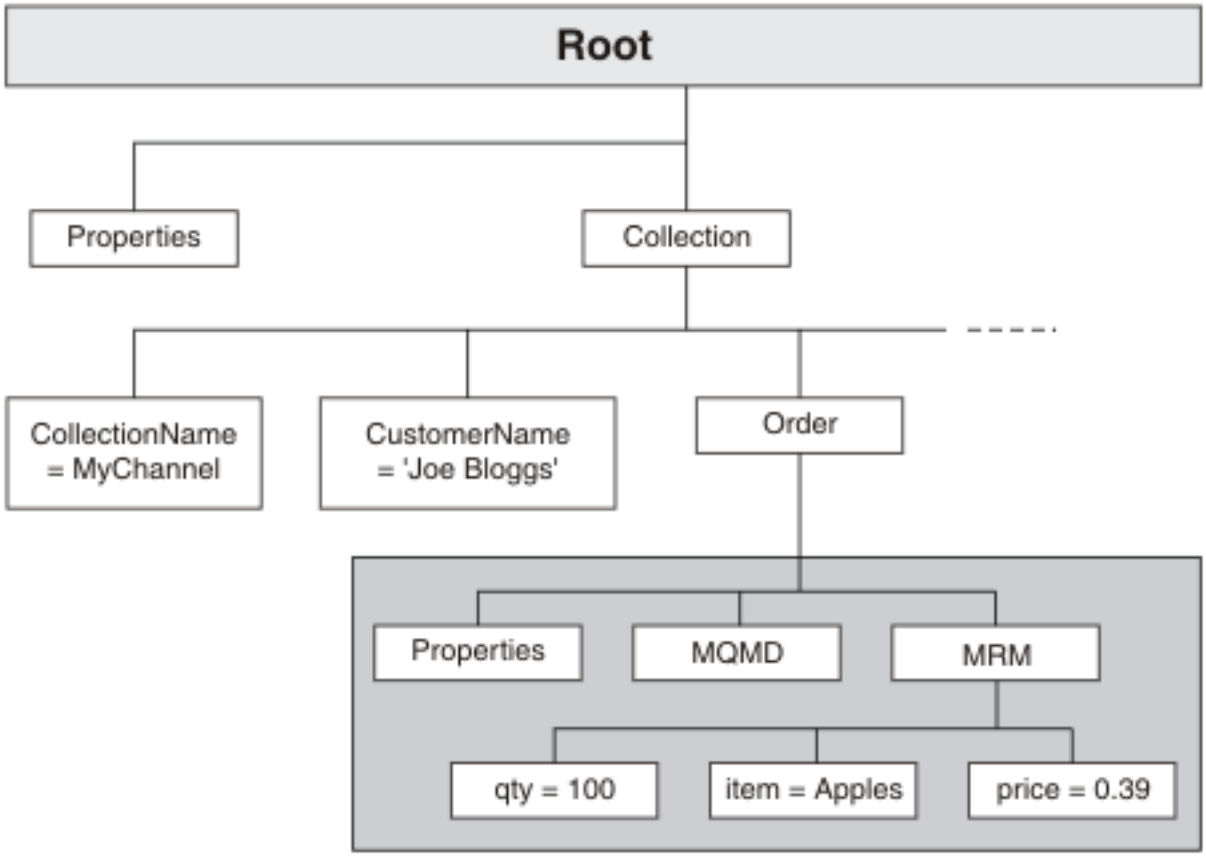
Name-value attributes

IBM App Connect Enterprise supports adding name-value attributes to a message collection to create a container. A message collection can have zero or more attributes. The name of an attribute must be unique within a message collection. A standard attribute for the message collection is an attribute called *CollectionName*.

You can add name-value attributes to a message collection to create CICS containers. Name-value attributes in the message collection, apart from *CollectionName*, can be used in lieu of full message-folders for simple data. For example, a name-value string attribute can be set in the message collection and used directly by the CICSRequest node without needing to create a message set for the element.

Name-value attributes can be produced from containers on output, as well as accepted for input. For information about creating an attribute instead of a message folder from a container, see CICSRequest node.

In the following example diagram, the CICS channel is represented by a message collection named Collection. Collection holds two containers that are represented by child messages named CustomerName and Order. *CollectionName* and CustomerName are both name-value attributes, however the *CollectionName* attribute is not treated as a container by the CICSRequest node, and is therefore not sent to CICS.



If the `CustomerName` attribute is to be treated as a character container by the CICSRequest node, the LocalEnvironment must reflect this.

LocalEnvironment

Each child message in a message collection is treated as having a default type of binary, which determines whether the data is converted to the CCSID in the CICS region. However, you can dynamically override this value to character, on a per message basis, in the local environment. For example, you can set the following value under `LocalEnvironment.Destination.CICS.RequestChannel.Containers`:

```
SET OutputLocalEnvironment.Destination.CICS.RequestChannel.Containers.<myContainerName> =
 CHARACTER;
```

When a message collection is emitted from the CICSRequest node following the request, the LocalEnvironment contains the returned type information for the containers. For example, when the response channel comes back from CICS, the LocalEnvironment shows the types of the containers that have come back in the following location: `LocalEnvironment.CICS.ResponseChannel.Containers.<myContainerName> = CHARACTER`

The channel name, which has a 16-character alphanumeric limit, can be overridden as follows:

```
SET OutputLocalEnvironment.Destination.CICS.RequestChannel.ChannelName = <myNewChannelName>;
```

If a single container is required for input only, a message collection does not need to be constructed. Instead a regular message can be used, however, you must set the 16-character maximum alphanumeric `ChannelName` in the LocalEnvironment. The 16-character maximum alphanumeric `SingleMessageContainerName` that needs to be created must also be provided in the following location:

```
SET OutputLocalEnvironment.Destination.CICS.RequestChannel.SingleMessageContainerName =
 <mySingleMessageContainerName>;
```

Because a message collection allows each container in the channel to be modeled as a separate message, each message has its own structure and parsing options. For example, one container might be XML and another might be based on a copybook, which can be represented by using XMLNSC and MRM messages within a message collection.

Each child message in the message collection contains message domain, set, type, format, CCSID, and encoding information in the `Properties` folder that is associated with the child message, which is serialized into a byte stream and sent to CICS. Each child message folder within the message collection that is being sent to CICS is serialized at the level of the last child of the message property domain. Not all CICS containers require a message set to represent them.

In the previous example, the `Order` container can be represented as MRM, and a message set can be created from the copybook ORDER_STRUCTURE to represent it. The returning channel is converted into a message collection, where every child message in the message collection represents a container from the channel. Child messages in the message collection are mapped to a list of message domain, set, type, format, CCSID, and encoding information by using the child message name, however CCSID, and encoding information are ignored for character messages. If a mapping cannot be found in the message, a default mapping can be provided.

Because it is not possible to know how many containers are in the response, a message collection is always produced as output.

You can use the CICSRequest node Response Message Parsing properties to map a returning container to a message domain, set, type, format, CCSID, and encoding information. In particular, the `Result data location` property can be used to reduce the result tree down to a single message folder, or down to a single field or subtree for output. For information about the `Result data location` property, see CICSRequest node.

The following details must be specified for the message to arrive at the CICSRequest node input terminal and be processed into a series of containers, and for those containers in the response channel to be placed back in the message as it leaves the node:

- The channel must be given a 16 character maximum alphanumeric name.

  Because the channel is represented by a message collection in IBM App Connect Enterprise, you can create the channel name by setting the message collection name. Message collection names are set by using the *`CollectionName`* attribute. For more information about creating a message collection and setting the message collection name, see “Creating a message collection by using ESQL” on page 1843.
- The following details must be specified for each container in the channel:
  - A 16 character maximum alphanumeric name.

    Because a container is represented by a child message in IBM App Connect Enterprise, you can create a container name by setting the child message name. For more information about creating a message collection and setting the child message name, see “Creating a message collection by using ESQL” on page 1843.
  - A container type; for example, `binary` or `character`.
  - A directory to use to place the response data into.

CICS Transaction Server for z/OS connectivity
Use the CICSRequest node to connect IBM App Connect Enterprise with CICS Transaction Server for z/OS applications.

The CICSRequest node that is available in IBM App Connect Enterprise provides connectivity to CICS applications by using IP InterCommunications (IPIC) protocol. IPIC is part of a CICS multi-version initiative to provide communications support over TCP/IP as an alternative to that provided over intersystem communication (ISC) and multiregion operation (MRO).

IPIC supports Distributed Program Link (DPL) requests over TCP/IP. The CICSRequest node communicates with CICS by sending Distributed Program Link (DPL) requests over TCP/IP-based IPIC. IPIC provides a multiplexed single socket connection to CICS Transaction Server for z/OS.

IBM App Connect Enterprise message flows can use the CICSRequest node to call programs that are running externally in a targeted CICS region. The CICSRequest node can be used by a message flow deployed to any integration node platform.

The CICSRequest node supports the following capabilities:

- Commareas
- Channels and containers
- Mirror transactions
- A direct connection to CICS (two-tier)
- A connection to CICS through CICS Transaction Gateway (three-tier)
- Local environment overrides for some properties
- Request timeout
- An integration node APPLID (client APPLID and qualifier) that can identify the application that is connecting to CICS, therefore identifying that IBM App Connect Enterprise is connected
- A CICS Connection policy
- Secure Sockets Layer (SSL) protocol connection to CICS
- Security identity
- User name, or user name and password identity propagation
- Resource statistics
- Transactionality

You can specify either a COMMAREA data structure or a channel data structure on the CICSRequest node to use as input for linking to CICS programs. The data structure that is specified as input returns the same data structure as output. Channels are an alternative for COMMAREAs, providing relief from the COMMAREA maximum size of 32766 bytes, and allowing greater flexibility in input/output data structures. For more information about using a COMMAREA or channel data structure, see "COMMAREA or channel data structures" on page 1171.

CICS channels hold a number of structures called containers. In IBM App Connect Enterprise, a CICS channel is represented as a message collection structure. A message collection can hold child messages, each treated as a container by the CICSRequest node. For information about using ESQL to create a message collection, see "Creating a message collection by using ESQL" on page 1843.

If a single container is required for input only, a message collection does not need to be constructed. Instead a regular message can be used, provided the 16-character maximum alphanumeric channel name and the single 16-character maximum alphanumeric container name are specified in the local environment. For more information about using single message mode, see "COMMAREA or channel data structures" on page 1171.

Because it is not possible to know how many containers are in the response, a message collection is always produced as output. However, the CICSRequest node `Result data location` property can be used to reduce the result tree down to a single message folder, or down to a single field or subtree for output. For information about the `Result data location` property, see CICSRequest node.

You can add name-value attributes to a message collection to create CICS containers. Name-value attributes in the message collection, apart from *`CollectionName`*, can be used in lieu of full message-folders for simple data. For example, a name-value string attribute can be set in the message collection and used directly by the CICSRequest node without needing to create a message set for the element. For more information about attributes, see "COMMAREA or channel data structures" on page 1171.

Name-value attributes can be produced from containers on output, as well as accepted for input. For information about creating an attribute instead of a message folder from a container, see CICSRequest node.

You can specify a mirror transaction name on the CICSRequest node for CICS tasks and programs to run under. This grouping greatly assists stat collection, accounting, and aids decision making about task

priority. For more information about mirror transactions, see “CICS Transaction Server for z/OS mirror transactions” on page 1183.

The CICSRequest node support in IBM App Connect Enterprise provides direct communication with CICS (two-tier connection) by sending Distributed Program Link (DPL) requests over TCP/IP-based IPIC, or communication with CICS through CICS Transaction Gateway (three-tier connection). For more information about the two-tier and three-tier connection models, see “CICS Transaction Server for z/OS overview” on page 1170 for a high-level overview, or “CICS Transaction Server for z/OS two-tier connectivity” on page 1177 and “CICS Transaction Server for z/OS three-tier connectivity” on page 1181 for detailed conceptual information.

For information about configuring the CICSRequest node to get connection details from a CICS Connection policy, see “Changing connection information for the CICSRequest node” on page 1194.

You can configure the CICSRequest node or a CICS Connection policy to use SSL protocol. For more information, see “Securing the connection to CICS Transaction Server for z/OS by using SSL” on page 1182.

You can use the **mqsisetdbparms** command to set a user ID and password for the CICSRequest node or CICS Connection policy. For detailed information about how to configure CICS security identity support, see command.

The CICSRequest node can use an identity that is present on an input message, and propagate it to CICS, by using the `Propagate` property on the security profile that is defined for the node. For more information, see “Propagating security credentials to CICS Transaction Server for z/OS” on page 1195 and “Identity and security token propagation” on page 2580.

You can use the CICSRequest node to connect to a CICS application by using a synchronous style of message flow. For details about how to use this node in a message flow, see CICSRequest node.

CICS Transaction Server for z/OS two-tier connectivity

The CICSRequest node support in IBM App Connect Enterprise provides direct communication with CICS Transaction Server for z/OS (two-tier connection) by sending Distributed Program Link (DPL) requests over TCP/IP-based IP InterCommunications (IPIC) protocol.

The CICSRequest node also supports communication with CICS through CICS Transaction Gateway (three-tier connection). For more information about three-tier connections, see “CICS Transaction Server for z/OS three-tier connectivity” on page 1181.

A direct two-tier connection from IBM App Connect Enterprise to CICS can be made by using the CICS Connection policy or by setting the properties directly on the CICSRequest node.

CICS Connection policy connections:

A CICS connection from IBM App Connect Enterprise is made to a listening TCPIPSERVICE resource in CICS. When that connection is established, the active connection between IBM App Connect Enterprise and CICS is represented by an IPCONN resource.

Each CICS Connection policy results in a separate connection to CICS, so for every policy that is being used, there is an IPCONN resource in CICS. The properties of the IPCONN resource determine the properties of the link between IBM App Connect Enterprise and CICS.

The IPCONN resource that represents an IBM App Connect Enterprise to CICS connection can be created in two different ways; autoinstall or pre-defined.

Autoinstall:

Autoinstalling a connection means that when IBM App Connect Enterprise connects, the resource is created, and when IBM App Connect Enterprise disconnects, the resource is discarded. In this setup, the IPCONN is created from a template IPCONN that is named by a user-replaceable-module (URM), which is named in the TCPIPSERVICE resource. Properties of the IPCONN are based on that template resource.

Pre-defined:

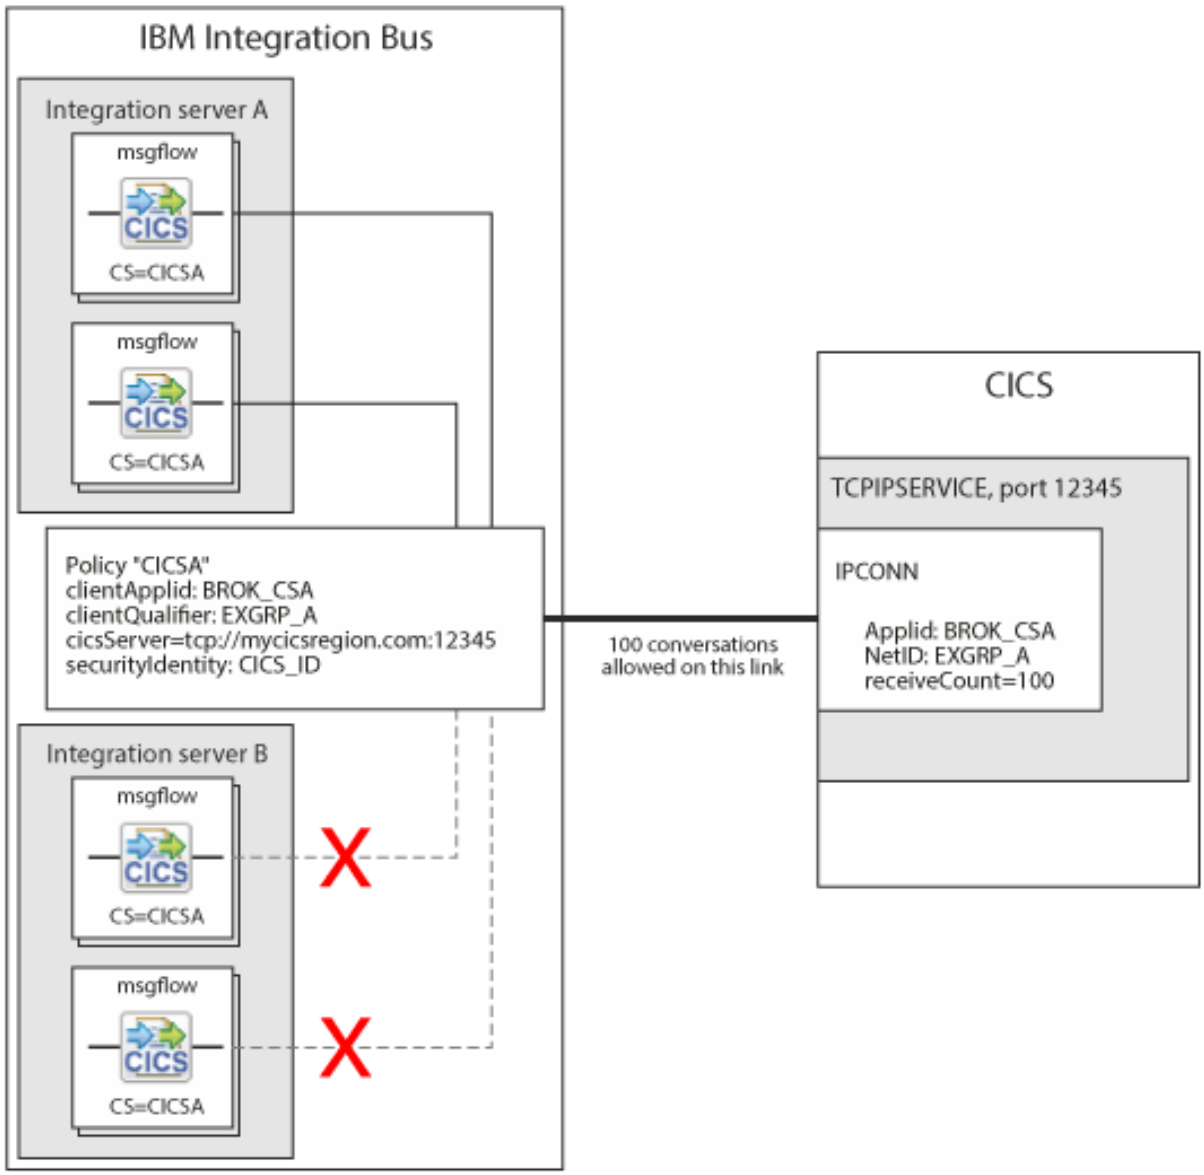
Alternatively, the IPCONN can be pre-defined by using standard CICS resource definition mechanisms, such as CICS Explorer, CEDA, or CICSPlex® Systems Manager (CICSPLEX SM). If the

IPCONN definition is created in advance, it is matched to the incoming connection by using the IPCONN APPLID and Network ID properties, which correlate to the `CICS APPLID` and `CICS APPLID qualifier` properties that can be set on a CICS Connection policy.

The advantage of pre-specifying the IPCONN is that you can tightly control the properties of incoming connections, including the security properties and the number of simultaneous requests. However the following rules apply:

- Do not configure different integration servers to use the same CICS Connection `CICS APPLID` and `CICS APPLID qualifier` combination to connect to the same CICS region. An IPCONN is tied to IBM App Connect Enterprise through the CICS Connection policy properties `CICS APPLID` and `CICS APPLID qualifier`. If this is attempted, only the first policy successfully connects.
- Do not specify a host name and port when defining the IPCONN resource in CICS. These fields are used for connections between CICS regions only, they must not be set for IBM App Connect Enterprise connections.

The following diagram shows how IBM App Connect Enterprise can directly connect to CICS by using a CICS Connection policy.



The two-tier direct CICS connection model is based on the following rules:

- Each policy name results in a separate connection to CICS.
- The CICS Connection policy must only be used from one integration server, because any further integration servers attempting to use the same policy thereafter fail to connect.
- The `CICS APPLID` and `CICS APPLID qualifier` properties in the policy are used to find the IPCONN resource in CICS. A chosen `CICS APPLID` and `CICS APPLID qualifier` combination must be unique to the CICS region. Only one IPCONN resource can exist with that combination.
- More than one message flow instance can use the CICS connection, however each request that goes through a CICSRequest node uses a conversation on the connection for the duration of the request.

When defining an IPCONN resource in CICS, consider the following properties:

- **CICS APPLID and Network ID**

  The CICS APPLID and Network ID properties must match the CICS Connection policy `clientApplid` and `clientQualifier` properties.

- **CICS host name and Port number**

  The CICS host name and port properties must be used for connections between CICS regions only, they must not be set for IBM App Connect Enterprise connections.

- **CICS TCPIPSERVICE**

  IPCONNs are owned by a parent TCPIPSERVICE resource in CICS.

- **CICS Receivecount**

  The CICS Receivecount property controls the number of simultaneous requests that can be performed over the connection. The number of simultaneous requests defaults to 100 for autoinstalled connections.

- **CICS Sendcount**

  The Sendcount property must be set to 0 because the Sendcount property is used for CICS connections only, and must not be used for IBM App Connect Enterprise connections.

- **CICS LINKAUTH**

  The CICS LINKAUTH property controls how the link security is managed. To use a resource in CICS, two security checks are performed; the "flowed" user, which checks the security credentials that are sent from IBM App Connect Enterprise, and the "link" user, which must also have permission for the resource. Both user IDs must have permission to use the resource before the request is granted. The link user ID is given low privileges, which means that even if the flowed user has many permissions, the link user ID can be used to cap the privilege of the connection. If LINKAUTH is set to SECUSER, the SECURITYNAME field is used to specify the link user ID. If set to CERTUSER, the link user is determined from an SSL client certificate that is mapped by RACF. If USERAUTH(IDENTIFY) or USERAUTH(VERIFY) is specified, the link user ID is not used. Only the user ID received from the TOR is used to determine security.

- **CICS USERAUTH**

  The CICS USERAUTH property determines how the flowed user security is configured. If USERAUTH is set to "LOCAL" or "DEFAULTUSER", no user ID or password is to be sent to CICS on a request. This means that all requests use the CICS region ID. If USERAUTH is set to "IDENTIFY", user IDs are flowed without a password. If USERAUTH is set to "VERIFY", user IDs and passwords are required. If USERAUTH(IDENTIFY) or USERAUTH(VERIFY) is specified, the link user ID is not used. Only the user ID received from the TOR is used to determine security.

Each CICSRequest node in a message flow acts as a request on one of the connections to CICS. Which connection is used is determined by the policy that is used.

For more information about configuring the CICSRequest node to get connection details from a CICS Connection policy, see “Changing connection information for the CICSRequest node” on page 1194.

You can configure the CICSRequest node or a CICS Connection policy to use SSL protocol. For more information, see “Securing the connection to CICS Transaction Server for z/OS by using SSL” on page 1182.

CICSRequest node connections:

If a CICS Connection policy is not specified on the CICSRequest node, and a host name is used directly in the `CICS server` property, the request shares a connection with other resources that have specified the same `CICS server` URL. The first CICSRequest node to be used opens the connection to CICS, regardless of whether a URL or a policy is specified in the `CICS server` property.

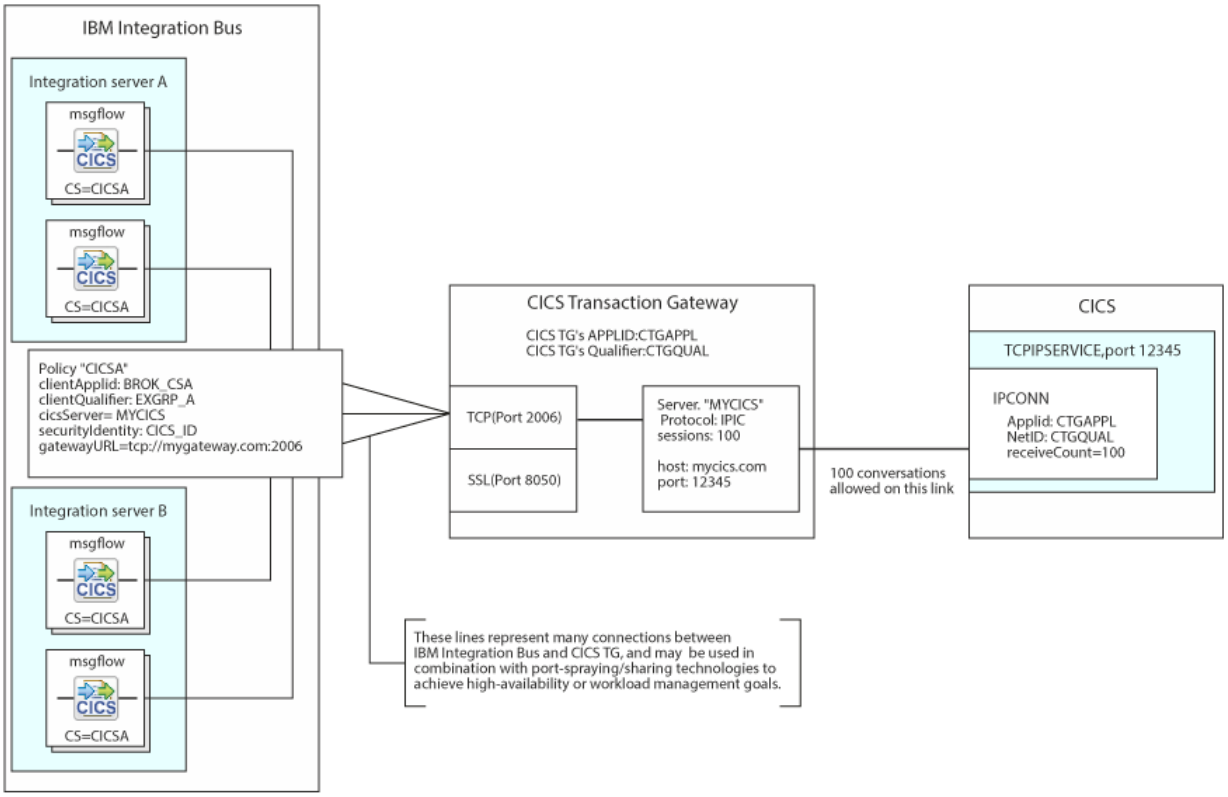
CICS Transaction Server for z/OS three-tier connectivity

The CICSRequest node support in IBM App Connect Enterprise can provide communication with CICS Transaction Server for z/OS through CICS TG (three-tier connection).

The CICSRequest node also supports direct communication with CICS (two-tier connection) by sending Distributed Program Link (DPL) requests over TCP/IP-based IP InterCommunications (IPIC) protocol. For more information about two-tier connections, see "CICS Transaction Server for z/OS two-tier connectivity" on page 1177.

A three-tier connection from IBM App Connect Enterprise to CICS through CICS TG can be made by configuring the `CICS Server` and `CICS Transaction Gateway URL` CICS Connection policy properties.

The following diagram shows how IBM App Connect Enterprise can make a connection to CICS through CICS TG by using the CICS Connection policy.



For more information about configuring the `CICS server` and `CICS Transaction Gateway URL` CICS Connection policy properties to make a three-tier connection, see CICS Connection policy (CICSConnection).

The three-tier connection to CICS through CICS TG connection model is based on the following rules:

- The number of connections that can be made to CICS TG is determined by the maximum number of simultaneous CICS requests in progress. Ensure that the Connection Manager and Worker Thread resources in your CICS TG deployment have sufficient capacity to handle the number of required IBM App Connect Enterprise connections.
- The `CICS APPLID` and `CICS APPLID qualifier` properties in the CICS Connection policy can be used to identify the IBM App Connect Enterprise connection within CICS TG. In addition, any CICS tasks that are started through the policy each contain point of origin information, including the specified client APPLID and qualifier, which you can find in the CICS task association data.
- Unlike two-tier connections, there is no restriction about sharing client APPLIDs between integration servers because the connection is made to CICS TG, and not to CICS directly.

For more information about configuring the CICSRequest node to get connection details from a CICS Connection policy, see "Changing connection information for the CICSRequest node" on page 1194.

Securing the connection to CICS Transaction Server for z/OS by using SSL
Configure the CICSRequest node to communicate with CICS Transaction Server for z/OS over the Secure Sockets Layer (SSL) protocol by updating a CICS Connection policy or the CICSRequest node to use SSL.

Before you begin

Ensure that you have completed the following tasks:

1. The CICSRequest node does not support a separate truststore, so the keystore file must provide both personal and signer certificates. If client-authentication (CLIENTAUTH) is enabled in the TCPIPSERVICE in CICS, the IBM App Connect Enterprise keystore file must also contain a personal certificate that is trusted by CICS.
2. Define the COMMAREA data structure as a message set, as described in "Defining a CICS Transaction Server for z/OS data structure" on page 1186.
3. Configure IP InterCommunications (IPIC) protocol on CICS, as described in "Preparing the environment for the CICSRequest node" on page 1187.

About this task

To configure the CICSRequest node to use SSL, complete the following steps:

Procedure

1. For client-authenticated (CLIENTAUTH) SSL connections, CICS expects the SSL client certificate to be mapped to a RACF user ID. Therefore the SSL client certificate must be mapped to a RACF user ID before attempting to establish the SSL connection to CICS. If the client certificate is not mapped to a RACF user ID, IBM App Connect Enterprise might display a `ECI_ERR_NO_CICS` response. You can map a client certificate to a RACF user ID by using the RACF command **RACDCERT**, which stores the client certificate in the RACF database and associates a user ID with it, or by using RACF certificate name filtering. Client certificates can be mapped one-to-one with a user ID, or a mapping from one to

the other can be provided to allow a many-to-one mapping. You can achieve this mapping by using one of the following methods:

- **Associating a client certificate with a RACF user ID**

  a. Copy the certificate that you want to process into an MVS™ sequential file. The file must have variable length, blocked records (RECFM=VB), and be accessible from TSO.

  b. Run the **RACDCERT** command in TSO by using the following syntax:

  ```
  RACDCERT ADD('datasetname') TRUST [ ID(userid) ]
  ```

  Where:

  – *datasetname* is the name of the data set containing the client certificate.

  – *userid* is the user ID to be associated with the certificate. This parameter is optional. If omitted, the certificate is associated with the user issuing the **RACDCERT** command.

  When you issue the **RACDCERT** command, RACF creates a profile in the DIGTCERT class. This profile associates the certificate with the user ID. You can then use the profile to translate a certificate to a user ID without giving a password. For full details of RACF commands, see z/OS Security Server RACF Command Language Reference.

- **RACF certificate name filtering**

  With certificate name filtering, client certificates are not stored in the RACF database. The association between one or more certificates and a RACF user ID is achieved by defining a filter rule that matches the distinguished name of the certificate owner or issuer (CA). A sample filter rule might look like the following example:

  ```
  RACDCERT ID(DEPT3USR) MAP SDNFILTER
  (OU=DEPT1.OU=DEPT2.O=IBM.L=LOC.SP=NY.C=US)
  ```

  This sample filter rule would associate user ID DEPT3USR with all certificates when the distinguished name of the certificate owner contains the organizational unit DEPT1 and DEPT2, the organization IBM, the locality LOC, the state/province NY, and the country US.

2. Turn on SSL support in the integration server by setting the `CICS Server` property on the CICS Connection policy.

   Alternatively you can configure the `CICS server` property directly on the CICSRequest node.

What to do next

When you have configured the integration server or the CICSRequest node to use SSL, develop a message flow that contains a CICSRequest node by following the steps in “Developing a message flow with a CICSRequest node” on page 1188.

CICS Transaction Server for z/OS mirror transactions

You can use a mirror transaction to group CICS Transaction Server for z/OS tasks and programs together. This grouping greatly assists stat collection, accounting, and aids decision making about task priority.

You can specify a mirror transaction name on the CICSRequest node for CICS tasks and programs to run under. For example, if each department in a business has a different mirror transaction name, work can be tracked back to the correct source, and decisions about task priority and quality of service (QoS) can be made in CICS. Potentially, different security privileges might be available depending on the transaction name chosen. Or the transaction name might be used as a way of indicating the origin of the task. Alternatively, a mirror transaction can be used to denote whether code page translation of the commarea data is required.

There are two ways that a mirror transaction can be specified:

Specifying a mirror transaction name that corresponds with a defined TRANSACTION resource in CICS:

You can specify a mirror transaction name by configuring the `Mirror transaction ID` property on the CICSRequest node Basic tab, however the `Mirror transaction ID` property value that you specify must correspond to a defined TRANSACTION resource in CICS. For example, if you have a defined TRANSACTION resource of ATRN in CICS, and you want tasks and programs to run under that transaction, you must configure ATRN as the `Mirror transaction ID` property value.

When the message flow containing the configured CICSRequest node is deployed, any CICS programs that are started thereafter appear in CICS as running under the specified mirror transaction.

Specifying a weaker form of mirror transaction that does not require a TRANSACTION resource to be defined in CICS:

You can use a weaker form of mirror transaction that does not change the TRANSACTION resource, but instead sets a variable called `EIBTRNID`, which is available to the called program. You can configure the `EIBTRNID` variable to tell the program what TRANSACTION resource it is running under, without the TRANSACTION resource being defined in CICS.

For example, you can specify this weaker form of mirror transaction by configuring the `Mirror transaction ID` property with the name of the required TRANSACTION resource; for example ATRN, and by selecting the `Set EIBTRNID only` property on the CICSRequest node Basic tab.

When the message flow containing the configured CICSRequest node is deployed, any CICS programs that are started thereafter appear in CICS as running under the specified mirror transaction.

If the value of the CICSRequest node `Mirror transaction ID` property is not set, the mirror transaction name defaults to `CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system.

The following table describes the mirror transaction handling that is applied depending on the configuration of the `Mirror transaction ID` and `Set EIBTRNID only` CICSRequest node properties. Where ATRN is an example of a user-defined transaction name:

Mirror transaction ID property value	**Set EIBTRNID only property value**	**Task and programs run under defined TRANSACTION resource:**	**EIBTRNID is:**
Blank	Cleared	`CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system	`CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system
ATRN	Cleared	ATRN	ATRN
ATRN	Selected	`CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system	ATRN

If you are considering whether to use a mirror transaction as a way of finding the point of origin of your data, using the CICS task association data might be a better alternative. All tasks that are initiated in CICS over IP InterCommunications (IPIC) protocol contain origin information, including source Internet Protocol (IP) and APPLID information.

The CICS mirror transaction properties can be changed by configuring the properties directly on the CICSRequest node, by using the **mqsiapplybaroverride** command, or by dynamically overriding these property values with elements in the message tree, on a per message basis, in the local environment. For more information about dynamically overriding CICSRequest node values, see "Local environment overrides for the CICSRequest node" on page 1185 and for information about the **mqsiapplybaroverride** command, see Configurable properties of message flow nodes.

Local environment overrides for the CICSRequest node
When you use the CICSRequest node in a message flow, you can override some of its properties with elements in the message tree.

You can dynamically override values, on a per message basis, in the local environment. You can override the CICS Transaction Server for z/OS program that you are calling, the COMMAREA length, mirror transactions, and the processing of the response message.

You can set the following values under `LocalEnvironment.Destination.CICS`.

Setting	Description
CICSProgramName	Overrides the `Program name` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.CICSProgramName = 'progx';` You can override the location of this value by using a property on the CICSRequest node.
CICSCommareaLen	Overrides the `Commarea length` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.CICSCommareaLen = 100;`
mirrorTran	Overrides the `Mirror transaction ID` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.mirrorTran = 'ATRN';`
eibtrnidOnly	Overrides the `Set EIBTRNID only` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.eibtrnidOnly = 'TRUE';` Valid values are TRUE, FALSE, YES, or NO. Where TRUE or YES represents a selected check box for the `Set EIBTRNID only` property in the IBM App Connect Enterprise Toolkit. Where FALSE or NO represents a cleared check box in the IBM App Connect Enterprise Toolkit.

You can set the following values under `LocalEnvironment.Destination.CICS.Response`.

Setting	Description
messageDomain	Overrides the `Message domain` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageDomain = 'MRM';`
messageSet	Overrides the `Message set` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageSet = '{com.test}:MyMessageSet';`
messageType	Overrides the `Message type` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageType = 'messageA';`
messageFormat	Overrides the `Message format` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageFormat = 'XML1';`
messageCCSID	Overrides the `Message coded character set ID` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageCCSID = 500;`

Setting	Description
messageEncoding	Overrides the `Message encoding` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageEncoding = 785;`

You can also set LocalEnvironment values for CICS channels and containers. For more information, see "COMMAREA or channel data structures" on page 1171.

Connecting to a CICS Transaction Server for z/OS application

Connecting to a CICS Transaction Server for z/OS application involves creating a message flow, building a message, and processing the response from the CICSRequest node.

About this task

To connect to a CICS application, complete the following steps.

Procedure

1. Define the COMMAREA data structure as a message set, as described in "Defining a CICS Transaction Server for z/OS data structure" on page 1186.
2. Configure IP InterCommunications (IPIC) protocol on CICS, as described in "Preparing the environment for the CICSRequest node" on page 1187.
3. Optional: Configure the CICSRequest node to communicate with CICS Transaction Server for z/OS over the Secure Sockets Layer (SSL) protocol, as described in "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 1182.
4. Develop a message flow that contains a CICSRequest node, as described in "Developing a message flow with a CICSRequest node" on page 1188.
5. Build a message to send to the CICSRequest node, as described in "Building a message for the CICSRequest node" on page 1191.
6. Process the response from the CICSRequest node, as described in "Processing responses from a CICSRequest node" on page 1193.

What to do next

You can change the connection details for the CICSRequest node by using the CICS Connection policy, as described in "Changing connection information for the CICSRequest node" on page 1194.

The CICSRequest node can also use an identity that is present on an input message, and propagate it to CICS, by using the `Propagate` property on the security profile that is defined for the node. For more information, see "Propagating security credentials to CICS Transaction Server for z/OS" on page 1195

Defining a CICS Transaction Server for z/OS data structure

Mapped data structures, such as COBOL copybooks or C structures, can be used to define an MRM message definition for a CICS Transaction Server for z/OS COMMAREA or a channel container.

Before you begin

- Optional: If you are using a COMMAREA data structure, read the COMMAREA concept information that is defined in the CICS Transaction Server for z/OS Version 4.1 product documentation online.
- Read the COMMAREA and channel concept information that is defined in "COMMAREA or channel data structures" on page 1171.

- Create a message definition file by using the New Message Definition File wizard in the IBM App Connect Enterprise Toolkit.
  - If you are using a C header file, see "Message Sets: Importing from C" on page 2300.
  - If you are using a COBOL data structure, see "Message Sets: Importing from COBOL copybooks" on page 2302.
  - For information about other data structures, see "Message Sets: Working with data structures" on page 2299.

About this task

After you have created the message definition, complete the following steps.

Procedure

1. Select the `Data structure` property value on the **Basic** tab of the CICSRequest node in accordance with the targeted CICS program. For example, if the target program is channel-based, select `Channel` as the data structure.
2. Ensure that the properties on the **Response Message Parsing** tab of the CICSRequest node specify the output COMMAREA or container structure.
3. Check that the upstream nodes are configured to provide the correct input structure.
4. Optional: If you are using a COMMAREA data structure, ensure that the CICSRequest node `Commarea length` property is large enough to hold the serialized input or output structures to avoid a memory leak in the CICS application.

What to do next

If you are using a channel data structure, create a message collection to represent the channel data structure, as described in "Creating a message collection by using ESQL" on page 1843.

Preparing the environment for the CICSRequest node

Before you can use the CICSRequest node, you must configure IP InterCommunications (IPIC) protocol on the target CICS Transaction Server for z/OS.

Before you begin

Read "CICS Transaction Server for z/OS connectivity" on page 1175 for background information.

About this task

The CICSRequest node can send IPIC requests over TCP/IP to CICS Transaction Server for z/OS. Complete the following steps on CICS to perform this configuration:

Procedure

1. Set the System Initialization (SIT) parameter **TCPIP=YES**.
2. Define the TCP/IP address and host name for CICS. By default, they are defined in the PROFILE.TCPIP and TCPIP.DATA data sets.

3. Add a TCP/IP listener to CICS by using the following **CEDA** command to define a TCPIPSERVICE resource in a group:

```
CEDA DEF TCPIPSERVICE(service-name) GROUP(group-name)
```

Ensure that the group in which you define the service is in the GRPLIST system initialization parameter, so that the listener starts when CICS is started. Key fields are explained as follows:

POrtnumber:
The port on which the TCP/IP service listens.

PROtocol:
The protocol of the service is IPIC.

TRansaction:
The transaction that CICS runs to handle incoming IPIC requests. Set the field to CISS, which is the default.

Backlog:
The Backlog field is the number of TCP/IP connection requests are sent to CICS, which are placed in a TCP/IP queue to be assigned an IPCONN connection to CICS. The default value is 1. Do not use a value of 0; a value of 0 indicates that no TCP/IP connection requests are to be assigned an IPCONN connection to CICS, which disables incoming connection requests.

Ipaddress:
The IP address, in dotted decimal form, on which the TCPIPSERVICE resource listens. For configurations with more than one IP stack, specify ANY to make the TCPIPSERVICE resource listen on all addresses.

SOcketclose:
Whether CICS waits before closing the socket after issuing a receive for incoming data on that socket. To ensure that the connection from the CICSRequest node always remains open, set SOcketclose to NO for IPIC connections.

SSl:
Whether the CICS TCP/IP service is to use Secure Sockets Layer (SSL) protocol for encryption and authentication. Valid values are NO, YES, or CLIENTAUTH. Where:

- NO indicates that SSL is not to be used.
- YES indicates that the personal certificate of the CICS region must be trusted by IBM App Connect Enterprise.
- CLIENTAUTH indicates that the personal certificate of the CICS region must be trusted by IBM App Connect Enterprise, and the IBM App Connect Enterprise personal certificate must be trusted by CICS.

  The CICSRequest node does not support a separate truststore, so the keystore file must provide both personal and signer certificates. For more information, see “Securing the connection to CICS Transaction Server for z/OS by using SSL” on page 1182.

4. Use the following command to install the TCPIPSERVICE definition:

```
CEDA INS TCPIPSERVICE(service-name) GROUP(group-name)
```

Developing a message flow with a CICSRequest node
To connect to a CICS Transaction Server for z/OS application, create a message flow that contains a CICSRequest node.

Before you begin

Ensure that you have completed the following tasks:

1. Define the COMMAREA or channel data structure, as described in “Defining a CICS Transaction Server for z/OS data structure” on page 1186.

2. Optional: If you are using a channel data structure, create a message collection to represent the channel data structure, as described in "Creating a message collection by using ESQL" on page 1843.
3. Configure IP InterCommunications (IPIC) protocol on CICS, as described in "Preparing the environment for the CICSRequest node" on page 1187.
4. Optional: Configure the CICSRequest node to communicate with CICS Transaction Server for z/OS over the Secure Sockets Layer (SSL) protocol, as described in "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 1182.

About this task

Complete the following steps to develop a message flow with a CICSRequest node.

Procedure

1. Create a message flow.
2. Add a CICSRequest node to the message flow.
3. Configure the following properties on the CICSRequest node.
   - `CICS server`: The `CICS server` property can be defined either as a policy name, for example *myCICSConnection*, or as a URL.

     You can either connect to CICS by using the two-tier connection model; for example, by making a direct connection from IBM App Connect Enterprise to CICS, or by using the three-tier connection model; for example, by connecting to CICS through CICS Transaction Gateway. For more information about the two-tier and three-tier connection models, see "CICS Transaction Server for z/OS overview" on page 1170 for a high-level overview, or "CICS Transaction Server for z/OS two-tier

connectivity" on page 1177 and "CICS Transaction Server for z/OS three-tier connectivity" on page 1181 for detailed conceptual information.

Using the two-tier connection model:
If you are making a direct two-tier connection from IBM App Connect Enterprise to CICS, you can define the `CICS server` property either as a policy name, for example *myCICSConnection*, or as a URL.

For more information about defining this property as a policy, see "Changing connection information for the CICSRequest node" on page 1194.

To define a URL, specify the protocol and the CICS host name and port number. The format of this value is *protocol*`://`*hostname*`:`*port*. Where:

- *protocol* can be `tcp` or `ssl`.
- *hostname* is the TCP/IP address of the CICS host.
- *port* is the port number of the TCPIPSERVICE listener in CICS that is listening for IPIC requests over TCP/IP or SSL.

For example: `tcp://mycicsregion.com:12345` or `ssl://mycicsregion.com:56789`. You can obtain the *hostname* and *port* values from the IPIC TCPIPSERVICE definition in the target CICS region.

Using the three-tier connection model:
If you are making a three-tier connection to CICS through CICS Transaction Gateway, the `CICS server` CICSRequest node property must be defined as a policy name, for example *myCICSConnection*.

For more information about defining this property as a policy, see "Changing connection information for the CICSRequest node" on page 1194.

To make a three-tier connection to CICS through CICS Transaction Gateway, you must configure the `CICS Server` and `CICS Transaction Gateway URL` CICS Connection policy properties (see CICS Connection policy (CICSConnection)).

- `Program name`: Specify the name of the program that you want to run in the target CICS region.

  You can override this property in the local environment by specifying a value in the following location:

  ```
  $LocalEnvironment/Destination/CICS/CICSProgramName
  ```

- `Data structure`: Specify whether to use a COMMAREA or a channel data structure. The default for this property is `Commarea`. The decision depends on the targeted CICS program, for example; whether the target program is channel-based or not.
- `Commarea length`:

  This property is not configurable if a value of `Channel` is selected for the `Data structure` property.

  The `Commarea length` property is the size, in bytes, of the COMMAREA that is used by the CICS program. The byte size value is sent to CICS, and before the program is started, an area of memory is created to match that number. For example, if you send a `Commarea length` value of `100`, 100 bytes are allocated. The program accesses this area as the `DFHCOMMAREA`.

  Ensure that the `Commarea length` property value is large enough to contain the input request data, or the output response data, but that it does not exceed the maximum value of 32767 bytes. If the

Commarea length value is not large enough to be used for the response data, or the request data, a memory leak occurs in CICS.

The size of the COMMAREA cannot be changed by the CICS program.

If the serialized request data is larger than the Commarea length, the data is truncated to the Commarea length.

You can obtain the Commarea length value from the CICS administrator or developer.

You can override this property in the local environment by specifying a value in the following location:

```
$LocalEnvironment/Destination/CICS/CICSCommareaLen
```

- Transaction mode: Specify whether requests to the CICSRequest node are to managed as transactional or non-transactional.
  - If you select Yes, the CICSRequest node takes part in the local transaction that is started by the message flow's input node.
  - If you select No, the CICSRequest node does not take part in the local transaction that is started by the message flow's input node.
  - If you select Automatic, the message transactionality is inherited from the Transaction mode setting on the Input node at the start of the message flow. For example, if the message flow is driven by an MQInput node, the CICSRequest node assumes the Transaction mode that is set on the MQInput node. By default, the Transaction mode property of the CICSRequest node is set to Automatic.

4. Save the message flow.
5. Deploy the message flow.

What to do next

When you have created and configured the message flow, build a message by following the steps in “Building a message for the CICSRequest node” on page 1191.

Building a message for the CICSRequest node

Create a message definition from a data structure and build a message by using another message flow node.

About this task

You can specify the location in the incoming message tree from which data is retrieved to form the request that is sent by the CICSRequest node. Specify this location by using the Data location Request property on the CICSRequest node. For more information, see “Combining a result message with an input message when fetching data from external systems” on page 1811.

Procedure

1. Find out what data needs to be in the body of the message to send to the CICSRequest node. The message body data must match the input structure that is required for your commarea, as defined in a message set definition based on the language structure. For example; COBOL or C copybook.
2. Ensure that the Commarea length Basic property value that is configured in the CICSRequest node is large enough to contain the input request data, or the output response data, but that it does not exceed the maximum value of 32767 bytes. If the Commarea length value is not large enough to be used for the response data, or the request data, a memory leak occurs in CICS. The size of the commarea cannot be changed by the CICS program. If the serialized request data is larger than the Commarea length, the data is truncated to the Commarea length. You can obtain the Commarea length value from the CICS administrator or developer.

Example

The following example shows a message that has been modeled in the MRM domain, which can be received by a CICSRequest node and sent to CICS.

COBOL copybook

This example shows the structure of the data that CICS is expecting. The copybook describes the binary layout of the data that the CICS program expects to receive.

```
01 DFHAXCS-REQUEST.
   10 AXCS-COMMAND                  PIC S9(9) COMP.
   10 AXCS-FILE                     PIC X(8).
   10 AXCS-RIFLD                    PIC X(6) VALUE SPACES.
   10 AXCS-DATA.
      15 AXCS-STAT                  PIC X(1)  VALUE SPACES.
      15 AXCS-RECID                 PIC X(6)  VALUE SPACES.
      15 AXCS-NAME                  PIC X(20) VALUE SPACES.
      15 AXCS-ADDRESS               PIC X(20) VALUE SPACES.
      15 AXCS-PHONE                 PIC X(8)  VALUE SPACES.
      15 AXCS-DATE                  PIC X(8)  VALUE SPACES.
      15 AXCS-AMOUNT                PIC X(8)  VALUE SPACES.
      15 AXCS-COMMENT               PIC X(9)  VALUE SPACES.
```

The example copybook can be used to create a binary structure that requires 98 bytes of COMMAREA or memory space, as shown in the following example:

Table 37.

Name	**Type and Size**
AXCS-COMMAND	4 byte integer (fullword)
AXCS-FILE	8 byte character string
AXCS-RIFLD	6 byte character string
AXCS-STAT	1 byte character string
AXCS-RECID	6 byte character string
AXCS-NAME	20 byte character string
AXCS-ADDRESS	20 byte character string
AXCS-PHONE	8 byte character string
AXCS-DATE	8 byte character string
AXCS-AMOUNT	8 byte character string
AXCS-COMMENT	9 byte character string
Total	**98 bytes**

The COBOL copybook structure must be imported as a message definition, see “Message Sets: Importing from COBOL copybooks” on page 2302 for further information, and a message containing such a structure must be passed to the CICSRequest node. A second copybook might be required to map the returning COMMAREA.

What to do next

Process the responses from the CICSRequest, as described in “Processing responses from a CICSRequest node” on page 1193.

Processing responses from a CICSRequest node
The CICSRequest node can return different response messages that indicate the success or failure of the request sent to CICS Transaction Server for z/OS.

Before you begin

Ensure that you have built a message for the CICSRequest node, as described in "Building a message for the CICSRequest node" on page 1191.

About this task

The CICSRequest node has four output terminals:

- Out: The output terminal from which the message tree is propagated, including the data returned from CICS.
- Failure: The output terminal to which a message is routed if a CICSRequest node exception is detected, or a CICSRequest node to CICS connection failure occurs.
- Error: The output terminal to which a message is propagated if a CICS error (abend) occurs.
- Timeout: The output terminal to which the message is propagated if a per-request timeout occurs when an individual request is sent to CICS, but the request takes too long.

You can select the location to which to send the response by configuring the `Output data location` Result property on the CICSRequest node. This property specifies the location in the message tree to which the CICSRequest node places the output.

Procedure

- **Processing successful calls**

  When a CICSRequest node successfully calls a CICS application, the resulting message is propagated to the Out terminal.

- **Processing CICS abends**

  An abend in CICS causes a message to be propagated from the Error terminal. The input message is propagated with a CICS\AbendCode field in the LocalEnvironment. If the Error terminal is not connected, the abend is lost.

  If an abend occurs and the CICSRequest node is configured to participate in the integration node transaction, all work carried out as part of the CICS task is immediately rolled back. If multiple CICS nodes are involved in the unit of work, the CICS activity of each of the nodes is rolled back, whether or not the abend is handled through an error or failure terminal. Any further work carried out by CICS as part of processing the message is carried out under a new unit of work.

  A unit of work is the work that is carried out by nodes in a flow that share the same resource; in this case, a unit of work is all the work that is carried out by CICSRequest nodes in a flow that are connected to the same CICS server (through a URL or policy defined in the **`CICS server`** property). For example, if a message flow contains five CICS nodes, three of which are connected to CICS server A and two of which are connected to CICS server B, all the work that is carried out by nodes connected to server A forms one unit of work, and all the work that is carried out by nodes connected to server B forms a separate unit of work. If an abend occurs in one of the CICS nodes that are connected to CICS server A, the work carried out by all the CICS nodes in the flow that are connected to server A is rolled back, because it forms a single unit of work. Any subsequent work that is carried out by a CICSRequest node connected to server A will start a new unit of work, and the unit of work for server B is unaffected by the rollback of the unit of work for server A.

- **Processing request timeouts**

  If a CICSRequest node is configured with a `Request timeout` Basic property, and a particular message takes longer than the specified time in seconds to be processed, the request fails and the message is propagated from the Timeout terminal. The output message contains the input message

body and a timeout exception in the ExceptionList. If the Timeout terminal is not connected and a timeout occurs, the request timeout exception is routed to the Failure terminal. If the Failure terminal is not connected, the integration node throws an exception and returns control to the closest upstream node that can process it. The default behavior is that the message is returned to the input node.

- **Handling failures in the CICS node**

  Any other failures are propagated to the Failure terminal. Possible failures include:

  – An inability to communicate with the target CICS region.

  – An internal CICSRequest node exception is detected.

  – An invalid message body. For example, a parsing error or input message is creating a structure that is larger than the `Commarea length` Basic property that is configured in the CICSRequest node. A similar situation for the returning COMMAREA cannot be detected. For example, if the returning data is larger than the value that is defined in the `Commarea length` property, a memory leak occurs in CICS. Therefore the `Commarea length` Basic property must be correctly configured.

Results

You can use the CICS Connection policy to change connection details for the CICSRequest node (see "Changing connection information for the CICSRequest node" on page 1194).

Changing connection information for the CICSRequest node

You can create a policy that the CICSRequest node or message flow refers to at run time for connection information, instead of defining the connection properties on the node or the message flow. The advantage being that you can change the host name and performance values without needing to redeploy your message flow.

Before you begin

- Read "CICS Transaction Server for z/OS overview" on page 1170 for background information.

About this task

Use the CICS Connection policy to change the CICS Transaction Server for z/OS connection information for the CICSRequest node (see CICS Connection policy (CICSConnection)). The advantage of using a policy is that you can change the host name, performance, and security identity values without needing to redeploy your message flow.

You can use the CICS Connection policy to configure the CICSRequest node to use Secure Sockets Layer (SSL) protocol (see "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 1182).

Procedure

- Create a CICS Connection policy by using the Policy editor in the IBM App Connect Enterprise Toolkit (see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327).
- Set the properties of the policy to appropriate values, then save the policy.
- Ensure that the CICS server property on the CICSRequest node is set to the name of the policy. The policy name must be in the format *{policyProjectName}:PolicyName*.
- You can deploy the CICS Connection policy in the same BAR file as the associated CICSRequest node, or in a standalone BAR file. If you deploy the policy in a standalone BAR file, you must deploy it before you start the message flow that contains the CICSRequest node.

Propagating security credentials to CICS Transaction Server for z/OS
The CICSRequest node can use an identity that is present in the Properties folder of the message tree structure for the security credentials in a request, by using the `Propagate` property on the security profile that is defined on the node.

About this task

If a CICSRequest node is configured with a security profile, it extracts security tokens from the input message at run time, and propagates an identity to CICS.

Procedure

To propagate an identity to be used for the CICS request security credentials, complete the following steps.

1. Ensure that an appropriate security profile exists for the CICSRequest node, or create a security profile, by following the instructions in "Creating a security profile" on page 2584.
2. Use the BAR editor to select a security profile for the CICSRequest node that has identity propagation enabled.

   For detailed instructions, see "Configuring a message flow for identity propagation" on page 2613.

Working with Salesforce

IBM App Connect Enterprise provides a SalesforceRequest node, which enables you to communicate with Salesforce.com to create, retrieve, update, and delete Salesforce records.

About this task

IBM App Connect Enterprise communicates synchronously with Salesforce by using Loopback connector technology from Strongloop. The Loopback connector invokes Salesforce by using the Force.com REST API to perform create, retrieve, update, and delete operations on predefined and custom Salesforce object types in a Salesforce system. For more information, see the Force.com REST API Developer Guide. The SalesforceRequest node is available on Windows and Linux x64 systems, in all operation modes.

The following topics contain information that you need to understand before you can use the Salesforce support in IBM App Connect Enterprise:

- "Salesforce overview" on page 1196

See the node for information about configuring and using the SalesforceRequest node.

See the following topics for information about the tasks involved in communicating with Salesforce, and in accessing, creating, and modifying Salesforce records:

- "Configuring a secure connection to Salesforce.com" on page 1196
- "Accessing and creating Salesforce data in a message flow " on page 1197
- "Creating Salesforce records" on page 1198
- "Retrieving Salesforce records " on page 1199
- "Filtering the records retrieved from Salesforce" on page 1200
- "Updating Salesforce records" on page 1204
- "Deleting Salesforce records " on page 1205
- "Using local environment variables with Salesforce nodes" on page 1211
- "Using Salesforce models" on page 1212

See "Example: Retrieving all Account records from Salesforce" on page 1202 for a step-by-step example of using a SalesforceRequest node in a message flow.

Salesforce overview

IBM App Connect Enterprise enables you to interact with your Salesforce.com account in the cloud, by using a SalesforceRequest node in a message flow. You can use this capability to create, retrieve, update, and delete records in your Salesforce system directly from IBM App Connect Enterprise.

If you use Salesforce to manage your customer information and interactions, you can now use the SalesforceRequest node in IBM App Connect Enterprise to directly access your Salesforce data and update it with the latest information. This capability provides a way of integrating and simplifying the interactions between the systems in your existing infrastructure.

For information about using the SalesforceRequest node to interact with Salesforce, see "Working with Salesforce" on page 1195.

Configuring a secure connection to Salesforce.com

Access your security information through your Salesforce.com account, and then use this information to configure a security identity by using the **mqsisetdbparms** command in IBM App Connect Enterprise.

Before you begin

Decide which credentials IBM App Connect Enterprise will use when accessing Salesforce.com.

About this task

Follow these steps to create a Salesforce Connected App for use with IBM App Connect Enterprise, and to create a secure connection between the systems:

Procedure

Follow these steps to create a Connected App:

1. Log on to Salesforce.com using your chosen credentials and navigate to the **Apps** page.
2. Create a new Connected App for use with IBM App Connect Enterprise, and set the following properties:
   a) Set the `Connected App Name` property to `IBM Integration Bus`
   b) Set the `API Name` to `IBM_Integration_Bus`
   c) Specify your chosen contact email address.
   d) Select the `Enable OAuth Setting` check box.
   e) Set the `Callback URL` to any valid secure URL (this URL will not be used by your IBM App Connect Enterprise Connected App).
   f) Set the `Selected OAuth scopes` to `Access and manage your data (api).`
   g) Click **Save**.
3. Click **Manage** and ensure that the OAuth policy **Permitted Users** is set to `All users may self-authorize`. If this option is not selected, connections might fail even if the correct credentials are supplied.

Follow these steps to access the required security information from your Salesforce system:

4. Make a note of your Consumer Key and your Consumer Secret, which you will need later when you configure security for the connection.

   The Consumer Key and Consumer secret are generated by Salesforce when you create a Connected App.

5. Obtain the security token for the chosen Salesforce credentials. You can get this from the email that was sent to the email address associated with the credentials when the security token was last reset. Alternatively, you can reset it now by following these steps:
   a) From the Setup page, click your name and then click the **My Settings** menu option.
   b) Click **Reset My Security Token**.
      A message is displayed, informing you that the existing security token will be invalidated.
   c) Click the **Reset Security Token** button to confirm that you want to continue.
      The new security token is sent to your email address.

   For more information, see https://help.salesforce.com/apex/HTViewHelpDoc?id=basics_nav_personal_settings.htm&language=en.

Follow these steps to configure a secure connection between IBM App Connect Enterprise and your Salesforce system:

6. Use the **mqsisetdbparms** command to configure a security identity for the connection, by setting the following parameters:

   -n *salesforce::securityIdentity*
   The name of the security identity that is used to authenticate a connection to a Salesforce system, where *securityIdentity* is the value of the `Security Identity` property in the SalesforceRequest node.

   -u *UserId*
   The Salesforce user ID

   -p *Password*
   The password for accessing the Salesforce system, suffixed with the security token that was sent to you by Salesforce when you reset your security token (in Step 4)

   -c *ClientIdentity*
   The name of the consumer key of your Connected App.

   -s *ClientSecret*
   The consumer secret of your Connected App.

   For example:

   ```
   mqsisetdbparms -w c:\workdir\ACEServ1 -n salesforce::sf1 -u myUserID -p myPassword -
   c myClientIdentity -s myClientSecret
   ```

   For more information, see command. For information about the security credentials that have been set on the integration server, see command.

7. In your message flow, specify `sf1` as the value in the `Security identity` property in the SalesforceRequest node.
   This security identity will be used when you connect to your Salesforce system from IBM App Connect Enterprise.

Accessing and creating Salesforce data in a message flow

You can use the SalesforceRequest node to communicate with Salesforce.com, enabling you to create, retrieve, update, and delete Salesforce records.

Before you begin

Configure a secure connection to Salesforce.com (see “Configuring a secure connection to Salesforce.com” on page 1196).

About this task

The following topics explain how to work with records in a Salesforce system:

- “Creating Salesforce records” on page 1198
- “Retrieving Salesforce records ” on page 1199

- "Updating Salesforce records" on page 1204
- "Deleting Salesforce records " on page 1205

JSON schema are supplied for a wide range of Salesforce objects, and you can use them as input and output for message maps in a Mapping node. For example, you can create the message tree for a Salesforce Account record in a Mapping node by using the JSON schema for the Account object. For more information, see "Using Salesforce models" on page 1212.

Creating Salesforce records
Use the SalesforceRequest node to create a new record in the Salesforce system, for a specified Salesforce object such as an Account.

About this task

You can create a new Salesforce record by specifying `Create` in the `Operation` property of the SalesforceRequest node, and specifying the Salesforce resource type (such as Account) in the `Salesforce object` property. The object can be overridden by the `LocalEnvironment.Destination.Salesforce.Request.object` local environment variable.

The record that you are creating must exist in the input message tree as a JSON object.

When the Salesforce record is created, the input message tree is copied to the location specified by the `Output data location` property, and augmented with the newly assigned Salesforce ID in an *Id* element of the message. If an *Id* element is already in the input message tree, it is ignored.

JSON schema are supplied for a wide range of Salesforce objects, and you can use them as input and output for message maps in a Mapping node. For more information, see "Using Salesforce models" on page 1212.

Procedure

1. Set up a Salesforce account on Salesforce.com.
2. Configure the connection to Salesforce.com.
   See "Configuring a secure connection to Salesforce.com" on page 1196 for more information.
3. Create a flow containing a SalesforceRequest node, and set the node properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Salesforce URL` property, specify the URL of the external Salesforce system.
      - In the `Operation` property, specify `Create`.
      - In the `Salesforce object` property, specify the Salesforce object (for example, `Account`) for which you are creating a new record.
      - In the `Security identity` property, specify the security identity that you will use when connecting to the Salesforce system. For information about configuring the security identity on the integration node, see "Configuring a secure connection to Salesforce.com" on page 1196.
      - In the `Timeout` property, specify the time (in milliseconds) that the node waits for Salesforce to process the operation.
   b) On the **Request** tab, set the `Data location` property to specify the location in the incoming message tree that contains the JSON object data to be created in Salesforce; this data forms the request that is sent from the SalesforceRequest node to the Salesforce system.
   c) On the **Result** tab, set the `Output data location` property to specify the location in the output message tree that will contain the data of the record that is created in Salesforce.

   For more information, see node.
4. Send the required message through the flow to the Salesforce system.
   You will receive a confirmation message from the Salesforce system, which will include the Salesforce ID of the new record.
5. Go to your Salesforce account to verify that the new record has been created correctly.

Retrieving Salesforce records
Use the SalesforceRequest node to retrieve records from the Salesforce system.

About this task

You can retrieve Salesforce records by specifying `Retrieve` in the `Operation` property of the SalesforceRequest node. You can retrieve all records of a particular type by specifying the object type in the `Salesforce object` property of the node. This object type can be overridden by a value specified in the `LocalEnvironment.Destination.Salesforce.Request.object` local environment variable.

Alternatively, you can retrieve a specific record by specifying a Salesforce ID in the `LocalEnvironment.Destination.Salesforce.Request.id` environment variable. The returned record appears as a JSON object in the location that is specified by the `Output data location` property of the node.

If an external ID name and value are specified in the `LocalEnvironment.Destination.Salesforce.Request.externalIdName` and `LocalEnvironment.Destination.Salesforce.Request.externalId` environment variables, all records with that external ID are returned. The returned records appear as a JSON array in the location specified by the `Output data location` property.

If neither a Salesforce ID nor an external ID is specified, all records of the specified type are returned by default.

You can control the records that are returned by using the `LocalEnvironment.Destination.Salesforce.Request.filter` environment variable to specify a filter with one of the following clauses:

- `where`
- `limit`
- `skip`
- `order`
- `field`

You can control which records are returned by specifying a filter with a `where`, `limit`, or `skip` clause. If no ID has been specified, this filter is used to select the records to be returned.

If you specify a filter with an `order` clause, the records are returned in the specified order. For more information, see "Filtering the records retrieved from Salesforce" on page 1200.

You can also restrict the records that are returned by specifying a filter with a `field` clause, so that only the specified field is returned. Filtering with a `field` clause optimizes performance by reducing unnecessary processing.

By default, the retrieval of records is determined by the following properties, in order of precedence:

- Salesforce ID
- External ID
- Filter

If no Salesforce records are found, the output tree contains nothing under JSON.data.

JSON schema are supplied for a wide range of Salesforce objects, and you can use them as input and output for message maps in a Mapping node. For example, you can transform the message tree for a returned Salesforce Account record in a Mapping node by using the JSON schema for the Account object. For more information, see "Using Salesforce models" on page 1212.

Procedure

Follow these steps to retrieve Salesforce records:

1. Set up a Salesforce account on Salesforce.com.

2. Configure a connection to Salesforce.com.

   For more information, see “Configuring a secure connection to Salesforce.com” on page 1196
3. Create a flow containing a SalesforceRequest node, and set the following properties on the **Basic** tab:
   a) In the `Salesforce URL` property, specify the URL of the external Salesforce system.
   b) In the `Operation` property, specify `Retrieve`.
   c) In the `Salesforce object` property, select the type of Salesforce records that you want to retrieve.
   d) In the `Security identity` property, specify the security identity that you will use when connecting to the Salesforce system. For information about configuring the security identity on the integration node, see “Configuring a secure connection to Salesforce.com” on page 1196.
   e) In the `Timeout` property, specify the time (in milliseconds) that the node waits for Salesforce to process the operation.

   For more information, see node.
4. Send the required message through the flow to the Salesforce system.

   You will receive a response from the Salesforce system to confirm that the records have been retrieved.

Example

See “Example: Retrieving all Account records from Salesforce” on page 1202 for a specific example of how to use the SalesforceRequest node to retrieve records from a Salesforce system.

Filtering the records retrieved from Salesforce
Use the **`filter`** element in the LocalEnvironment.Destination.Salesforce.Request.filter environment variable to restrict the records that are retrieved from the Salesforce system.

About this task

You can restrict the records that are returned by using the LocalEnvironment.Destination.Salesforce.Request.filter environment variable to specify a filter with a `where`, `limit`, or `skip` clause. You can also specify a filter with an `order` clause, and the records are returned in the specified order. The returned records appear as a JSON array in the location that is specified by the `Output data location` property of the SalesforceRequest node. By default, records are returned with all fields populated even if the field value is *null*. If a filter is specified with a `field` clause, only the specified field is returned.

The LocalEnvironment.Destination.Salesforce.Request.filter environment variable enables you to specify filter clauses, using child elements of the **`filter`** element:

```
filter
     where <value>
     limit <value>
     skip <value>
     order (1..n)
          <fieldname>/<value>
     field (1..n)
          <fieldname>/<value>
```

You can specify the child elements of the **`filter`** element to restrict the Salesforce records that are retrieved. The available elements are shown in the following table:

Table 38. Elements used for filtering the records retrieved from a Salesforce system		
Element	**Type**	**Description**
where	string	A condition expression used to filter the set of returned records. The expression syntax is a Salesforce Object Query Language (SOQL) condition expression.
limit	positive integer	Imposes a maximum number of records in the returned set.
skip	positive integer	Removes the first *n* records from the returned set.
order	structure	One child, the name of which must match the name of a field of the record. The value is either *ASC* or *DESC* (case-sensitive) and is used to order the returned set. You can specify multiple `order` clauses, which are applied in the order in which they appear in the `filter` tree.
field	structure	One child, the name of which must match the name of a field of the record. The value can be either *true* or *false* (or *1* or *0*), and controls whether the field is included as part of each returned record. You can specify multiple `field` clauses.

For example, to retrieve the Name and Phone fields for 5 (limit) Contact objects in order of Name (ascending), Email (ascending), and Phone (descending), ignoring the first 2 (skip) records, specify the following statements:

```
SET OutputLocalEnvironment.Destination.Salesforce.Request.operation = 'retrieve';
SET OutputLocalEnvironment.Destination.Salesforce.Request.object = 'Contact';
SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.limit = 5;
SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.skip = 2;
SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.order[1].Name = 'ASC';
SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.order[2].Email = 'ASC';
SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.order[3].Phone = 'DESC';

SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.field[1].Name = true;
SET OutputLocalEnvironment.Destination.Salesforce.Request.filter.field[2].Phone = true;
```

You can also use filtering to retrieve a large number of records in manageable batches, by using repeated invocations of the SalesforceRequest node with different `skip` and `limit` values. For example:

```
/customers?filter[limit]=10&filter[skip]=0
/customers?filter[limit]=10&filter[skip]=10
/customers?filter[limit]=10&filter[skip]=20
```

In this example, each REST request returns ten records; the first request returns the first ten records, the second request returns the next ten records, and the third request returns the next ten records.

Example: Retrieving all Account records from Salesforce
Create a message flow to retrieve all Account records from a Salesforce system by using a SalesforceRequest node.

About this task

This message flow receives an XML message over HTTP using an HTTPInput node, and then uses a SalesforceRequest node to send a `Retrieve` request to Salesforce to retrieve all Account records. A Compute node then uses ESQL to move data for each Account into an XML reply message that is returned to the calling client application.

Procedure

Follow these steps to create the required message flow:

1. Create a message flow containing an HTTPInput node (called `GetSFAccounts`), a SalesforceRequest (called `GetAllAccounts`), a Compute node (called `CopyAccounts`), and an HTTPReply node (called `ReplyWithAccount`):

   For information about how to create message flows, see "Creating a message flow" on page 574.
2. On the HTTPInput node, set the following properties:
   a) On the **Description** tab, set the `Node name` property to `GetSFAccounts`
   b) On the **Basic** tab, set the `Path suffix for URL` property to `/sfaccounts`
   c) On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.

3. On the SalesforceRequest node, set the following properties:
   a) On the **Description** tab, set the `Node name` property to `GetAllAccounts`
   b) On the **Basic** tab, set the following properties:
      i) Set the `Salesforce URL` property to `https://login.salesforce.com`
      ii) Set the `Operation` property to `Retrieve`
      iii) Set the `Salesforce object` property to `Account`
      iv) Set the `Security identity` property to SF. For information about configuring the security identity, see "Configuring a secure connection to Salesforce.com" on page 1196.
      v) Set the `Timeout (milliseconds)` property to `120000`.
   c) On the **Result** tab, set the following properties:
      i) Set the `Output data location` property to `$OutputLocalEnvironment/SalesforceData`
      ii) Select the `Copy local environment` property.

   The Account records that are returned from the Salesforce system are populated into the output message tree from the SalesforceRequest node under LocalEnvironment.SalesforceData.JSON.Data.
4. On the Compute node, specify the following ESQL statements:

```
CREATE COMPUTE MODULE GetAllSalesForceAccounts_Compute
    CREATE FUNCTION Main() RETURNS BOOLEAN
    BEGIN
        CALL CopyMessageHeaders();

        DECLARE ptrSalesForceAccounts REFERENCE TO
 InputLocalEnvironment.SalesforceData.JSON.Data;

        CREATE FIELD OutputRoot.XMLNSC.SalesforceAccounts;
        DECLARE ptrNewAccount REFERENCE TO OutputRoot.XMLNSC.SalesforceAccounts;

        MOVE ptrSalesForceAccounts FIRSTCHILD TYPE Name NAME 'Item';

        WHILE lastmove(ptrSalesForceAccounts) DO
            -- An Account was returned from Salesforce so populate a child element
            -- called Account as the last child of OutputRoot.XMLNSC.SalesforceAccounts with
 the
            -- Name, Type, BillingStreet and BillingCity of the returned account data
            CREATE LASTCHILD OF ptrNewAccount NAME 'Account';
            MOVE ptrNewAccount LASTCHILD;
            CREATE LASTCHILD OF ptrNewAccount NAME 'Name' VALUE ptrSalesForceAccounts.Name;
            CREATE LASTCHILD OF ptrNewAccount NAME 'Type' VALUE ptrSalesForceAccounts.Type;
            CREATE LASTCHILD OF ptrNewAccount NAME 'BillingStreet' VALUE
 ptrSalesForceAccounts.BillingStreet;
            CREATE LASTCHILD OF ptrNewAccount NAME 'BillingCity' VALUE
 ptrSalesForceAccounts.BillingCity;
            MOVE ptrSalesForceAccounts NEXTSIBLING REPEAT TYPE NAME;
            MOVE ptrNewAccount PARENT;
        END WHILE;

        RETURN TRUE;
    END;

    CREATE PROCEDURE CopyMessageHeaders() BEGIN
       DECLARE I INTEGER 1;
       DECLARE J INTEGER;
       SET J = CARDINALITY(InputRoot.*[]);
       WHILE I < J DO
           SET OutputRoot.*[I] = InputRoot.*[I];
           SET I = I + 1;
       END WHILE;
    END;
```

```
END MODULE;
```

The Compute node moves the Name, Type, BillingStreet, and BillingCity fields for each Account into an XML reply message, which is returned to the calling client application by using the ESQL statements defined on the node.

The format of the XML message that is returned is shown in the following example:

```
<SalesforceAccounts>
     <Account>
          <Name>....</Name>
          <Type>....</Type>
          <BillingStreet>....</BillingStreet>
          <BillingCity> … .</BillingCity>
     </Account>
     <Account>
          <Name>....</Name>
          <Type>....</Type>
          <BillingStreet>....</BillingStreet>
          <BillingCity> … .</BillingCity>
     </Account>
</SalesforceAccounts>
```

For more information about specifying the ESQL statements, see node.

5. On the HTTPReply node, set the Node name property (on the **Description** tab) to ReplyWithAccount.

Updating Salesforce records
Use the SalesforceRequest node to update records in the Salesforce system.

About this task

You can update Salesforce records by specifying Update in the Operation property of the SalesforceRequest node, and specifying the object type in the Salesforce object property. The object type can be overridden by the LocalEnvironment.Destination.Salesforce.Request.object environment variable.

The fields of the Salesforce record to be updated must appear in the input message tree as a JSON object. Fields that do not require updating do not have to appear in the tree.

If a Salesforce ID is specified in the LocalEnvironment.Destination.Salesforce.Request.Id environment variable, the record with that Salesforce ID value is updated.

If a Salesforce ID is not specified, and an external ID name and value are specified in the LocalEnvironment.Destination.Salesforce.Request.externalIdName and LocalEnvironment.Destination.Salesforce.Request.externalId environment variables, the record with that external ID is updated. If the record does not exist, it is created. If neither a Salesforce ID nor an external ID is specified in the local environment, but an Id element is found in the input message tree, that value is used as a Salesforce ID and the record with that Salesforce ID is updated.

When the record is updated, the input message tree is copied to the location specified by the Output data location property of the node, and augmented with the Salesforce ID in an Id element. The Salesforce Id is not provided in the Output tree if an external Id has been specified, unless a new Salesforce record is created (if it did not previously exist). If an external Id is specified but the Salesforce record cannot be found, the Salesforce record is created. This is called an *upsert* operation and occurs only if an external Id has been specified.

JSON schema are supplied for a wide range of Salesforce objects, and you can use them as input and output for message maps in a Mapping node. For example, you can create the message tree to update a Salesforce Account record in a Mapping node by using the JSON schema for the Account object. For more information, see “Using Salesforce models” on page 1212.

Procedure

Follow these steps to update a Salesforce record of a specified type (for example, an Account object):

1. Set up a Salesforce account on Salesforce.com.
2. Configure a connection to Salesforce.com.
   For more information, see "Configuring a secure connection to Salesforce.com" on page 1196.
3. Create a flow containing a SalesforceRequest node, and set the node properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Salesforce URL` property, specify the URL of the external Salesforce system.
      - In the `Operation` property, specify `Update`.
      - In the `Salesforce object` property, select the type of Salesforce object that you want to update (for example, `Account`).
      - In the `Security identity` property, specify the security identity that you will use when connecting to the Salesforce system. For information about configuring the security identity on the integration node, see "Configuring a secure connection to Salesforce.com" on page 1196.
      - In the `Timeout` property, specify the time (in milliseconds) that the node waits for Salesforce to process the operation.
   b) On the **Request** tab, set the `Data location` property to specify the location in the incoming message tree that contains the JSON objects data that will be used to update Salesforce.

   For more information, see node.
4. Send the required message through the flow to the Salesforce system.
   You will receive a response from the Salesforce system to confirm that the records have been updated.
5. Go to your Salesforce account to verify that the records have been updated correctly.

Deleting Salesforce records
Use the SalesforceRequest node to delete a record from a Salesforce system.

About this task

You can delete a Salesforce record by specifying `Delete` in the `Operation` property of the SalesforceRequest node, and specifying the Salesforce ID of the record in the LocalEnvironment.Destination.Salesforce.Request.id environment variable.

When the Salesforce record is deleted, a JSON object containing the Salesforce ID of the deleted record appears in the location that is specified by the `Output data location` property of the node.

Procedure

Follow these steps to delete a Salesforce record:

1. Set up a Salesforce account on Salesforce.com.
2. Configure a connection to Salesforce.com.
   For more information, see "Configuring a secure connection to Salesforce.com" on page 1196.

3. Create a flow containing a SalesforceRequest node, and set the node properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Salesforce URL` property, specify the URL of the external Salesforce system.
      - In the `Operation` property, specify `Delete`.
      - In the `Salesforce object` property, select the type of Salesforce object that you want to delete.
      - In the `Security identity` property, specify the security identity that you will use when connecting to the Salesforce system. For information about configuring the security identity on the integration node, see "Configuring a secure connection to Salesforce.com" on page 1196.
      - In the `Timeout` property, specify the time (in milliseconds) that the node waits for Salesforce to process the operation.
   b) On the **Results** tab, set the `Output data location` property to control where the JSON object that contains the ID of the deleted record will be placed in the output message tree.

   For more information, see node.
4. Ensure that the Salesforce ID of the record that you want to delete is set in LocalEnvironment.Destination.Salesforce.Request.id.
5. Send the required message through the flow to the Salesforce system.

   If the delete operation is successful, the output tree will contain the ID of the deleted Salesforce record.
6. Go to your Salesforce account to verify that the record has been deleted successfully.

SalesforceRequest node: Input and output message trees

Following a `create` or `update` operation, the output message body contains the input message body augmented with data from the Salesforce system. Following a `retrieve` or `delete` operation, the input message body is discarded and replaced.

The data that is added varies according to the operation performed by the SalesforceRequest node (create, retrieve, update, or delete):

- Following a `create` operation, the output message body contains the input message body augmented with the Salesforce ID of the newly created Salesforce record
- Following a `retrieve` operation, the output message body contains the following data:
  - If you specified a Salesforce ID, the output message body contains a JSON object for the record
  - If you did not specify a Salesforce ID, the output message body contains a JSON array for zero or more records
- Following an `update` operation, the output message body contains the following data:
  - If you specified a Salesforce ID, the output message body contains the input message body augmented with the Salesforce ID of the updated Salesforce record
  - If you specified an External ID and the Salesforce record already existed, the output message body contains the input message body
  - If you specified an External ID and the Salesforce record did not previously exist, the output message body contains the input message body augmented with the Salesforce ID of the newly created Salesforce record
- Following a `delete` operation, the output message body contains the Salesforce ID of the Salesforce record that was deleted.

The following table shows example input and output message bodies for each operation:

Table 39. SalesforceRequest node - input and output message bodies. Example input message bodies to the SalesforceRequest node and the output message bodies following a create, retrieve, update, or delete operation.

Operation	input message body to SalesforceRequest node	output message body from SalesforceRequest node
create	(0x01000000:Object):JSON = (['json' : 0x7fe8bc1b65c0] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-32' (CHARACTER) (0x03000000:NameValue):Type = 'good' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'Romsey Road' (CHARACTER) (0x03000000:NameValue):BillingCity = 'Winchester' (CHARACTER) (0x03000000:NameValue):BillingState = 'Hampshire' (CHARACTER) (0x03000000:NameValue):BillingPostalCode = 'SO21 2JN' (CHARACTER) (0x03000000:NameValue):BillingCountry = 'United Kingdom' (CHARACTER) (0x03000000:NameValue):Phone = '01962815000' (CHARACTER) (0x03000000:NameValue):Fax = '01962816666' (CHARACTER) (0x03000000:NameValue):AccountNumber = '001122334455' (CHARACTER) (0x03000000:NameValue):Website = 'http://www.ibm.com' (CHARACTER)))	(0x01000000:Object):JSON = (['json' : 0x7fe8dc2d9a70] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-32' (CHARACTER) (0x03000000:NameValue):Type = 'good' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'Romsey Road' (CHARACTER) (0x03000000:NameValue):BillingCity = 'Winchester' (CHARACTER) (0x03000000:NameValue):BillingState = 'Hampshire' (CHARACTER) (0x03000000:NameValue):BillingPostalCode = 'SO21 2JN' (CHARACTER) (0x03000000:NameValue):BillingCountry = 'United Kingdom' (CHARACTER) (0x03000000:NameValue):Phone = '01962815000' (CHARACTER) (0x03000000:NameValue):Fax = '01962816666' (CHARACTER) (0x03000000:NameValue):AccountNumber = '001122334455' (CHARACTER) (0x03000000:NameValue):Website = 'http://www.ibm.com' (CHARACTER) (0x03000000:NameValue):Id = '00158000003M6LzAAK' (CHARACTER)))

update (using Id)	LocalEnvironment: (0x01000000:Name):Destination = ((0x01000000:Name):Salesforce = ((0x01000000:Name):Request = ((0x03000000:NameValue):Id = '00158000003M6LzAAK' (CHARACTER)))) (0x01000000:Object):JSON = (['json' : 0x7fe88c359150] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-32' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'Test Road' (CHARACTER) (0x03000000:NameValue):BillingCity = 'Hedge End' (CHARACTER) (0x03000000:NameValue):BillingState = 'Hampshire' (CHARACTER) (0x03000000:NameValue):BillingPostalCode = 'SO30' (CHARACTER) (0x03000000:NameValue):BillingCountry = 'United Kingdom' (CHARACTER)))	(0x01000000:Object):JSON = (['json' : 0x7fe8dc43c460] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-32' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'Test Road' (CHARACTER) (0x03000000:NameValue):BillingCity = 'Hedge End' (CHARACTER) (0x03000000:NameValue):BillingState = 'Hampshire' (CHARACTER) (0x03000000:NameValue):BillingPostalCode = 'SO30' (CHARACTER) (0x03000000:NameValue):BillingCountry = 'United Kingdom' (CHARACTER) (0x03000000:NameValue):Id = '00158000003M6LzAAK' (CHARACTER)))
update (using external Id and the Salesforce record did not already exist)	LocalEnvironment: (0x01000000:Name):Destination = ((0x01000000:Name):Salesforce = ((0x01000000:Name):Request = ((0x03000000:NameValue):externalIdName = 'MyExternalId__c' (CHARACTER) (0x03000000:NameValue):externalId = 'special4' (CHARACTER)))) (0x01000000:Object):JSON = (['json' : 0x7f80f817c0a0] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-82' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'New Road' (CHARACTER)))	(0x01000000:Object):JSON = (['json' : 0x7f80d0188760] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-82' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'New Road' (CHARACTER) (0x03000000:NameValue):Id = '00158000003MBiuAAG' (CHARACTER)))
update (using external Id and the Salesforce record already existed)	LocalEnvironment: (0x01000000:Name):Destination = ((0x01000000:Name):Salesforce = ((0x01000000:Name):Request = ((0x03000000:NameValue):externalIdName = 'MyExternalId__c' (CHARACTER) (0x03000000:NameValue):externalId = 'special4' (CHARACTER)))) (0x01000000:Object):JSON = (['json' : 0x7f80f817c0a0] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-82' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'New Road' (CHARACTER)))	(0x01000000:Object):JSON = (['json' : 0x7f80d0188760] (0x01000000:Object):Data = ((0x03000000:NameValue):Name = 'Account-82' (CHARACTER) (0x03000000:NameValue):BillingStreet = 'New Road' (CHARACTER)))
delete	LocalEnvironment: (0x01000000:Name):Destination = ((0x01000000:Name):Salesforce = ((0x01000000:Name):Request = ((0x03000000:NameValue):id = '00158000003M82WAAS' (CHARACTER)))) No Input data	(0x01000000:Object):JSON = (['json' : 0x7fe128478650] (0x01000000:Object):Data = ((0x03000000:NameValue):Id = '00158000003M82WAAS' (CHARACTER)))

Using local environment variables with Salesforce nodes

The SalesforceRequest node supports a number of local environment message tree variables, which you can use to dynamically alter the values that are set in the node properties.

The following table shows the environment variables that can be set to control the behavior of the SalesforceRequest node:

Local environment variable	Type	Description
LocalEnvironment.Destination.Salesforce.RequestURL	String	The URL of the external Salesforce system. Overrides the **Salesforce URL** property on the SalesforceRequest node.
LocalEnvironment.Destination.Salesforce.RequestOperation	String	The operation to be requested on the Salesforce system: • `Create` • `Update` • `Retrieve` • `Delete` This environment variable overrides the **Operation** property on the SalesforceRequest node.
LocalEnvironment.Destination.Salesforce.RequestObject	String	The Salesforce object type for the request. This environment variable overrides the **Salesforce object** property on the SalesforceRequest node.
LocalEnvironment.Destination.Salesforce.RequestId	String	The Salesforce ID of a Salesforce record. This value is used for the following operations: • `Retrieve` (optional) • `Update` (optional) • `Delete` (required) This Salesforce `Id` is assigned to a record when it is created on the Salesforce system.
LocalEnvironment.Destination.Salesforce.RequestExternalIdName	String	The name of an external ID field of a Salesforce record. This value is used for the following operations: • `Retrieve` (optional) • `Update` (optional)
LocalEnvironment.Destination.Salesforce.RequestExternalId	String	The external ID of a Salesforce record. This value is used for the following operations: • `Retrieve` (optional) • `Update` (optional)
LocalEnvironment.Destination.Salesforce.RequestFilter	String or structure	The filter to be used for restricting the records returned by a `Retrieve` operation. For more information, see "Retrieving Salesforce records " on page 1199.

Local environment variable	Type	Description
LocalEnvironment.Destination.Salesforce.RequestTimeoutMilliseconds	integer	The time (in milliseconds) that the node waits for Salesforce to process the operation. This environment variable overrides the **Timeout (milliseconds)** property on the SalesforceRequest node.

Using Salesforce models

JSON schema are supplied for a wide range of Salesforce objects, and you can use them as input and output for message maps in a Mapping node. For example, you can create the message tree for a new Account record, or transform the message tree for a returned Account record, by using the JSON schema for the Salesforce Account object.

About this task

The JSON schema for Salesforce objects are provided with IBM App Connect Enterprise in the *install_dir*/server/sample/Salesforce directory, where *install_dir* is the directory in which you installed IBM App Connect Enterprise.

Procedure

To reference the Salesforce object schema from a Mapping node, complete the following steps:

1. Create a shared library.

   Note: The map and the JSON schema that it references must all be held in the same shared library.
2. Import into the shared library the schema for the objects that you want to map.
3. If you have added custom fields to your Salesforce objects, edit the schema to add the custom fields, and save it.

   For information about the JSON schema, see JSON schema requirements for message maps.
4. Add a reference to the shared library from the application that contains your message flow.
5. Drag and drop a Mapping node onto the message flow canvas and then double-click the Mapping node to launch the **New Message Map** wizard.
6. Specify a name for the map, change the container to be the shared library that holds the JSON schema, and click **Next**.
7. Select as input or output the required Salesforce object from the list under **JSON schema**. Each object appears as both a JSON object and a JSON array:
   - Use the JSON object if creating a message tree prior to a Salesforce Create or Update operation.
   - Use the JSON object if transforming a message tree after a Salesforce Retrieve operation that used a Salesforce ID.
   - Use the JSON array if transforming a message tree after all other Salesforce Retrieve operations.
8. Select the other output or input to the map and click **Finish**.

Working with LoopBack connectors

IBM App Connect Enterprise provides a LoopBackRequest node, which enables you to issue synchronous requests to backend data sources by using LoopBack connectors such as MongoDB, Cloudant, or PostgreSQL.

About this task

You can use a LoopBackRequest node in a message flow to access or create records through a LoopBack connector. First, you must install your chosen connector to work with IBM App Connect Enterprise, and

then configure the data source for the connector. You can then specify the security credentials that are required to access it. The following topics describe the steps involved in completing those tasks:

1. “Installing the LoopBack connector” on page 1213
2. “Configuring the data source and models for your LoopBack connector” on page 1214
3. “Specifying security credentials for connecting to a secured data source” on page 1216

When you have completed these tasks, you can use a LoopBackRequest node in a message flow to create, retrieve, update, and delete records, as described in the following topics:

- “Accessing and creating records by using the LoopBackRequest node” on page 1217
- “Creating records by using a LoopBackRequest node” on page 1218
- “Retrieving records by using a LoopBackRequest node” on page 1219
- “Filtering the records retrieved through a LoopBack connector” on page 1220
- “Updating records by using a LoopBackRequest node” on page 1223
- “Deleting records by using a LoopBackRequest node” on page 1224

The LoopBackRequest node operations are synchronous and non-transactional, which means that, if a message flow fails and rolls back after the LoopBackRequest node, the operation on the data source will still complete.

The LoopBackRequest node supports a number of local environment message tree variables, which you can use to dynamically alter the values that are set in the node properties. For information about defining these environment variables, see “Using local environment variables with LoopBackRequest nodes” on page 1226.

For more information about configuring and using the LoopBackRequest node in a message flow, see node.

When you pass data to a data source through a LoopBackRequest node (when you create or update a record, for example), you must use the JSON domain for providing data in the input message. Replies to a LoopBack request are provided as JSON domain messages.

If you want to use a Mapping node to create the input or process the output data, you must use one of the supported options for defining a message model for the LoopBack connector JSON data. For more information, see Creating or transforming a JSON output message by using a message map.

For help with diagnostics, check the user trace and the LoopBack activity log, which contains information that is created when a LoopBackRequest node issues a request. For information about the type of information that is included, see “LoopBack Activity Log” on page 2865.

Installing the LoopBack connector

Install and configure the required LoopBack connector for use with IBM App Connect Enterprise.

About this task

Before you can use the LoopBackRequest node in a message flow, you must install the relevant LoopBack connector.

Procedure

Follow these steps to install and configure your LoopBack connector to work with IBM App Connect Enterprise:

1. Open the IBM App Connect Enterprise Command Console and change to the `node_modules` subdirectory of the work path directory (which is defined by the MQSI_WORKPATH environment variable).
   For example, on Windows:

   ```
   cd %MQSI_WORKPATH%\node_modules
   ```

   and on UNIX:

   ```
   cd $MQSI_WORKPATH/node_modules
   ```

2. From the `node_modules` subdirectory, run the `npm` command, specifying the name of your chosen LoopBack connector.

   For example, to install the MongoDB LoopBack connector:

   ```
   npm install loopback-connector-mongodb
   ```

   Note: Ensure that you use the version of `npm` that is provided with IBM App Connect Enterprise, by running the `npm` command from the Command Console. If you install the connector by using any other method, the modules will be incompatible.

   Some LoopBack connectors might depend on native libraries that are built during the installation process, and which require compiler tools to be accessible on the system. For example, the LoopBack Oracle connector requires changes to the library path so that the connector can locate the Oracle InstantClient that is packaged with the connector. On Windows, you could enable this by adding the following line to a common profile in the *work_path*`\common\profiles\loopback.cmd` file:

   ```
   set PATH=%PATH%;%MQSI_WORKPATH%\node_modules\instantclient\vc11;%MQSI_WORKPATH%\node_modules
   \instantclient;
   ```

   On Linux, you could enable the Oracle connector to locate the InstantClient, by adding the following line to a common profile in the *work_path*`/common/profiles/loopback.sh` file:

   ```
   export LD_LIBRARY_PATH=$LD_LIBRARY_PATH:/$MQSI_WORKPATH/node_modules/instantclient:
   ```

   If you encounter problems when installing LoopBack connectors, contact the connector author for assistance.

   Some LoopBack connectors might also require you to configure the environment in which the connector is running, such as modifying the library path. See “Setting up a command environment” on page 64 for information on how to configure the command environment to make these settings available to IBM App Connect Enterprise.

   Some LoopBack connectors might be incompatible if they use native libraries that are used internally by IBM App Connect Enterprise.
3. Check the `node_modules` subdirectory to confirm that the required LoopBack connector and any dependent modules have been installed.

What to do next

Configure the data source for your installed connector, as described in “Configuring the data source and models for your LoopBack connector” on page 1214.

Configuring the data source and models for your LoopBack connector

Ensure that the data source for your LoopBack connector has been configured.

Before you begin

Install the required LoopBack connector as described in “Installing the LoopBack connector” on page 1213.

About this task

When you have installed a LoopBack connector to be used with IBM App Connect Enterprise, you must configure the data source for the connector, by adding a connector-specific data-source stanza to the `datasources.json` file.

Procedure

Follow these steps to configure the data source for your chosen LoopBack connector:

1. Create or update a LoopBack `datasources.json` file, in the IBM App Connect Enterprise *workpath*`/connectors/loopback` directory. This `datasources.json` file can be specific to the integration node or the integration server.

   In most circumstances, the `/connectors/loopback` directory is created automatically; however, if it does not exist, you must create it.

   The LoopBackRequest node searches for its configured data-source stanza in the following order:

   a. *workpath*/*integration_node*/*integration_server*/connectors/loopback

   b. *workpath*/*integration_node*/connectors/loopback

   c. *workpath*/connectors/loopback

2. Modify the `datasources.json` file by adding a JSON data-source stanza that configures the data source that you want to access.

   The LoopBack `datasources.json` file must provide all the properties that are required by the chosen connector. The details of the properties are defined by the installed LoopBack connector. For connecting to a secured connector, the security credentials can be provided in the `datasources.json` file; however, they are stored in plain text in the `workpath` folder. For an alternative approach to providing security credentials, see "Specifying security credentials for connecting to a secured data source" on page 1216.

   The LoopBack `datasources.json` file can contain properties for multiple data sources; for example, it could contain the following code, which provides data-source stanzas for both a `mongodb_dev` and a `mongodb_stage` MongoDB connector:

   ```
   {
     "mongodb_dev": {
       "name": "mongodb_dev",
       "connector": "mongodb",
       "host": "127.0.0.1",
       "port": 27017,
       "database": "devDB",
       "username": "devUser",
       "password": "devPassword"
     },
     "mongodb_stage": {
       "name": "mongodb_stage",
       "connector": "mongodb",
       "port": 27018,
       "host": "staging.org.co.uk",
       "database": "stageDB"
     }
   }
   ```

   The content of the LoopBack `datasources.json` properties for the data sources are defined and used by the installed LoopBack connector; the LoopBackRequest node passes the JSON stanza to the installed connector when it is initialized at flow deployment or restart.

3. Optional: You can provide a model definition file that is specific to the data-source stanza.

   Some LoopBack connectors require that the data model to be interacted with is defined through a LoopBack JSON model. When the LoopBackRequest node interacts for the first time with a named LoopBack object, which is either specified as a node property or dynamically overridden in the local environment, it looks for a LoopBack JSON model file in a subdirectory of the directory that contains the `datasources.json` file. This subdirectory, which you must create, must have exactly the

same name and case as the data-source stanza that is specified on the LoopBackRequest node. For example, if the `datasources.json` file is provided only at the node location, the model would be:

```
workpath/connectors/loopback/datasource_name/model_name.json
```

The *model_name* part of the *model_name*`.json` file must match exactly (including the case) the **LoopBack object** name that is either specified on the LoopBackRequest node or overridden with the **LocalEnvironment.Destination.Loopback.Request.object** local environment variable.

The name that is specified in the **LoopBack object** property of the LoopBackRequest node is the base name of the model file (excluding the `.json` file extension), and the **name** property in the model file defines the LoopBack object that will be interacted with. Typically, these names are the same, but they can be different; for example, if the name of the object in the LoopBack connected system contains a character that would be invalid in a file name. If the names are different, a BIP3880 message is issued.

The following example shows how you could provide LoopBack JSON model files for working with the `dev` and `staging` MongoDB data sources:

```
<workpath>
   \---connectors
         \---loopback
             +---datasources.json
             |
             +---mongodb_dev
             |   +---customer.json
             |   +---order.json
             |   \---test.json
             |
             \---mongodb_stage
                 +---customer.json
                 \---order.json
```

For more information about using models, see "Using models with LoopBack connectors" on page 1229.

What to do next

Optionally, you can provide security credentials for the LoopBack connector by running the command, as described in "Specifying security credentials for connecting to a secured data source" on page 1216.

Specifying security credentials for connecting to a secured data source

You can use the **mqsisetdbparms** command to specify the security credentials used by a LoopBackRequest node to connect to a secured data source.

About this task

You can associate a user name, password, client identity, and client secret with connections to a secured LoopBack connector. Alternatively, you can specify the security credentials in the `datasources.json` file; however, the data is stored in the file in plain text.

Procedure

Follow these steps to configure the security credentials for connections to a LoopBack connector:

1. Run the **mqsisetdbparms** command, specifying the following parameters:

   -n loopback::*securityIdentity*
   The name of the security identity that is used to authenticate a connection to a LoopBack connector, where *securityIdentity* is the value of the **Security identity** property in the LoopBackRequest node.

   -u *userID*
   The user ID for connecting to the LoopBack connector application.

   -p *password*
   The password for accessing the LoopBack connector application.

   -c *clientIdentity*
   (Optional) The name of the client ID of the LoopBack connector application.

   -s *clientSecret*
   (Optional) The client secret of the LoopBack connector application.

   For example:

   ```
   mqsisetdbparms INODE -n loopback::lbreqid1 -u myLoopBackUserID -p myLoopBackPassword
   ```

2. The specified credentials are passed to the LoopBack connector and are used to connect to a data source.

What to do next

Create a message flow and add a LoopBackRequest node to enable you to create, retrieve, update, or delete records through your LoopBack connector. For more information, see "Accessing and creating records by using the LoopBackRequest node" on page 1217.

Accessing and creating records by using the LoopBackRequest node

You can use the LoopBackRequest node to interact with the LoopBack framework, enabling you to create, retrieve, update, and delete records in backend data sources such as MongoDB, Cloudant, and PostgreSQL.

Before you begin

Complete the tasks in the following topics:

- "Installing the LoopBack connector" on page 1213
- "Configuring the data source and models for your LoopBack connector" on page 1214
- "Specifying security credentials for connecting to a secured data source" on page 1216

About this task

The following topics explain how to work with records in a client system by using a LoopBackRequest node:

- "Creating records by using a LoopBackRequest node" on page 1218
- "Retrieving records by using a LoopBackRequest node" on page 1219
- "Updating records by using a LoopBackRequest node" on page 1223
- "Deleting records by using a LoopBackRequest node" on page 1224

When you pass data to a data source through a LoopBackRequest node (when you create or update a record, for example), you must use the JSON domain for providing data in the input message. Replies to a LoopBack request are provided as JSON domain messages. For more information, see "Using models with LoopBack connectors" on page 1229.

Creating records by using a LoopBackRequest node
Use the LoopBackRequest node to create a new record in a backend data source by using a LoopBack connector.

About this task

You can use a LoopBackRequest node in a message flow to create a new data record through a LoopBack connector in a backend data source such as MongoDB, Cloudant, or PostgreSQL.

You create a new record by specifying `Create` in the `Operation` property of the LoopBackRequest node, and specifying the resource type (such as Account) in the `LoopBack object` property. The object can be overridden by the `LocalEnvironment.Destination.Loopback.Request.object` local environment variable. For more information about using environment variables, see "Using local environment variables with LoopBackRequest nodes" on page 1226.

The record that you are creating must exist in the input message tree as a JSON object. When the record is created, the input message tree is copied to the location specified by the `Output data location` property. The output data might also be augmented with additional data that was created in the backend data source.

Procedure

1. Create a flow containing a LoopBackRequest node, and set the node properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Data source` property, specify the name of the data source stanza for your chosen connector in the LoopBack `datasources.json` file.
      - In the `Operation` property, specify `Create`.
      - In the `LoopBack object` property, specify the type of object (for example, `Account`) for which you are creating a new record.
      - In the `Security identity` property, specify the security identity that you will use when connecting to the LoopBack connector. For information about configuring the security identity on the integration node, see "Specifying security credentials for connecting to a secured data source" on page 1216.
      - In the `Timeout (milliseconds)` property, specify the time (in milliseconds) that the node waits for the LoopBack connector to process the operation.

      These properties can be overridden dynamically in the flow, as described in "Using local environment variables with LoopBackRequest nodes" on page 1226.
   b) On the **Request** tab, set the `Data location` property to specify the location in the incoming message tree that contains the JSON object data to be created in the external application; this data forms the request that is sent from the LoopBackRequest node to the connected system.
   c) On the **Result** tab, set the `Output data location` property to specify the location in the output message tree that will contain the data of the record that is created.

      Input and output messages are in the JSON domain. For more information, see "Combining a result message with an input message when fetching data from external systems" on page 1811.

   For more information about the properties of the LoopBackRequest node, see node.
2. Send the required message through the flow to the backend data source.

   You will receive a confirmation message, which might be augmented with additional data from the backend data source. The message will be in the JSON domain and can be created and processed by any suitable transformation node. To use the Mapping node, you must provide a message model of the data, as described in Creating or transforming a JSON message by using a JSON schema.
3. Check the backend data source to verify that the new record has been created correctly.

   You can also check the activity log for additional information about events related to the LoopBackRequest node. If the Loopback operation was not successful, the node reports by raising an exception with a BIP message that might include an error returned from the installed LoopBack

connector. If the failure terminal is connected, the node will propagate the exception list to it, otherwise the flow will roll back.

Retrieving records by using a LoopBackRequest node
Use a LoopBackRequest node in a message flow to retrieve data records through a LoopBack connector such as MongoDB, Cloudant, or PostgreSQL.

Before you begin

Complete the tasks in the following topics:

- "Installing the LoopBack connector" on page 1213
- "Configuring the data source and models for your LoopBack connector" on page 1214
- "Specifying security credentials for connecting to a secured data source" on page 1216

About this task

You retrieve records by specifying `Retrieve` in the `Operation` property of the LoopBackRequest node. You can retrieve all records of a particular type by specifying the object type in the `LoopBack object` property of the node. This object type can be overridden by a value specified in the `LocalEnvironment.Destination.Loopback.Request.object` local environment variable.

Alternatively, you can retrieve a specific record by specifying an ID in the `LocalEnvironment.Destination.Loopback.Request.id` environment variable. The returned record appears as a JSON object in the location that is specified by the `Output data location` property of the node.

If an external ID name and value are specified in the `LocalEnvironment.Destination.Loopback.Request.externalIdName` and `LocalEnvironment.Destination.Loopback.Request.externalId` environment variables, all records with that external ID are returned. The returned records appear as a JSON array in the location specified by the `Output data location` property.

You can control the records that are returned by using the `LocalEnvironment.Destination.Loopback.Request.filter` environment variable to specify a filter with the following clauses:

- `where`
- `limit`
- `skip`
- `order`
- `field`

If your installed LoopBack connector supports additional capabilities beyond those provided by these filter options, you can use the `filterString` local environment variable instead of `filter`. If both `filter` and `filterString` are specified, `filterString` takes precedence. For more information, see "Filtering the records retrieved through a LoopBack connector" on page 1220.

By default, the retrieval of records is determined by the following properties, in order of precedence:

- ID
- External ID
- Filter

If no records are found, the output tree contains nothing under JSON.data.

If you have configured a model for use with your LoopBack connector, see "Using models with LoopBack connectors" on page 1229, for additional information.

Procedure

Follow these steps to retrieve records by using a LoopBackRequest node:

1. Create a flow containing a LoopBackRequest node, and set the following properties on the **Basic** tab:
   a) In the `Data source` property, specify the name of the data source stanza for your chosen connector in the LoopBack `datasources.json` file.
   b) In the `Operation` property, specify `Retrieve`.
   c) In the `LoopBack object` property, select the type of object that you want to retrieve.
   d) In the `Security identity` property, specify the security identity that you will use when connecting to the LoopBack application. For information about configuring the security identity on the integration node, see "Specifying security credentials for connecting to a secured data source" on page 1216.
   e) In the `Timeout (milliseconds)` property, specify the time (in milliseconds) that the node waits for the LoopBack connector to process the operation.

   These properties can be overridden dynamically in the flow, as described in "Using local environment variables with LoopBackRequest nodes" on page 1226. For more information about the LoopBackRequest node properties, see node.
2. Send the required message through the flow to the LoopBack application.

   The node emits the JSON data of the record, which can be an empty message if no record is found. The message will be in the JSON domain and can be created and processed by any suitable transformation node. To use the Mapping node, you must provide a message model of the data, as described in Creating or transforming a JSON message by using a JSON schema.
3. Check that the records have been retrieved correctly.

   You can also check the activity log for additional information about events related to the LoopBackRequest node. If the Loopback operation was not successful, the node reports by raising an exception with a BIP message that might include an error returned from the installed LoopBack connector. If the failure terminal is connected, the node will propagate the exception list to it, otherwise the flow will roll back.

Filtering the records retrieved through a LoopBack connector
Use the **`filter`** element in the LocalEnvironment.Destination.Loopback.Request.filter environment variable to restrict the content of records that are retrieved from the LoopBack application.

About this task

You can restrict the content of records that are returned by using the `LocalEnvironment.Destination.Loopback.Request.filter` environment variable to specify a filter with a `where`, `limit`, or `skip` clause. You can also specify a filter with an `order` clause, and the records are returned in the specified order. The returned records appear as a JSON array or a JSON object in the location that is specified by the `Output data location` property of the LoopBackRequest node. By default, records are returned with all fields populated; however, you can use a filter with a `field` clause to restrict the data that is returned by explicitly selecting or excluding fields.

Examples are shown of how to set the values by using ESQL; however, you can also set them by using a transformation node such as a Mapping node. To access the LocalEnvironment from a Mapping node, see Customizing a message map to include a message assembly component.

By using the *LocalEnvironment.Destination.Loopback.Request.filter* environment variable, you can specify filter clauses, by using child elements of the **`filter`** element:

```
filter
     where <value>
     limit <value>
     skip <value>
     order (1..n)
          <fieldname>/<value>
     field (1..n)
          <fieldname>/<value>
```

You can specify the child elements of the **filter** element to restrict the content of the records that are retrieved. The available elements are shown in the following table:

Table 40. Elements used for filtering the content of records retrieved from a backend data source

Element	Type	Description
where	string	A condition expression used to filter the set of returned records.
limit	positive integer	Imposes a maximum number of records in the returned set.
skip	positive integer	Removes the first *n* records from the returned set before returning the number of results up to the specified `limit`.
order	structure	One child, the name of which must match the name of a field of the record. The value is either *ASC* or *DESC* (case-sensitive) and is used to order the returned set. You can specify multiple `order` clauses, which are applied in the order in which they appear in the `filter` tree.
field	structure	One child, the name of which must match the name of a field of the record. The value can be either *true* or *false* (or *1* or *0*), and controls whether the field is included as part of each returned record. You can specify multiple `field` clauses.

Examples

The following examples show some of the query filter options that you can use with the LoopBackRequest node.

The filtering options that are available to you depend on the capabilities of the specific LoopBack connector that you are using. The precise syntax and outcome of the filter also depend on the type and version of the installed LoopBack connector.

Get documents from MongoDB, where **price** is *>= 325* and **phone** begins with *08*:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.where = '{"and": [{"price":
 {"gte":325}},
 {"phone": {"regexp": "^08"}}]}';
```

Get all records in descending **totalEmployees** order and ascending **companyName** order, retrieving only the **companyName** field, and explicitly excluding the **totalEmployees** field:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.order[1].totalEmployees = 'DESC';
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.order[2].companyName = 'ASC';
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.field[1].companyName = true;
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.field[2].totalEmployees = false;
```

- When you use a `field` clause that explicitly selects the set of fields to be returned, some connectors continue to return the **id** field unless it is explicitly excluded.

- You can use a model along with a **filter** and a `field` clause that explicitly selects the set of fields to be returned. When you use this option, some connectors return a `null` value for all field values that are not explicitly selected or excluded.

When you use a Mapping node to achieve this task, you can create the required fields by adding a user-defined element. For more information, see Adding a user-defined element.

When you use an ESQL Compute node to achieve this task, you must set the **Compute mode** to include *LocalEnvironment*.

Query by **id**, where the model defines the **identity field** as **companyId**. In this case, the **companyId** value is space-padded to match the length of a fixed-length character column in the backend database:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.id = '500  ';
```

Query by **externalId** and **externalIdName** by using **companyId** as the value for **externalIdName**. In this case, the **companyId** value is space-padded to match the length of a fixed-length character column in the backend database:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.externalId = '100  ';
SET OutputLocalEnvironment.Destination.Loopback.Request.externalIdName = 'companyId';
```

Query using **companyId** in a `filter.where` clause. In this case, the **companyId** value is space-padded to match the length of a fixed-length character column in the backend database:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.where = '{"companyId":"400  "}';
```

Query using **totalEmployees** *>= 325* in a `filter.where` clause. Get two records and skip over the first one:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.where = '{"totalEmployees":
 {"gte":325}}';
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.limit = 2;
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.skip = 1;
```

Query that uses **totalEmployees** *<= 430* and **companyName** begins with *B*:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filter.where = '{"and":
 [{"totalEmployees": {"lte":430}},
 {"companyName": {"like": "B%"}}]}';
```

Query that uses **filterString**, where **totalEmployees** is *<= 430* and **companyName** does not begin with *B*. Get only one record (`limit=1`) and ignore the first one (`skip=1`):

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filterString = '{"where": {"and":
 [{"totalEmployees":
 {"lte":430}}, {"companyName": {"nlike": "B%"}}]}, "limit":1, "skip":1}';
```

Query that uses **filterString** where **totalEmployees** is *<= 430* and **companyName** does not begin with *B*. Get the records in ascending **companyName** order and then descending **totalEmployees** order. Request the **companyName** field and explicitly exclude the **totalEmployees** field:

```
SET OutputLocalEnvironment.Destination.Loopback.Request.filterString = '{"where": {"and":
 [{"totalEmployees": {"lte":430}},
 {"companyName": {"nlike": "B%"}}]}, "order": ["companyName ASC", "totalEmployees DESC"],
 "fields": {"companyName": true,
 "totalEmployees": false}}';
```

Updating records by using a LoopBackRequest node
Use a LoopBackRequest node in a message flow to update data records through a LoopBack connector such as MongoDB, Cloudant, or PostgreSQL.

Before you begin

Complete the tasks in the following topics:

- "Installing the LoopBack connector" on page 1213
- "Configuring the data source and models for your LoopBack connector" on page 1214
- "Specifying security credentials for connecting to a secured data source" on page 1216

About this task

You can update records by specifying `Update` in the `Operation` property of the LoopBackRequest node, and specifying the object type in the `LoopBack object` property. The object type can be overridden by the `LocalEnvironment.Destination.Loopback.Request.object` environment variable.

The fields of the data record to be updated must appear in the input message tree as a JSON object. Fields that do not require updating do not have to appear in the tree.

If an ID is specified in the LocalEnvironment.Destination.Loopback.Request.Id environment variable, the record with that ID value is updated. If no record is found with a matching ID, an error is returned.

If an ID is not specified, but an external ID name and value are specified in the LocalEnvironment.Destination.Loopback.Request.externalIdName and LocalEnvironment.Destination.Loopback.Request.externalId environment variables, the record with that external ID is updated. In some cases, multiple records might match the same external ID. If no ID or external ID is specified, you can use a `filter.where` clause to specify the records to be updated. For more information about filtering, see "Filtering the records retrieved through a LoopBack connector" on page 1220.

When records are updated, data is returned from the installed LoopBack connector, such as a count of the updated records.

You can use JSON schema as input and output for message maps in a Mapping node, see "Using models with LoopBack connectors" on page 1229.

Procedure

Follow these steps to update a data record of a specified type (for example, an `Account` object):

1. Create a flow containing a LoopBackRequest node, and set the node properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Data source` property, specify the name of the data source stanza for your chosen connector in the LoopBack `datasources.json` file.
      - In the `Operation` property, specify `Update`.
      - In the `LoopBack object` property, select the type of object that you want to update (for example, `Account`).
      - In the `Security identity` property, specify the security identity that you will use when connecting to the LoopBack connector. For information about configuring the security identity

on the integration node, see "Specifying security credentials for connecting to a secured data source" on page 1216.

- In the `Timeout (milliseconds)` property, specify the time (in milliseconds) that the node waits for LoopBack connector to process the operation.

These properties can be overridden dynamically in the flow, as described in "Using local environment variables with LoopBackRequest nodes" on page 1226.

b) On the **Request** tab, set the `Data location` property to specify the location in the incoming message tree that contains the JSON objects data that will be used to update the data record.

For more information, see node.

2. Ensure that the ID of the record that you want to update is set in the LocalEnvironment.Destination.Loopback.Request.id local environment variable.

   Alternatively, you can update records by specifying the appropriate values in the LocalEnvironment.Destination.Loopback.Request.externalId and LocalEnvironment.Destination.Loopback.Request.externalIdName local environment variables.

3. Send the required message through the message flow to the LoopBack application.

   You will receive a response from the application to confirm that the records have been updated.

4. Check the backend data source to verify that the records have been updated correctly.

   You can also check the activity log for additional information about events related to the LoopBackRequest node. If the Loopback operation was not successful, the node reports by raising an exception with a BIP message that might include an error returned from the installed LoopBack connector. If the failure terminal is connected, the node will propagate the exception list to it, otherwise the flow will roll back.

Deleting records by using a LoopBackRequest node

Use a LoopBackRequest node in a message flow to delete a data record through a LoopBack connector such as MongoDB, Cloudant, or PostgreSQL.

Before you begin

Complete the tasks in the following topics:

- "Installing the LoopBack connector" on page 1213
- "Configuring the data source and models for your LoopBack connector" on page 1214
- "Specifying security credentials for connecting to a secured data source" on page 1216

About this task

You delete a record by specifying `Delete` in the `Operation` property of the LoopBackRequest node, and specifying the ID of the record in the LocalEnvironment.Destination.Loopback.Request.id environment variable. If no record is found with a matching ID, an error is returned.

If no ID is specified, but an external ID name and value are specified in the LocalEnvironment.Destination.Loopback.Request.externalIdName and LocalEnvironment.Destination.Loopback.Request.externalId environment variables, the records with that external ID are deleted. In some cases, multiple records might match the same external ID. If no ID or external ID is specified, you can use a `filter.where` clause to specify the records to be deleted. For more information about filtering, see "Filtering the records retrieved through a LoopBack connector" on page 1220.

When records are deleted, a result is returned from the installed connector, such as a count of the deleted records.

Procedure

Follow these steps to delete a record:

1. Create a flow containing a LoopBackRequest node, and set the node properties:
   a) On the **Basic** tab, set the following properties:
      - In the `Data source` property, specify the name of the data source stanza for your chosen connector in the LoopBack `datasources.json` file.
      - In the `Operation` property, specify `Delete`.
      - In the `LoopBack object` property, select the type of object that you want to delete.
      - In the `Security identity` property, specify the security identity that you will use when connecting to the LoopBack application. For information about configuring the security identity on the integration node, see "Specifying security credentials for connecting to a secured data source" on page 1216.
      - In the `Timeout (milliseconds)` property, specify the time (in milliseconds) that the node waits for the waits for the LoopBack connector to process the operation.

      These properties can be overridden dynamically in the flow, as described in "Using local environment variables with LoopBackRequest nodes" on page 1226.
   b) On the **Results** tab, set the `Output data location` property to control where the JSON object that contains the count of the deleted records will be placed in the output message tree.

   For more information, see node.
2. Ensure that the ID of the record that you want to delete is set in the LocalEnvironment.Destination.Loopback.Request.id local environment variable.

   You can also delete records by specifying values in the LocalEnvironment.Destination.Loopback.Request.externalId and LocalEnvironment.Destination.Loopback.Request.externalIdName local environment variables.
3. Send the required message through the flow to the LoopBack application.

   If the delete operation is successful, the output tree will contain the count of the deleted records.
4. Go to your account in the backend data source to verify that the record has been deleted successfully.

   You can also check the activity log for additional information about events related to the LoopBackRequest node. If the Loopback operation was not successful, the node reports by raising an exception with a BIP message that might include an error returned from the installed LoopBack connector. If the failure terminal is connected, the node will propagate the exception list to it, otherwise the flow will roll back.

Scaling throughput of IBM App Connect Enterprise message flow applications that use LoopBackRequest nodes

Due to the single threaded event loop mechanism that exists in the Node.js architecture, you might need to adopt a specific approach to performance scaling when you are running IBM App Connect Enterprise message flow applications that useLoopBackRequest nodes. You might find that you do not achieve the scaling that you require just by increasing the additional instances on these message flows. If that is the case, you can continue to scale performance by running instances of such applications in separate integration servers.

The IBM App Connect Enterprise LoopBackRequest node exploits the industry standard Node.js framework and enables message flows to connect with external systems by using user-installed LoopBack connectors.

Node.js architecture uses the single threaded event loop model that manages the requests and responses of all worker threads by using a non-blocking callback mechanism. In IBM App Connect Enterprise, each integration server is a separate process and, therefore, can host a single Node.js instance. As a consequence, all message flow threads in an integration server must send LoopBackRequest node requests and responses to the external system by using the single threaded event loop in Node.js. These threads then wait for the callback to be sent back through the single threaded event loop after the required action has been completed by the interaction of the LoopBack connector worker thread and the external system.

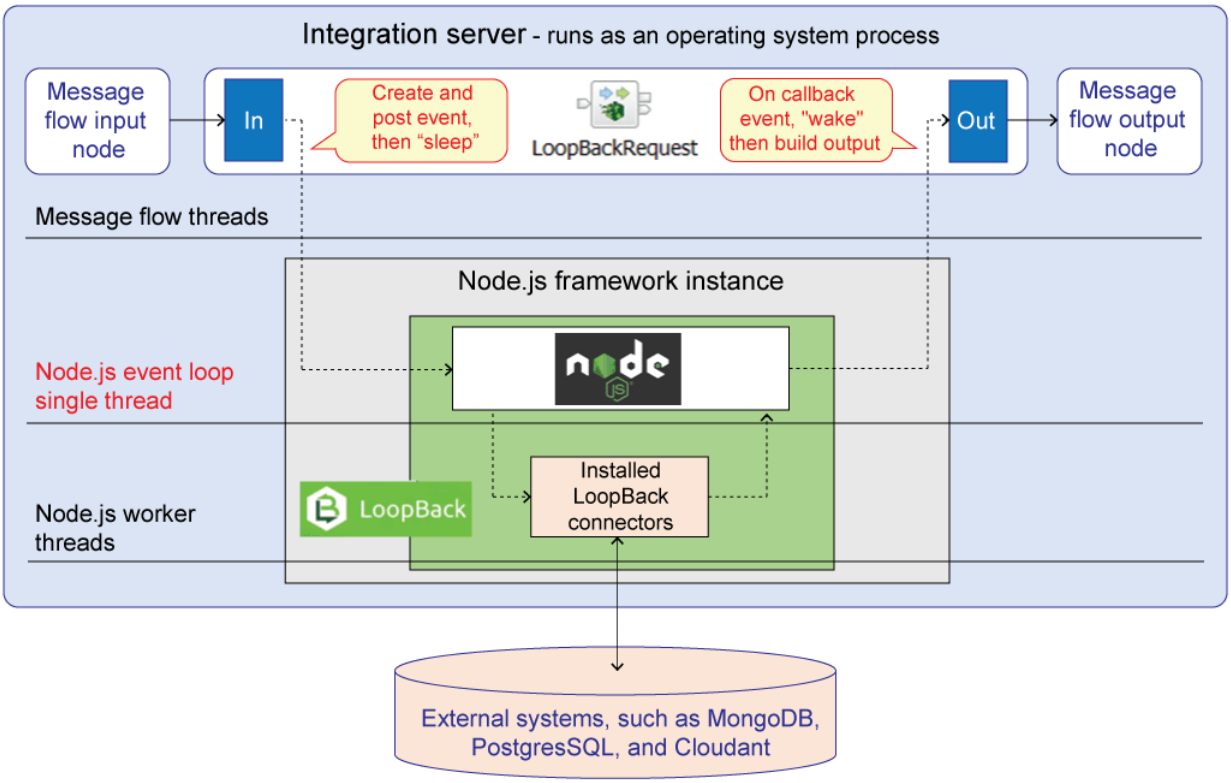

Figure 3. The flow of activity between an IBM App Connect Enterprise integration server that is using LoopBackRequest nodes to interact with an external system.

To achieve throughput scaling of IBM App Connect Enterprise message flow applications that use LoopBackRequest nodes, start by increasing the number of thread instances that are available to the message flow application in a single integration server. Use the **Additional instances** property on the message flow input node or set the workload management **Additional instances** property of the message flow to set the number of message flow threads that are available. If further increases to the **Additional instances** property no longer scale the throughput, run instances of the message flow application in separate integration servers.

Using local environment variables with LoopBackRequest nodes

The LoopBackRequest node supports a number of local environment message tree variables, which you can use to dynamically alter the values that are set in the node properties.

The following table shows the environment variables that can be set to control the behavior of the LoopBackRequest node. The table includes examples of how to set the value by using ESQL; however, you can also set them by using transformation nodes, such as a Mapping node. To access the LocalEnvironment from a Mapping node, see Customizing a message map to include a message assembly component.

Local environment variable	Type	Description
LocalEnvironment.Destination.Loopback.Request.operation	string	The operation to be requested on the external system: • `Create` • `Update` • `Retrieve` • `Delete` This environment variable overrides the **`Operation`** property on the LoopBackRequest node.
LocalEnvironment.Destination.Loopback.Request.object	any	The object for the request. This environment variable overrides the **`LoopBack object`** property on the LoopBackRequest node, and applies for all operations.
LocalEnvironment.Destination.Loopback.Request.id	string	The LoopBack object ID of the record to be accessed by this request. This value is used for the following operations: • `Retrieve` (optional) This environment variable causes a single record to be retrieved, and takes precedence over the `externalId`, `filter`, and `filterString` environment variables. • `Update` (optional) This environment variable causes a single record to be updated, and takes precedence over the `externalId` environment variable. If this environment variable is not set, either the `externalId` or `filter.where` environment variable must be set. • `Delete` (optional) This environment variable causes a single record to be deleted, and takes precedence over the `externalId` environment variable. If this environment variable is not set, either the `externalId` or `filter.where` environment variable must be set. This `Id` is assigned to a record when it is created on the external system.

Local environment variable	Type	Description
LocalEnvironment.Destination.Loopback.Request.externalIdName	string	The name of an external ID field of a record in the external system. This value is used for the following operations: • `Retrieve` (optional) Causes a set of records that have the field name specified in this environment variable to be retrieved. • `Update` (optional) Causes a set of records that have the field name specified in this environment variable to be updated. • `Delete` (optional) Causes a set of records that have the field name specified in this environment variable to be deleted.
LocalEnvironment.Destination.Loopback.Request.externalId	string	The external ID of a record in the external system. This value is used for the following operations: • `Retrieve` (optional) Causes a set of records that have the external ID values given in this environment variable to be retrieved. This variable takes precedence over `filter.where` and `filterString` environment variables. • `Update` (optional) Causes a set of records that have the external ID values given in this environment variable to be updated. If neither the `Id` nor `filter.where` environment variable is set, this variable is required. • `Delete` (optional) Causes a set of records that have the external ID values given in this environment variable to be deleted. If neither the `Id` nor `filter.where` environment variable is set, this variable is required.

Local environment variable	Type	Description
LocalEnvironment.Destination.Loopback.Request.filterString	String	A pre-built string format of the JSON filter object for this request. Used only for `Retrieve` (optional). You can use it to set any filter that the connector supports, for example: `{"where": {"and": [{"thing1":"isOne"}, {"thing2":"isTwo"}]}}` If `filterString` and `filter.where` are both specified, only `filterString` is used.
LocalEnvironment.Destination.Loopback.Request.filter	Structure	The filter to be used for restricting the records acted upon by an operation. • `Retrieve` (optional) Restricts the records returned by a `Retrieve` operation. You can specify the following sub-fields to set parts of the JSON filter object for this request: – `where` – `limit` – `skip` – `order` – `field` • `Update` (optional) Restricts the records updated by an `Update` operation to those that are specified by the `where` sub-field. • `Delete` (optional) Restricts the records deleted by a `Delete` operation to those that are specified by the `where` sub-field. For more information, see "Filtering the records retrieved through a LoopBack connector" on page 1220.
LocalEnvironment.Destination.Loopback.Request.timeoutMilliseconds	Integer	The time (in milliseconds) that the node waits for the external system to process the operation. This environment variable overrides the **`Timeout (milliseconds)`** property on the LoopBackRequest node.

Using models with LoopBack connectors

Interactions between the LoopBackRequest node and some types of backend data source require LoopBack models to be defined.

Some LoopBack connectors require that the data model to be interacted with is defined through a LoopBack JSON model. When the LoopBackRequest node interacts for the first time with a named LoopBack object (which is either specified as a node property or dynamically overridden in the local

environment), it looks for a LoopBack JSON model file in a subdirectory of the directory that contains the `datasources.json` file. For information about configuring the model, see "Configuring the data source and models for your LoopBack connector" on page 1214.

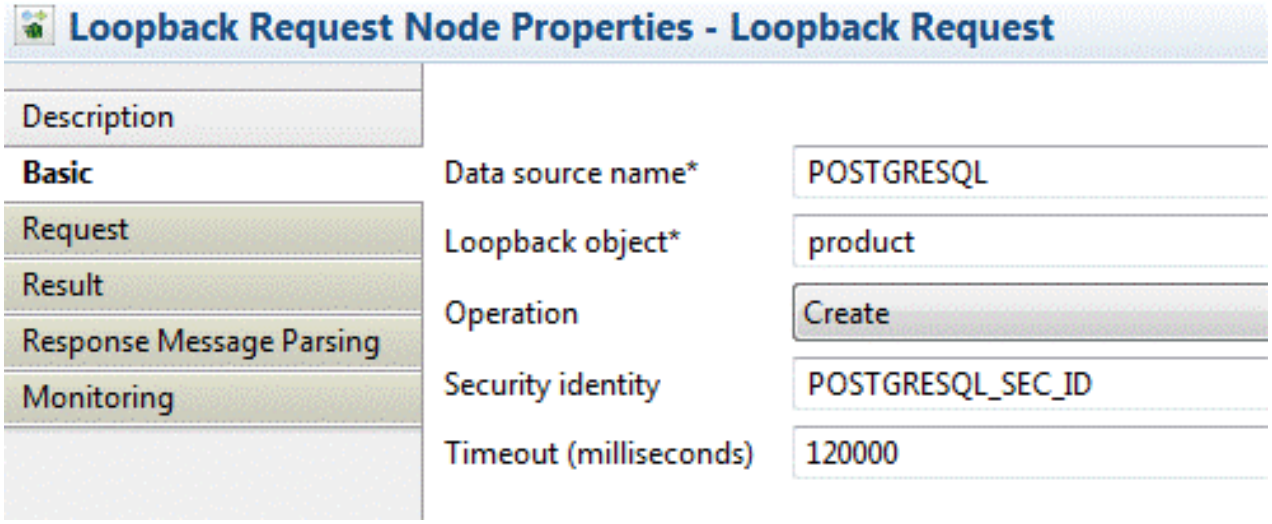
A LoopBack model is typically required for data sources that are backed by relational databases, where table objects with a rigid data structure are used. With these types of data source, the model can be used to define property mappings between the database columns and the LoopBack properties that are used by the LoopBackRequest node.

In the following example, the integration node called `IIB10` uses a `datasources.json` file that is located in the *MQSI_WORKPATH*`\IIB10\connectors\loopback` directory, where *MQSI_WORKPATH* is defined by the MQSI_WORKPATH environment variable. The `datasources.json` file includes the following stanza, called POSTGRESQL, to connect to the PostgreSQL database:

```
"POSTGRESQL": {
    "host": "localhost",
    "port": 5432,
    "database": "loopback",
    "name": "postgreSQL",
    "connector": "postgresql"
  }
```

The `product.json` file is copied into the *MQSI_WORKPATH*`\IIB10\connectors\loopback\POSTGRESQL` directory. For the LoopBackRequest node to use the model, the **LoopBack object** property on the node (or the LocalEnvironment.Destination.Loopback.Request.object variable, if used) must match exactly the name of the model, excluding the `.json` file extension. Typically, these names are the same, but they can be different; for example, if the name of the object in the LoopBack connected system contains a character that would be invalid in a file name. If the names are different, a BIP3880 message is issued.

In this case, the **LoopBack object** property is configured as shown in the following diagram:



The following example shows how to use a LoopBack model to interact with a `product` table that is defined in a PostgreSQL database:

```
CREATE TABLE public.product
(
  product_id serial NOT NULL,
  product_name character varying(20),
  sell_by date,
  number_in_stock integer,
  obsolete boolean,
  CONSTRAINT product_pk PRIMARY KEY (product_id)
)
```

The LoopBack PostgreSQL connector supports discovery, so the StrongLoop® and API Connect model-generation tools were used to generate the following LoopBack model for the `product` table. This model was output to the `product.json` file:

```
{
  "name": "Product",
  "base": "PersistedModel",
  "idInjection": false,
  "options": {
    "validateUpsert": true
  },
  "postgresql": {
    "schema": "public",
    "table": "product"
  },
  "properties": {
    "numberInStock": {
      "type": "number",
      "required": false,
      "length": null,
      "precision": 32,
      "scale": 0,
      "postgresql": {
        "columnName": "number_in_stock",
        "dataType": "integer",
        "dataLength": null,
        "dataPrecision": 32,
        "dataScale": 0,
        "nullable": "YES"
      },
      "_selectable": true,
      "comments": "Items in stock"
    },
    "obsolete": {
      "type": "boolean",
      "required": false,
      "length": null,
      "precision": null,
      "scale": null,
      "postgresql": {
        "columnName": "obsolete",
        "dataType": "boolean",
        "dataLength": null,
        "dataPrecision": null,
        "dataScale": null,
        "nullable": "YES"
      },
      "_selectable": true,
      "comments": "Flag if stock is obsolete"
    },
    "productId": {
      "type": "number",
      "id": true,
      "required": true,
      "length": null,
      "precision": 32,
      "scale": 0,
      "postgresql": {
        "columnName": "product_id",
        "dataType": "integer",
        "dataLength": null,
        "dataPrecision": 32,
        "dataScale": 0,
        "nullable": "NO"
      },
      "_selectable": false,
      "comments": "Unique product number"
    },
    "productName": {
      "type": "string",
      "required": true,
      "length": 20,
      "precision": null,
      "scale": null,
      "postgresql": {
        "columnName": "product_name",
        "dataType": "character varying",
        "dataLength": 20,
        "dataPrecision": null,
        "dataScale": null,
```

```
        "nullable": "YES"
      },
      "_selectable": true,
      "comments": "Description of product"
    },
    "sellBy": {
      "type": "date",
      "required": false,
      "length": null,
      "precision": null,
      "scale": null,
      "postgresql": {
        "columnName": "sell_by",
        "dataType": "date",
        "dataLength": null,
        "dataPrecision": null,
        "dataScale": null,
        "nullable": "YES"
      },
      "_selectable": true,
      "comments": "Expiry date"
    }
  },
  "validations": [],
  "relations": {},
  "acls": [],
  "methods": {}
}
```

For more information about the StrongLoop and API Connect model-generation tools, see the documentation on the StrongLoop website.

In the PostgreSQL `product` table, the `product_id` column is defined with a data type of `serial`, which results in values for the column being generated automatically when a row is inserted into the table. To reflect this, the LoopBack `product.json` model has been updated to include a `generated` property for the `productId`. The `required` attribute has also been changed to `false`, which stops the model checking that the data in requests sent from the LoopBackRequest node includes a `productId` when a row is created, because this value will be generated automatically. The updated model is shown in the following example:

```
"productId": {
      "type": "number",
      "id": true,
      "required": false,
      "generated": true,
      "length": null,
      "precision": 32,
      "scale": 0,
      "postgresql": {
        "columnName": "product_id",
        "dataType": "integer",
        "dataLength": null,
        "dataPrecision": 32,
        "dataScale": 0,
        "nullable": "NO"
      },
      "_selectable": false,
      "comments": "Unique product number"
    }
```

The model can also be used to set default values for data values; in the following example, the `obsolete` value defaults to `false`:

```
"obsolete": {
      "type": "boolean",
      "required": false,
      "default": false,
      "length": null,
      "precision": null,
```

Routing messages

Route messages through your message flow by using one or more of the techniques described in this section.

About this task

- “Using nodes for decision making” on page 1233
- “Routing using publish/subscribe applications” on page 1235
- “Using Operational Decision Manager (ODM) business rules” on page 1241

Some nodes use fields in your messages to make routing decisions. You might need to define a model of your messages to enable access to the fields in the message for these nodes. For information about how to develop a message model, and why you might want to develop a message model, see “Constructing message models” on page 2133.

Using nodes for decision making

You can use several built-in nodes in different ways to control the path that a message takes through the message flow.

Before you begin

Read the concept topic about message flow nodes.

About this task

These nodes let you decide how messages are processed by specifying the route that each message takes through the message flow based on dynamic values such as message structure and content.

For more information, see the following topics:

- “Testing the message structure (Validate node)” on page 1233
- “Controlling the order of processing in a message flow” on page 1234
- “Using the destination list to route messages (RouteToLabel and Label nodes)” on page 1235

You can use one of the following nodes to determine the path taken by a message through the message flow based on its content:

- node
- Filter node (ESQL)
- JavaCompute node
-
- Windows node
- node

You can use any of the following nodes to route messages by using information from a database:

- node
- node

Testing the message structure (Validate node)

Use the Validate node to test the characteristics of the message structure.

About this task

If you set the Validate node properties appropriately, you can request that one or all of the message domain, message set, and message type are compared to a specific value. If the message matches those

values for which you have requested the check, it is routed through the match terminal and is processed by the sequence of nodes that you have connected to that terminal.

If the message does not match any one of those values for which you have requested the check, it is routed through the failure terminal and is processed by the sequence of nodes that you have connected to that terminal.

For example, you might design a message flow that provides additional processing for all messages that are in the MRM domain. You can include a Validate node that tests just that characteristic of the message, and passes it to a sequence of nodes that provide the specialized processing. If the message is not in the MRM domain, the extra nodes are bypassed, and the failure terminal is wired up directly to the node that follows the sequence required for MRM messages only.

Controlling the order of processing in a message flow

Use the FlowOrder node to control the order of processing in a message flow.

About this task

When you connect message flow nodes together, the integration node determines the way in which the different connections are processed. This includes the order in which they are processed. If you have connected more than one message flow node or sequence of nodes to a single output terminal, you cannot predict whether one sequence is processed before another for a message.

If the order of processing is important in your message flow, use the FlowOrder node to force a prescribed order of processing of the messages that are propagated by this node.

The FlowOrder node has two output terminals that you can connect to control the order in which subsequent nodes process the message. The output terminals, named First and Second, are always processed in that order.

When you connect a message flow node or sequence of nodes to the First terminal, the input message is passed to the next node, and all processing defined by all subsequent nodes in this sequence is completed before control returns to the FlowOrder node.

The input message is then propagated to the next node in the sequence of nodes connected to the Second terminal.

The message passed to both sequences of nodes, from the First terminal and the Second terminal, is identical. It is always the message that the FlowOrder node receives as input. The message that the FlowOrder node propagates to the Second terminal is in no way affected by the processing of the message that has been performed by the sequence of nodes connected to the First terminal.

The FlowOrder node provides no other processing on the input message; it is used only for imposing order on subsequent processing.

Testing the message content (Filter node)

You can use the Filter node to determine the path taken by a message through the message flow based on its content.

About this task

You can customize the Filter node by using ESQL statements to determine if the message content meets some condition. The condition tested must yield a Boolean result, that is it must be true or false (or unknown). You can create the test to reference information from a database, if applicable.

You can connect nodes following the Filter node to the corresponding terminals of the Filter node, and process the message according to its content.

Using the destination list to route messages (RouteToLabel and Label nodes)

You can determine the path that a message takes through the message flow by using the RouteToLabel and Label nodes.

About this task

These nodes provide a more flexible way to process messages than the Filter node, which depends on the Boolean result of an ESQL expression for its logic.

When you use RouteToLabel and Label nodes, you must include a Compute node that determines, by using some combination of message content, database content, and ESQL logic, how messages are to be processed next. Configure the Compute node to create a destination list (in the DestinationList folder in the local environment subtree) that contains the destination for each message, specified as the LabelName of a Label node. The Compute node passes the message to the RouteToLabel node, which reads the destination list and propagates the message to either the first or last item on the destination list, according to the value that is specified for the RouteToLabel node's Mode property. Although there is no limit to the number of destinations that the Compute node writes in the destination list, the RouteToLabel node propagates the message only to a single label node. This use of the destination list is in contrast to its use to define the final recipients of the output messages. For more information about the procedure for creating a destination list, see “Creating destination lists” on page 610.

If you intend to derive destination values from the message itself, or from a database, you might also need to cast values from one type to another. For more information about the local environment, see “Local environment tree” on page 509. For more information about casting, see Supported casts.

Routing using publish/subscribe applications

You can route your messages to applications using the publish/subscribe method of messaging.

In IBM App Connect Enterprise, you can send publication messages to publish/subscribe brokers, and receive messages from them by using subscriptions. There are two situations where you can achieve additional functionality by using IBM App Connect Enterprise for publish/subscribe. These situations are where you want to:

- Provide additional transformation or routing function, or both, at publication time
- Filter messages based on the content of the body of the message

Developing publish/subscribe applications

For background information about the publish/subscribe method of messaging, see the following topics:

- “Publish/subscribe overview” on page 1236
- “Publishers” on page 1236
- “Publications” on page 1236
- “Subscribers” on page 1237
- “Filters” on page 1238
- “Subscription points” on page 1238

Publish/Subscribe in IBM App Connect Enterprise 12.0

In IBM App Connect Enterprise 12.0, publish/subscribe functions are provided by the MQTT and Publication (IBM MQ) message flow nodes. IBM App Connect Enterprise uses publish/subscribe to notify applications of significant events that occur in integration nodes. IBM App Connect Enterprise provides a built-in MQTT broker to support these integration node events. The MQTT broker is enabled by default for all events, apart from monitoring events. If you have installed IBM MQ, you can also use the IBM MQ pub/sub broker in place of, or alongside, the built-in MQTT broker. If you have a queue manager that is specified on the integration node, the MQ pub/sub broker is enabled by default for all types of

event, including monitoring events. You can choose which type of pub/sub broker to use based on your processing requirements and your existing architecture.

Publish/subscribe overview

Publish/subscribe is a style of messaging application in which the providers of information (publishers) have no direct link to specific consumers of that information (subscribers), but the interactions between publishers and subscribers are controlled by pub/sub brokers.

In a publish/subscribe system, a publisher does not need to know who uses the information (publication) that it provides, and a subscriber does not need to know who provides the information that it receives as the result of a subscription. Publications are sent from publishers to the pub/sub broker, subscriptions are sent from subscribers to the pub/sub broker, and the pub/sub broker forwards the publications to the subscribers.

This style of messaging contrasts with a point-to-point style of messaging application, in which the application that sends messages needs to know the destinations of the messages that it sends.

The pub/sub broker ensures that messages are delivered to the correct subscribers. IBM App Connect Enterprise supports two types of pub/sub broker (MQTT and MQ), and you can choose which type to use based on your processing requirements and your existing architecture. A built-in MQTT broker is provided with IBM App Connect Enterprise, and MQTT publication is enabled by default for all events that are generated by the integration node, apart from business events. You can specify an alternative MQTT broker if you choose not to use the built-in MQTT broker. If you have installed IBM MQ, you can use the MQ pub/sub broker that is provided with IBM MQ.

A typical publish/subscribe system has more than one publisher and more than one subscriber. An application can be both a publisher and a subscriber.

The publisher generates a message that it wants to publish and defines the topic of the message. A subscriber registers a request for a publication by specifying the topic (or topics) of the published messages that it is interested in. Subscriptions to an MQ pub/sub broker might include the following information:

- The subscription point from which it wants to receive publications.
- The content filter that should be applied to the published message.
- The name of the queue (known as the subscriber queue) on which publications that match the criteria selected are placed. This queue can be a cluster queue, so that publications can be distributed to clustered subscribers.

Publishers

A *publisher* is an application that makes information about a specified topic available to a pub/sub broker in a publish/subscribe system. The pub/sub broker can be an MQ broker (queue manager) or an MQTT broker.

In a publish/subscribe system, an application, known as the publisher, can send a message to a pub/sub broker. Another application, known as the subscriber, can send a subscription request to the pub/sub broker, which then sends relevant publication messages to the message queue or port of the subscriber.

A published message can be requested by more than one subscriber, and a subscriber can request messages, on the same or different topics, from more than one publisher.

Publications

A *publication* is a piece of information about a specified topic that is available to a pub/sub broker in a publish/subscribe system. The pub/sub broker can be an MQ broker (queue manager) or an MQTT broker.

Typically, a pub/sub broker distributes a publication that it receives to all applications that have registered a subscription for the publication. If the pub/sub broker is an MQ broker (queue manager), it also distributes the publication to all other queue managers connected to it, either directly or through a network of queue managers that have subscribers for the publication.

Local publications

If your application uses an MQ pub/sub broker, publishers can restrict access to their publications to only those subscribers that are registered to the same pub/sub broker as the publisher. This publication is known as a *local publication*.

If you are using an MQTT broker, all publications are local. Local publications are not forwarded to other pub/sub brokers.

Global publications

A publication whose distribution is not restricted to subscribers that are registered to the same pub/sub broker as the publisher is known as *global publication*. Global publications can be published through MQ pub/sub brokers (queue managers) only. A global publication is forwarded to all MQ pub/sub brokers, connected either directly or through a network of queue managers, that have one or more subscribers for the publication.

State and event information

Information being published can be categorized either as *state* information or as *event* information.

State information is information about the current state of something. The current price of stock or the current score in a soccer match are both examples of state information.

Event information is information about an individual event that occurs. A change in the price of stock or the scoring of a particular goal in a soccer match are both examples of event information.

When an event occurs, the current state information is no longer required and is superseded by new state information.

If a publication contains state information, it is often published as a retained publication. A new subscriber typically wants the current information immediately; the subscriber does not want to wait for an event that causes the information to be republished.

Retained publications

Typically, a pub/sub broker discards a publication after it has been delivered to subscribers. However, a publisher can specify (in the case of the *Publish* message, by specifying the *RetainPub* option) that it wants the pub/sub broker to keep a copy of the publication, which is then called a *retained publication*.

If a retained publication has been published, new subscribers to that publication receive the publication without having to wait for it to be published again.

For example, a subscriber that registers a subscription for a stock price receives the latest published stock price immediately, and does not have to wait for the stock price to be republished.

An MQTT pub/sub broker retains only one publication for each topic. An MQ pub/sub broker retains only one publication for each combination of topic and subscription point.

Subscribers

A *subscriber* is an application that requests information about a specified topic from a pub/sub broker. A pub/sub broker can be either an MQ pub/sub broker (queue manager) or an MQTT broker.

The subscribing application might be an IBM App Connect Enterprise, IBM MQ, or MQTT client application.

The subscriber sends a subscription request to a pub/sub broker (MQTT or MQ), specifying which publications it wants to receive. The request defines the topic for each publication, and, for IBM MQ, it also defines the filter and the subscription point.

Messages that are published by a publisher can be received by more than one subscriber, and a subscriber can receive messages, on the same or different topics, from more than one publisher.

Subscription topics can also include wildcards, allowing them to match a range of related topics.

Filters

A *filter* is an expression, which might include wildcard characters, that is applied to the content of a publication message to determine whether it matches a subscription.

Filters are supported only if your application is using an MQ pub/sub broker; they are not supported by MQTT brokers.

When you register a subscription, in addition to specifying a topic and subscription point, you can specify a filter to select publications according to their contents. In the IBM MQ subscription properties, filters are referred to as *selectors*. For more information, see the IBM MQ product documentation online. IBM App Connect Enterprise must know how to parse the contents of the message correctly, which can be achieved in a number of ways:

- The message is a self-defining XML message.
- The message template is defined in the MQRFH2 header.

  If the message has an MQRFH header, the message set and type are taken from that header. Otherwise, the message is assumed to be as defined in the properties (domain, set, type, and format) of the input node.

The filter itself is entered as an ESQL expression; for example:

```
Body.Name LIKE 'Smit%'
```

This example means that the contents of a field called Name in the body of a publication message are extracted and compared with the string given in the expression. If the string in the message starts with the characters "Smit", the expression evaluates to TRUE and the publication is sent to the subscriber.

If you want to select publications using filters only, without specifying a topic, you can register a subscription with the required filter and a topic of "#" (all topics). You then receive publications on only those topics for which you have access authority.

Subscription points

A *subscription point* is the name that a subscriber uses to request publications from a particular set of Publication nodes. It is the property of a Publication node that differentiates that Publication node from other Publication nodes in the same message flow.

A subscriber that registers a subscription without specifying a subscription point receives publications from any unnamed Publication node in the message flow, if there is a match with the topic and filter specified by the subscriber. Subscription points are valid only if your application is emitting to an MQ pub/sub broker; they are not supported by MQTT brokers.

This behavior applies to all message flows running in all integration nodes connected in the same network, unless the local has been specified when registering the subscription.

Using subscription points

If you have more than one Publication node in a message flow, you can differentiate between them by specifying subscription points. Choose values that indicate the type of message that is routed to each Publication node.

Example

Consider an application that publishes stock prices. The prices that are available from the first Publication node in the message flow are in dollars. This Publication node uses the default subscription point.

You can define a second path through the message flow that takes the price in dollars, and converts this using a defined conversion value, to produce the same message but with the stock price in pounds. These messages are published at a second Publication node that has its subscription point property set to *Pounds*.

You might have another message flow, in the same integration node or a connected integration node, that publishes stock prices in pounds on the same topic. Make sure that it uses the *Pounds* subscription point,

and that all other message flows that publish their stock prices in dollars use the default subscription point.

Subscribers specifying the relevant topic (for example, *stock*) can then choose whether to receive the information in dollars or in pounds, by using the default subscription point or the *Pounds* subscription point when they subscribe.

Content-based filtering using ESQL

IBM MQ supports message selection based on `Root.MQMD` and message properties; IBM App Connect Enterprise provides extra options.

Content based filters in IBM App Connect Enterprise extend IBM MQ message selectors to allow the use of ESQL expressions to filter on the entire message.

You can use the following items:

Correlation names

In content based filters, the message can be accessed using the `Root`, `Body`, and `Properties` correlation names.

Any other correlation name is interpreted as an IBM MQ message property, apart from the following list of excluded reserved names:

- `Database`
- `DestinationList`
- `Environment`
- `LocalEnvironment`
- `ExceptionList`
- `LocalEnvironment`

Any other top level identifier is assumed to be an IBM MQ message property, and is accepted.

Trees

The content based filtering engine does not update the message tree. It accesses the message tree as read-only. Any statements that attempt to modify the tree are rejected.

By supporting ESQL, content based filtering in IBM App Connect Enterprise supports fully-qualified Namespaces, as documented in ESQL reference.

ESQL expressions

Content based filtering accepts any ESQL expression, with the exclusion of database access, that returns a Boolean value.

Enabling content-based filtering with publish/subscribe

IBM MQ provides the ability to specify a filter when a subscription is made, but this can only refer to items in headers. IBM App Connect Enterprise can act as a content filtering provider for IBM MQ, and so allows extended filters to be specified by subscribers that can refer to elements in the body of publications.

Before you begin

- Read about Selectors on IBM MQ.
- Read the following overview of how IBM MQ selects content of messages.

  When an application publishes on a topic string, where one or more subscribers have a selection string selecting on the content of the message, IBM MQ requests that the extended message selection

provider parse the publication and inform IBM MQ whether the publication matches the selection criteria specified by each subscriber with a content filter.

If the extended message selection provider determines that the publication matches the subscriber's selection string, the message continues to be delivered to the subscriber.

If the extended message selection provider determines that the publication does not match, the message is not delivered to the subscriber. This might cause the IBM MQ MQPUT or MQPUT1 call to fail with reason code MQRC_PUBLICATION_FAILURE. If the extended message selection provider is unable to parse the publication, reason code MQRC_CONTENT_ERROR is returned and the MQPUT or MQPUT1 call fails.

If the extended message selection provider is unavailable or is unable to determine whether the subscriber should receive the publication, reason code MQRC_SELECTION_NOT_AVAILABLE is returned and theIBM MQ MQPUT or MQPUT1 call fails.

When a subscription is being created with a content filter and the extended message selection provider is not available, the IBM MQ MQSUB call fails with reason code MQRC_SELECTION_NOT_AVAILABLE. If a subscription with a content filter is being resumed and the extended message selection provider is not available, the IBM MQ MQSUB call returns a warning of MQRC_SELECTION_NOT_AVAILABLE, but the subscription is allowed to be resumed.

- Each queue manager that supports Extended Message Selection (Content Based Filtering), requires a broker that is associated with it and Content Based Filtering enabled on at least one integration server. If a client subscribes and specifies a content-based filtering expression against a queue manager that does not have this function enabled, it receives MQRC_SELECTION_NOT_AVAILABLE on the subscription request.
- Linux Windows UNIX On Linux, UNIX and Windows systems, grant authorization for the system to the queue manager: `setmqaut -t <qmgr> +system -p <brokerUserId>`

About this task

IBM App Connect Enterprise extends the message selection support provided by IBM MQ. IBM App Connect Enterprise does this by allowing ESQL statements rather than SQL92 statements, and filtering based on message content. See “Content-based filtering using ESQL” on page 1239 for details of the scope and exclusions of supported ESQL.

The main external differences in the current implementation of content-based filtering are:

- Content based filtering is no longer limited to IBM MQ MQRFH2 subscribers. IBM App Connect Enterprise provides content filtering services for the following IBM MQ subscribers:

  MQRFH2
  MQSUB

  If you are performing content filtering based on the *NameValueData* field, within an MQRFH2 header, on z/OS, the data can be present either in the first or second MQRFH2 header. For example, the filter:

  ```
  Root.MQRFH2.mcd.Msd='XML'
  ```

  might not work as you expect on z/OS. Use the following syntax to search all MQRFH2 headers:

  ```
  FOR ANY Root.MQRFH2[] AS I (I.mcd.Msd='XML')
  ```

- IBM MQ message properties are supported as part of the filter expression.
- If the publication does not contain an `mcd` folder, the payload is assumed to be XMLNSC.

Read the following steps to see how to enable content-based filtering on IBM App Connect Enterprise.

Procedure

1. Set the `cbfEnabled` property of the `ContentBasedFiltering` object for the integration server in which you want content-based filtering to run.

   Note that you must explicitly enable the `cbfEnabled` property for content based filtering to work; the default setting is for content based filtering to be off.
2. Restart the integration server for the change to take effect.

   If you enable content based filtering in multiple integration servers on z/OS, content based filtering is active in only one integration server at any time. Subsequent integration servers for which content based filtering is enabled, propagate the following messages to the syslog on start up (for each content based filtering thread) and then every 30 minutes, as they fail to connect to the queue manager:

   ```
   BIP2111E MQ04BRK jheg1 15 IBM App Connect Enterprise INTERNAL ERROR: DIAGNOSTIC INFORMATION
    'Error occurred in Content Based Filtering Thread'. : ImbCbfWorker(909)
   BIP2624E MQ04BRK jheg1 14 UNABLE TO CONNECT TO QUEUE MANAGER 'MQ04': MQCC=2;
    MQRC=2002; MESSAGE FLOW NODE 'ContentBasedFiltering'. : ImbCbfWorker(214)
   ```

   If you stop the integration server that is currently providing content based filtering services, another integration server for which content based filtering is enabled connects to the queue manager and provides content based filtering services.

   Both the `evaluationThreads` and `validationThreads` properties default to one if content-based filtering is enabled.

   Evaluation threads are used to validate content filters against a given publication at publication time. A network with a high number of publications might require the `evaluationThreads` property to be increased (up to a maximum of 32) to handle the workload at publication time.

   Validation threads are used to validate syntax of content filters at subscription time. A publish/subscribe network with a high number of subscribers, especially if dynamic subscribers, might require the `validationThreads` property to be increased (up to a maximum of 32) to handle the high throughput of subscription requests.

   It is possible to enable this function in multiple integration servers, but you must ensure that any message sets required to parse any published message (and referenced in the `mcd` folder of that message) are deployed to all the integration servers that have been enabled for content-based filtering.

   Any errors encountered parsing the message within the evaluation thread cause IBM MQ to return MQRC_CONTENT_ERROR to the publishing application. The parsing error appears as well in the event log as an IBM App Connect Enterprise exception.

   Example of a subscription <psc> folder processing ESQL and message properties in the filter:

   ```
   <psc>
   <Topic>topic</Topic>
      <Filter>
      SUBSTRING(Root.XMLNSC.Name.FirstName FROM 1 FOR 1) = ‘J' and usr.flag = ‘yes'
      </Filter>
   </psc>
   ```

Using Operational Decision Manager (ODM) business rules

You can configure message flows in IBM App Connect Enterprise to execute Operational Decision Manager (ODM) business rules, by using either an ODMRules node or a JavaCompute node.

Business rules are policies, constraints, or required operations that apply to a specific set of business conditions or dependencies. For example, a bank could use a business rule to decide whether a credit check is required for a customer opening a new account; the rule could stipulate that a credit check is required for new customers, but not for existing ones.

When working with IBM Operational Decision Manager, business rules are organized in rulesets and RuleApps. A ruleset is a decision-making program that can be processed by a rule engine to yield a

decision, based on input and output parameters. The decision-making logic is implemented as rules, decision tables, and ruleflows. A RuleApp is a deployable management unit for ODM Rule Execution Servers and can contain one or more rulesets.

You can use an node in a message flow to execute a set of ODM business rules contained in a ruleset. An ODMRules node can be used to execute rulesets that have XML parameters. You must attach an ODM Server policy to an ODMRules node to control how it accesses a remote ODM Rule Execution Server; for more information, see ODM Server policy (ODMServer).

Alternatively, you can use a node to execute ODM business rules. A JavaCompute can be used to execute rulesets that have either Java or XML parameters. You must attach an ODM Server policy to a JavaCompute node to control how it accesses a remote ODM Rule Execution Server; for more information, see ODM Server policy (ODMServer). You can also use the Process via Operational Decision Manager ruleset wizard to create template Java code that connects to an Operational Decision Manager (ODM) Server.

Rulesets that are used by an integration server can be updated either automatically or manually when they are changed in the ODM Rule Execution Server (RES). You can update the rulesets automatically by configuring properties in an ODMServer policy, as described in "Configuring automatic ruleset updates" on page 1248, or manually by using the administration REST API, as described in "Configuring manual ruleset updates" on page 1249. This update mechanism applies to rulesets that are loaded from the ODM Rule Execution Server and to rulesets that have been downloaded to the local file system.

When a ruleset is loaded for the first time (whether through an ODMRules node or a JavaCompute node), it must be compiled by the ruleset engine before it can be used. This compilation can take several seconds, particularly for rulesets that contain XML parameters. By default, this compilation takes place when the first message attempts to execute the ruleset, but you can choose to compile the ruleset when it is loaded during flow startup, by setting the **`Ruleset load strategy`** property in the ODMServer policy. For more information, see ODM Server policy (ODMServer).

For more information about using ODM business rules, see the following topics:

- "Executing ODM business rules by using an ODMRules node" on page 1242
- "Configuring the ruleset path" on page 1243
- "Using a local ruleset archive" on page 1244
- "Executing ODM business rules by using a JavaCompute node" on page 1245
- "Creating ODM classes by using the Process via Operational Decision Manager ruleset wizard" on page 1247
- "Discovering and applying ruleset updates" on page 1248

Executing ODM business rules by using an ODMRules node

You can use an ODMRules node to execute IBM Operational Decision Manager (ODM) business rules.

Before you begin

Read "Using Operational Decision Manager (ODM) business rules" on page 1241.

About this task

You can use an ODMRules node to execute business rules contained in a ruleset, by completing the following steps:

Procedure

1. Create a message flow containing an node. For more information, see "Creating a message flow" on page 574.

2. Create an ODM Server policy that contains details of either a remote Operational Decision Manager (ODM) Rule Execution Server or a ruleset archive that has been downloaded and stored in the local file system.

   For more information, see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327 and "Using a local ruleset archive" on page 1244.
3. Configure the ODMRules node to use the ODM Server policy that you created in step 2, either by specifying the policy name in the **Policy** field (in the form *policyProject*}:*policyName*), or by clicking **Browse** and selecting the required policy from the displayed list.
4. Configure the ruleset path in the ODMRules node, as described in "Configuring the ruleset path" on page 1243.

   When the ruleset path configuration wizard has completed, it populates the parameters table.
5. Configure a **Data location** XPath for each of the parameters listed in the table. Validation of the node cannot complete until this step has been completed.

   You can either enter the XPath manually or click the ellipsis (**...**) button to open the standard XPath editor, as described in node. For each parameter, the location is identified in the message tree. For IN and INOUT parameters, the location specifies where the required parameter data can be found in the input message tree, and that part of the message tree is serialized as XML. The resulting XML is then set as the parameter value when the ruleset is evaluated. For the IN and INOUT parameters, the location must exist so that it can be serialized. For the INOUT and OUT parameters, after executing the ruleset, the XPath location is used to inflate the XML that is obtained from the ruleset execution into the message tree.
6. When the **Data location** for has been configured for each parameter, save the changes.

Configuring the ruleset path

You can use the **Ruleset path** property of the ODMRules node to define the set of Operational Decision Manager (ODM) business rules that are to be evaluated for message processing.

Before you begin

Read the following topics:

- "Using Operational Decision Manager (ODM) business rules" on page 1241
- "Executing ODM business rules by using an ODMRules node" on page 1242

About this task

The set of rules to be evaluated for message processing is defined by the **Ruleset path** property of the node.

Procedure

Configure the ruleset path by completing the following steps:

1. On the **Basic** tab of the ODMRules node, click **Configure** next to the **Ruleset path** field.

   You can then use the interactive panels to choose a ruleset from those that are already deployed to a Rule Execution Server; you cannot edit the field manually.

   The value of the field follows the Operational Decision Manager (ODM) syntax: `'/RuleApp/RuleAppVersion/ruleset/rulesetVersion'`. The RuleAppVersion and RulesetVersion can reference either a specific version or the `latest` version. For example:

   ```
   '/SaleApp/1.1/SaleSet/2.0'
   ```

   ```
   '/SaleApp/latest/SaleSet/latest'
   ```

   ```
   '/SaleApp/2.2/SaleSet/latest'
   ```

2. When the Rule Set wizard opens, set the following properties in the **Connect to an ODM Server** panel to define access to the Rule Execution Server:
   a) In the **`URL of the ODM Rule Execution Server`** field, specify the Rule Execution Server context root URL. For example: `http://localhost:9080/res/`.
   b) In the **`Username`** field, specify the username to be used to access the server.
   c) In the **`Password`** field, specify the password to be used to access the server.
3. Click **Next**.
   A query is sent to the Rule Execution Server, and the results of the query are used to populate the fields on the **Select a Ruleset for the ODMRules node** panel:

Table 41. Select a Ruleset for the ODMRules node

Field	Description
RuleApp	The RuleApp containing the ruleset to be used. The drop-down menu offers a choice of applications deployed on the server.
RuleApp version	The version number of the RuleApp. The drop-down menu contains the available versions and the string 'latest'.
Ruleset	The name of the ruleset to use from the rule application selected above. The drop-down menu offers a choice of rulesets in the application.
Ruleset version	The version number of the ruleset. The drop-down menu contains the available versions and the string 'latest'.
Selected ruleset parameters	The list of parameters of the ruleset with their respective names, types, and directions. The `Direction` can be IN, OUT, or INOUT, for input, output, and bi-directional parameters respectively. The `Kind` field is always XML for the ODMRules node.
Create/update the xsd(s) required for the ruleset	If selected, the Toolkit imports the XSD schemas describing the message formats that are used by the ruleset and makes them available in the project.

4. Click **Finish**.

Using a local ruleset archive

You can configure an ODM Server policy to specify a local ruleset archive instead of an Operational Decision Manager Rule Execution Server.

Before you begin

Read the following topics:

- “Using Operational Decision Manager (ODM) business rules” on page 1241
- “Executing ODM business rules by using an ODMRules node” on page 1242

About this task

You can download an archive of rulesets from the Operational Decision Manager Rule Execution Server (RES) and store it on a local file system. You can then configure an ODM Server policy to specify this locally-stored archive as the location for the ruleset to be used by the message flow rather than accessing a ruleset on the ODM server.

Procedure

Configure an ODM Server policy to specify a local archive by completing the following steps:

1. Download an archive of the required rulesets from the Operational Decision Manager Rule Execution Server and store it on your local file system.
2. Create and configure an ODM Server policy.

   For information about creating a policy, see "Creating policies with the IBM App Connect Enterprise Toolkit" on page 327.
3. Set the **Rule Execution Server URL** property of the ODM Server policy to specify the location of the downloaded archive file.
   For example:

   ```
   file:/Users/admin/ACE/rulesets/ruleApp_Sale_1.0.jar
   ```

   or

   ```
   file:///c:\Users\Administrator\Downloads\ruleApp_Sale_1.0.jar
   ```
4. Save and deploy the policy.

   The message flow containing the node functions in the same way as it would if the ODM Server policy was configured to connect to a Rule Execution Server, but it accesses the rulesets that are stored on the local file system instead of connecting to the Rule Execution server.

Executing ODM business rules by using a JavaCompute node

You can use a JavaCompute node to execute IBM Operational Decision Manager (ODM) business rules.

Before you begin

- Read "Using Operational Decision Manager (ODM) business rules" on page 1241.
- Create a message flow containing a node.

About this task

You can use a JavaCompute node to execute rules contained in a ruleset, by using an embedded rule engine.

Procedure

To use a JavaCompute node to execute rules contained in a ruleset, complete the following steps:

1. Obtain a connection to an ODM server
2. Obtain a ruleset
3. Execute the ruleset

Obtaining a connection to an ODM server

About this task

Obtain a connection to an ODM Rule Execution server during the `onSetup` method of a JavaCompute node, by calling the `getODMServer` method and supplying the name of an ODMServer policy:

```
String odmServerPolicyName = "{myPolicyProject}:myODMServerPolicy";
MbODMServer odmServer = getODMServer(odmServerPolicyName);
```

This method initializes a connection to the ODM Rule Execution server, which must be running when the message flow that references the JavaCompute node is deployed or started. The `getODMServer` method can be called only from within the `onSetup` method. MbODMServer objects must not be shared between JavaCompute nodes and must not be cached for longer than the lifetime of the current node. MbODMServer objects that are obtained in the `onSetup` method can be used in the `evaluate` method to look up rulesets.

Obtaining a ruleset

About this task

When an MbODMServer object has been retrieved, it can be used to retrieve a ruleset from the ODM server for execution when the message flow is running. To retrieve a ruleset, call the `getRuleset` method on the MbODMServer object and supply the fully qualified path to the ruleset, in the form `'/RuleAppName/RuleAppVersion/rulesetName/rulesetVersion'`. You can specify either a particular version or `latest` to use the most recent version. For example:

```
MbODMRuleset odmRuleset = odmServer.getRuleset("/myRuleApp/1.0/my_ruleset/1.0");
```

```
MbODMRuleset odmRuleset = odmServer.getRuleset("/myRuleApp/Latest/my_ruleset/latest");
```

```
MbODMRuleset odmRuleset = odmServer.getRuleset("/myRuleApp/1.0/my_ruleset/latest");
```

When it is first referenced, the `Latest` version of a ruleset or RuleApp is loaded and cached at the application level. As a result, all message flows and nodes inside the application have the same `Latest` version, regardless of when they are first referenced. The latest version is re-evaluated when the application is stopped and restarted.

The `getRuleset` method retrieves the ruleset from the ODM server and makes it available in the embedded rule engine, ready for execution.

Rulesets define ruleset parameters, which are used to pass data between the ruleset and the calling application. The ruleset can have parameters of type `Java` or XML, and rulesets that support both parameter types can be called from a JavaCompute node. If the ruleset has parameters of type `Java`, the classes that define the Java objects for those parameters must be made available to the JavaCompute node at development time and at runtime. If you use the JavaCompute node wizard to query the ODM server and generate template Java code, you also have the option of downloading the class files that define the parameters and make them available to the Java project that contains the JavaCompute node.

The `getRuleset` method can be called during the JavaCompute node's `onSetup` or `evaluate` methods, and if the same rule is requested multiple times, all calls after the first one return the version that has been downloaded and cached. MbODMRuleset objects must not be shared between JavaCompute nodes and must not be cached for longer than the lifetime of the current node. MbODMRulesets can be retrieved during a JavaCompute node's `onSetup` method and then used by its `evaluate` method, to avoid delaying the execution of the first message.

Executing a ruleset

About this task

When executing a ruleset, you must build up a map of parameters to supply to the `execute` method of the MbODMRuleset. The map must contain an entry for each parameter defined as an IN or INOUT parameter in the ruleset definition. For parameters of type XML, you must supply a Java string that contains an XML representation of the `xsd` type (simple or complex) defined for that parameter. For parameters of type `Java`, you must supply an instance of the Java class defined for that parameter. To execute the ruleset, call the `execute` method of the MbODMRuleset, passing in the map of parameters:

```
Map<String, Object> ruleInParameters = new HashMap<String, Object>();
MyObject myObj1 = new MyObject();
ruleInParameters.put("ruleParameter_Java_1", myObj1);
ruleInParameters.put("ruleParameter_XML_2", "<Customer><name>John Doe</name><age>33</age></
Customer>");
MbODMRulesetExecutionResponse ruleResponse = odmRuleset.execute(ruleInParameters);
```

The result of calling the `execute` method is an instance of an MbODMRulesetExecutionResponse. This object gives access to the map of OUT and INOUT parameters of the ruleset through the `getOutputParameters` method, and to some execution statistics:

```
Map<String, Object> ruleOutParameters = ruleResponse.getOutputParameters();
MyResultObject myResult1 = (MyResultObject)ruleOutParameters.get("ruleResponseParameter1");
long rulesFired = ruleResponse.getTotalRulesFired();
```

You can use normal message tree access and modification techniques to retrieve data from the incoming message tree to build the parameters supplied to the ruleset `execute` method, and to build or modify the outgoing message tree with details from the result parameters. The `execute` method of the MbODMRuleset can be called multithreaded, and it does not need to be looked up for each flow instance.

Executing rulesets by using a JavaCompute node

About this task

When you create a JavaCompute node, you are presented with a series of templates, one of which is **Process via Operational Decision Manager ruleset**. Select this option to query the available rulesets in an ODM Rule Execution server; the wizard guides you through selecting a ruleset and then generates template Java code with details about the rule and how to call it. For more information, see "Creating ODM classes by using the Process via Operational Decision Manager ruleset wizard" on page 1247.

Creating ODM classes by using the Process via Operational Decision Manager ruleset wizard

You can use the **Process via Operational Decision Manager ruleset** wizard within a JavaCompute node to create Java code that executes a ruleset retrieved from an Operational Decision Manager (ODM) Server.

Before you begin

- Read "Using Operational Decision Manager (ODM) business rules" on page 1241 for information about using ODM business rules with IBM App Connect Enterprise.
- Create a JavaCompute node in your message flow.

About this task

You can use the **Process via Operational Decision Manager ruleset** wizard to query the available rulesets in an ODM Rule Execution server, select a ruleset, and then generate Java code with details about the rule and how to call it.

When you create a JavaCompute node, templates are available to help you develop your Java code. Select **Process via Operational Decision Manager ruleset** to use the wizard.

For information about using a JavaCompute node to execute ODM business rules, see "Executing ODM business rules by using a JavaCompute node" on page 1245.

Alternatively, you can use an ODMRules node in a message flow to execute a set of business rules, as described in node.

Procedure

Complete the following steps to use the **Process via Operational Decision Manager ruleset** wizard to query the available rulesets in an ODM Rule Execution server, select a ruleset, and then generate Java code with details about the rule and how to call it:

1. In the IBM App Connect Enterprise Toolkit, double-click the JavaCompute node in your message flow and click **Process via Operational Decision Manager ruleset**.
2. Follow the instructions in the wizard.
3. Click **Finish**.

Discovering and applying ruleset updates

Rulesets that are used by an integration server can be refreshed either automatically or manually when they are changed in the Operational Decision Manager (ODM) Rule Execution Server.

You can discover and apply updates to ODM rulesets automatically, by configuring properties in an ODMServer policy, or manually, by using the administration REST API. IBM App Connect Enterprise queries the ODM Rule Execution Server for information about all rulesets that are currently in use in the integration server, either through an ODMRules node or a JavaCompute node. Checks are made to see whether either of the following conditions has been met:

- An existing ruleset has been updated.
- A new ruleset has been deployed that allows a `latest` ruleset reference to resolve to a later version (as described in "Configuring the ruleset path" on page 1243).

If either of these cases is true, the new ruleset is downloaded and used by the integration server.

When a new ruleset is loaded, the details are reported by the integration server through BIP messages that are sent to the event log:

- `bip4337. Ruleset '&1' from ODMServer policy '&2' has been updated.`
- `bip4338. Ruleset '&1' from ODMServer policy '&2' has been updated and now resolves to ruleset '&3'.`

If any problems occur when the updated ruleset is being downloaded or compiled, the issues are reported through BIP error messages.

To discover and apply ruleset updates, complete the steps in one of the following topics:

- "Configuring automatic ruleset updates" on page 1248
- "Configuring manual ruleset updates" on page 1249

Configuring automatic ruleset updates

You can configure IBM App Connect Enterprise to discover and apply updates to Operational Decision Manager (ODM) rulesets automatically, by setting properties in an ODMServer policy.

Before you begin

Read "Using Operational Decision Manager (ODM) business rules" on page 1241.

About this task

To discover and apply ruleset updates automatically, complete the following steps:

Procedure

1. Complete the steps in one of the following tasks, according to your chosen method:
   - "Executing ODM business rules by using an ODMRules node" on page 1242
   - "Executing ODM business rules by using a JavaCompute node" on page 1245
2. Set the following properties in the ODMServer policy that is specified by your ODMRules or JavaCompute node:
   a) Set the **`Ruleset refresh mode`** property to `polling`.
   b) Optional: Set the polling interval that you require by specifying a value (in seconds) in the **`Ruleset refresh polling interval`** property.
   The default value for this property is `600` seconds (10 minutes).
   For more information, see ODM Server policy.
3. Deploy the ODMServer policy. For more information about policies, see "Overriding properties at run time with policies" on page 324 and "Policies overview" on page 324.

4. Run the flows that use the ODMServer policy as usual.

   When a ruleset has been updated in the rule execution server or in the local file system, the updated ruleset is discovered and applied automatically when the polling interval expires. When the update has completed, a message is written to the syslog, and the changes to the ruleset are applied automatically to the flows that use it.

Configuring manual ruleset updates
You can use the administration REST API to discover and apply updates to Operational Decision Manager (ODM) rulesets.

Before you begin

Read "Using Operational Decision Manager (ODM) business rules" on page 1241.

About this task

To discover and apply ruleset updates manually, complete the following steps:

Procedure

1. Complete the steps in one of the following tasks, according to your chosen method:
   - "Executing ODM business rules by using an ODMRules node" on page 1242
   - "Executing ODM business rules by using a JavaCompute node" on page 1245
2. Use the administration REST API to discover and apply ruleset updates manually, by making an HTTP POST call to the appropriate URL:
   - Use the following URL to refresh all policies:

     ```
     http://host:4414/apiv2/resource-managers/odm/refresh-ruleset-cache
     ```

   - Use the following URL to refresh a specific set of policies:

     ```
     http://host:4414/apiv2/resource-managers/odm/refresh-ruleset-cache?
     policy={myProject}:myPolicy&policy={myOtherProject}:myOtherPolicy
     ```

   - Use the following URL to refresh policies in a single project:

     ```
     http://host:4414/apiv2/resource-managers/odm/refresh-ruleset-cache?
     project=myProject&policy=myPolicy&policy=myOtherPolicy
     ```

3. The REST call starts a ruleset refresh in the background, and a message confirms that the update request has been started. The ruleset update is therefore asynchronous from the REST call. After the request has been made, messages are written to the syslog when the rulesets are updated.

   For more information about using the administration REST API, see "Managing resources by using the administration REST API" on page 334.

Transforming and enriching messages

Transform and enrich messages by using one or more of the following techniques.

About this task

Use one or more of the following options for transforming and enriching the messages in your message flows.

Visual transformation
Use the Mapping node to transform the incoming message, create new output messages, and interact with information in a database by using a graphical data map.

Stylesheet
Use the XSLTransform node to transform the incoming XML message by using an XSL stylesheet.

Programming languages
Use the following nodes to route and transform the incoming message, and create new output messages, by using programming languages:

- .NETCompute node:
  - Uses the .NET C#, VB or F# programming languages.
  - Can also interact with .NET modules.
- JavaCompute node:
  - Uses Java.
  - Can also use JAXB to model message data.
- Compute node:
  - Uses the ESQL language.

For more information about these options, see "Client application programming interfaces" on page 499. To use some of these options for transforming and enriching messages, you might need to create a model of the messages that you want to transform. For information about how to develop a message model, and why you might want to develop a message model, see "Constructing message models" on page 2133.

For details of the tasks that are associated with these options, use the instructions in the following sections:

- "Data Analysis" on page 1250
- Using message maps
- "Developing ESQL" on page 1607
- "Developing Java" on page 1751
- "Using XSL Transform" on page 1789
- "Using .NET" on page 1790
- "Combining a result message with an input message when fetching data from external systems" on page 1811

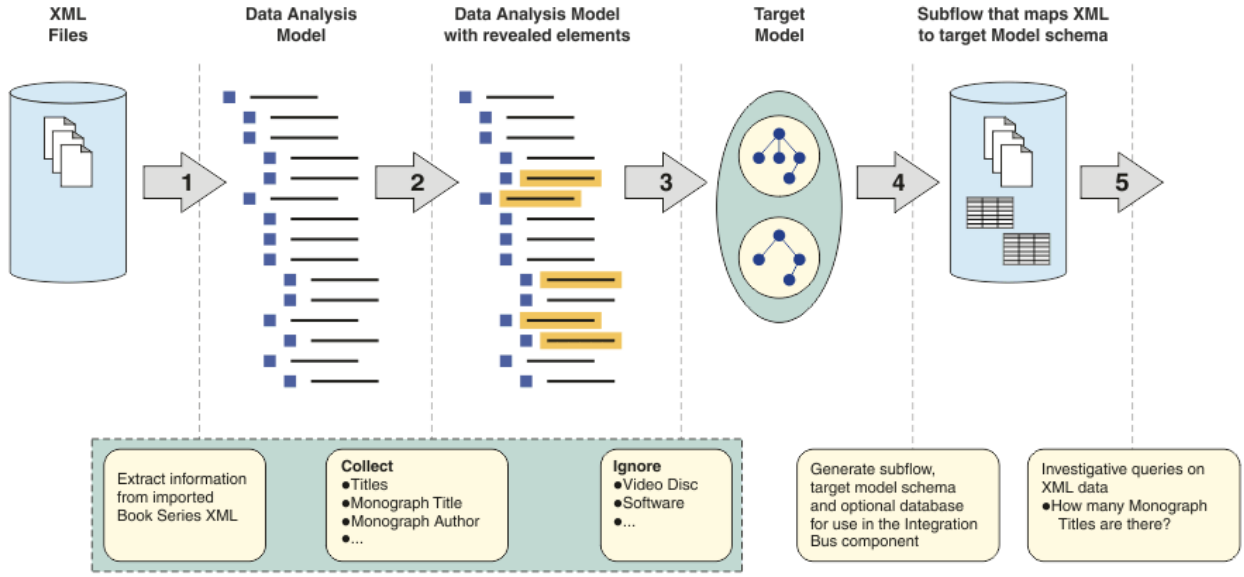
Data Analysis

Data Analysis analyzes and filters information in complex XML documents. You can use this analysis to create a library, that contains Data Analysis tools to quickly and easily transform your data in IBM App Connect Enterprise.

XML files are flexible, but can be long and complex. You might be interested in a small subset of data. However, it can be difficult to construct a model to filter and analyze this subset of data using traditional methods. Existing business intelligence (BI) tools work best with well-structured relational data.

In a Data Analysis project, you analyze a set of sample XML documents according to the content of the data. This content is defined in a Data Analysis profile that you specify when you create the project. When you analyze your sample XML documents, new data and new data structures within them are retained in the Data Analysis model. Repeated data and data structures are not added. After this analysis is complete, you can explore your Data Analysis model, which is a summary of your sample data, select relevant elements in the Data Analysis model, and then add them to a target model. Use the target model to produce a library that contains your Data Analysis tools, which you can use at run time to transform incoming data. The Data Analysis tools that are created include a map, schema file, validation stylesheet and subflow.

An overview of the process is shown in the following figure:



The key steps are as follows:

1. Create a Data Analysis project. See “Creating a Data Analysis project” on page 1251.
2. Analyze sample XML documents. See “Analyzing sample XML documents” on page 1252.
3. Create a target model. See “Creating a target model” on page 1255.
4. Populate and edit your target model. See “Populating a target model from your sample XML documents” on page 1255 and “Modifying a target model in the Target Model editor” on page 1256.
5. View and edit your target model in database format. See “Editing the database representation of the target model in the Target Model editor” on page 1260 and “Data Analysis database setup” on page 1259.
6. Create a library that contains Data Analysis tools. See “Creating Data Analysis tools” on page 1258.
7. Use the Data Analysis tools to work with your data in the Integration Development perspective.

Creating a Data Analysis project

Create a Data Analysis project to create, contain, and develop your Data Analysis model, target models, and Data Analysis tools.

Procedure

1. In the IBM App Connect Enterprise Toolkit, click **File** > **New** > **Data Analysis Project**.
   The **New Data Analysis Project** wizard opens.
2. Complete the fields in the **New Data Analysis Project** wizard and click **Finish**.
   The Data Analysis perspective and the Data Analysis Project Overview open.

Results

Your Data Analysis project is created and the Data Analysis Project Overview is open in the editor area.

What to do next

Create a Data Analysis model by analyzing sample XML documents. See “Analyzing sample XML documents” on page 1252.

Analyzing sample XML documents

Use the Data Analysis Project Overview to analyze sample XML documents, and to add data structures that conform to your schema into a Data Analysis model. Select elements and attributes from your Data Analysis model to form a target model, which you use to create a library that contains Data Analysis tools.

Before you begin

- Create a Data Analysis project. See "Creating a Data Analysis project" on page 1251.
- Ensure that your sample documents are in XML format. The sample XML documents must be representative of your relevant data so that you can later produce a useful target model. If data is missing from your sample XML documents, subsequent input may not conform to the generated target model.
- Ensure that the sample XML documents conform to a schema and that the schema is available. If sample data does not conform to your schema, you cannot analyze your sample XML documents, nor load the relevant data from within them.

Procedure

1. In the Data Analysis Project Overview, click **Analyze documents**.

   The **Analyze documents** wizard opens.
2. Complete the steps in the **Analyze documents** wizard and click **OK**.

   The **Summary of Analyzed Documents** window opens, and shows whether you successfully analyzed your documents.

   Note:

   - At most, the analysis adds 10 identical data items or data structures from each document. When you analyze additional documents, pre-existing data or data structures are ignored and therefore are not displayed in any of the views.
   - The time that is taken to analyze the sample XML documents increases with file size.
3. Click **OK** to close the **Summary of Analyzed Documents** window.
4. Optional: Repeat these steps to analyze additional sample documents.

Results

Your sample XML documents are analyzed, ready for you to create a target model.

What to do next

You can now complete the following task:

- Create a target model. See "Creating a target model" on page 1255.

Exploring data in the Data Analysis Model view

Use the Data Analysis Model view to explore your analyzed data.

Click the following headings to learn how to use the Data Analysis Model view to explore your data:

- "Sorting elements" on page 1253
- "Highlighting elements" on page 1253
- "Choosing which element to display" on page 1254
- "Displaying data from a selected element" on page 1254
- "Viewing document analysis history" on page 1254

Sorting elements

By default, the elements are displayed in the order in which they are added from the analysis of your sample XML documents. Click the **Display the tree in an alphabetical order** icon ( ) at the top of the view to view the elements in alphabetical order. Click this icon again to return the list to the original order.

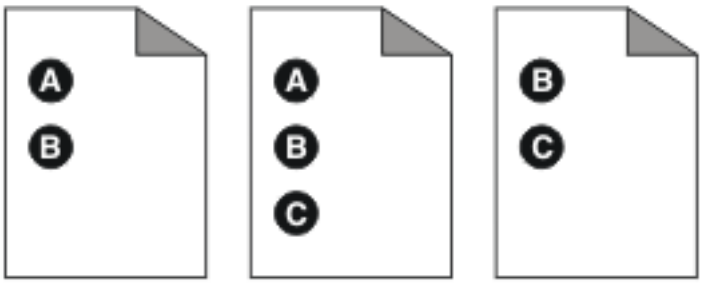
Highlighting elements

Highlight elements in the Data Analysis Model view to identify elements that have common features. Right-click in the Data Analysis Model view and then select one of the following options:

Highlight All Coexisting Elements

Use this option to highlight all elements that are in one or more of the same sample XML documents as your selected element. This action shows where combinations of data structures occur. The selected element is highlighted in the Data Analysis Model view, and is also identified at the bottom of the view, as the *Focus Element*. The percentage next to each element indicates the percentage of documents that contain both that element and the focus element.

This concept is illustrated by the following examples, in which each of three sample XML documents contain a combination of elements A, B, and C:



Example 1: Element A is the focus element.

Element B is in all of the sample XML documents that contain element A, so the percentage of coexistence for B is 100%.

Element C is in only one of the two sample XML documents that contain element A, so the percentage of coexistence is 50%.

These figures are displayed in the tree as B [100%] and C [50%].

Example 2: Element B is the focus element.

Element A is in two of the three sample XML documents that contain element B, so the percentage of coexistence is 66.6%.

Element C also has a percentage of coexistence is 66.6%, for the same reason.

Highlight Elements Based on Sample Documents

Use this option to highlight elements that were added to the Data Analysis model during the analysis of your sample XML documents. Use the **Sample Documents** window to select the sample XML documents. The elements that were added from the selected documents are highlighted.

For example, if you select documents 'exampleDoc1' and 'exampleDoc5' in the **Sample Documents** window, the elements that are highlighted are those that were added when documents 'exampleDoc1' and 'exampleDoc5' were analyzed.

Highlight Elements Based on Time

Use this option to highlight elements that were added or modified after a certain time, which you specify. You can use one of the following options to determine how the elements are highlighted:

- **Added After**
- **Added or Modified After**

- **Modified After**

Tip: Click **Off** in the lower left corner of the Data Analysis Model view to turn off any highlighting.

Choosing which element to display

View a greater or smaller number of elements to help provide context or focus. Use one of the following options to change how many elements are displayed:

Expand All Descendants
Display elements that are nested under other elements. Display descendant elements by clicking **Expand All Descendants** on the Data Analysis Model view menu, or click the **Expand All Descendants** icon () at the top of the view.

Collapse All Descendants
Hide elements that are nested under other element to focus on parent elements. This action reduces the amount of displayed data. Collapse descendant elements by clicking **Collapse All Descendants** on the Data Analysis Model view menu, or click the **Collapse all descendants** icon () at the top of the view.

Show Only Coexisting Elements
Show only elements that are in the same documents as the focus element. This action shows where data structure combinations occur. The focus element is highlighted in the tree and is also identified at the bottom of the view. When you highlight all coexisting elements, a percentage is displayed next to individual elements. This percentage indicates the percentage of documents that contain both the displayed element and the focus element. See "Highlighting elements" on page 1253 for an explanation of coexisting elements.

Displaying data from a selected element

To display data from a specific element, select the element and click **Show Data Under the Selected Element** from the Data Analysis Model view menu. This action prevents excess data from being displayed and reduces the time that you spend searching for data. The data from the selected element is displayed in the Data Filter view.

Tip: Click **Off** in the Data Filter view to turn off this option.

Viewing document analysis history

Use the **Show Document Analysis History** option in the Data Analysis Model view menu to display the following information about each time that you analyze your sample XML document:

- Start time
- Completion time
- Total amount of documents examined
- A list of documents that were successfully analyzed
- The number of documents that were successfully analyzed
- The number of schema validation errors
- The number of XML parsing errors
- The number of elements that were added to the Data Analysis model

Next:

- Explore your data further.
- Add to your target model. See "Populating a target model from your sample XML documents" on page 1255.
- Create a library that contains your Data Analysis tools. See "Creating Data Analysis tools" on page 1258.

Creating a target model

Create a target model, which is based on the data from your analyzed sample XML documents. Use your target model to create a library that contains Data Analysis tools to transform data.

Before you begin

- Create a Data Analysis project. See “Creating a Data Analysis project” on page 1251.
- Analyze your sample XML documents. See “Analyzing sample XML documents” on page 1252.

Procedure

1. In the Data Analysis Project Overview, click **Create a new target model**.
   The **Confirm** window opens.
2. In the **Confirm** window, click **OK** to save your Data Analysis project.
   The **New Target Model** wizard opens.
3. Complete the fields in the **Target Model** wizard and click **Finish**.

Results

Your target model is created and the Target Model editor opens in the Editor area.

What to do next

- Populate your target model. See “Populating a target model from your sample XML documents” on page 1255.
- Add more sample XML documents to the Data Analysis model. See “Analyzing sample XML documents” on page 1252.
- Create your library that contains Data Analysis tools. See “Creating Data Analysis tools” on page 1258.

Populating a target model from your sample XML documents

Populate your target model, so that you can use it to create a library that contains your Data Analysis tools.

Before you begin

Before your start:

- Create a Data Analysis project. See “Creating a Data Analysis project” on page 1251.
- Analyze sample XML documents. See “Analyzing sample XML documents” on page 1252.
- Create a target model. See “Creating a target model” on page 1255.

About this task

You can populate your target model from the Data Filter view, the Data Paths view, and the Data Analysis Model view.

To populate your target model, complete the following steps:

Procedure

1. In the Data Filter view, search for data structures by typing in the **Filter (by Element Name or Element Data)** field.
   The search results are displayed in the table.
2. In the Data Filter view, click an element to display a list of instances where that data structure is contained in your sample XML documents.
   This list is displayed in the Data Paths view.

3. Drag elements from the Data Analysis Model view, Data Filter view or, Data Paths view to the Target Model editor to populate the target model. If you drag an element from the Data Filter view that has multiple possible data paths, a **Data Paths** window opens. Select a data path from the list and click **Finish**.

Results

Your target model is populated.

What to do next

- Edit your target model. See "Modifying a target model in the Target Model editor" on page 1256.
- Create your Data Analysis tools. See "Creating Data Analysis tools" on page 1258.

Modifying a target model in the Target Model editor

You can use the Target Model editor to alter the structure of your target model to meet the requirements of the downstream application.

Before you begin

- Create a target model. See "Creating a target model" on page 1255.
- Populate your target model. See "Populating a target model from your sample XML documents" on page 1255.

About this task

Double-click the following headings to learn how to modify your target model with the Target Model editor:

- "Creating local elements" on page 1256
- "Renaming elements and attributes" on page 1256
- "Moving elements" on page 1257
- "Deleting elements and attributes" on page 1257
- "Restoring deleted elements and attributes" on page 1257

Creating local elements

About this task

Create local elements in your target model

Procedure

1. Right-click the Target Model editor and select **New Child Local Element** or **New Sibling Local Element**. The **New Element** window opens.
2. Type the name for your new element in the **Element name** field and click **OK**.

Results

Your new element is created.

Renaming elements and attributes

About this task

Rename elements or attributes so that your target model is compatible with other applications.

Procedure

1. In the Target Model editor, right-click the element or attribute that you want to rename, and select **Rename** from the menu.

   The **Rename** window opens.
2. In the **New name** field, type the new name for your element or attribute and click **OK**.

Results

Your element or attribute is renamed.

Moving elements

About this task

Move elements in the Target Model editor so that they are attached to different data structures. Change the order of sibling elements to affect the function of your Data Analysis tools.

Procedure

In the Target Model editor, drag the element or attribute from one position to another under its parent element.

Results

Your element or attribute is in a new position within the target model structure.

Deleting elements and attributes

About this task

Delete elements or attributes from your target model.

Procedure

- To delete an element or attribute, complete the following step:
  a) In the Target Model editor, right-click the element or attribute that you want to delete and select **Delete** from the menu.

  The element or attribute is deleted.
- To delete elements or attribute that have similar data paths to the one that is in focus:
  a) In the Target Model editor, right-click an element or attribute and select **Delete similar elements or attributes**.

     The **Item selection for removal** window is displayed.
  b) Select the elements or attributes that you want to delete from the list and click **Ok**. The element or attribute that is in focus is also displayed on this list.

  The selected elements or attributes are deleted.

Restoring deleted elements and attributes

About this task

Restore a deleted element or attribute to your target model.

Procedure

- To restore a deleted element, drag it from the Data Analysis Model view to the Target Model editor.
- To restore a deleted attribute, select **Restore Deleted Attributes** from the context menu in the Target Model editor.

Results

Your element or attribute is restored.

What to do next

- Use your target model to create Data Analysis tools. See “Creating Data Analysis tools” on page 1258.
- Prepare your database to use with the Data Analysis perspective. See “Data Analysis database setup” on page 1259.
- Use the Target Model editor to work with the data from your database. “Editing the database representation of the target model in the Target Model editor” on page 1260.

Creating Data Analysis tools

Use your target model to create a library. This library contains Data Analysis tools, which you use to transform your data.

Before you begin

- Analyze your sample XML documents. See “Analyzing sample XML documents” on page 1252.
- Create a target model. See “Creating a target model” on page 1255.
- Populate your target model. See “Populating a target model from your sample XML documents” on page 1255.
- Modify your target model. See “Modifying a target model in the Target Model editor” on page 1256.

About this task

You can use your target model to create a library, which contains the following Data Analysis tools:

- Schemas
- Maps
- Subflows
- Validation style sheets

Procedure

1. In the Target Model editor, click **Generate** to open the **Generate Data Analysis Tools** wizard.
2. Optional: In the **Generate Data Analysis Tool** wizard, select **Insert transformed messages into database**.
3. Complete the steps in the wizard and click **Finish**.

Results

A library that contains your Data Analysis tools is created. Your subflow opens in the editor.

What to do next

- Open the Application Development view and use your Data Analysis tools to work with your data.
- Work with the database. See “Editing the database representation of the target model in the Target Model editor” on page 1260 and “Data Analysis database setup” on page 1259.

Data Analysis database setup

Set up your database so that you can use it with Data Analysis.

Before you begin

- Create a database in one of the supported databases. The following databases are supported:
  - DB2
  - Oracle
  - Microsoft SQL Server

  Note: Remember to set a large enough page size to view the column lengths in the target model. If the page size is too small, an error message is produced in the database during table creation.
- Create a Data Analysis project. See "Creating a Data Analysis project" on page 1251.
- Analyze your sample data. See "Analyzing sample XML documents" on page 1252.
- Create your target model. See "Creating a target model" on page 1255.
- Generate your Data Analysis tools. See "Creating Data Analysis tools" on page 1258.

Procedure

1. In the Integration Development perspective, generate the DDL script:
   a) In the Project Explorer view, expand the project folder.
   b) In the Data Models folder, expand the `.dbm` file.
   c) Right-click the database name and select **Generate DDL**.
   d) To configure the DDL script, follow the steps in the **Generate DDL** wizard and click **Finish**.
   - Your SQL script is generated. This script shows the commands that are used to create your database tables.
   - The 'DOCID' column is added to your database. At runtime this column is populated with a unique string, to provide a map with a unique input key for database operations. Alternatively, you can set the input key yourself, by setting

     ```
     LocalEnvironment.Database.Input.Key
     ```

     in your local environment.
   - The 'ID' column is added to your database. The 'ID' is the foreign key that links related tables together.

   Tip: If you do not have a `.dbm` file, open the **Generate Data Analysis Tools** wizard and check the **Insert transformed messages into database** box.
2. If you are configuring a Microsoft SQL Server 2008, above the `Create Schema` line in your SQL script insert `DROP SCHEMA "SCHEMA_NAME" GO`. For example:

   ```
   DROP SCHEMA "MYSCHEMA"
    GO

    CREATE SCHEMA "MYSCHEMA"
    GO

    CREATE TABLE "MYSCHEMA"."MYTABLE" (
     "COLUMN1" VARCHAR(1000) NOT NULL,
     "COLUMN2" INT NULL
    )
    GO
   ```
3. If you are using Oracle, ensure that your schema name is the same as your username.
4. In your database configuration manager, run the SQL script.
5. In IBM MQ, create a JDBC connection so that the schema that is specified in the map is used.

Editing the database representation of the target model in the Target Model editor

Use the Target Model editor to view and edit your database representation, which is generated from your target model.

Before you begin

- Create your target model. See "Creating a target model" on page 1255.
- Populate your target model. See "Populating a target model from your sample XML documents" on page 1255.
- Set up your database. See "Data Analysis database setup" on page 1259.

About this task

See the following topics to learn how to use different features in the Target Model editor:

- "Viewing your database representation" on page 1260
- "Renaming tables and columns" on page 1260
- "Assigning different data types to elements" on page 1261
- "Deleting cell contents" on page 1261
- "Highlighting elements or attributes that are in the same table" on page 1261

Viewing your database representation

About this task

View your target model in a database format. You can later use IBM App Connect Enterprise to insert information into an existing database.

Procedure

1. Click the **Enable relational database mapping** icon ().
   The **Destination Database Platform Selection** wizard opens.
2. Complete the **Destination Database**, and **Destination Schema** fields, and select the product and version of your database. Click **OK**.
   Blank Table, Column, and SQL Data Type columns are displayed. The **Relational mapping options** icon (), at the upper right of the Target Model editor, is also in focus.
3. To generate the default SQL table naming for your target database, click the **Relational mapping options icon** () and select **Generate Default SQL Table Naming**.

Results

The Target Model editor is populated with the details of your target model, in a database format.

Renaming tables and columns

About this task

Rename tables or columns to change the location of an element within your database representation.

Procedure

1. Double-click the table or column cell that you want to alter.
   The cell is highlighted for editing.
2. Type the new name of the table or column.

Results
The selected table or column is renamed.

Assigning different data types to elements

About this task
Change the SQL Data Type of elements to change the type of data the elements can hold.

Procedure
1. Double-click the SQL Data Type cell that you want to alter.
   An ellipsis button is displayed in the cell.
2. Click the ellipsis button to display the **SQL Data Type** window.
3. Complete the fields and click **OK**.

Results
The SQL Data Type is changed.

Deleting cell contents

About this task
Delete the contents of cells in your database representation.

Procedure
- To delete the contents of individual cells, complete the following steps:
  a) Double-click the cell to highlight it for editing.
  b) Press the Delete key.
- To delete the contents of a row, but not the element name, complete the following steps:
  a) Right-click a cell in the row that you want to delete the contents of.
  b) Select **Reset SQL Naming** from the menu.
- To delete the contents of all of the cells, except for the element names, complete the following steps:
  a) Click the **Relational mapping options icon** () at the upper-right of the target model editor.
  b) Select **Reset SQL Naming** from the menu.
  The contents of cells are deleted.

Highlighting elements or attributes that are in the same table

About this task
Highlight elements or attributes that are in the same table so that it is easier to view the contents of a specific table.

Procedure
1. Right-click a cell in the table that you want to highlight.
2. Select **Show Elements or Attributes With the Same Table**

Results
Elements and attributes that are from the same table are highlighted.

What to do next

Create your Data Analysis tools. See “Creating Data Analysis tools” on page 1258.

Moving target models between Data Analysis projects

You can move similar target models from one Data Analysis project to another.

Before you begin

- Create and populate a target model. See “Creating a target model” on page 1255 and “Populating a target model from your sample XML documents” on page 1255.

  Note: Save your target model before you move it to another Data Analysis project.
- Create an additional Data Analysis project. See “Creating a Data Analysis project” on page 1251.

About this task

You might want to use a target model in another Data Analysis project than the one in which it was created. Complete the following steps to move your target model to an alternative Data Analysis project:

Procedure

1. In the Application Development view, copy and paste your target model to the alternative Data Analysis project.
2. Double-click your target model.
   - If the target model is not compatible with the Data Analysis project that you moved it to, the **Compatibility Check Result** window opens.
   - If the target model is compatible, the **Link Model** window opens.

   Important: To make an incompatible target model compatible with the new Data Analysis project, delete some target model elements in the **Compatibility Check Result** window. The more incompatible a target model is, the more elements are deleted. If a target model has no elements that are compatible with the new target model, then all of its elements are deleted.
3. Complete the steps in the **Compatibility Check Result** or **Link Model** window.

   Your target model is linked to the alternative Data Analysis project.

Results

The relocated target model opens in the Target Model editor.

What to do next

- Modify the target model. See “Modifying a target model in the Target Model editor” on page 1256.
- Create Data Analysis tools. See “Creating Data Analysis tools” on page 1258.
- Create or move new target models. See “Creating a target model” on page 1255.

Glossary File Lookup Service

Glossary File Lookup Service uses glossary files to transform the data element code in your sample XML documents into more readable display names. These display names are viewed in your Data Analysis project.

Data element code in your sample XML documents can be difficult to understand, because it often consist of strings of numbers rather than descriptive words. Glossary files contain codes for each data element and their equivalent display names. The Glossary File Lookup Service extracts the display names, and shows them instead of the data element codes in your Data Analysis project. The Glossary File Lookup Service makes it easier to use Data Analysis because it is simpler to understand display names than their equivalent data element codes.

The Glossary File Lookup Service is in **Window** > **Preferences** > **Integration Development** > **Data Analysis**.

Using message maps

You can use a message map to graphically transform an input message into a required output message; to enrich the output message with data from a database; to dynamically set routing or destination control for the output message; and to modify data in a database system. You can use drag actions to make connections, select transforms, and build logic to transform your message data without programming.

About this task

A message map is the IBM App Connect Enterprise implementation of a graphical data map. It is based on XML schema and XPath 2.0 standards, with additional support for JSON schema draft 4.

A message map offers the ability to achieve the transformation of a message without the need to write code. It provides a visual image of the transformation, and simplifies its implementation and ongoing maintenance.

You can use a message map to adopt any of the following integration requirements graphically:

- **Transform a message**: You can use a message map to graphically transform a message assembly, message body, and properties, according to the transforms and XPath functions defined in the message map. You can use the full set of XPath 2.0 expressions and functions to implement data calculations and manipulations in a message map. To define the input and output messages to a map, you can use a schema base message model, which defines the structure of the data and provides information about the data type, or you can define it dynamically in the map by using the **Add user defined** function.
- **Enrich a message with data available in an external database**: You can use a message map to enrich, or conditionally set the output message with data from a database table. The table data structure must be defined to the message map, and an SQL `where` clause can be used to select specific rows. The resulting row data is presented as an extra input in the message map, according to the database schema.
- **Modify data located in an external database**.
- **Route a message based on content**: You can use a message map to graphically route a message. You can modify the local environment tree to set a dynamic message destination.

Procedure

Read the following sections to learn how to design, create, configure, and troubleshoot a message map and its associated resources:

- Graphical data maps offer the ability to achieve the transformation of a message without the need to write code. Depending on the data transformation re-usability and manageability requirements, you can use a message map, a submap, or a local map. For more information, see “Graphical Mapping overview” on page 1264.
- You can create a graphical data map, a message map, or a submap to transform a message.

  For more information, see “Creating message maps” on page 1378.
- You can edit a message map by using the Graphical Data Mapping editor.

  For more information, see “Editing message maps” on page 1394.
- You can use the Graphical Data Mapping editor to set the value of an output element by using an expression, a transform, or a function.

  For more information, see “Setting the value of an output element by using a transform or a function” on page 1480.
- You can reference a message map during the development phase. You can also reference a message map dynamically at run time.

  For more information, see “Referencing message maps in your solution” on page 1537.

- You can diagnose and solve problems that you encounter when you use a message map.
  For more information, see “Troubleshooting a message map” on page 1587.
- IBM App Connect Enterprise does not support WebSphere Message Broker Version 7.0 legacy message maps (`.msgmap`). You can import message flows that contain legacy message maps into the IBM App Connect Enterprise Toolkit. However, you can view these message flows in read-only mode only, and you cannot deploy and run them. If you try to deploy a BAR file that contains a legacy message map, you see a BIP2355 error message. Before you run a message flow that contains a legacy message map or a legacy Mapping node, you must convert them by following the instructions in “Using or converting legacy resources into message maps” on page 1588.
- You can use the Graphical Data Mapping editor to access a user-defined policy.
  For more information, see “Accessing a user-defined policy from a graphical data map” on page 1370

Graphical Mapping overview

Graphical data maps offer the ability to achieve the transformation of a message without the need to write code. You can use a message map, a submap, or a local map. To define the input and output messages to a map, you can use an XML, JSON, or DFDL schema message model, which defines the structure of the data and provides information about the data type, or you can define it dynamically in the map by using the **Add user defined** function.

Message maps

A message map is the IBM App Connect Enterprise implementation of a graphical data map. It is based on XML schema and XPath 2.0 standards, with additional support for JSON schema draft 4 and Swagger 2.0.

A message map offers the ability to achieve the transformation of a message without the need to write code. It provides a visual image of the transformation, and simplifies its implementation and ongoing maintenance.

You can use a message map to graphically transform, route, and enrich a message. You can use a message map to modify data in a database system. You can use drag actions to make connections, select transforms, and build logic to transform your message data without programming.

For more information, see “Message maps” on page 1268.

Defining a map input and output

To enable graphical transformation, you must provide a model of the data so that the Graphical Data Mapping editor can display it. You can use an XML, JSON, or DFDL schema message model, or you can define a model dynamically in the map by using the **Add User-Defined** function. Predefined models are also provided for SOAP and BLOB message types. You can also transform data from other parts of the IBM App Connect Enterprise message assembly, including the Properties folder, the Environment, the Local Environment, and transport headers, such as HTTP or MQMD.

For more information, see “Message maps” on page 1268.

Submaps

A *submap* is a reusable form of message map.

You use a submap to reuse common data transformations. You define in the submap the mapping functions that transform a set of elements from the input object to the output object.

You can reuse submaps in other products that support graphical data maps.

Note: If you plan to reuse data transformations across different products, read “Guidelines for developing reusable graphical data mapping assets” on page 1273.

For more information, see “Submaps” on page 1271.

Local maps

A *local map* is a subset of data transformations between input elements and output elements that are part of a message map. You define a local map by creating a **Local map** transform in a message map.

A local map is not an independent resource. There is no physical file that is associated with a local map.

The scope of a local map is the message map. A local map is processed with the message map.

Local maps provide a way of breaking up a large message map into nested groups of mapping elements.

You can use local maps to simplify the overall message map presentation. You can structure complex data transformations into nested groups that are easier to manage and implement.

For more information, see "Local map" on page 1334.

Legacy message maps

A legacy message map is a message map that was created as a `.msgmap` file in earlier versions of WebSphere Message Broker (for example, in WebSphere Message Broker Version 7).

IBM App Connect Enterprise uses graphical data maps in `.map` format, which were introduced in WebSphere Message Broker Version 8. These message maps replace the previous message maps that were in `.msgmap` format.

Before you can use a legacy message map in IBM App Connect Enterprise, you must convert it into a message map, as described in "Using or converting legacy resources into message maps" on page 1588.

Choosing a type of graphical data map

Use the following table to identify the type of map that you must create when you transform data graphically in the Graphical Data Mapping editor:

Table 42. Types of map based on design requirements

	Recommended use	Type of resource	Supported in IBM App Connect Enterprise
Message map	Graphical data mapping	`.map` file	Yes
Submap (See notes below.)	Reuse of common data transformations	`.map` file	Yes
Local map	Reduce complexity when you read and manage a message map	No file. It is embedded within a Message map	Yes
Legacy message map	Reuse of maps that are developed in earlier versions of IBM App Connect Enterprise	`.msgmap` file	These files must be converted into `.map` files before they can be used in IBM App Connect Enterprise. (See notes below.)

Notes:

1. Legacy message maps must be converted into `.map` message map format before they can be deployed or modified by IBM App Connect Enterprise.
2. Submaps are not supported for use with JSON schema models.

Note:

Editing a graphical data map

You edit a message map or a submap in the Graphical Data Mapping editor.

The Graphical Data Mapping editor saves message maps as `.map` files.

For more information, see "Graphical Data Mapping editor" on page 1266 and "Editing message maps" on page 1394.

Mapping operations

You can use transforms to map graphically your data in the Graphical Data Mapping editor.

For more information, see "Transforms (Mapping operations)" on page 1280.

XPath

In the Graphical Data Mapping editor, you can use XPath functions in any of the following ways:

- You can define an XPath function to transform data by using a built-in XPath transform. For more information, see "Built-in XPath transforms" on page 1342.
- You can define complex XPath expressions that combine multiple XPath functions to transform data by using the **Custom XPath** transform. For more information, see "Custom XPath" on page 1315.
- You can define XPath expressions to set a condition on a transform or to filter an element in a repeating element. For more information, see "Defining an XPath conditional expression for a transform" on page 1433.
- You can use XPath inline when you specify an argument to an XPath function. For more information, see "Built-in XPath transforms" on page 1342.

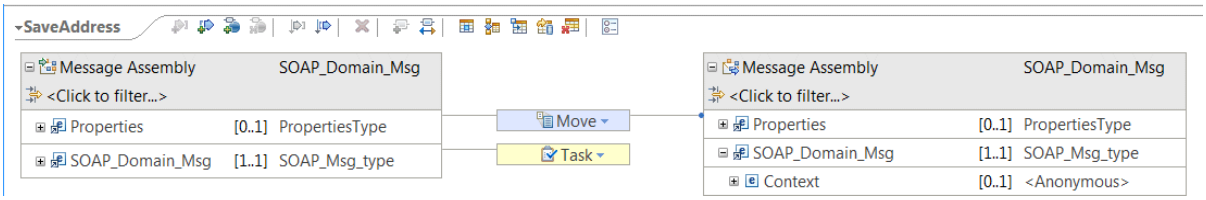
Built-in IBM App Connect Enterprise functions

You can use built-in IBM App Connect Enterprise functions to retrieve Integration Bus data and perform data-type conversion and formatting. The `iib:` functions are available through content assist in the "Custom XPath" on page 1315 transform. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282

Graphical Data Mapping editor
Use the Graphical Data Mapping editor to create and edit graphical data maps.

You can use the Graphical Data Mapping editor to take input (source) objects and transform them before you save the resulting output (target) objects.

Here is an example of the Graphical Data Mapping editor:



The input objects are shown on the left side of the canvas, and the output objects are shown on the right side. You can create connections between the input and output elements by clicking one element, and dragging the mouse to the element that you want to connect to. You can create connections either from left to right or from right to left. You can also right-click on either element and use the **Quick link** menu action to open a window where you can search for and select the other element.

You can use the Graphical Data Mapping editor to construct a graphical data map by using a wide variety of mapping transform functions. The transforms operate either from an input element to an output element on the canvas, or by directly setting the value of an output element.

You can use the functions either by using drag-and-drop, or from a menu action on the input or output element. The Graphical Data Mapping editor inserts the most appropriate mapping function on the newly created transform connection. For transforms that require multiple input connections, you can drag more connections onto the transform, and you can then select either a primary or supplementary connection mode. The Graphical Data Mapping editor adjusts the type of transform based on the new connections. When you create a connection, you can optionally change the type of transform function or start setting properties.

Some types of transforms involve complex input and outputs. They are edited by entering a nested view. The editor provides arrow buttons and breadcrumb navigation for nested transforms.

For information about the transforms that you can use in a graphical data map, see "Transform types in the Graphical Data Mapping editor" on page 1282.

The Graphical Data Mapping editor properties

The **Properties** pane displays the properties of the message map, its input and output elements, and transformations. For information about configuring the properties, see "Configuring the general properties of a message map" on page 1395.

When you are working with the maximized view of the Graphical Data Mapping editor, you can bring the **Properties** pane back into focus in either of the following ways:

- Right-click the object and then select **Show in** > **Properties view**.
- Use the appropriate keyboard combination, which, by default, is `Alt+Shift+Q, R`. You can configure these keyboard shortcuts by selecting **Window** > **Preferences** > **General** > **Keys**.

Actions supported in the Graphical Data Mapping editor

Table 43. List of actions supported in the Graphical Data Mapping editor

Icon	Label	Action
	**Add an input object**	Adds an input object to the map by selecting a map input.
	**Add an output object**	Adds an output object to the map by selecting a map output.
	**Add environment mapping**	Adds the Environment tree to the map.
	**Remove environment mapping**	Removes the Environment tree from the map.
	**Sort mapping by source**	Sorts the mapping objects so that the appearance of transforms is prioritized by the source.
	**Sort mapping by target**	Sorts the mapping object so that the appearance of transforms is prioritized by the target.
	**Delete selected elements**	Deletes the element or elements that are currently highlighted.
	**Create a new transform**	Creates a transform for the map.
	**Auto map input to output**	Automatically maps elements by using the **Automap Wizard**.

Table 43. List of actions supported in the Graphical Data Mapping editor (continued)		
Icon	**Label**	**Action**
	**Put key-value pair to cache**	Add a key-value pair to the global cache.
	**Get a key-value pair from cache**	Get a key-value pair from the global cache.
	**Remove a key-value pair from cache**	Remove a key-value pair from the global cache.
	**Select rows from a database**	Selects rows of data from a database table.
	**Call a database routine**	Calls a database routine to obtain the data to include in the map.
	**Insert a row into a database table**	Inserts one row into a database table.
	**Update rows in a database table**	Update one or more rows in a database table.
	**Delete rows from a database table**	Delete one or more rows in a database table.
	**Show object preferences**	Opens the **Preferences** window for the currently selected object.

Casting data structures

In the Graphical Data Mapping editor, you can use the **Cast** function to cast data structures.

Wildcards can be used to create a flexible message model that can be redefined when a more detailed definition is required. You define a wildcard as `xsd:any` in your schema.

When your message model schemas contain one or more wildcards, you can use the **Cast** function to redefine parts of the input or output model in a message map.

For more information, see "Casting elements in a message map" on page 1398.

Adding user-defined elements

In the Graphical Data Mapping editor, you can use the **Add User-Defined** function to add dynamically user-defined elements that define an `xsd:any` element in your message model.

For more information, see "Adding and renaming a user-defined element" on page 1410.

Message maps
You can use a message map to graphically transform, route, and enrich a message. You can use a message map to modify data in a database system. You can use drag actions to make connections, select transforms, and build logic to transform your message data without programming.

A message map is the IBM App Connect Enterprise implementation of a graphical data map. It is based on XML schema and XPath 2.0 standards, with additional support for JSON schema draft 4 and Swagger 2.0.

You can use a message map to achieve the transformation of a message without the need to write code, providing a visual image of the transformation, and simplifying its implementation and ongoing maintenance.

The message map can be in the same container as the Mapping node (such as an application), or it can be in a referenced shared library. If multiple solutions are likely to use the same message map, store the map in a shared library.

Input and output data to a message map

In IBM App Connect Enterprise, the logical tree structure is the internal representation of a message. It is also known as the message assembly.

When a message arrives to IBM App Connect Enterprise, a parser is called. Each parser is suited for a particular type of message, and is known as a message domain. A parser converts the bit stream of an input message to its internal format. The data structure that you define in a message map for an input or an output message is the IBM App Connect Enterprise internal representation of the message.

To configure the input and the output to a message map, you define an input message assembly and one or more output message assemblies.

- You can have 1 input to a message map.
- You can have multiple outputs in a message map.

For more information, see "Input and output messages to a message map" on page 1276.

Supported message domains

The following message domains are supported when you use message maps:

- DFDL: You use this domain to manipulate general text or binary data streams including industry standards.
- XMLNSC: You use this domain to manipulate XML documents.
- SOAP: You use this domain to manipulate SOAP messages.
- DataObject: You use this domain to manipulate data without a stream representation.
- BLOB: You use this domain to manipulate messages with content that cannot be interpreted and subdivided into smaller sections of information.
- JSON: You use this domain to manipulate JSON documents.
- MRM: This domain is maintained for compatibility with earlier versions of IBM App Connect Enterprise.

Message assembly components

You can configure a message map to include the following message assembly components:

- The Properties folder.
- The message tree transport headers: For more information, see "Mapping transport headers" on page 1461.
- The local environment tree: For more information, see "Mapping data in the local environment tree" on page 1464.
- The message body
- The Environment tree: For more information, see "Mapping the environment tree" on page 1471

Note: Other message assembly components, such as the Exception list tree, are passed on unchanged. They cannot be modified in a message map.

Message body

You define the message body by defining a message model in any of the following ways:

- Define a message model by using a predefined message model.
- Define a message model by using a user-provided message model.
- Define a message model by adding user-defined elements

You can use message models for any messages that you want to include in a mapping. You can select the message model from your existing message models in your application, integration service, or library when you create a message map. The mapping facility supports message models that are provided in

DFDL schema and XML schema files, REST API swagger 2.0 documents, JSON schema draft 4, or MRM message sets. For more information, see "Input and output messages to a message map" on page 1276.

In a message map, input and output body objects are defined by reference to message models, which provide a definition of the message structure and type through the following components:

- Simple elements and attributes, which define the type, range, and default values
- Complex elements, which build the structure of the message
- Repeating simple or complex elements
- Other (embedded) messages

If your message model includes wildcards (`xsd:any`), you can use a **Cast** function to redefine these data elements to a global type or element from any message schema in your application. For more information, see "Casting elements in a message map" on page 1398. You can also qualify your wildcards by adding dynamically user-defined elements.

Creating a message map

When you create a new message map, you can select the model that defines the input and output messages for that map. You can select data type defined models from XML, DFDL or JSON schema, or Message Sets. You can also select predefined messages for SOAP, JSON, or BLOB. Alternatively, when you implement an operation in a REST API project and you create a message map from within the subflow for that operation, you can choose to create the map with inputs and outputs for that REST API operation defined automatically, including the path and query parameters. To create the message map with input and outputs defined automatically, select **Message map with the input and output for REST API operation *operation_name*** in the **Specify a new message map file** dialog. For more information, see "Creating a message map" on page 1382.

Editing a message map

You edit a message map in the Graphical Data Mapping editor. You can create, modify, or delete a message map.

The Graphical Data Mapping editor saves message maps as `.map` files.

For more information, see "Editing message maps" on page 1394.

Mapping behavior

By default, any message assembly component that is not included in the message map is copied from input to output unchanged.

To modify a message assembly component, you add the header or folder to the input and output message assembly in the message map, and provide transformations.

To delete a message assembly component, you add the component to the input message assembly, but not the output message assembly in the message map.

To create a message assembly component, you add the component only to the output message assembly in the message map.

Mapping operations

You can use any of the following transforms to map graphically your data in the Graphical Data Mapping editor:

- **Core mapping transforms**: You can use built-in structural and functional mapping operations to graphically construct the required message transformations to build the output message.
- **Custom transforms**: You can use custom transformations to define specialized transformations in XPath 2.0, Java, or ESQL functions.

- **XPath functions** (`fn:`*`functionName`*): You can use XPath 1.0 and XPath 2.0 functions to transform data in a message map.
- **Database transforms**:
  - You can use the **Select** transform to query one or more database tables, and retrieve data that you can use in the message map. You can use the data to set output element values, define conditions, or use as input to build other transforms conditions. Database tables can be set as extra outputs of a message map.
  - You can use a **database routine** transform to call a stored procedure from a database, and retrieve data that you can use in the message map. You can use the data to set output element values, define conditions, or use as input to build other transforms conditions.

    Note: For information about the support for stored procedures, see "Support for stored procedures" on page 1318.
  - You can use the **Insert** transform to add one new row of data, or multiple rows of data, into a database table.
  - You can use the **Update** transform to modify a row of data, or multiple rows of data, in a database table.
  - You can use the **Delete** transform to delete a row of data, or multiple rows of data, in a database table.
- **Cast** function: You can use the **Cast** function to cast schema types.

For more information, see "Transforms (Mapping operations)" on page 1280.

Local maps

You can use local maps as navigation aids. You view the map elements in a hierarchical way. Unlike submaps, local maps are not separate files and they are not reusable. They provide a way of breaking up a large map into nested groups of mapping elements and processing the complex elements of the whole message.

Deploying a message map

Message map files are deployed to the IBM App Connect Enterprise run time environment to enable them to be run in a message flow.

When you build and deploy a BAR file for an integration solution, the message map files are automatically included.

When you deploy independent resources, the BAR file editor provides a resource category to allow message maps to be selected for deployment.

If your message map file is used by multiple solutions, you might store the map in a shared library. Shared libraries that are referenced by applications must be deployed with or before the applications that refer to them. You can deploy the shared libraries directly to the integration server before you deploy the applications. Alternatively, you can include the applications and shared libraries in a BAR file and deploy the BAR file. If you update the message map in a shared library, those changes are available automatically to all applications that refer to that shared library.

Submaps
You can use a **submap** to use the same mapping transformation in multiple message maps.

You use submaps to define a set of mapping functions that you can reuse in multiple message maps.

A **submap** transform references another map. It calls or invokes a map from a separate file, which can be stored in a library, an application, an integration service, or an Integration project.

A submap can contain components of the message body only, such as global elements and global types. A submap does not contain Properties, message headers, or the Local Environment tree. The elements or types that define the input and outputs of a submap must be defined as globals in an XML or DFDL

message model. You cannot use user-defined elements as a submap input or output unless it is defined using a global type in an XML or DFDL schema. You cannot use a JSON data element defined from a JSON schema, or REST API swagger document, as a submap input or output.

For more information, see "Creating a submap" on page 1386.

When you use submaps, you must consider the following behavior:

- You can only use a submap to define transformations between DFDL or XML global elements or global types.
- A submap cannot be used to transform local anonymous complex types, that is, `xs:any` elements.
- A submap can be placed in any project that is visible to the main map that calls the submap.

Editing a submap

You edit a submap transform in the Graphical Data Mapping editor.

The Graphical Data Mapping editor saves submaps as `.map` files.

For more information, see "Graphical Data Mapping editor" on page 1266.

Input and output data to a submap

To configure the inputs and the output to a submap transform, you connect one or more inputs, and a single output.

The input and output message data for a submap must be defined by a user-provided message model in a schema file.

Note: You cannot use submap transforms with input or output from the following places:

- A user-defined element, unless its type is set to a global type in a DFDL or XML schema.
- A JSON data type defined in JSON schema or a REST API swagger document.

You must have message models for any messages that you want to include in a mapping. You can select the message model from your existing message models in your application, integration service, or library when you create a message map. The mapping facility supports message models that are provided in DFDL schema and XML schema files, REST API swagger 2.0 documents, JSON schema draft 4, or MRM message sets.

In a message map, input and output objects are defined by reference to message models. They provide a definition of the message structure and type through the following components:

- Simple elements and attributes, which define the type, range, and default values
- Complex elements, which build the structure of the message
- Repeating simple or complex elements
- Other (embedded) messages

If your message model includes wildcards (`xsd:any`), you can use a **Cast** function to redefine these data elements to a global type or element from any message schema in your application. For more information, see "Casting elements in a message map" on page 1398. You can also define dynamically a wildcard by adding user-defined elements.

Mapping operations

You can use any of the following transforms to map graphically your data in the Graphical Data Mapping editor:

- **Core mapping transforms**: You can use built-in structural and functional mapping operations to graphically construct the required message transformations to build the output message.
- **Custom transforms**: You can use custom transformations to define specialized transformations in XPath 2.0, Java, or ESQL functions.

- **XPath functions** (`fn:`*`functionName`*): You can use XPath 1.0 and XPath 2.0 functions to transform data in a message map.
- **Database transforms**:
  - You can use the **Select** transform to query one or more database tables, and retrieve data that you can use in the message map. You can use the data to set output element values, define conditions, or use it as input to build other transforms conditions. Database tables can be set as extra outputs of a message map.
  - You can use a **database routine** transform to call a stored procedure from a database, and retrieve data. You can use the data to set output element values, define conditions, or use as input to build other transforms conditions.

    Note: For information about the support for stored procedures, see "Support for stored procedures" on page 1318.
  - You can use the **Insert** transform to add one new row of data, or multiple rows of data, into a database table.
  - You can use the **Update** transform to modify a row of data, or multiple rows of data, in a database table.
  - You can use the **Delete** transform to delete a row of data, or multiple rows of data, in a database table.
- **Cast** function: You can use the **Cast** function to cast schema types.

For more information, see "Transforms (Mapping operations)" on page 1280.

Creating a submap

A submap can be referenced from other message maps.

When you construct your transformation map, you create a submap to group part of the message transformation. The submap must be in a project visible to the main map that they are called from.

To create a submap, you define a **Submap** transform between the input object and the output object in your message map. The submap can then be used to enable reuse of common transformations for sections of, or the whole of, the message.

You can also refactor existing transform logic into a submap from a local transform, by using the context menu action.

For more information, see "Calling a submap" on page 1540.

Reusing a submap

You can use a submap to reuse common data transformations.

You can reuse submaps in other solutions, and in other products that support graphical data maps.

Note: If you plan to reuse a submap across different products, read "Guidelines for developing reusable graphical data mapping assets" on page 1273.

Guidelines for developing reusable graphical data mapping assets
You can create graphical data maps (`.map` files) for reuse by other products that include the Graphical Data Mapping editor.

When you create graphical data maps that you want to reuse in other products, ensure that your graphical data maps conform to the following guidelines:

Build your reusable mapping structures as a submap

Many products use extra metadata to supplement the business message data, but a reusable transformation asset that is contained in a submap processes only the common business data.

Create a submap to contain the mapping structures that you want to reuse in other products, and then call this submap from a top-level mapping structure. You can use the Graphical Data Mapping editor to refactor a local map to a submap; see “Converting a local map into a submap” on page 1388.

For more information about submaps, see “Creating a submap” on page 1386.

Custom transforms can be only Custom Java and Custom XPath

Create custom transforms in your reusable submaps by using only **Custom Java** and **Custom XPath** transforms. Other custom transform types, such as Custom ESQL in IBM App Connect Enterprise, are product-specific, and cannot be used.

Considerations for mapping messages modeled in message sets
You can use the Graphical Data Mapping editor to transform XML messages that are defined in XML Schema (`.xsd` files). Message Set modeling in IBM App Connect Enterprise supports XML Schema extensions.

The Graphical Data Mapping editor supports both XML and text or binary messages that are modeled in IBM App Connect Enterprise message sets, with the following considerations:

- Message sets provide facilities for defining message composition. When these extensions are used to redefine a wildcard in a message, they are not shown in the message map. The Graphical Data Mapping editor provides equivalent facilities for modeling choice in schema wildcards by using the Cast function. For more information about the Cast function, see “Mapping xsd:any on an input or output message” on page 1397.

  When you create a message map or convert a message map that includes a schema wildcard from a message set with XML Schema extensions, you must manually add a Cast function from the wildcard to the required schema element.
- The message map requires the message set schema (`.xsdzip` file) to be deployed to run your message map. If your existing message set is used for text and binary formats only, you can deploy your message map with only a `.dictionary` file in the BAR file. In this case, you must modify the message set to additionally set the XMLNSC domain support option, so it is added to a BAR with both a `.dictionary` file and `.xsdzip` file. If this option is not set, a warning is displayed in the **Problems** view, along with a quick fix action.

Designing a message map

You can use a message map to graphically transform, route, or update an external system. For best performance and capability, you must design it to include the most appropriate transforms.

Procedure

Consider the following guidance to design a message map:

1. Design the data model of your input and output message per the solution requirements.

   The function of a message map is completely dependent on the data models that define the input and the output message structures of a map. At run time, the Graphical Data Mapping engine accesses the input message with the assumption that it conforms exactly to the provided input schema model. Additionally, it must account for all possible states of the data when executing the transformations that you have defined in the map against the data models. You might or might not have control over the data models in your solution. If you can influence the data model, these are some of the key points to consider:

   a) If you are working with XML schema models, you must always enable schema validation when you are developing a message map. The schema validation ensures that the input message to the map matches the model that has been used to define the map, and prevents invalid mapping due to any mismatch.

      Validation is the process of checking the structure of a message, and optionally the values within, based on a description called a schema. The Mapping node relies on schema definitions, but it does not enforce them. If the input message does not conform to the schema being used, the output

you expect to see might not be produced. During the development of your integration solutions, it is recommended that you enable validation. However, for other environments such as test or production, you should leave validation on only if your solution requires it, because of the extra processing involved. For more information, see Validating messages.

If you are working with DFDL schema models, and the message has been received by an input node, the input to the map is validated by the DFDL parser. If the DFDL tree is constructed by other means, ensure that it is valid by running test serialize, which you can do by using a trace node.

If you are working with JSON models, there is currently no internal support for JSON schema validation. Ensure that your message is valid by using an external tool.

b) Set the cardinality of each element in a data model to specific values whenever possible.

When you define a logical model, you can configure the cardinality of each element by setting the **minoccurs** and the **maxoccurs** properties.

Avoid, whenever possible, configuring maximum flexibility unless actually required. Only set **minoccurs** to 0, when an element needs to be optional. Only set **maxoccurs** above 1 if the element will actually repeat.

c) Define an element as nillable when you know that the application will need to handle out of bound value in the data.

2. Identify the type of message map.

a) Use a message map to graphically transform, route, and enrich a message. You can use a message map to modify data in a database system.

For more information, see “Message maps” on page 1268.

b) Use a submap to define a set of mapping functions that you can reuse in multiple message maps.

For more information, see “Submaps” on page 1271.

For example, the Mapping node invokes a map that deals with a message assembly. You can put the mapping for common parts of the message data into a submap to enable reuse.

3. Identify the input and output components to a message map.

- You can select an XML schema, DFDL schema, or message set to define the message body.
- You can choose any of the following message assembly components: the Properties tree, the local environment tree, or the environment tree.
- You can add database tables.

You should only include a component when you need to read data or write data:

- To read elements of an input component, add the component to the input message assembly only. The Graphical Data Mapping editor passes to the output the input component unchanged.
- To modify elements of an input component, add the component to the input message assembly and to the output message assembly. Then, define transforms between its elements.
- To initialize an input component, that is, to create a new component in your output message, add the component only to the output message assembly.
- To add an input component, add the component to the output message assembly and populate at least one field. The Graphical Data Mapping editor creates a new output structure containing the results of your transformations.
- To delete an input component from the input message, add the component to the output message assembly and do not set any field.

For more information, see “Choosing a mapping action” on page 1450.

4. For each output element, identify the transform and the input elements required to calculate its value.

   When the transformation of an element from input to output becomes more than just a simple **Move**, or type conversion (**xs:type**), you can call on the full set of standard XPath 2.0 operators and functions to manipulate the data as required.

   The Graphical Data Map editor offers the XPath functions as transform types in the pick list as well as in the content assist (Ctrl-space) when you edit expressions and conditions.

   - “Choosing a transform to set the value of a simple type output element” on page 1358
   - “Choosing a transform to set the value of a complex output element” on page 1360
   - “Choosing a transform to map repeating elements” on page 1362
   - “Choosing a transform to concatenate input data” on page 1364
   - “Choosing a transform to perform an arithmetic operation” on page 1366
   - “Choosing a transform to define a conditional mapping” on page 1367
   - “Choosing a transform to map an input message to multiple output messages” on page 1368
5. Define a conditional expression for each transform to determine at run time whether the transform is applied or not.

   For more information, see “Defining an XPath conditional expression for a transform” on page 1433.
6. Use structural transforms to enhance the readability and maintenance of your map and, in some situations, reduce the runtime overheads of your map. Use the transforms **If**, **Local Map** or **Submap**, and **For each** to group transforms.

   Using structural transforms has the following advantages:

   a. You can define a conditional expression that determines whether a nested map is applied at run time. For example, if a set of child fields should only be mapped dependent on some attribute of the folder, place all the child elements inside an **If** transform. The nested mappings are executed only when the condition evaluates to **true**.

   b. You can use a **Local Map** transform between the parent folders that are defined as optional (<code>minOccurs=0</code>) instead of mapping directly between child elements in the folders. By using a **Local Map**, you create a more efficient transformation because, by default, the nested mapping is executed only if the primary input is optional (`minOccurs=0`) and is available at run time. Alternatively, you can add your own condition, which can also use additional supplemental inputs.

   c. When you use a **Local Map** transform, you can convert the map to a submap if the need for reuse comes at a later stage. You can use an action in the Graphical Data Mapping editor to re-factor the **Local Map** into a **Submap**.

   d. You can use the Auto map wizard (automap) to create **Move** transforms to create mappings from input to output elements within structural transforms that are based on some correlation of the names of the input and output elements. By using the structural transform, the scope of the automap is reduced, which enables a better match to be achieved.

   For more information, see “Using nested maps” on page 1371.
7. When you need to process data, rather than just move it from source to target, use custom transforms to define specialized transformations.

   a) “Custom XPath” on page 1315

   b) “Custom Java” on page 1312

   c) “Custom ESQL” on page 1308

   From a performance point of view, it is recommended that you use **XPath** transforms or the **Custom XPath** transform as your first choice, then **Custom Java**. You can also use **Custom ESQL**.

Input and output messages to a message map

In a message map, you must define a model for the input message and an output message. You can choose from a predefined message format, or you can use an XML, DFDL, or JSON schema message

model, to define the structure of the data and provide information about the data type. Alternatively, you can define it dynamically in the map by using the **Add User-Defined** function.

When a message arrives to IBM App Connect Enterprise, a parser is called. Each parser is suited for a particular type of message, and is known as a message domain. A parser converts the bit stream of an input message to an internal format. A parser is also called when a logical tree that represents an output message is converted into a bit stream.

Note: The data structure that you define in a message map for an input or an output message is the IBM App Connect Enterprise internal representation of the message.

Message domains

The following message domains are supported in a message map:

DFDL
XMLNSC
SOAP
DataObject
BLOB
JSON
MRM

Message assembly

In a message map, the *source message assembly* describes the input message and the *target message assembly* describes the output message.

A message assembly includes the properties tree, any relevant headers, the local environment tree, the Environment tree, and the message body.

- When you create a top-level message map, only the Properties folder is initially included. A **Move** transformation from the input Properties folder to the output Properties folder is created by default where all input values are copied to the corresponding output values unchanged.
- The structure of the Properties folder, the transport headers, and the local environment tree are predefined in IBM App Connect Enterprise.
- You can define the local environment tree **Variables** folder structure by using the **Cast** function. You can also define elements of the **Variables** folder by using the **Add User-Defined** function.
- You can define one or more elements under the **Variables** folder of the Environment tree. You can use the function to model Environment elements. Elements that are not defined in the map are maintained unchanged.
- The input message body is defined by associating an input message model such as a DFDL schema, a JSON schema, or an XML schema. You can also define the input message body by using the **Add User Defined** function, for example, to define the structure of a JSON message.
- The output message body is defined by associating an output message model such as a DFDL schema, a JSON schema, or an XML schema. You can also define the output message body by using the **Add User Defined** function, for example, to define the message body structure of a JSON message.

The **Output domain** property target message assembly is set to define the message domain in which an output message is to be built, based on the message type that you selected for the map output. You can change it if necessary.

The message map uses the schema types of the output elements to create and set the elements of the output message tree.

Message models

The following message models are supported in a message map:

- Predefined message model
- XML schema-based message model
- DFDL schema-based message model for text and binary formats
- JSON schema-based model, from a REST API swagger document, or a JSON schema in a shared library
- Schemaless message model, that is, a message model of a message that has a well-defined format but no schema definition available as an `xsd` file.

You can select any of the following supplied message models as your input or output message format:

- **SOAP_Domain_Msg {}**: Use this message model to handle messages in the SOAP domain; it allows you to add mapping casts to define the content of the SOAP body and header by using a schema model.
- **JSON Object Message**: Use this message model for JSON object data in the JSON domain, by using the **Add User Defined** function.
- **JSON Array Message**: Use this message model for JSON array data in the JSON domain, by using the **Add User Defined** function.
- **BLOB {}**: Use this message model to handle messages in the BLOB domain, or when you do not need to process any message body data.

Advanced XML schema structures valid in input and output messages
You can use several advanced schema structures in graphical data maps.

You can use any of the following XML features in message models that are defined as inputs or outputs to the Graphical Data Mapping editor:

- "Substitution groups" on page 1278
- "Wildcards (xsd:any)" on page 1278
- "Derived types" on page 1279
- "List types (xs:list)" on page 1279
- "Union types (xs:union)" on page 1279

Substitution groups

A *substitution group* is an XML schema feature that provides a means of substituting one element for another in an XML message.

- The element that can be substituted is called the **head** element.
- The **substitution group** is the list of elements that can be used in its place.

The head element and any mapped substitutions are shown by default in the Graphical Data Mapping editor. The mapped substitutions are listed beneath the head element.

You create mappings to or from members of substitution groups in the same way as you map other elements.

Wildcards (`xsd:any`)

You can use *wildcards* to create open content models. You can define `xsd:any` and `xsd:anyAttribute` wildcards.

Wildcards are characterized for the following attributes:

- The namespace attribute: You can use this attribute to specify the namespace that the elements or attributes that match the wildcard can come from.
- The processContents attribute: You can use this attribute to specify how the XML content matched by the wildcard is validated.

When you use wildcards in the Graphical Data Mapping editor, you must consider the following behavior:

- You can wire a `xs:any` or a `xs:anyAttribute` as the input or output of a **Submap** transform. Then, when you configure the **Submap** transform, you can define that input or output to be a particular type.

- A wildcard element can be instantiated only with another element.
- A wildcard attribute can be instantiated only with another attribute.
- You can use a global element or attribute as a wildcard replacement.

For more information, see "Mapping xsd:any on an input or output message" on page 1397.

Derived types

A *derived type* is a data type that is related to another data type known as the base type or super type.

In a message map, you can cast a base type to a derived type or extension type. You can define transformations between subtypes of a data type.

When you use derived types in the Graphical Data Mapping editor, you must consider the following behavior:

- For an element of a specific type, the base type and the mapped derived types are shown by default. All attributes and elements of the base and derived types are displayed.
- You create mappings to or from a derived type and its elements in the same way that you map any base type and its elements.
- When you map an input element to an output element with a derived schema type or an extension schema type, the created output element is set with the relevant `xsi:type` attribute for that schema type.

List types (`xs:list`)

You can use `xs:list` to define a simple type element as a list of values of a specified data type. For example:

```
<xs:simpleType name='CustomerName'>
 <xs:list itemType='string'/>
</xs:simpleType>
```

When you use `xs:list` in the Graphical Data Mapping editor, you must consider the following behavior:

- You map a simple type element that is defined as a list of values in the same way that you would map any other simple type attribute or element.

Union types (`xs:union`)

You can use `xs:union` to define a simple type as a collection of values from specified simple data types. It allows a value to conform to any one of several different simple types. For example:

```
<xs:element name="zipUnion">
 <xs:simpleType>
  <xs:union memberTypes="USStateName StateID"/>
 </xs:simpleType>
</xs:element>
<xs:element name="USStateName">
  <xs:simpleType>
    <xs:restriction base="xs:string">
      <xs:minInclusive value="0"/>
      <xs:maxInclusive value="100"/>
    </xs:restriction>
  </xs:simpleType>
</xs:element>
<xs:element name="StateID">
  <xs:simpleType>
    <xs:restriction base="xs:integer">
      <xs:minInclusive value="0"/>
      <xs:maxInclusive value="100"/>
    </xs:restriction>
  </xs:simpleType>
</xs:element>
```

When you use `xs:union` in the Graphical Data Mapping editor, you must consider the following behavior:

- You map a simple type element that is defined as a collection of values in the same way that you would map any other simple type attribute or element.
- You must check that the value of an element is processed with the correct type when you use an element that is defined with a union type.

  For example, you can use the expression **$zipUnion != ''** to check that the value of the element **zipUnion** is not an empty string. The Graphical Data Mapping editor might fail at run time with **BIP3949E** if the element **zipUnion** is not of string type.

  ```
  BIP3949E: An error occurred during the processing of a message.
  ```

  To prevent this error, you can explicitly define the type of the element by using the **xs:string()** function:

  ```
  xs:string($zipUnion) != ''
  ```

  For more information, see "Cast type (xs:type)" on page 1299.

Transforms (Mapping operations)
In the Graphical Data Mapping editor, you can define mapping operations such as transforms, cast functions, or XPath 2.0 functions. Mapping operations define the transformation actions on input data, and set the result to the output element.

Mapping operations to transform graphically your data

You can use any of the following transforms to map graphically your data in the Graphical Data Mapping editor:

- **Core mapping transforms**: You can use built-in structural and functional mapping operations to graphically construct the required message transformations to build the output message. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.
- **Custom transforms**: You can define specialized transformations to build custom ESQL functions, XPath 2.0, or Java. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.
- **XPath functions**: You can use XPath 1.0 and XPath 2.0 functions to transform data in a message map. You can also build compound XPath expressions by using the **Custom XPath** transform; see "Custom XPath" on page 1315.

  All XPath 2.0 functions are supported in the form `fn:`*`functionName`*.

  For more information about XPath, see the online document W3C XML Path Language (XPath) 2.0.
- **App Connect Enterprise mapping functions**. You can use a set of IBM App Connect Enterprise mapping functions (`iib:`*`functionName`*), for example, to access a user-defined property value. For more information, see "Custom XPath" on page 1315.
- **Database transforms**:
  - You can use the **Select** transform to query one or more database tables, and retrieve data. You can use the data in the message map to set output element values, define conditions, or use as input to build other transforms conditions. Database tables can be set as extra outputs of a message map. For more information, see "Selecting data from a table" on page 1523.
  - You can use a **database routine** transform to call a stored procedure from a database, and retrieve data. You can use the data in the message map to set output element values, define conditions, or use as input to build other transforms conditions.

    Note: For information on the support for stored procedures, see "Support for stored procedures" on page 1318.

- **Cache transforms**: By using **Cache** transforms you can interact with data that is stored in a global cache. For more information, see "Accessing a global cache by using a Mapping node" on page 1514.

  You can use the following transforms:

  - **Cache Put** transform: You use the **Cache Put** transform to add a key-value pair into the global cache. For more information, see "Adding key-value pairs to the global cache by using a Mapping node" on page 1515.
  - **Cache Get** transform: You use the **Cache Get** transform to retrieve a value from the global cache by providing the associated key. For more information, see "Retrieving a value from the global cache by using a Mapping node" on page 1517.
  - **Cache Remove** transform: You use the **Cache Remove** transform to remove a key-value pair from the global cache. For more information, see "Removing a key-value pair from the global cache by using a Mapping node" on page 1519.

Mapping operations to modify data in a database

Database tables can be set as more outputs of a message map.

You can use any of the following transforms to modify data in a database:

- **Insert** transform: You use the **Insert** transform to add one new row of data, or multiple rows of data, into a database table. For more information, see "Inserting data into a table" on page 1525.
- **Update** transform: You use the **Update** transform to modify a row of data, or multiple rows of data, in a database table. For more information, see "Updating data in a table" on page 1527.
- **Delete** transform: You use the **Delete** transform to delete a row of data, or multiple rows of data, in a database table. For more information, see "Deleting data from a table" on page 1528.
- **Database routine** transform: You use a **database routine** transform to call a stored procedure or user-defined function from a database to insert, delete, or update data in one database table. For more information, see "Calling a stored procedure from a map" on page 1532.

At design time, you must have a database definition file (`.dbm` file) in an available Data Design project for each database that you want to access. A data definition file contains one connection per database system.

At run time, you must have a JDBC connection of Type 4 defined for each database that your message map uses. You must configure a JDBC Providers policy per database. The JDBC Providers policy name for a runtime database must be the same name as the development database name that you use in your message map.

For more information, see "Modifying data in a database by using mapping " on page 1525.

Cast function to define a schema type

In the Graphical Data Mapping editor, you can use the **Cast** function to cast schema types.

You must cast a schema in any of the following instances:

- Cast the value that you assign to an output element so it matches the output element schema definition type.
- Cast the value of an element that you use as a parameter to a function where the parameter is of a different type.
- Cast the value of an element that you use as a condition on a transform where the type is different.
- Cast the value of an element when you work with a database, and the types differ.

To cast a schema, you can use the `xs:`*`castOperation`* functions, where *castOperation* is the name of the cast function.

Mapping behavior driven by the type of operation

When the transformations in the message map are constructed, the values for output message elements can be derived from any of the following components:

- Input message elements, through any of the following mapping operations:
  - **Move**, **Convert**, and other built-in transforms in the Graphical Data Mapping editor.
  - XPath 2.0 functions (prefix `fn:`). All XPath 2.0 functions are supported by the Mapping node. For more information about XPath, see W3C XML Path Language (XPath) 2.0.
  - Database input by using a database **Select** transform.
  - Schema type casts. For more information, see "Mapping xsd:any on an input or output message" on page 1397.
- Extra functions, which allow multiple input values to produce the output value, such as **concat** and **join**.
- The result of database **Select**, **Insert**, **Update**, **Delete**, and **Database routine** transforms.
- Constant values, through an **Assign** operation that uses a supplied value.
- Custom functions, user-defined XPath, Java, or ESQL.

The logic to derive values can be simple or complex. In addition to the transformation operations that set an output value, structural transforms are provided to enable conditional statements, loops, and nesting of transform logic into local maps.

For information about the supported transform types, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Transform types in the Graphical Data Mapping editor
In the Graphical Data Mapping editor, you can map elements and attributes between the input and output objects. You can apply a transform to the mapping that specifies the action to be performed on the input data. The result of the transform is stored in the output element.

The following table shows the standard mapping transforms that are provided by the Graphical Data Mapping editor:

Table 44. Core mapping transforms in the Graphical Data Mapping editor:

Transform	Description
"Assign" on page 1289	Sets a value in the output element. There is no input element. Column values set via **Assign** transform will always be passed as character string.
"Setting the value of a simple output element to a default or fixed value" on page 1485	Sets a specific value type in the output element. **Cast** can also move and convert an input element to become a specific value type in the output element.
"Concat" on page 1301	Creates a string concatenation that allows you to retrieve data from two or more entities and link them into a single result.
"Convert" on page 1303	Copies the input element to the output element and changes the type. The transform takes a single simple input and creates a single simple output with a different type.
"Create" on page 1304	Creates an empty element, a nil element, or a simple type element by using a default value that is based on the element's type.
"Custom XPath" on page 1315	Enables you to enter any XPath expressions and built-in IBM Integration Bus functions to be used in the transform.

Table 44. Core mapping transforms in the Graphical Data Mapping editor: (continued)	
Transform	**Description**
"Custom Java" on page 1312	Enables you to enter your own Java code to be used in the transform.
"Custom ESQL" on page 1308	Enables you to enter your own ESQL code to be used in the transform.
"Move" on page 1335	Copies data from the input element to the output element.
"Normalize" on page 1336	Normalizes the input string by removing white space such as spaces, tabs, and returns, and moves the resulting normalized string to the output element.
"Substring" on page 1340	Extracts information as required, and moves the extracted string to the output element.
"Task" on page 1341	Describes a manual task or point of concern that might need to be reviewed or resolved before a message map can be used in your solution.
"Built-in XPath transforms" on page 1342	All XPath 2.0 functions are supported, in the form `fn:<function_name>`.

In addition to the core mapping transforms, several structural transforms are provided. The structural transforms control how nested elements are displayed in the Graphical Data Mapping editor, but they have no effect on the data itself. The structural transforms are described in the following table:

Table 45. Structural mapping transforms in the Graphical Data Mapping editor:	
Transform	**Description**
"Append" on page 1285	Appends occurrences of an output array in the order of the inputs.
"Remove" on page 1336	Removes an element.
"For Each" on page 1320	Iterates over an input array element (either a simple type or a complex type).
"Group" on page 1328	Takes a single input array and produces a set of nested output arrays that collate elements of the input array.
"If, Else if, and Else" on page 1331	You can control the flow of the mapping by setting conditions.
"Join" on page 1332	Joins elements from two or more inputs.
"Local map" on page 1334	Provides a hierarchical view of element transforms in the message map.
"Submap" on page 1339	References another map. It calls a map from this map file or another map file, which can be stored in a library, an application, an integration service, or an Integration project.

The following table shows the database transforms that are provided by the Graphical Data Mapping editor:

Table 46. Database transforms in the Graphical Data Mapping editor:	
Transform	**Description**
"Database Routine" on page 1318	Calls a stored procedure or user-defined function from a database.
"Delete" on page 1319	Deletes one or more rows in a database table that is matched by a Where clause.
"Failure" on page 1319	Enables the map to take-on error handling for any exceptions that are raised by the database server in a database transform, instead of having such exceptions stop the map and be reported.
"Insert" on page 1332	Inserts a row into a database table.
"Return" on page 1338	Enables extra processing after a successful Insert, Update, or Delete database operation, or Database Routine call. Provides the results from the database operation or call as inputs.
"Select" on page 1338	Retrieves data from rows in a database table, so that the data can be used as input in a message map.
"Update" on page 1342	Updates one or more rows in a database table that is matched by a Where clause with a single set of data values.

You can use **Cache** transforms to interact with data that is stored in a global cache. The **Cache** transforms are described in the following table:

*Table 47. **Cache** transforms in the Graphical Data Mapping editor:*	
Transform	**Description**
"Cache Put" on page 1293	Adds a key-value pair to a map in a global cache.
"Cache Get" on page 1291	Gets a value from a map in a global cache, by providing the key that is associated with the value.
"Cache Remove" on page 1296	Removes a key-value pair from a map in a global cache.
"Cache Return" on page 1297	Returns or transforms values if the **Cache** transform succeeds.
"Cache Failure" on page 1290	Returns or transforms values if the **Cache** transform fails.

You can use built-in IBM App Connect Enterprise functions to retrieve IBM App Connect Enterprise data and perform data-type conversion and formatting. The `iib:` functions are described in the following table, and are available through content assist in the "Custom XPath" on page 1315 transform:

Table 48. Built-in App Connect Enterprise functions in the Graphical Data Mapping editor:	
Function	**Description**
iib:getUserDefinedProperty('*propertyName*')	Access user-defined properties from a Mapping node
iib:hexBinaryValue($<var>)	Convert the value to a hex binary format string

Table 48. Built-in App Connect Enterprise functions in the Graphical Data Mapping editor: (continued)	
Function	**Description**
iib:base64BinaryValue($<var>)	Convert the value to a base64 binary format string
iib:nullValue()	Create a null/nil output element
iib:uuidValue()	Create a new UUID value

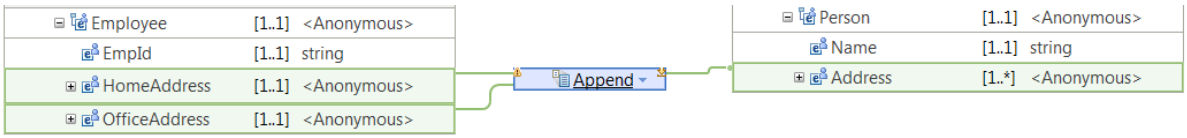
Append
You can use the **Append** transform to create an output array in the order of the inputs.

Overview

The **Append** transform is not available in the list of available transforms until you wire at least two inputs to a transform.

To build an output array of N elements where you have N inputs available in a flat structure, you wire each input to the **Append** transform.

For example, the following figure shows two flat structures, *HomeAddress* and *OfficeAddress* wired into an **Append** transform to create the *Address* array.



To build an output array of N elements where you have less than N unique inputs to wire into the **Append** transform, you can wire the same input multiple times.

If your input to the **Append** transform is repeating, you can use the **For Each** transform.

The only way to control the order of populating an output array is by using the **Append** transform. You must provide input connections to the **Append** transform and set their order in the **Properties** page.

Note: You must use the **For Each** transform, instead of the **Append** transform, when you need to create an output array where the input element is repeating. In the nested map of a **For Each** transform, you can use an **If** transform to define the condition under which the **Append** transform is applied for each instance of the input element.

Inputs to the Append transform

The **Append** transform takes multiple inputs of either simple type or complex type.

Inputs of single, non-repeating elements are also allowed. Each single input element adds an extra occurrence to the output array.

You wire inputs to the **Append** transform as **primary** connections.

You can wire the same input into an **Append** transform more than once if you need to produce more than one array instance from a single input.

The **Append** transform iterates over multiple inputs in the specified order to append data. The order of inputs into the transform is recognized, and is set in the **Order** property page.

The **Append** transform provides a nested transform for each input in the output array.

The nested transforms are performed for each input sequentially, producing occurrences of the output array. First over all elements in the first input, then over all elements in the second input.

When you connect a repeating input, each instance adds an extra occurrence to the output array. You can use the **Cardinality** property page on the transform to specify a subset of indexes the transform should process. The first index element is 1.

Output of the Append transform

The output of an **Append** transform can be a simple type array or a complex type array.

The output array size is the sum of the input elements wired to the **Append** transform.

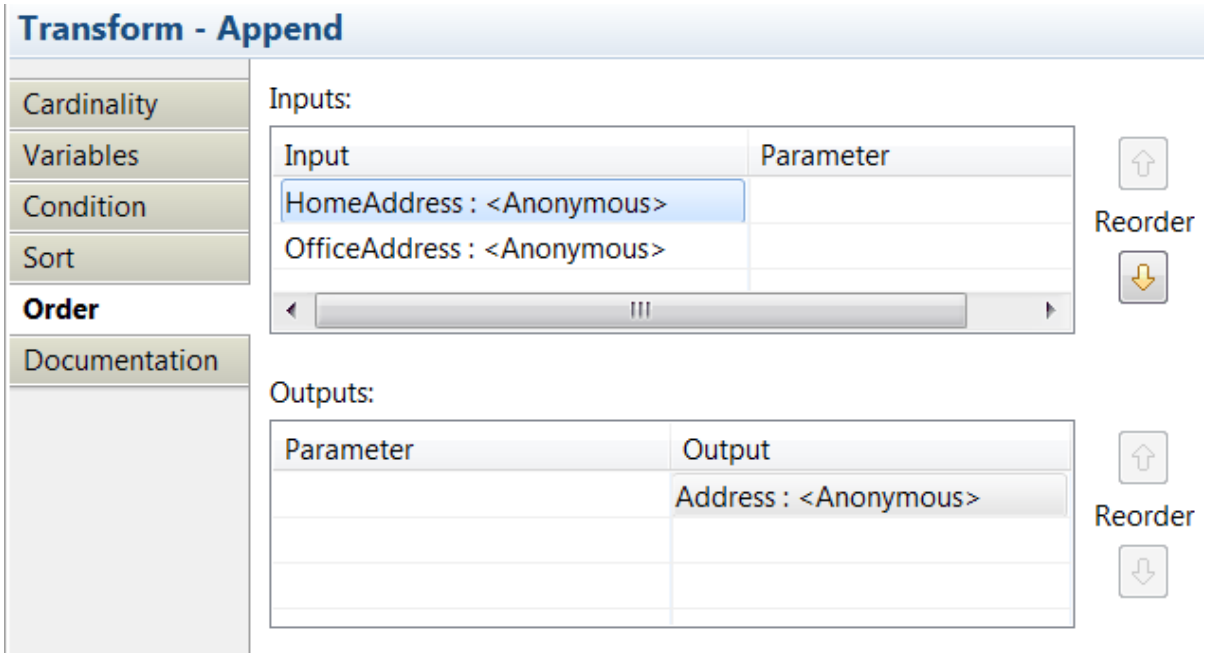
Note: You can define any number of inputs to the **Append** transform. The Graphical Data Mapping editor does not validate the number of inputs. You must ensure that the number of wired inputs to the **Append** transform correspond to the value configured in the **Maximum occurrence** property of the output array.

Order of the inputs

By default, the order of the inputs to the **Append** transform is the order in which you wire the inputs.

You can modify the order by reordering the inputs in the **Order** tab of the transform properties.

Note: You can only order inputs that are connected with a primary connection to the transform.



Inside the nested map

When you define a transform inside the nested map of an **Append** transform, you can only connect one input element to any transform that you define.

The Graphical Data Mapping editor reports error **CWMSL259E** if you connect multiple inputs to a transform inside the nested map.

If your input element is a repeating element, you can only use a **For Each** transform or an **If** transform on the repeating input.

- You can use the **For Each** transform to build an output instance for every index that is applied. The **Cardinality** and **Filter Inputs** properties determine which indexes of the repeating input are applied.
- You can use the **If** transform to build a single output instance. The **If** condition determines which index of the repeating element is applied to calculate the output value.

If the input element and the output element to an **Append** transform have a global type, you can use a **Submap** instead of a **Local map**.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Append** transform. You can then use one or more of these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Note:

- You can use only inputs that are connected with a primary connection to the transform.
- All inputs will be present in the nested map of the **Append** transform and by default mapped to produce an occurrence of the output.

If you need an input element to define a condition and you do not want the input element to be part of the output array, complete the following steps:

1. Connect the input element with a primary connection to the **Append** transform.
2. Define your condition.
3. In the nested map associated with the **Append** transform, a **Local Map** is added. Within the **Local Map**, a **Move** transform is defined for each input element. Delete the **Move** transform associated with the input element so that the input element is not appended to the output value.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see “Configuring the properties of a transform” on page 1431, “Defining an XPath conditional expression for a transform” on page 1433 and “Defining a Java conditional expression for a transform” on page 1439.

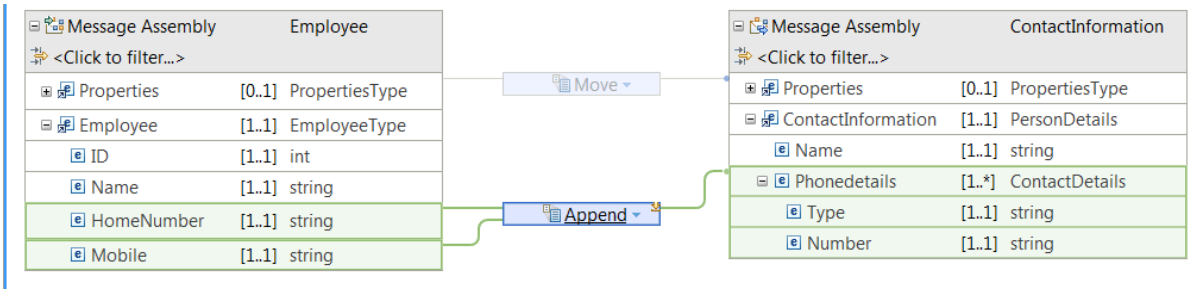
If your conditional expression requires the value of an input element that is not used in the **Append** transform to set the output element, you must use the **If** transform to define when the transform is applied at run time. For more information, see “If, Else if, and Else” on page 1331.

Example

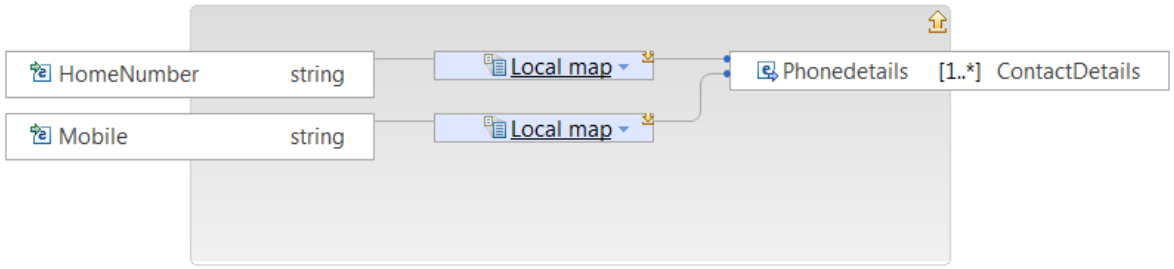
This example shows how to create an output array with two indexes by using the **Append** transform.

You connect two input elements (**HomeNumber** and **Mobile**) to the **Append** transform. These inputs will be used to set the value of multiple indexes in the output repeating element **Phonedetails**.

You also define a connection from the **Append** transform to the repeating element **Phonedetails**.

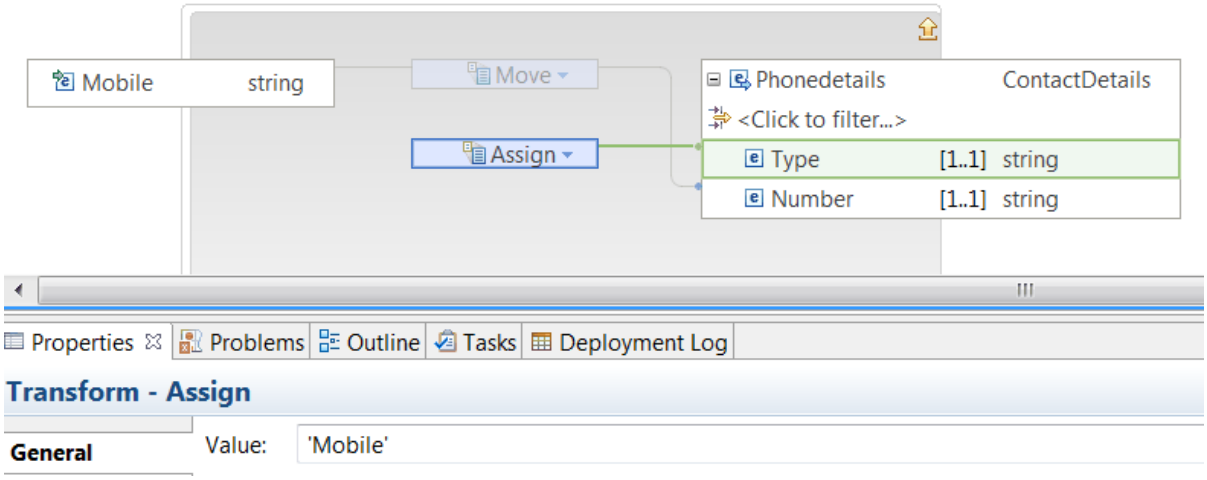


When you open the nested map associated to the **Append** transform, you get two **Local Map** transforms, one per input element.

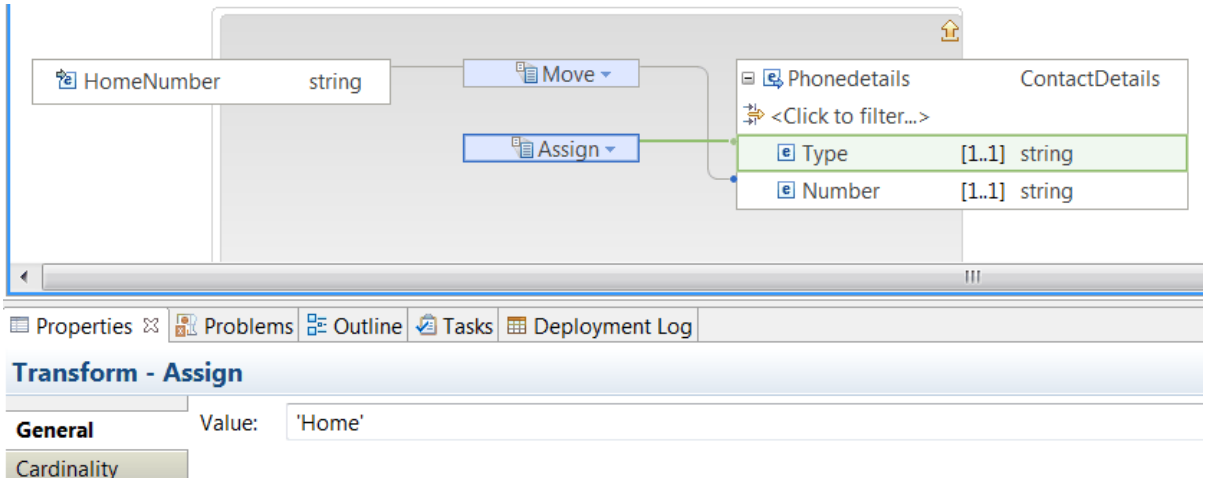


Inside each **Local Map** transform, you define the transformation logic that sets the output values for one index of the output repeating structure **Phonedetails**.

The following figure shows the nested map associated with the **Local Map** transform for the input element **Mobile**:

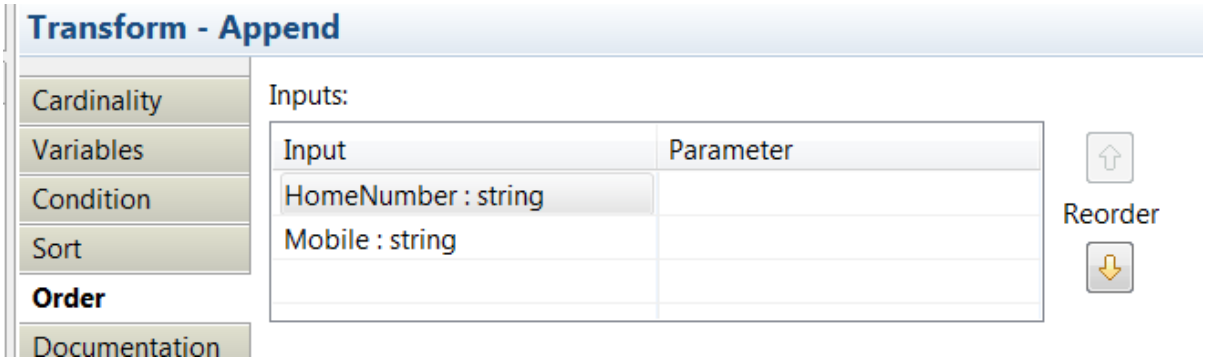


The following figure shows the nested map associated with the **Local Map** transform for the input element **HomeNumber**:



You can configure the order in which the indexes are created. You set the order in which indexes are created in the **Order** tab of the Properties view of the **Append** transform.

In this example, the first index contains the information of the home number. The second index contains the information of the mobile number.



Assign
You can use the **Assign** transform to set the value of an output element to a constant or fixed value.

Overview

The **Assign** transform sets a value that can be a fixed value or it can be the result of a function that has no input; for example, a current date function.

You cannot use the value of an input element to set the value of an output element with the **Assign** transform.

The output element is set to a constant value.

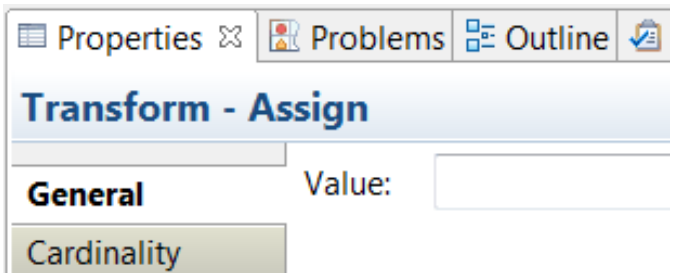
The output element must be a simple type element.

For more information about assigning a value to an output element, see "Setting the value of an output element to a simple data type" on page 1481.

Assign a value

You must assign a value in the **Value** field that is located in the **General** tab of the **Assign** transform **Properties** view.

If you do not specify a value, an empty element is created.



Define when the transform is applied at run time

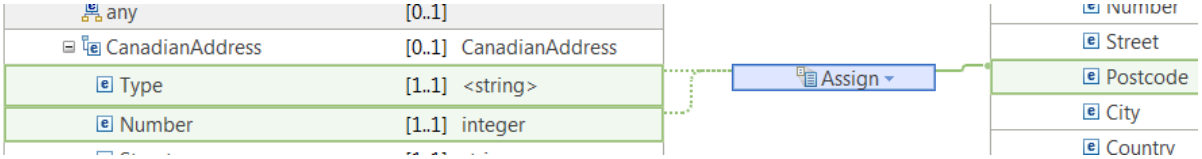
You can define multiple connections between input elements and the **Assign** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see “Configuring the properties of a transform” on page 1431, “Defining an XPath conditional expression for a transform” on page 1433 and “Defining a Java conditional expression for a transform” on page 1439.

To add inputs to the transform, you can define **supplement** connections between input elements and the **Assign** transform.



When you define more connections, you can configure the following properties to define how those inputs are displayed in the message map:

- **Sort**: You can sort the inputs to the transform by ascending order, descending order, case order, or data order.
- **Order**: You can display the order of input connections to a transform. You can reorder them.

Note: You only can sort and order inputs that are connected with a primary connection to the transform.

Default values

The following table lists the default values set when you use the **Assign** transform:

*Table 49. Default values set by using the **Assign** transform*

Type	Default value
string	Empty string
dateTime	`2002-01-01T11:00:00`
Boolean	`false`
decimal	`0.0`
double	`0.0`
hexBinary	`00`
long	`0`
duration	`P1Y`
time	`00:00:00`
date	`2002-01-01`

Cache Failure

You can use the **Cache Failure** transform to handle exceptions that might occur if a **Cache** transform fails.

Overview

Include a **Cache Failure** transform in your **Cache Put**, **Cache Get**, or **Cache Remove** transform group to specify a nested mapping that is called if the **Cache** transform fails. If you include a **Cache Failure** transform, exception errors are passed to the nested mapping instead of stopping the message map.

Note: If the conditions that are required to call a **Cache** transform are not met, the map stops and generates a mapping exception that cannot be handled by a **Cache Failure** transform.

A **Cache Failure** transform is an optional transform that can be added or removed as required

A **Cache Failure** transform does not perform any transformation. The **Cache Failure** nested mapping provides predefined input elements that provide data from an exception that is encountered when the cache operation runs. You can also map elements from the input tree to the **Cache Failure** transform, and connect the **Cache Failure** transform to one or more output elements. You can then use the nested map to create or transform values and map them to the output elements that you connected to the **Cache Failure** transform.

Note: If you add a **Cache Failure** transform but do not include any mapping in the nested map, the details of any exceptions in the associated cache operation are not reported anywhere; instead, the map displays a warning.

Predefined elements

The **Cache Failure** nested mapping has the following predefined input elements:

Element	Description
ID	The identifying code of the exception. This is the "BIP" code of the `MbException`.
Message	The message that is associated with the exception. For example: `A duplicate key was encountered while interacting with map 'SYSTEM.BROKER.DEFAULTMAP'. A client attempted operation 'put' with map 'SYSTEM.BROKER.DEFAULTMAP' from grid 'WMB', using key 'MyKey'. This attempt failed because an entry already exists with the same key. This operation requires that a key of the same name does not already exist in the map. : Duplicate key exception`
Inserts	The details that are specific to the exception. For example, in the previous message, the following entities are the inserts: • The cache map name: `SYSTEM.BROKER.DEFAULTMAP` • The operation: `put` • The cache name: `WMB` • The key: `MyKey`

Run time behavior

The handling of **Cache** transform exceptions is determined by the configuration of the corresponding **Cache Failure** transform:

- If the **Cache Failure** transform is present in the **Cache** transform group, and is connected to one or more output objects, the exception is caught and processed by the **Cache Failure** transform.
- If the **Cache Failure** transform is present in the **Cache** transform group but is not connected to any output objects, the exception is caught by the **Cache Failure** transform, and is ignored.
- If the **Cache Failure** transform is not present in the **Cache** transform group and the **Cache** transform generates an exception, the exception is handled by the Mapping node in your message flow in the same way as other message flow exceptions.

Cache Get

You can use the **Cache Get** transform to get a value from the global cache, by providing the key that is associated with the value.

Overview

The **Cache Get** transform accepts only input connections, which provide values for the parameters in the nested mapping.

You can assign or map only single values of type simple value to the key. If a mapped element is not of the appropriate data type, you can use the Cast type (**xs:type**) transform to assign the data type. If the element can contain multiple values, set the Cardinality property to ensure that a single value is mapped to the key; see "Configuring the cardinality of a user-defined element" on page 1412.

When you add a **Cache Get** transform to your graphical map, a **Cache Return** transform is automatically included; see "Cache Return" on page 1297. The **Cache Return** transform provides a single predefined input element, which contains the value from the key-value pair that is associated with the key that is mapped to the **Cache Get** transform. You can connect the **Cache Return** transform to any output element to map the data that is returned from the cache. You can also map elements from the input tree to the **Cache Return** transform, and connect the **Cache Return** transform to one or more output elements. You can then use the nested map to create or transform values and map them to the output elements that you connected to the **Cache Return** transform.

You can also add a **Cache Failure** transform to your **Cache Get** transform if you want to handle exceptions that might occur if the **Cache Get** transform fails; see "Cache Failure" on page 1290.

For more information, see "Retrieving a value from the global cache by using a Mapping node" on page 1517.

Note: The **Cache Get** transform does not have any conditional properties. To configure conditional execution, you must embed the **Cache Get** transform inside an **If** transform.

Parameters

The **Cache Get** nested mapping has a number of parameters that you configure by mapping values or assigning fixed values. The following table describes the parameters that you can set when you use the **Cache Get** transform:

Parameter	Mandatory	Description	Result if no value is configured
Key	Yes	The name of the key in the key-value pair that is contained in the global cache map.	Error
MapName	You must specify a value for this parameter if you specify a value for the **CacheName** parameter.	The name of the global cache map that contains the key-value pair.	The default map in the cache is used. If you are using the embedded cache, the default map is SYSTEM.BROKER.DEFAU
CacheName	No. But if you specify this parameter, you must also specify the **MapName** parameter.	The name of the global cache WXSServer policy to be used.	The embedded cache in the integration node is used as the cache.

Cache Put
You can use the **Cache Put** transform to insert a key-value pair into the global cache.

Overview

The **Cache Put** transform accepts only input connections, which provide values for the parameters in the nested mapping.

You can assign or map only single values to a key-value pair in the global cache. By default, the schema type of the **Value** parameter in the **Cache Put** transform is defined as `xsd:anySimpleType`. The **Value** parameter can accept any simple-typed input mapping to create a cache entry value. The cache entry is created with a Java Object type that is determined by the schema type of the mapped input element; see "Java Object types that are created for each schema input type" on page 1295. To ensure that the mapped input element has a specific schema type, and hence that the cache entry is always created with a specific Java Object type, you can apply a mapping cast to the **Value** parameter and map the input element to the resulting target element; see "Casting elements in a message map" on page 1398. Alternatively, you can use an `xs:type` transform to cast the mapped input element, or assigned value; see "Cast type (xs:type)" on page 1299.

If the element can contain multiple values, set the Cardinality property to ensure that a single value is mapped to the key or value; see "Configuring the cardinality of a user-defined element" on page 1412.

The key-value pair is stored in a map that is in the global cache.

You can choose which of the following actions the **Cache Put** transform takes by selecting from the following options on the General tab of the **Properties** pane for the **Cache Put** transform:

Insert an entry in cache
A new key-value pair is added to the global cache. If the cache already contains an entry that has the same key, an error is produced. This option is the default option.

Update an entry in cache
The value that is associated with an existing key in the global cache is updated. If the cache does not already contain an entry that has the same key, an error is produced.

Insert or update an entry in cache
The global cache is queried to determine if the cache contains an entry that has the key. If the cache already contains an entry that has the same key, the value that is associated with the key is updated in the cache. If the cache does not already contain an entry that has the same key, a new key-value pair is added to the cache.

Note: The operation might fail if the key is being concurrently added or deleted.

You can add a **Cache Return** transform to your **Cache Put** transform group if you want to return values after a successful **Cache Put** transform; see "Cache Return" on page 1297.

You can add a **Cache Failure** transform to your **Cache Put** transform group if you want to handle exceptions that might occur if the **Cache Put** transform fails; see "Cache Failure" on page 1290.

For more information, see "Adding key-value pairs to the global cache by using a Mapping node" on page 1515 .

Note: The **Cache Put** transform does not have any conditional properties. To configure conditional execution, you must embed the **Cache Put** transform inside an **If** transform.

Parameters

The **Cache Put** nested mapping has a number of parameters that you configure by mapping values or assigning fixed values. The following table describes the parameters that you can set when you use the **Cache Put** transform:

Parameter	Mandatory	Description	Result if no value is configured
Value	Yes	The value in the key-value pair that is inserted into the global cache map. For information about the Java Object types that are created for each schema input type, see “Java Object types that are created for each schema input type” on page 1295.	Error
Key	Yes	The name of the key in the key-value pair that is inserted into the global cache map. You use this key name to retrieve the associated value by using the **Cache Get** transform.	Error
MapName	You must specify a value for this parameter if you specify a value for the **CacheName** parameter or the **TimeToLive** parameter.	The name of the global cache map to receive the key-value pair. If the cache map does not exist, the map is created before the key-value pair is added.	The default map in the cache is used. If you are using the embedded cache, the default map is SYSTEM.BROKER.DEFAU
CacheName	No. But if you specify this parameter, you must also specify the **MapName** parameter, and you must not specify the **TimeToLive** parameter.	The name of the global cache WXSServer policy to be used.	The embedded cache in the integration node is used as the cache.
TimeToLive	No. But if you specify this parameter, you must also specify the **MapName** parameter, and you must not specify the **CacheName** parameter.	The time (in seconds) until the key-value pair is removed from the global cache. Enter `0` or `-1` to configure the key-value pair to remain in the cache until the integration node is restarted, or the cache is cleared by using the **mqsicacheadmin** command; see mqsicacheadmin command. **Note:** The cache ignores negative values other than -1.	The cache entry does not expire.

Note: You can set these parameters by using user-defined properties. Then, you can provide values for the user-defined properties dynamically by using a BAR file override. For more information, see “Accessing user-defined properties from a Mapping node” on page 1479.

Java Object types that are created for each schema input type
When you map an input element to a **Cache Put `Value`** parameter, the type of Java object that is created in the global cache is determined by the `http://www.w3.org/2001/XMLSchema` schema input.

When you map an input element to the **`Value`** parameter, you are prompted to apply a mapping cast to redefine the default `xs:anySimpleType` schema type to a specific schema type (see "Casting elements in a message map" on page 1398), so that the global cache entry is created with a specific Java Object type. If you do not use a mapping cast on the **`Value`** parameter, the Java Object type that is created in the global cache might vary depending on the type of the mapped input element.

The following table details the Java Object type that is created in the global cache for each type of `http://www.w3.org/2001/XMLSchema` schema input.

Note: Regardless of the type of the input element in the **Cache Put** nested mapping, if the input element has a nil value and you do not specifically cast the target parameter to a concrete type, the entry that is created in the global cache is a null value.

Type of the input element that is mapped to the Cache Put `Value` parameter	Type of Java object that is created in global cache
boolean	java.lang.Boolean
byte	java.lang.Byte
decimal	java.math.BigDecimal
double	java.lang.Double
float	java.lang.Float
int	java.lang.Integer
unSignedshort	java.lang.Integer
integer	java.lang.BigInteger
negativeInteger	java.lang.BigInteger
nonNegativeInteger	java.lang.BigInteger
nonPositiveInteger	java.lang.BigInteger
postiveInteger	java.lang.BigInteger
unsignedLong	java.lang.BigInteger
long	java.lang.Long
unsignedInt	java.lang.Long
short	java.lang.Short
unsignedByte	java.lang.Short
string	java.lang.String
date	java.lang.String (XML formatted string)
dateTime	java.lang.String (XML formatted string)
gDay	java.lang.String (XML formatted string)
gMonth	java.lang.String (XML formatted string)

Type of the input element that is mapped to the Cache Put Value parameter	Type of Java object that is created in global cache
gMonthDay	java.lang.String (XML formatted string)
gYear	java.lang.String (XML formatted string)
gYearMonth	java.lang.String (XML formatted string)
time	java.lang.String (XML formatted string)
dayTimeDuration	java.lang.String (XML formatted string)
duration	java.lang.String (XML formatted string)
yearMonthDuration	java.lang.String (XML formatted string)
anyUri	java.lang.String
base64Binary	java.lang.String
hexBinary	java.lang.String
normalizedString	java.lang.String
qName	java.lang.String

Cache Remove
You can use the **Cache Remove** transform to remove a key-value pair from the global cache.

Overview

The **Cache Remove** transform accepts only input connections, which provide values for the parameters in the nested mapping.

You can assign or map only single values of type simple value to the key. If a mapped element is not of the appropriate data type, you can use the Cast type (**xs:type**) transform to assign the data type. If the element can contain multiple values, set the Cardinality property to ensure that a single value is mapped to the key; see “Configuring the cardinality of a user-defined element” on page 1412.

You can add a **Cache Return** transform to your **Cache Remove** transform group if you want to perform some mapping after a successful **Cache Remove** transform. The **Cache Remove** transform provides the value of the entry that has been removed. You can then map this value in the **Cache Return** transform; see “Cache Return” on page 1297.

You can add a **Cache Failure** transform to your **Cache Remove** transform group if you want to handle exceptions that might occur if the **Cache Remove** transform fails; see “Cache Failure” on page 1290.

For more information, see “Removing a key-value pair from the global cache by using a Mapping node” on page 1519.

Note: The **Cache Remove** transform does not have any conditional properties. To configure conditional execution, you must embed the **Cache Remove** transform inside an **If** transform.

Parameters

The **Cache Remove** nested mapping has a number of parameters that you configure by mapping values or assigning fixed values. The following table describes the parameters that you can set when you use the **Cache Remove** transform:

Parameter	Mandatory	Description	Result if no value is configured
Key	Yes	The name of the key in the key-value pair that is contained in the global cache map.	Error
MapName	You must specify a value for this parameter if you specify a value for the **CacheName** parameter.	The name of the global cache map that contains the key-value pair.	The default map in the cache is used. If you are using the embedded cache, the default map is SYSTEM.BROKER.DEFAU
CacheName	No. But if you specify this parameter, you must also specify the **MapName** parameter.	The name of the global cache WXSServer policy to be used.	The embedded cache in the integration node is used as the cache.

Cache Return
You can use the **Cache Return** transform to return values after a successful **Cache** transform.

Overview

Include a **Cache Return** transform in your **Cache Put**, **Cache Get**, or **Cache Remove** transform group to specify a nested mapping that is called if the **Cache** transform completes successfully.

A **Cache Return** transform does not perform any transformation. The **Cache Return** nested mapping provides predefined input elements that provide data from the successful cache operation. You can also map elements from the input tree to the **Cache Return** transform and connect the **Cache Return** transform to one or more output elements. You can then use the nested map to create or transform values and map them to the output elements that you connected to the **Cache Return** transform.

The predefined Value input element in the **Cache Return** nested mapping has a default schema type of `xs:anySimpleType`. If you know the type of the Java object in the cache, you can map directly to a target element that has the schema type that matches the Java Object type; see "Schema types that are returned for each supported Java Object type" on page 1298.

If the entry in the cache might have one of several Java Object types, you can apply mapping casts to the predefined Value input element. You can apply mapping casts for the schema types that match each of the Java Object types; see "Casting elements in a message map" on page 1398. Alternatively, you can use an `xs:type` transform to cast the predefined Value input element; see "Cast type (xs:type)" on page 1299. For example, if the Java Object type of the cache entry might be `java.lang.Integer` or `java.lang.String`, you would apply a mapping cast for a schema type of `xs:int`, and a mapping cast for a schema type of `xs:string`.

Predefined elements

The **Cache Return** nested mapping has a number of predefined input elements that vary depending on the associated **Cache** transform. The following table describes the predefined input elements that are included with each **Cache** transform:

Element	Cache transforms in which element in included	Description
Value	**Cache Get** **Cache Remove**	The value from the key-value pair that is associated with the key that is mapped to the **Cache** transform. For information about the schema type that is returned for each type of Java object in the cache, see "Schema types that are returned for each supported Java Object type" on page 1298. **Note:** At run time, the **Value** element does not exist in the following situations: • There was no matching entry in the cache. • (For **Cache Remove** transforms only.) A matching entry was removed from the cache but the entry had a null value. You can test for the existence of the **Value** element by using the XPath expression `fn:exists($Value)` in the Condition tab of the transform that maps the **Value** element to the output element.
Count	**Cache Put**	The number of entries added to the global cache or removed from the global cache.

Schema types that are returned for each supported Java Object type

When you retrieve an entry from the global cache, the type of the Java object in the cache determines the `http://www.w3.org/2001/XMLSchema` schema type of the returned Value element.

The following table details the `http://www.w3.org/2001/XMLSchema` schema type of the Value element that is returned for each of the supported Java Object types.

Type of Java object that is in global cache	Schema type of the Value element that is returned
`java.lang.Boolean`	`boolean`
`java.lang.Byte`	`byte`
`java.math.BigDecimal`	`decimal`
`java.lang.Double`	`double`
`java.lang.Float`	`float`
`java.lang.Integer`	`int`
`java.lang.BigInteger`	`integer`
`java.lang.Long`	`long`
`java.lang.Short`	`short`
`java.lang.String`	`string`

Note: If you map the returned Value element to a target element that has a different schema type, a type cast occurs; see Casting from primitive types to primitive types. The cast might fail if the schema types

are incompatible. If the global cache entry was created by a **Cache Put** transform, the Java Object type of the cache entry is detailed in the following topic: "Java Object types that are created for each schema input type" on page 1295.

For example, if a **Cache Put** transform maps an element of schema type `xs:dateTime` to a cache entry, the cache entry is created with a Java Object type of `java.lang.String`. If you use a **Cache Get** transform to retrieve the entry from the cache, the Value element is returned with a schema type of `xs:string`. In the nested mapping for the **Cache Return** transform, you can map the returned Value element to a target element of schema type `xs:dateTime`.

Cast type (`xs:type`)
You can use an **xs:type** transform to cast the value of a simple element to a specific data type.

Overview

For example, you might want to assign a value with a specific data type to a target element that is defined as `xs:anySimpleType`.

When you use an **xs:type** transform, you can have zero or more input elements mapped to the transform, but only a single output element. You can cast one value to set the output element. This value is set in the **Value** column of the **General** tab on the Properties page. The value can be one of the following entities:

- A literal value
- A single input value
- An XPath expression that uses zero or more of the input values

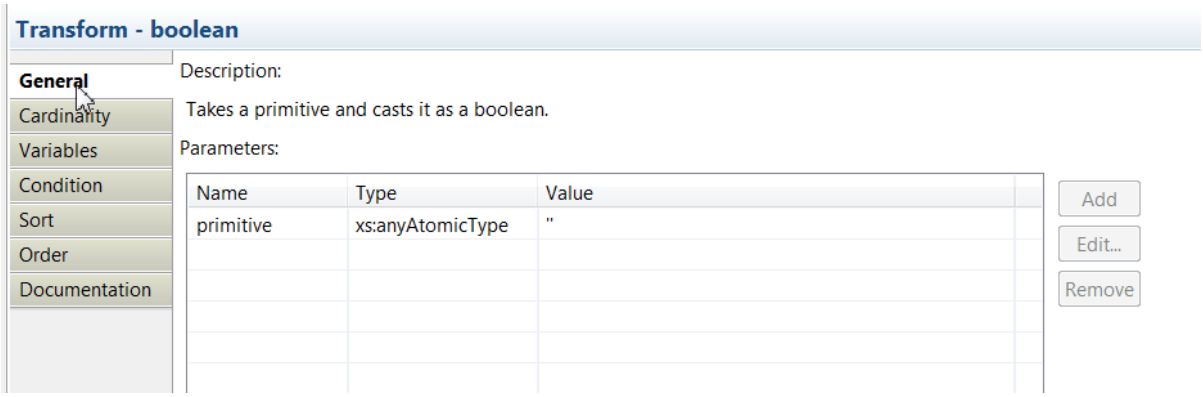
You can also use any of the input elements to build an XPath conditional expression that determines whether the **xs:type** transform is applied or not. You set this conditional expression on the **Condition** tab of the Properties page.

You must choose the **xs:type** transform according to the output element data type. For example, if you have an output element with a Boolean data type, you must choose **xs:boolean** transform.

For more information about casting a specific value type to an output element, see "Setting the value of an output element with a explicit data type" on page 1483.

Assign a value

You can set a fixed value or define an XPath expression in the **Value** field that is located in the **General** tab of a **xs:type** transform properties view.



To define an XPath expression, you click **Edit**. Then, you can use content-assist to enter the expression. As part of the expression, you can use any input elements for which you define connections to the transform.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **xs:type** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

When you define multiple input connections, you can configure the following properties to define how those inputs are displayed in the message map:

- **Sort**: You can sort the inputs to the transform by ascending order, descending order, case order, or data order.
- **Order**: You can display the order of input connections to a transform. You can reorder them.

You can use the input connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Note: You only can sort and order inputs that are connected with a primary connection to the transform.

`xs:type` transforms

You can use any of the following `xs:any` transforms:

- **xs:NOTATION**: This function takes a primitive and casts it as notation.
- **xs:Qname**: This function takes a primitive and casts it as a qualified name.
- **xs:anyURI**: This function takes a primitive and casts it as anyURI.
- **xs:base64Binary**: This function takes a primitive and casts it as base64Binary.
- **xs:boolean**: This function takes a primitive and casts it as boolean.

  You can use any of the following values: `true` Or `false`.
- **xs:dateTime**: This function takes a primitive and casts it as dateTime.
- **xs:date**: This function takes a primitive and casts it as date.
- **xs:dayTimeDuration**: This function takes a primitive and casts it as dayTimeduration.
- **xs:decimal**: This function takes a primitive and casts it as decimal.
- **xs:double**: This function takes a primitive and casts it as double.
- **xs:float**: This function takes a primitive and casts it as float.
- **xs:gDay**: This function takes a primitive and casts it as gDay.
- **xs:gMonthDay**: This function takes a primitive and casts it as gMonthDay.
- **xs:gMonth**: This function takes a primitive and casts it as gMonth.
- **xs:gYearMonth**: This function takes a primitive and casts it as gYearMonth.
- **xs:gYear**: This function takes a primitive and casts it as gYear.
- **xs:hexBinary**: This function takes a primitive and casts it as hexBinary.
- **xs:integer**: This function takes a primitive and casts it as integer.
- **xs:int**: This function takes a primitive and casts it as signed 32-bit integer.
- **xs:string**: This function takes a primitive and casts it as string.

- **xs:time**: This function takes a primitive and casts it as time.
- **xs:yearMonthDuration**: This function takes a primitive and casts it as yearMonthDuration.

For more information, see Casting from primitive types to primitive types.

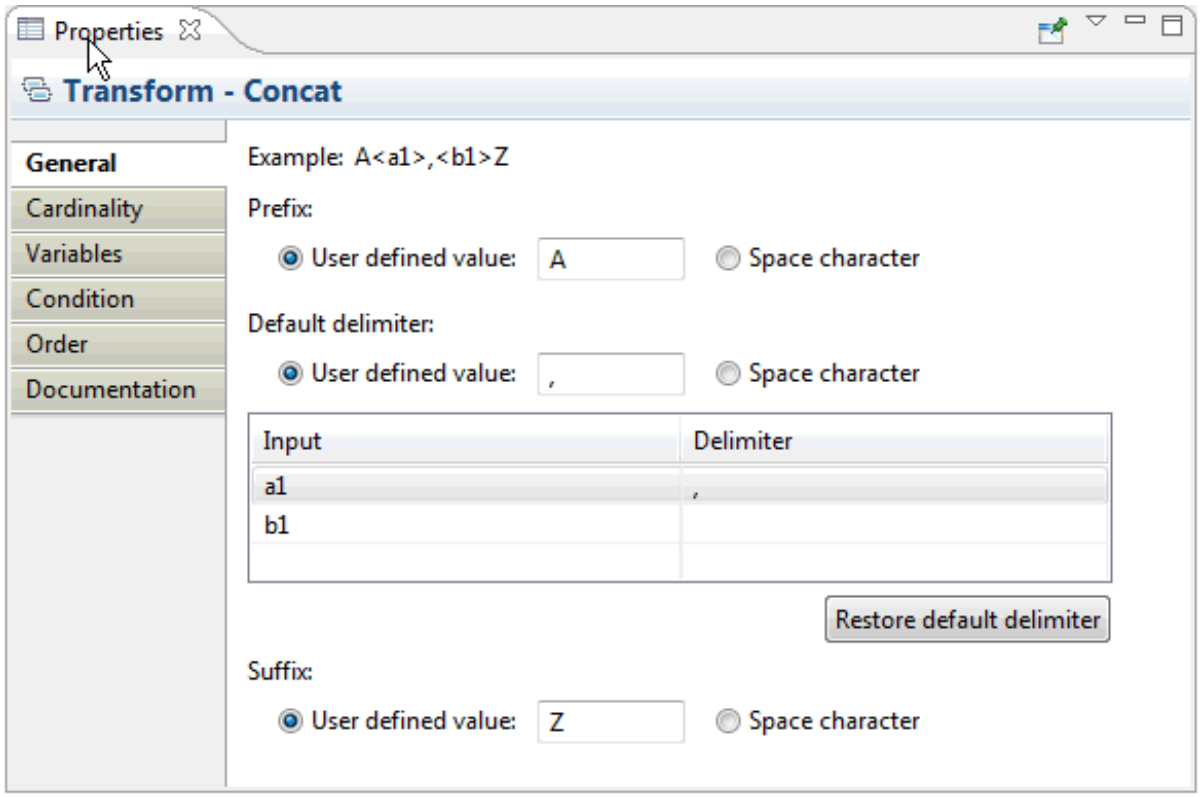
Concat
You can use a **Concat** transform to concatenate data from two or more simple elements into a string output element.

Overview

The **Concat** transform concatenates two or more simple inputs into a string output element.

When you configure the **Concat** transform, you can specify a prefix, a suffix, and a delimiter through the Properties page:

You can specify an alphanumeric character to be the delimiter between the strings,. You can also use a string prefix and a string suffix.



For example, you can concatenate the strings from the elements `firstname` and `lastname`, and specify a space as the delimiter, a prefix of `Mr. `, and a comma as the suffix, with the following result: `Mr. firstname lastname,`

When can you use the Concat transform?

You can use the **Concat** transform when the following premises apply:

- You want to concatenate data from two or more single type inputs.
- The input types to the **Concat** transform can be any simple or primitive data types.

  Note: Simple type input elements that are not of type **xs:string** will be cast to **xs:string**.
- All the inputs to the **Concat** transform, that are connected as primary connections, are used to calculate the value of the output string element.

- You might need to define a prefix.
- You might need to define the same delimiter between input values.
- You might need to define a suffix.

You cannot select and use the **Concat** transform when any of the following criteria on inputs applies:

- One of the inputs to the **Concat** transform is a complex type element.
- One of the inputs is a repeating element, that is, the input element cardinality is set to [1..*] or [0..*].

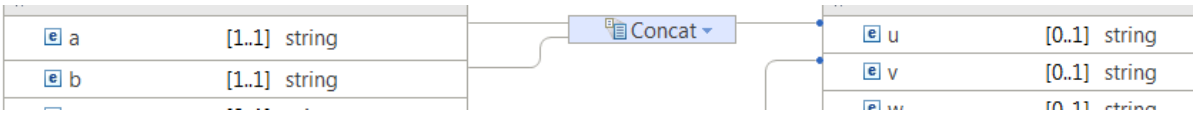
Inputs to the Concat transform

The **Concat** transform takes multiple simple type elements.

You wire inputs to the **Concat** transform as primary connections.

You can wire the same input into a **Concat** transform more than once.

The **Concat** transform concatenates input data in order. The order of inputs into the transform is recognized, and is set in the **Order** property page.



Order of the inputs

By default, the order of the inputs to the **Concat** transform is the order in which you wire the inputs.

You can modify the order by reordering the inputs in the **Order** tab of the transform properties.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Concat** transform. You can then use one or more of these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Note: You only can use inputs that are connected with a primary connection to the transform, and all inputs will be concatenated. It is not possible to have an input that is only used in the condition.

Note: When you need to apply the **Concat** transform conditionally, use an **If** transform and place the **Concat** transform within the nested mapping of the **If**.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see “Configuring the properties of a transform” on page 1431, “Defining an XPath conditional expression for a transform” on page 1433 and “Defining a Java conditional expression for a transform” on page 1439.

If your conditional expression requires the value of an input element that is not used in the **Concat** transform to set the output element, you must use the **If** transform to define when the transform is applied at run time. For more information, see “If, Else if, and Else” on page 1331.

Warning error

By default, you cannot connect a repeating simple element to a **Concat** transform. However, if you have a map where you have defined a **Concat** transform, and you change the cardinality of one of the input elements so it becomes a repeatable simple type, the **Concat** transform will show a warning.

The warning message is the following:

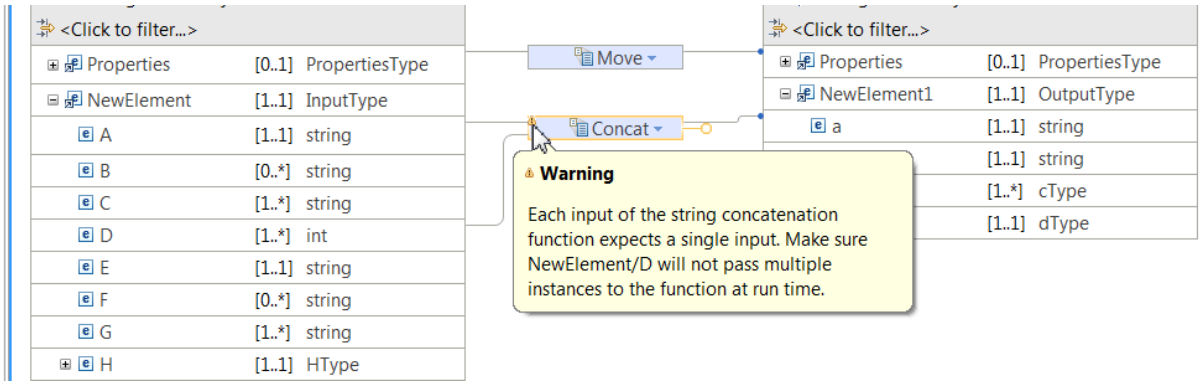
```
Each input of the string concatenation function expects a single input. Make
sure {0} will not pass multiple instances to the function at run time.
```

The warning is displayed because at least one input is not of single type.

When a **Concat** transform has such a warning, the run time behavior is the following:

- If the input XML has no more than one instance of the repeatable input, the **Concat** transform produces the expected result at run time.
- If the input XML has more than one instance of the repeatable input, the **Concat** transform results in a run time exception.

Example for a repeating single input element to a Concat transform:



Convert
The **Convert** transform implements a schema type cast on the input to match the output. If the type cast cannot be performed on the input instance value, an exception is thrown and the map processing stops.

Overview

Use the **Convert** transform to move a simple input element to an output element, when both elements are defined in the relevant schema models with different types.

You can only connect one input to the **Convert** transform. You must use a primary connection to connect the input element to the transform.

For example, you might have an input element with type `xsd:int` and an output element with type `xsd:decimal`. The **Convert** transform changes the input with an `int` type to an output with a `decimal` type.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Convert** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see “Configuring the properties of a transform” on page 1431, “Defining an XPath conditional expression for a transform” on page 1433 and “Defining a Java conditional expression for a transform” on page 1439.

You can use the input connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Create
You can use the **Create** transform to initialize an output element, set an output element to nil, or set an output element to fixed value defined by the schema.

Overview

For simple types, you cannot use the value of an input element to set the value of an output element in a **Create** transform.

However, you can define zero or more **supplement** connections between input elements and the **Create** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied.

You can use the **Create** transform to create the following types of output element:

- An empty element. For more information, see “Initializing a simple or complex output element by using the Create transform” on page 1491.
- An element with `xsi:nil="true"`, also called a nil element. For more information, see “Choosing an XPath conditional expression that tests for a nil value in a transform ” on page 1438.
- A simple type element with a default value that is specified by the schema. For more information, see “Setting the value of a simple output element to a default or fixed value” on page 1485.
- A complex element with child elements populated by using the **Assign** transform or the **Move** transform from supplemental wired inputs.

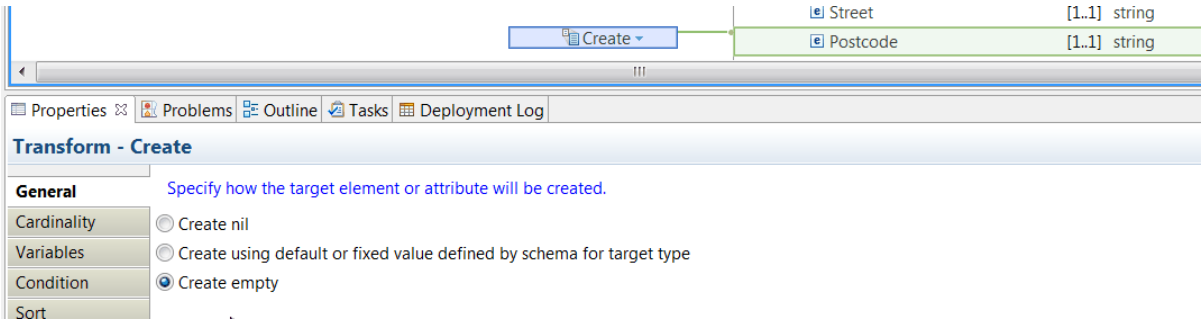
Set the value of a string type output element

By default, the option **Create empty** is preselected. You must choose this option to initialize a single type output element.

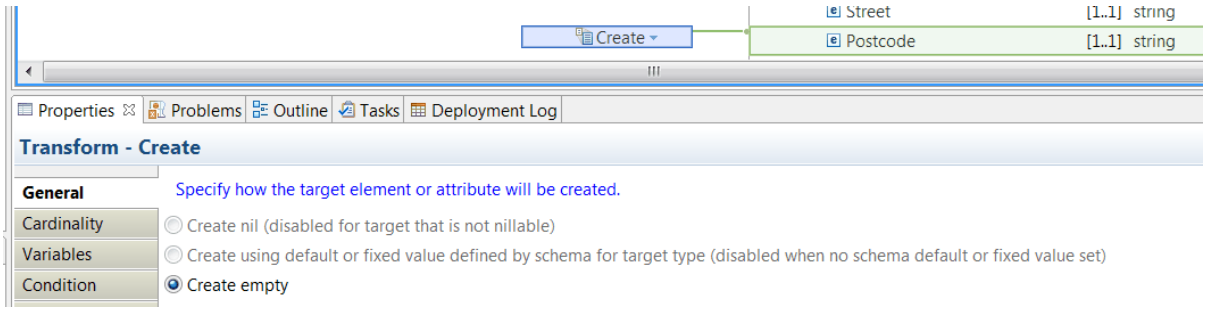
For example, for an element that is defined in the schema model as `<element name="Postcode" type="string" nillable="true" default="30567" />`, you can choose any of the following options:

- Create nil
- Create by using a default or a fixed value that is defined by schema for target type
- Create empty

The following figure shows the properties view for the **Create** transform defined for that element:



For example, if the output element is defined in the schema model as `<element name="Postcode" type="string" nillable="false" />`, you can choose to create the output element as empty.



The option to create a nil element is available only when the target is nillable.

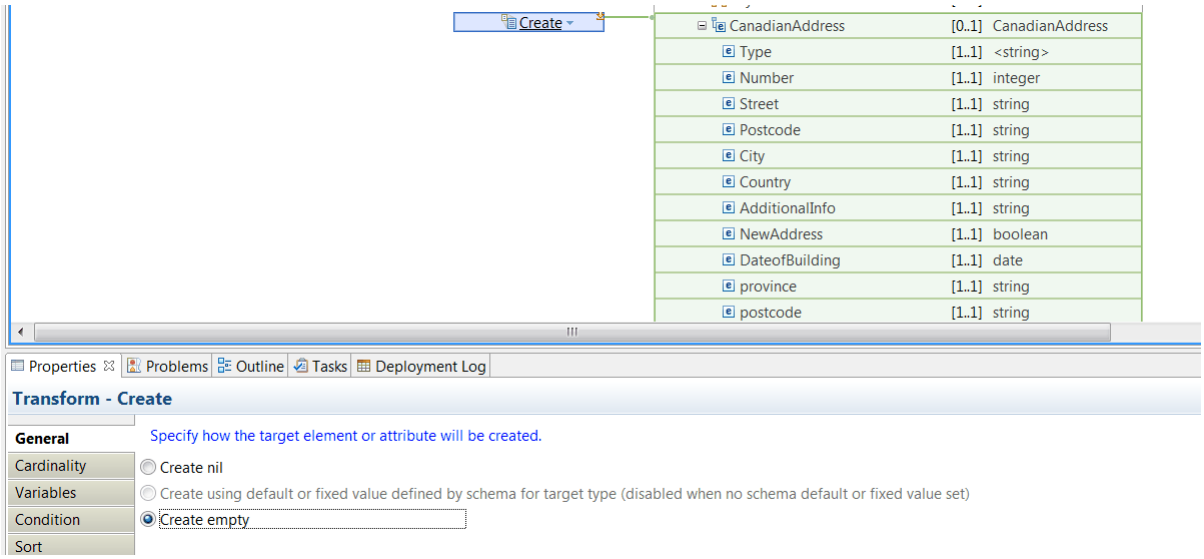
The option to create an element with the default value is only available when the target has a default value that is defined in the schema file.

Set the value of a complex type output element

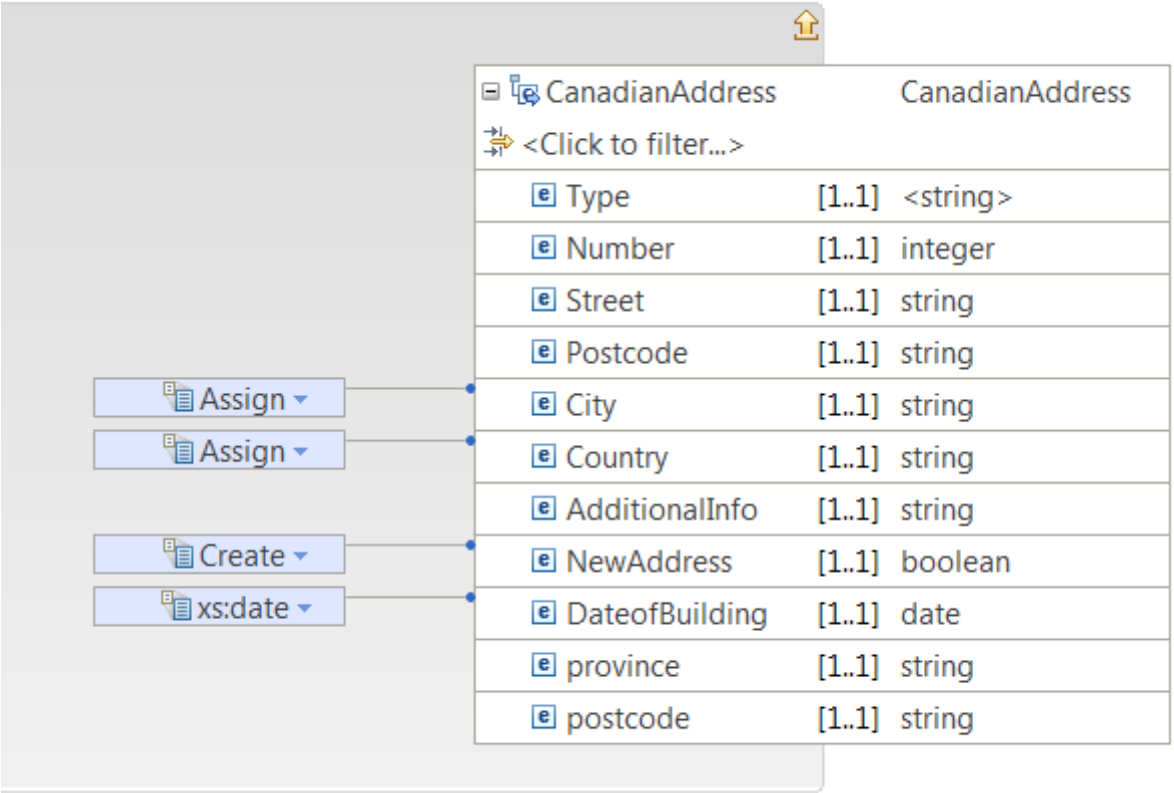
By default, the option **Create empty** is preselected. You must choose this option to initialize a complex output element.

Note: You can initialize or set to nil complex output elements.

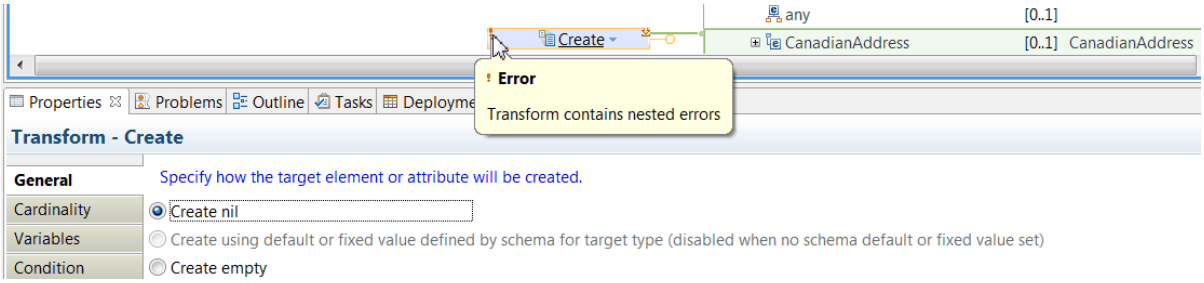
When you define a **Create** transform to initialize a complex type output element, a nested map is created containing the complex structure elements. You configure each element within the nested map individually, that is, you initialize, set to nil, or set to a default value each individual element.



When you initialize a complex type, you can use the nested map that is associated with the **Create** transform to provide values for the child element. You can define and configure each element by using transforms that do not require an input, for example the **Assign** transform, an **xs:type** transform, or the **Create** transform. You can also wire a supplemental input to move input values to the child elements.



When you define a **Create** transform to set to nil a complex type output element, a nested map is created containing the complex structure elements. You can get the error `Transform contains nested errors` if you try to configure any element within the nested map individually.



Specify how a simple data type element or attribute is created

You must specify how an output element or an attribute is created in the **General** tab of the **Create** transform properties view.

The following table lists simple data types with their default options preselected when you define a **Create** transform. It lists the options that you can choose to set the value of an output element of that type:

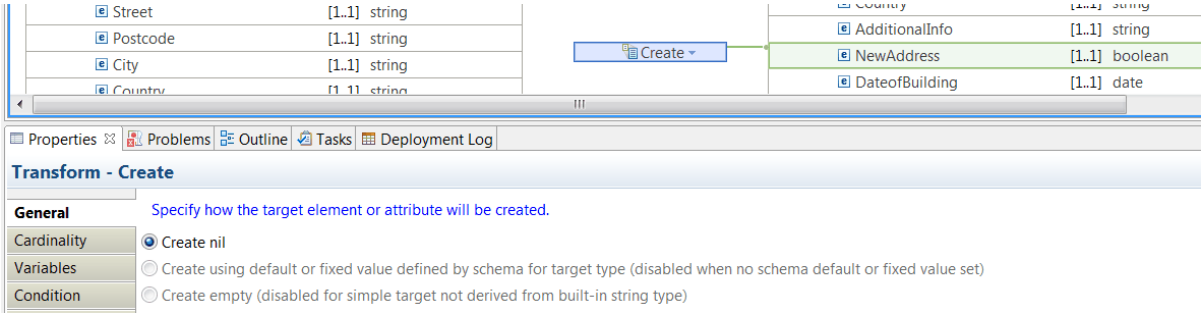
*Table 50. Configuration choices available when you define a **Create** transform to set the value of an output element*

Data type	Default option	Output element can be set to empty	Output element can be set to nil (the element is defined as *nillable="true"*)	Output element can be set to fixed or default value (the *default* property is set in the schema)
String	Create empty	valid	valid	valid
Integer	Create nil	not valid	valid	valid
Boolean	Create nil	not valid	valid	valid
date	Create nil	not valid	valid	valid
dateTime	Create using default or fixed value defined by schema for target type	not valid	not valid	valid
double	Create using default or fixed value defined by schema for target type	not valid	not valid	valid
float	Create using default or fixed value defined by schema for target type	not valid	not valid	valid
hexBinary	Create empty	valid	valid	valid
int	Create using default or fixed value defined by schema for target type	not valid	not valid	valid
time	Create using default or fixed value defined by schema for target type	not valid	not valid	valid

For example, for the following schema definition of an output element:

```
<element name="NewAddress" type="boolean" nillable="true" />
```

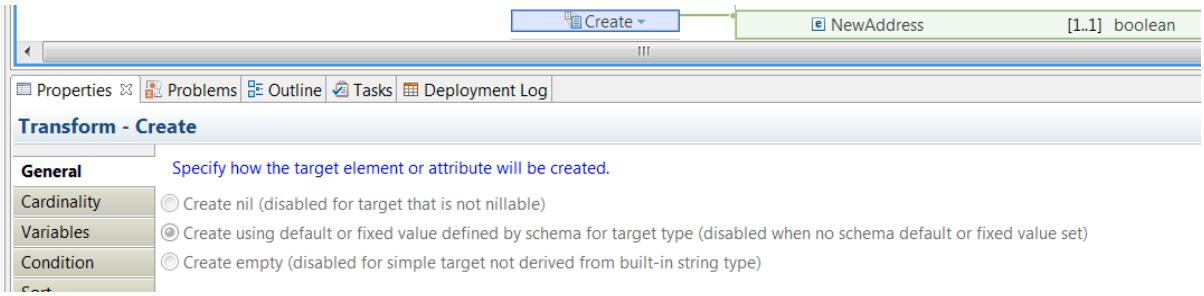
When you define a **Create** transform to set the value of a Boolean element, you can create the element as nil.



For example, for the following schema definition of an output element:

```
<element name="NewAddress" type="boolean" nillable="false" />
```

When you define a **Create** transform to set the value of a Boolean element, you can specify a fixed value, and the choice is preselected.



Define when the transform is applied at run time

You can define multiple connections between input elements and the **Create** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Note: You can use only inputs that are connected with a **supplement** connection to the transform.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see “Configuring the properties of a transform” on page 1431, “Defining an XPath conditional expression for a transform” on page 1433 and “Defining a Java conditional expression for a transform” on page 1439.

Custom ESQL
You use the Custom ESQL transform to call your own ESQL code from a graphical data map.

In the Graphical Data Mapping editor, select **Custom ESQL** from the **Custom Transforms** list. You can then use the transform properties to select ESQL code that is stored in your workspace. When you select the ESQL route, the Parameters table **Name** and **Type** columns are populated. You must then select an input element or XPath expression in the **Value** column for each parameter. You can use the content assist in the **Value** column to help you to assign the required element, literal, or XPath expression.

The following topics contain further information about ESQL types and functions:

- “Equivalent ESQL types and schema types” on page 1309
- “Equivalent ESQL and XPath mapping functions” on page 1311

The ESQL file that contains the referenced ESQL module must be visible for mapping to be selectable. Ensure that the application, library, or project references are set to make the ESQL file accessible to the map. When you deploy the map, ensure that the ESQL file is also deployed, and that **Compile and in-line resources** is not selected.

Requirements for ESQL modules that are called from a graphical data map

The following requirements apply to ESQL modules that are called from a graphical data map:

- The syntax of an ESQL procedure is shown in CREATE PROCEDURE statement. The procedures that can be called from a Custom ESQL transform in a graphical data map must conform to the following requirements:
  - Only IN parameters are allowed
  - A RETURN is required
- A return data type must be a simple scalar.
- An input parameter data type must be a simple scalar, or an ESQL REFERENCE where the reference variable meets the following criteria:
  - The reference variable is used to access only the input element or descendants of the input element.
  - The input element and any descendants that are accessed by using the reference variable are defined in the input message model.
  - The input element must exist. If the input element does not exist, the map fails and reports that the ESQL procedure input is the wrong data type.

    Note:

    If there is a chance that the input element might not exist, you can prevent the ESQL procedure from being called by adding a condition that uses `fn:exists(`*`inputElementVariable`*`)`.
- An ESQL module with no inputs can be used to assign to an output element.
- Each input parameter to the ESQL module can be taken from an input element that is wired into the custom ESQL transform or specified as a constant.
- The ESQL must not include SQL calls to a data source. The Graphical Data Mapping editor provides facilities to include database operations in the map. For more information, see "Mapping database content" on page 1523.

Note: The target element of a Custom ESQL transform is always created and given the value that is returned by the associated ESQL procedure. If the ESQL procedure returns ESQL NULL, the transform creates an element with an empty value. If you do not want an element to be created, you can add a conditional expression.

Equivalent ESQL types and schema types

When you need to process the data to set a target value, you can implement a function in Java or ESQL. If you choose to use ESQL functions, you can invoke them from your map in a custom ESQL transform.

The following table shows the equivalence between schema types and ESQL types:

XML Schema simple type	ESQL data type in message tree
anyURI	CHARACTER
base64Binary	BLOB
boolean	BOOLEAN
byte	INTEGER
date	DATE
dateTime	TIMESTAMP

XML Schema simple type	ESQL data type in message tree
dayTimeDuration	INTERVAL
decimal	DECIMAL
double	FLOAT
duration	INTERVAL
ENTITIES	Repeating set of elements in the tree, each of type CHARACTER
ENTITY	CHARACTER
float	FLOAT
gDay	DATE
gMonth	DATE
gMonthDay	DATE
gYear	DATE
gYearMonth	DATE
hexBinary	BLOB
ID	CHARACTER
IDREF	CHARACTER
IDREFS	Repeating set of elements in the tree, each of type CHARACTER
int	INTEGER
integer	DECIMAL
language	CHARACTER
long	INTEGER
Name	CHARACTER
NCName	CHARACTER
negativeInteger	DECIMAL
NMTOKEN	CHARACTER
NMTOKENS	Repeating set of elements in the tree, each of type CHARACTER
nonNegativeInteger	DECIMAL
nonPositiveInteger	DECIMAL
normalizedString	CHARACTER
NOTATION	CHARACTER
positiveInteger	DECIMAL
QName	CHARACTER
short	INTEGER
string	CHARACTER

XML Schema simple type	ESQL data type in message tree
time	TIME
token	CHARACTER
unsignedByte	INTEGER
unsignedInt	INTEGER
unsignedLong	DECIMAL
unsignedShort	INTEGER
yearMonthDuration	INTERVAL

Equivalent ESQL and XPath mapping functions
You can implement some data mapping functions either by using XPath functions or by supplying equivalent ESQL functions in a Custom ESQL transform.

The following functions in the ESQL language have equivalent XPath functions built into the Graphical Data Mapping editor. You can invoke these functions directly without having to write ESQL modules in an ESQL file to be called from the map:

Table 51. Equivalent ESQL and XPath functions

ESQL function	XPath function
EXTRACT YEAR FROM	fn:year-from-date fn:year-from-dateTime
EXTRACT MONTH FROM	fn:month-from-date fn:month-from-dateTime
EXTRACT DAY FROM	fn:day-from-date fn:day-from-dateTime
EXTRACT HOUR FROM	fn:hours-from-dateTime fn:hours-from-duration fn:hours-from-time
EXTRACT MINUTE FROM	fn:minutes-from-dateTime fn:minutes-from-duration fn:minutes-from-time
EXTRACT SECOND FROM	fn:seconds-from-dateTime fn:seconds-from-duration fn:seconds-from-time
EXTRACT DAYS FROM	fn:days-from-duration
EXTRACT MONTHS FROM	fn:months-from-duration
CURRENT_DATE	fn:current-date
CURRENT_TIME	fn:current-time
CURRENT_TIMESTAMP	fn:current-dateTime

Table 51. Equivalent ESQL and XPath functions (continued)	
ESQL function	**XPath function**
LOCAL_TIMEZONE	fn:implicit-timezone
ABS (ABSVAL)	fn:abs
CEIL (CEILING)	fn:ceiling
FLOOR	fn:floor
LEFT	fn:substring
CONTAINS	fn:contains
ENDSWITH	fn:ends-with
LENGTH	fn:string-length
LOWER (LCASE)	fn:lower-case
REPLACE	fn:replace
RIGHT	fn:substring
STARTSWITH	fn:starts-with
SUBSTRING ... FROM	fn:substring
SUBSTRING ... BEFORE	fn:substring-before
SUBSTRING ... AFTER	fn:substring-after
SUBSTRING ... FROM ... FOR	fn:substring(fn:substring(...), $for)
SUBSTRING ... BEFORE ... FOR	fn:substring(fn:substring-before(...), $for)
SUBSTRING ... AFTER ... FOR	fn:substring(fn:substring-after(...), $for)
TRANSLATE	fn:translate
UPPER (UCASE)	fn:upper-case
FIELDNAME	fn:local-name
FIELDNAMESPACE	fn:namespace-uri
CARDINALITY	fn:count
EXISTS	fn:exists

Custom Java
In the Graphical Data Mapping editor, you can use the Custom Java transform to enter Java code in a message map.

Overview

You can use a Custom Java transform to process elements that have a simple type, and the type matches a native Java type.

You can use a Custom Java transform to process input and outputs that are arrays or complex types. For more information, see "Processing complex or repeating elements in a Custom Java transform" on page 1498.

Guidelines to design a Java method to transform simple types

The Java class that you provide to the map must have a static method that returns the appropriate type for the value of the output element, and takes parameters of the appropriate type for the wired inputs.

For example, the following Java method can be used in a Custom Java transform that has three input elements, of types `xs:string`, `xs:decimal`, and `xs:boolean`, and the output element has a `xs:decimal` type:

```
public static BigDecimal calSomething(String memType, BigDecimal stdCost, boolean flag) {
 BigDecimal actualCost = stdCost;
 if (flag & memType.startsWith("gold")) {
  BigDecimal discRate = new BigDecimal(0.9);
  actualCost = actualCost.multiply(discRate);
 }
 return actualCost;
}
```

Guidelines to design a Java method to transform complex or repeating types

You can use a Custom Java transform to process input and outputs that are arrays or complex types. The IBM App Connect Enterprise `Java plugin API MbElement Java class` passes data only in a Custom Java Transform. The `Java DOM API` passes data in Custom Java Transforms and in Transform condition expressions.

You can use the MbElement class in a Java method to pass a complex type, a wildcard **xsd:any**, or a wildcard **xsd:anySimpleType**.

Make a Java class visible

To make a Java class visible in the transform, ensure that the Java project the class is in is referenced by the project that contains the map.

1. In the **Application development** page, right-click the project where the map is defined.
2. Select **Managed included projects**.
3. Select the Java project, and then click **OK**.

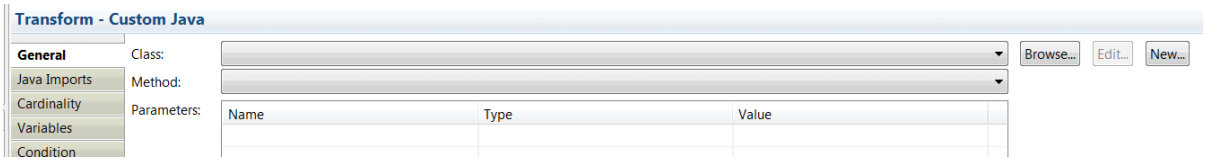
Note: Notice that if the Java project that contains the Java class does not build in Eclipse, then the Java class is not visible anywhere in the map. You must resolve all the Java errors, which you can see in the **Problems** tab, before you can configure the **Java imports** tab in the **Properties** page of the map.

Call a Java method

You can only configure one call to a Java method in a Custom Java transform. You can define more operations (java method or XPath expression) on the parameters that are required by the method.

You can configure the Java class, and a Java method in the **General** tab of the **Properties** page of the transform. The method that you specify defines the transformation logic that is applied by the Custom Java transform.

Note: The Java class that contains the method must be available in a Java project in your workspace. The Java class must be visible to the project that contains the map.



When you add a Java call in the **General** tab of the **Properties** page of a **Custom Java** transform in your map, an import is automatically added in the map to refer to the package qualified Java class, and a prefix

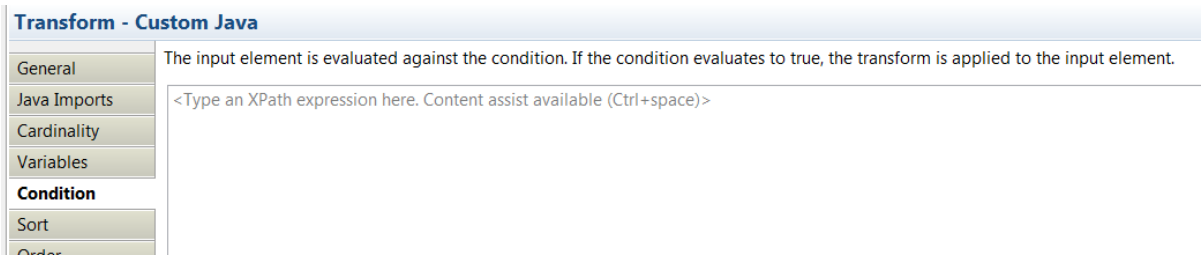
based on the class name is added. All the **public static methods** in this Java class are then available in content assist when building expressions in other transforms.

For more information, see "Mapping an element by using a Custom Java transform" on page 1496.

Define when the transform is applied at run time

You can define **supplement** connections between input elements and the Custom Java transform. You can then use any input element in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

To configure the conditional expression, you define an XPath expression or a Java expression in the **Condition** tab that is available in the **Properties** page of the transform.



To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression that includes XPath, Java, and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

By default, if the Java method does not provide a value, the transform creates an element with an empty value. If you do not want an element to be created, you can add a conditional expression in the **Condition** tab.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433, and "Defining a Java conditional expression for a transform" on page 1439.

Mappings between the schema type, the Java type, and the IBM App Connect Enterprise message assembly type

The following table shows the mappings between the schema type, the Java type, and the IBM App Connect Enterprise message assembly type:

Table 52. Mapping the schema type, Java type, and message tree element type

Schema type	Java type	IBM App Connect Enterprise message assembly tree element type
xs:anyURI	java.lang.String	CHARACTER
xs:base64Binary	byte[]	BLOB
xs:boolean	boolean, java.lang.Boolean	BOOLEAN
xs:byte	byte, java.lang.Byte	INTEGER
xs:date	javax.xml.datatype.XMLGregorianCalendar	DATE
xs:dateTime	javax.xml.datatype.XMLGregorianCalendar	TIMESTAMP
xs:dayTimeDuration	javax.xml.datatype.Duration	INTERVAL

Table 52. Mapping the schema type, Java type, and message tree element type (continued)		
Schema type	**Java type**	**IBM App Connect Enterprise message assembly tree element type**
xs:decimal	java.math.BigDecimal	DECIMAL
xs:double	double, java.lang.Double	FLOAT
xs:duration	javax.xml.datatype.Duration	INTERVAL
xs:float	float, java.lang.Float	FLOAT
xs:gDay	javax.xml.datatype.XMLGregorianCalendar	DATE
xs:gMonth	javax.xml.datatype.XMLGregorianCalendar	DATE
xs:gMonthDay	javax.xml.datatype.XMLGregorianCalendar	DATE
xs:gYear	javax.xml.datatype.XMLGregorianCalendar	DATE
xs:gYearMonth	javax.xml.datatype.XMLGregorianCalendar	DATE
xs:hexBinary	byte[]	BLOB
xs:int	int, java.lang.Integer	INTEGER
xs:integer	java.math.BigInteger	DECIMAL
xs:long	long, java.lang.Long	INTEGER
xs:negativeInteger	java.math.BigInteger	DECIMAL
xs:nonNegativeInteger	java.math.BigInteger	DECIMAL
xs:nonPositiveInteger	java.math.BigInteger	DECIMAL
xs:normalizedString	java.lang.String	CHARACTER
xs:positiveInteger	java.math.BigInteger	DECIMAL
xs:short	short, java.lang.Short	INTEGER
xs:string	java.lang.String	CHARACTER
xs:time	javax.xml.datatype.XMLGregorianCalendar	TIME
xs:unsignedByte	Short	INTEGER
xs:unsignedInt	Long	INTEGER
xs:unsignedLong	java.math.BigInteger	DECIMAL
xs:unsignedShort	Int	INTEGER
xs:yearMonthDuration	javax.xml.datatype.Duration	INTERVAL

Custom XPath
You can use the **Custom XPath** transform to provide a data value for a simple target element, or values for a repeating simple target element by using an XPath expression.

Overview

You define the XPath expression in the **General** tab of the Properties view.

You can use context assist by pressing **Ctrl+Space** while constructing the XPath expression. For more information, see “Using content assist (Mapping syntax)” on page 1443.

When to use the Custom XPath transform

You can use the **Custom Xpath** transform to perform any of the following mappings:

- Implement an arithmetic operation, such as add, subtract, or multiply. For more information, see "Choosing a transform to perform an arithmetic operation" on page 1366.
- Implement complex XPath expressions. You can extend built-in transformation functions by using custom XPath expressions. For more information about XPath, see XPath tutorial or W3C XML Path Language (XPath) 2.0.
- To access user-defined properties. For more information, see "Accessing user-defined properties from a Mapping node" on page 1479.
- To set an output to null or nill, use `iib:nullValue()`. For more information, see "Creating a nil output element" on page 1487.
- To set an output hex binary BLOB value, use `iib:hexBinaryValue($<var>`
- To set an output base64 binary value, use `iib:base64BinaryValue( $<var>`
- To set a new UUID value, use `iib:uuidValue()`

Inputs

Inputs are optional to **Custom XPath** transforms. If required, you can connect any input elements to a Custom XPath transform and access them as part of the XPath expression.

Outputs

You can use a **Custom XPath** transform to set the data value of a simple target element, or to set the values for a repeating simple target element.

By default, if the XPath expression does not provide a value, the transform creates the target element with an empty value. If you do not want the target element to be created, you can add a conditional expression in the Condition tab.

Note: The **Custom XPath** transform returns values, not elements. You cannot use a **Custom XPath** transform to create elements other than the simple target element. For this reason, you cannot populate a complex structure from a **Custom XPath** transform.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Custom XPath** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

You can use any inputs that are connected with primary connections to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression that comprises XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

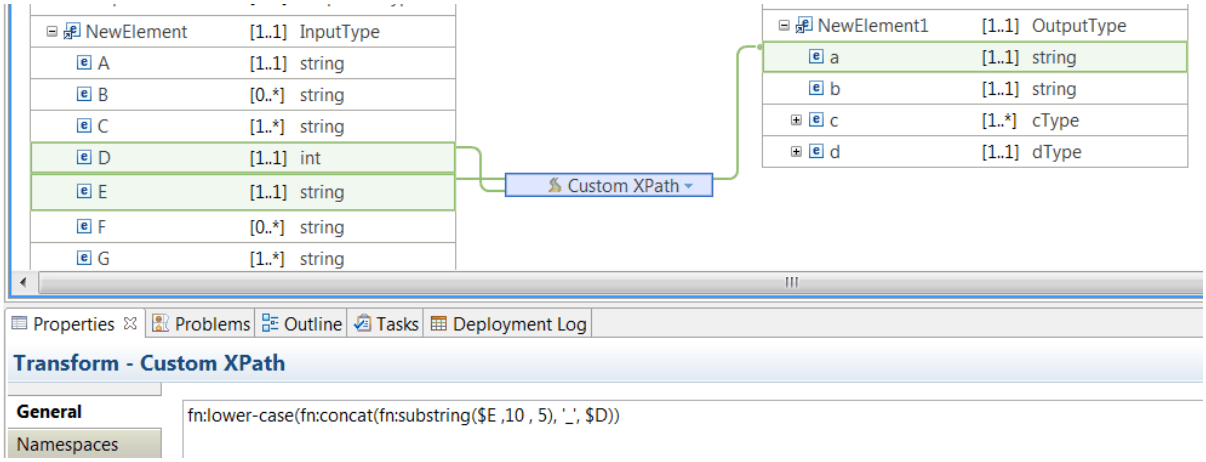
Example

The following figure shows a **Custom XPath** transform that performs the following calculation:

1. Uses the **fn:substring** XPath function to obtain part of the information provided in element **E**.
2. Uses the **fn:concat** XPath function to concatenate the result of the **fn:substring** function, with the delimiter **_**, and the element **D**.
3. Uses the **fn:lower-case** XPath function to put in lower case the result of the **fn:concat** function.

The XPath expression is a complex expression where you nest multiple XPath functions to perform the calculation. The XPath expression is the following:

```
fn:lower-case(fn:concat(fn:substring($E,10,5),'_',$D))
```



If you input the following message:

```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>A1</A>
  <B>B1</B>
  <C>Field_1</C>
  <D>1000</D>
  <E>CUSTOMER_AREA1</E>
  <F>Optional1</F>
  <G>Optional1</G>
</NewElement>
```

you get the following output value:

```
<NewElement1>
 <a>area1_1000</a>
</NewElement1>
```

Example: How to perform an arithmetic operation

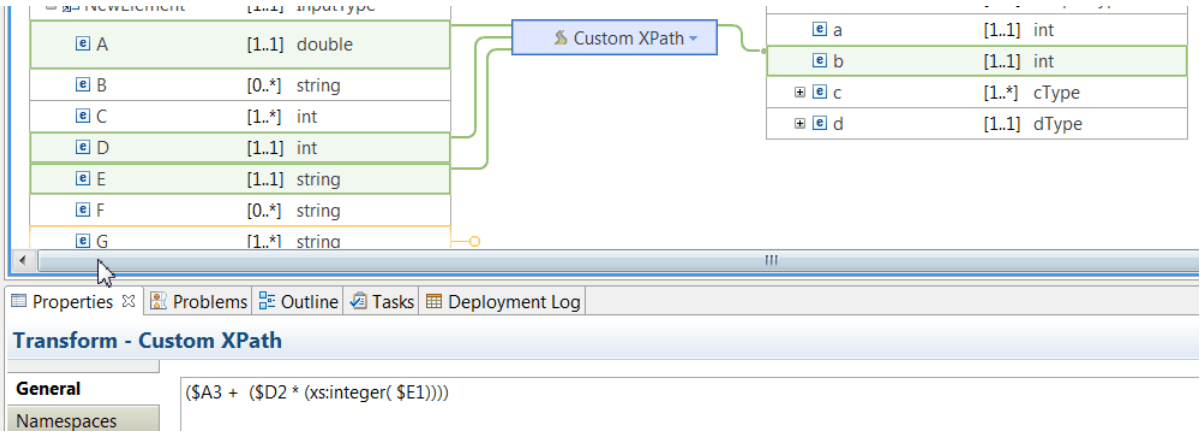
This example shows how to perform an arithmetic operation by using a **Custom XPath** transform.

The transform has 3 inputs, that are used as part of the calculation that determines the value of the output element **b**.

Note: You can only use as arguments of an arithmetic operation non-repeating simple type input elements.

The operations consists on adding the value of the input element **A** to the value of calculating **D** times **E**. The value of **E** is of type string. The value of **E** is cast to an integer.

```
($A3 + ($D2 * (xs:integer($E1))))
```



When you transform the following message, the value of **b** is **120010**.

```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>10</A>
  <C>2</C>
  <C>10</C>
  <D>1000</D>
  <E>120</E>
  <F>Optional1</F>
  <G>Optional1</G>
</NewElement>
```

Database Routine
You can use the Database Routine transform to call a stored procedure in a database, setting the parameter values by mapping input elements.

The definition of the stored procedure used during the creation of your Database Routine transform is specified in a database definition file (`.dbm` file) that you select from the Data Design project.

You create the information that is provided in the database definition file by running discovery against your database server. For more information, see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475. The information available varies depending on the vendor of your database server. Some information, such as the content of any Result Sets returned, is not provided. If you want to map data from any columns in these Result sets, you must define them in the Database Routine setup.

For more information, see "Calling a stored procedure from a map" on page 1532.

Limitations

Note: For information about the support for stored procedures, see "Support for stored procedures" on page 1318.

Support for stored procedures
When you call stored procedures from a map, you must be aware of the following limitations:

- Stored procedures from only the following databases are supported:
  - IBM DB2
  - Oracle

- The following entities are not supported in database calls from a graphical data map:
  - Stored procedure parameters of type **Array**
  - Database user-defined functions
  - Oracle stored procedures that are contained within packages
  - Oracle stored procedures that include IN or INOUT SYS_REFCURSOR parameters
- Stored procedures that return result sets that contain user-specified column names (column names that do not exist in any table) can be called, but you cannot include these column names in mappings.

Delete
The **Delete** transform deletes one or more rows of data from a database table.

Use the **Delete** transform to delete one or more rows of data that match a configured **Where** clause from a database table. For more information, see "Deleting data from a table" on page 1528.

The database table structure needed to create your Delete transform is specified in a database definition file (`.dbm` file) that you select from the Data Design project used to create the message map. The database definition can be discovered by connecting to a data server from the tooling.

When your message map has been deployed to an integration server, and your message map is run, the database server that is used by the IBM App Connect Enterprise runtime component to process your Delete transform is specified by the JDBC Providers policy. The JDBC Providers policy name must have the same name as the database name that is specified in your Delete transform during development.

Failure
Use the **Failure** transform to handle exceptions that might be raised by the configured database server when your message map runs SQL statements to implement the action of a database transform.

If you want the message map to handle exceptions that are returned from the database server when the SQL operation is run, instead of such exceptions stopping the message map and being reported, you can add a **Failure** transform to the transform group.

The **Failure** transform is an optional transform that can be added or removed as required.

The **Failure** transform does not perform any transformation. You must transform the input and output elements within the nested map.

Handling database warnings

When you create a database transform, select **Treat warning as error** if you want the database warnings to be treated as errors.

If this option is selected, the first SQL operation that results in a warning from the selected database raises an exception.

Run time behavior

The way that database exceptions are handled is determined by the configuration of the corresponding **Failure** transform in a message map:

1. If the **Failure** transform is present in the message map, and is connected to one or more output objects, then the exception is caught and processed by the **Failure** transform.
2. If the **Failure** transform is present in the message map, but is not connected, then the exception is caught by the **Failure** transform, and is ignored.
3. If the **Failure** transform has been deleted from the message map, then the exception is handled by the Mapping node in your message flow, and is handled in the same way as other message flow exceptions.
4. If you want the message map to stop running when the database transform receives an SQL exception, remove the **Failure** transform. For more information, see "Handling database exceptions in a graphical data map" on page 1535.

For Each

You can use the **For Each** transform to iterate over one input array element, which can be either a simple type or a complex type repeating structure, and set the value of an output element.

Overview

The **For Each** transform contains a nested map. You must map the elements in the nested map, otherwise no action is executed when the transform runs.

You can configure the **For Each** transform to run when there are input elements that match your input selection criteria.

You can configure the **For Each** transform to execute once when the input array is empty by setting the **Allow Empty input** condition in the **Filter Inputs** property tab.

You can specify the indexes of the input array that participate in the **For Each** operation by setting the **Cardinality** property.

You can specify an XPath condition over the indexes that participate in the **For Each** operation by setting the **Filter Inputs** property. This condition determines which indexes are applied.

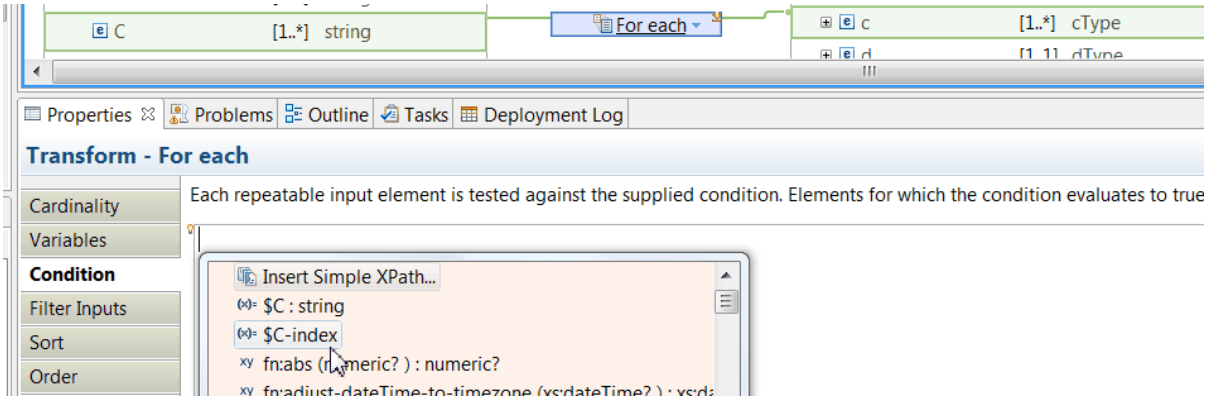
Note: The XPath condition is tested against each instance of the input array, after you apply the **Cardinality** property.

Inputs

You can define multiple inputs to a **For Each** transform.

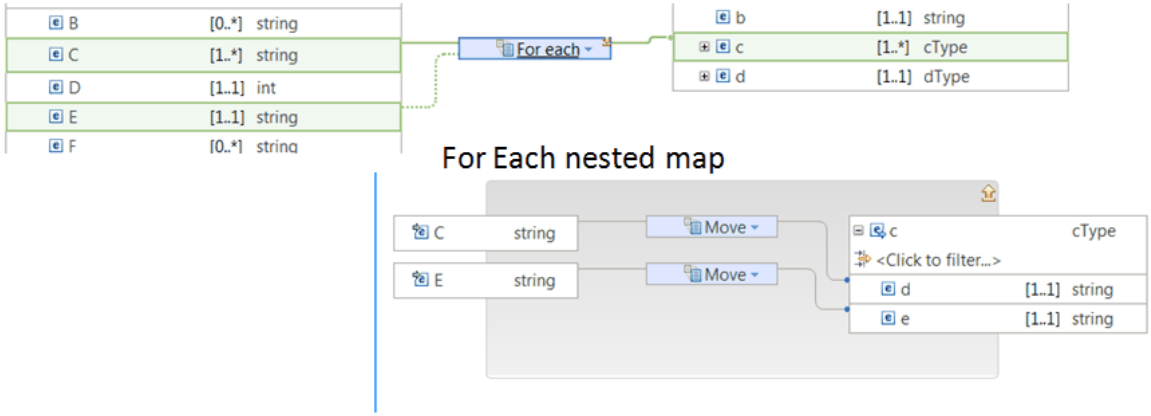
- The **For Each** transform can have only one **primary** input connection, and the input must be repeatable.
  - The Graphical Data Mapping editor counts the indexes from **1** to **N** for each processed input.
  - When the input array element is empty or no inputs match a provided filter condition, the Graphical Data Mapping editor sets the index variable to **0**.
  - The Graphical Data Mapping editor provides a variable that contains the index value of each iteration of the **For Each** transform. The name is as follows: *$VarName-index*, where *VarName* is the name of the repeating element.

    Note: Always use content assist to get the element name assigned by the Graphical Data Mapping editor to the repeating element.



- Extra connections to the **For Each** transform must be of type **Supplement**. You can use these inputs in any of the following ways:
  - You might want to create a **Filter Inputs** expression based on the value of the input. You can use it to determine which indexes to apply as part of the transformation.

  - You might want to pass an extra element into the nested transform. This input is available in the mapping of each iteration that is run by the **For Each** transform.



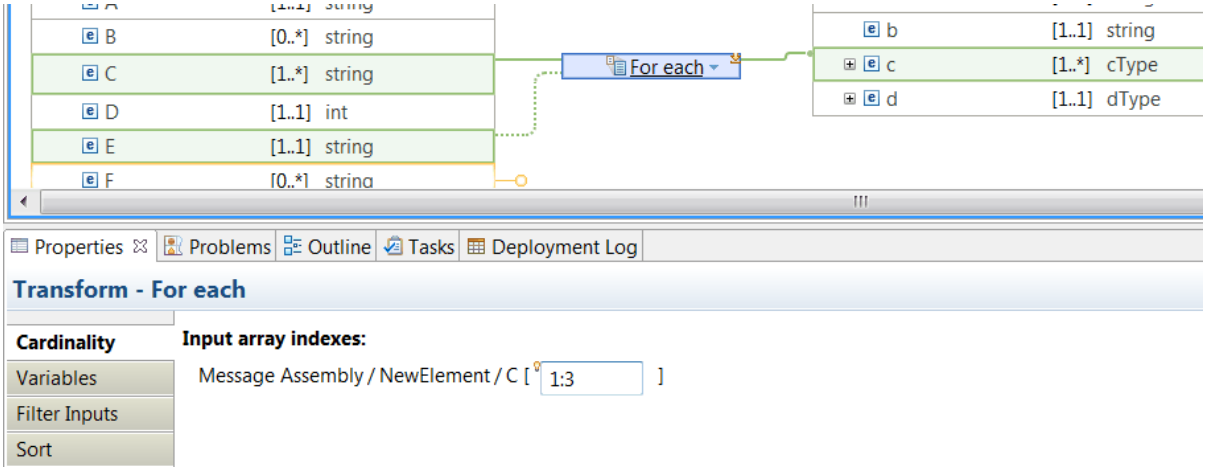
- You can configure the **Cardinality** property page on the **For Each** transform to indicate which index of an input array to iterate over.
- You can configure the **Filter Inputs** property page to specify the matching criteria for filtering input repeating elements.

Cardinality

The **Cardinality** property determines the inputs that participate in the **For Each** operation.

The first index element is 1.

You configure the **Cardinality** tab in the Properties view to specify the indexes that are processed by the transform. For more information, see “Selecting the indexes of input array elements” on page 1363.



Filter Inputs

Configure the **Filter Inputs** property tab to specify an XPath expression that determines which instances of the repeating input are processed in the nested mapping. Each element of the repeatable input is tested against the condition. The transform runs for those elements that satisfy the condition.

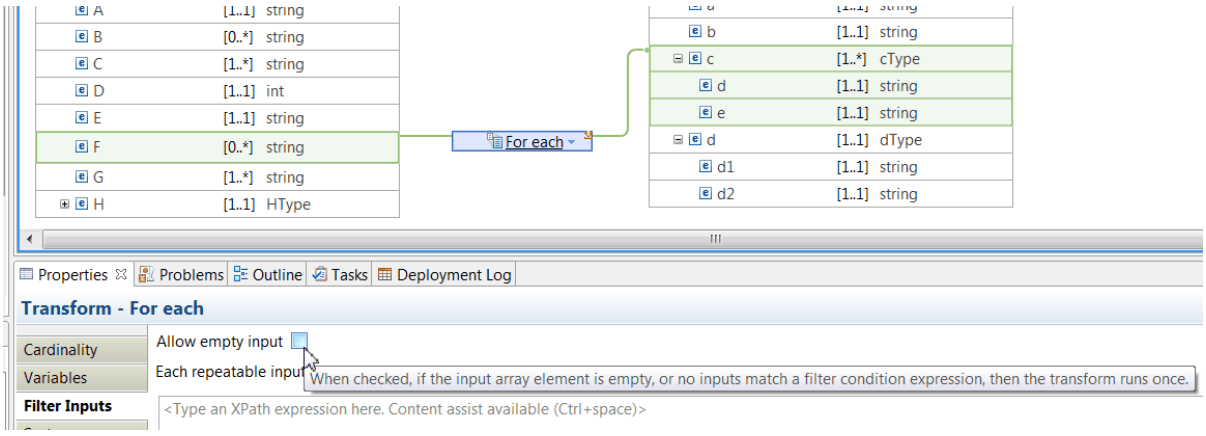
Note: The XPath condition is tested against each instance of the input array, after the **Cardinality** property is applied.

You can use XPath, or methods from Java classes to define the **Filter Inputs** expression. You can also create a complex expression comprising XPath and Java.

You can use context assist by pressing **Ctrl+Space** while you construct the **Filter Inputs** expression. For more information, see "Using content assist (Mapping syntax)" on page 1443.

Note: To obtain the exact name of the variables that are associated with the inputs, use content assist.

Enable **Allow Empty input** when the input array element is empty or no inputs match a provided filter condition, so that the transform is still entered exactly once. In this case, the primary input in the nested transform is missing, and the index variable is zero.



Outputs

The output element of a **For Each** transform can be a simple element, or a complex element, that can be a repeating element or a non-repeating element.

The output array size is equal to the input array size, minus any elements that are filtered out after applying the **Cardinality** and the **Filter Inputs** properties.

Variable $VarName-index

In the **For Each** transform, you can use the *$VarName-index* variable to indicate the index of the input array that the Graphical Data Mapping editor is processing.

Note: The *$VarName-index* variable reports indexes after the **Cardinality** property is applied.

For example, you might have an input array with 6 elements. When you set the **Cardinality** property of a **For each** transform to 1 , 3, you are telling the Graphical Data Mapping editor that you only want to process index 1 and index 3 of your input array. In this use case, the *$VarName-index* has a value of 1 for the first entry and a value of 3 for the second entry.

You can use the variable *$VarName-index* as part of the XPath condition that you can define to filter inputs, or as part of any transformation within the nested map that is associated to the **For each** transform.

The fist value of *$VarName-index* is 1 when your input array is not empty.

The value of *$VarName-index* is 0 when your input array is empty. You must enable the **Allow Empty input** property.

Variable $VarName-count

In the nested mapping of the **For Each** transform, you can use the *$VarName-count* variable to determine the number of times the Graphical Data Mapping editor enters the nested mapping to allow populating the output array.

The variable *$VarName-count* initial value is **1** . The maximum value is determined by the **Cardinality** and the **Filter Inputs** properties that are applied.

You cannot use the variable *$VarName-count* as part of the XPath condition that you can define to filter inputs.

You can use the variable *$VarName-count* as part of any transformation within the nested map that is associated to the **For each** transform.

For example, you might have an input array with 6 elements.

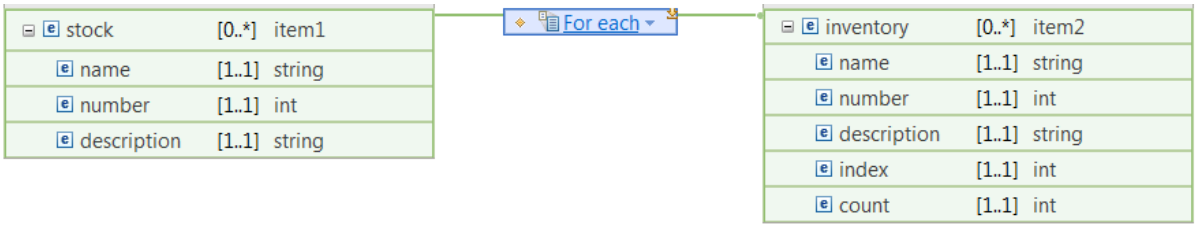
- When you set the **Cardinality** property of a **For each** transform to 1 : 3, you are telling the Graphical Data Mapping editor that you only want to process index 1, index 2 and index 3 of your input array. In this use case, the nested map is executed 3 times and the *$VarName-count* variable is equal to 1 the first time is executed, 2 the second time is executed, and then 3.
- When you have a **Filter expression** that only matches index 1 and 3 of you input array, the *$VarName-count* variable is equal to 1 the first time the nested mapping is entered for the data of input index 1. The *$VarName-count* variable is equal to 2 on the second time the nested mapping is entered for the data of input index 3.

The value of *$VarName-count* is 1 when you enable **Allow Empty input** in a **For each** transform and the nested mapping is entered as a result of the empty condition.

Example 1: Filter inputs by configuring the cardinality property

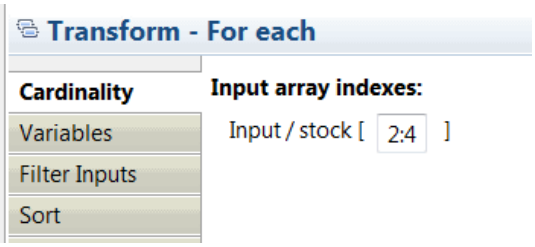
In this example, the **For Each** transform only runs for a restricted number of elements of the repeating element. The rest of the elements in the array are not considered.

The **For Each** transform iterates over instances 2, 3, and 4 between the input element **stock** and the output element **inventory**.



To restrict the number of instances, you can configure the **Cardinality** tab in the **Properties** page of the transform. You must set the following value in the **Cardinality** property tab:

```
2:4
```



When you run the following message through the **For Each** transform,

```
<?xml version="1.0" encoding="UTF-8"?>
<tns:Input xmlns:tns="http://www.example.org/schema" xmlns:xsi="http://www.w3.org/2001/
XMLSchema-instance" xsi:schemaLocation="http://www.example.org/schema foo.xsd ">
  <tns:stock>
    <tns:name>apple</tns:name>
    <tns:number>1</tns:number>
    <tns:description>fruit</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>banana</tns:name>
    <tns:number>2</tns:number>
    <tns:description>fruit</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>cap</tns:name>
    <tns:number>3</tns:number>
    <tns:description>accessory</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>door</tns:name>
    <tns:number>4</tns:number>
    <tns:description>furniture</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>elephant</tns:name>
    <tns:number>5</tns:number>
    <tns:description>animal</tns:description>
  </tns:stock>
 </tns:Input>
```

you get the following output:

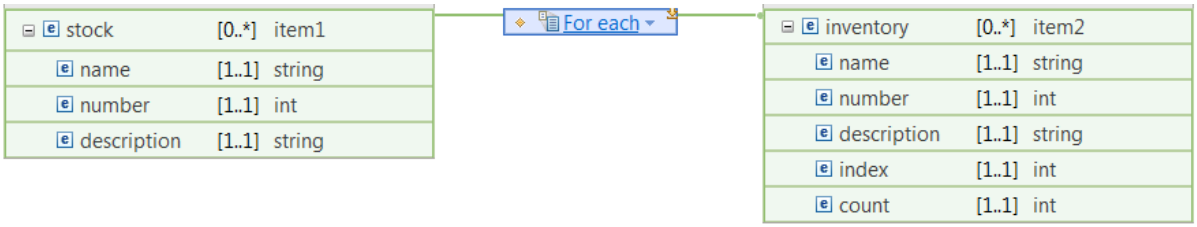
```
<?xml version="1.0" encoding="UTF-8"?><io:Output xmlns:io="http://www.example.org/schema">
  <io:inventory>
    <io:name>banana</io:name>
    <io:number>2</io:number>
    <io:description>fruit</io:description>
    <io:index>1</io:index>
    <io:count>1</io:count>
  </io:inventory>
  <io:inventory>
    <io:name>cap</io:name>
    <io:number>3</io:number>
    <io:description>accessory</io:description>
    <io:index>2</io:index>
```

```
    <io:count>2</io:count>
  </io:inventory>
  <io:inventory>
    <io:name>door</io:name>
    <io:number>4</io:number>
    <io:description>furniture</io:description>
    <io:index>3</io:index>
    <io:count>3</io:count>
  </io:inventory>
 </io:Output>
```

Example 2: Filter inputs by configuring the Filter Inputs property

In this example, the **For Each** transform only runs for a restricted number of elements of the repeating element. The rest of the elements in the array are not considered. The **For Each** transform iterates over instances where the name of a stock item is a string with more than 4 characters.

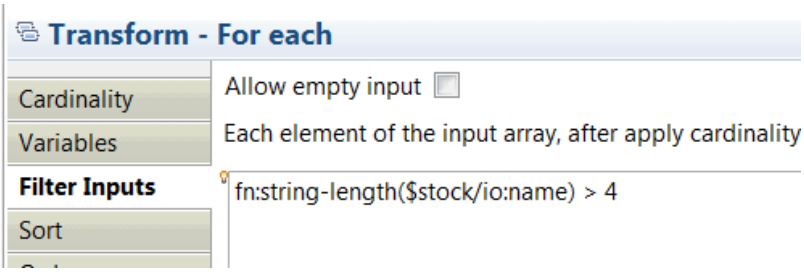
In the **For Each** transform, the input element is **stock** and the output element is **inventory**.



The **For Each** transform iterates over instances where the value of **stock.name** is a string with more than 4 characters.

To restrict the number of instances, you can configure the **Filter Inputs** tab in the **Properties** page of the transform. You must set the following value in the **Filter Inputs** property tab:

```
fn:string-length($stock/io:name) > 4
```



When you run the following message through the **For Each** transform,

```
<?xml version="1.0" encoding="UTF-8"?>
<tns:Input xmlns:tns="http://www.example.org/schema" xmlns:xsi="http://www.w3.org/2001/
XMLSchema-instance" xsi:schemaLocation="http://www.example.org/schema foo.xsd ">
  <tns:stock>
    <tns:name>apple</tns:name>
    <tns:number>1</tns:number>
    <tns:description>fruit</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>banana</tns:name>
    <tns:number>2</tns:number>
    <tns:description>fruit</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>cap</tns:name>
    <tns:number>3</tns:number>
    <tns:description>accessory</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>door</tns:name>
```

```
    <tns:number>4</tns:number>
    <tns:description>furniture</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>elephant</tns:name>
    <tns:number>5</tns:number>
    <tns:description>animal</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>flower</tns:name>
    <tns:number>6</tns:number>
    <tns:description>decoration</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>gold</tns:name>
    <tns:number>7</tns:number>
    <tns:description>money</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>honey</tns:name>
    <tns:number>8</tns:number>
    <tns:description>food</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>igloo</tns:name>
    <tns:number>9</tns:number>
    <tns:description>cold</tns:description>
  </tns:stock>
  <tns:stock>
    <tns:name>jeep</tns:name>
    <tns:number>10</tns:number>
    <tns:description>car</tns:description>
  </tns:stock>
</tns:Input>
```

you get the following output:

```
<?xml version="1.0" encoding="UTF-8"?><io:Output xmlns:io="http://www.example.org/schema">
  <io:inventory>
    <io:name>apple</io:name>
    <io:number>1</io:number>
    <io:description>fruit</io:description>
    <io:index>0</io:index>
    <io:count>1</io:count>
  </io:inventory>
  <io:inventory>
    <io:name>banana</io:name>
    <io:number>2</io:number>
    <io:description>fruit</io:description>
    <io:index>1</io:index>
    <io:count>1</io:count>

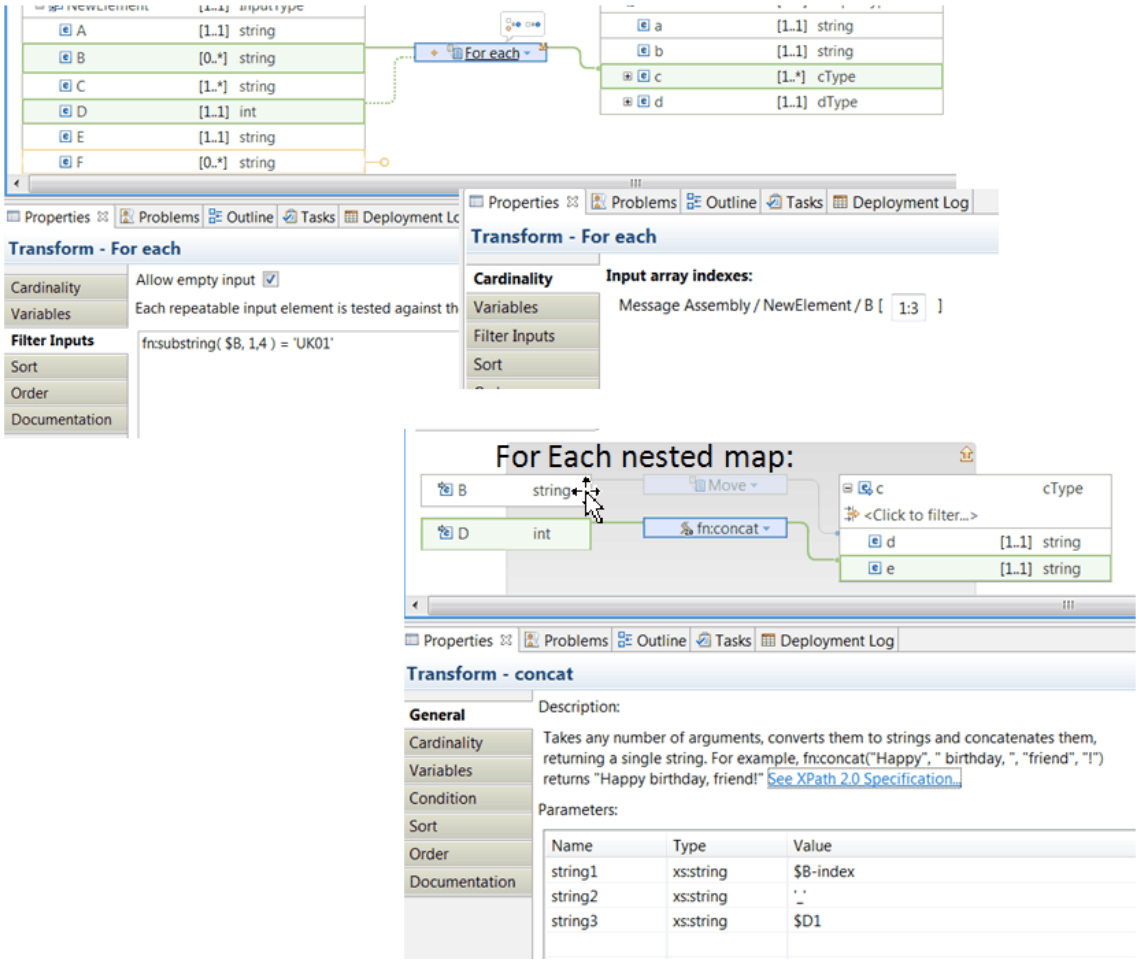
    <io:count>4</io:count>
  </io:inventory>
  <io:inventory>
    <io:name>igloo</io:name>
    <io:number>9</io:number>
    <io:description>cold</io:description>
    <io:index>8</io:index>
    <io:count>5</io:count>
  </io:inventory>
```

```
</io:Output>
```

Example 3: Filter inputs by configuring the Cardinality and the Filter Inputs properties

In this example, the **For Each** transform only runs for the first three elements of the repeating element. The rest of the elements in the array are not considered. For each element in the array, if the first 4 characters of the element B start with UK01, then the transformation inside the nested map is executed.

Inside the nested map, the **fn:concat** transform calculates the value of element **e** based on the input element index and the input element **D**.



When you run the following message through the **For Each** transform,

```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>A1</A>
  <C>Field_1</C>
  <C>Field_2</C>
  <C>Field_3</C>
  <D>1000</D>
  <E>CUSTOMER_AREA1</E>
</NewElement>
```

you get the following output:

```
<NewElement1>
 <c>
```

```
  <d/>
  <e>0_1000</e>
 </c>
</NewElement1>
```

Note: If the repeating element is empty, then the nested map is executed once because the option **Allow Empty input** is selected.

When you run the following message through the **For Each** transform,

```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>A1</A>
  <B>UK011234567</B>
  <B>B2</B>
  <B>UK019999999</B>
  <B>UK01xxxxxxx</B>
  <C>Field_1</C>
  <C>Field_2</C>
  <C>Field_3</C>
  <D>1000</D>
  <E>CUSTOMER_AREA1</E>
</NewElement>
```

you get the following output:

```
<NewElement1>
 <c>
  <d>UK011234567</d>
  <e>1_1000</e>
 </c>
 <c>
  <d>UK019999999</d>
  <e>3_1000</e>
 </c>
</NewElement1>
```

Group
You can use the **Group** transform to map a single list of elements into a nested list of elements based on an input element.

Overview

For example, you can use the **Group** transform to map a single list of company employee records into a nested list of employees by department.

The **Group** transform provides a nested transform for mapping each collated input array occurrence to the output nested array structure.

The nested transforms are performed sequentially for each collated group of input elements that have matching values in the element that you have selected to group by in the **General** tab.

Inputs and outputs

The input to a **Group** transform must be a repeating complex type, such as an array or a list, and contain a simple type element that will be used for collating groups.

The output to a **Group** transform must be a repeating complex type, that includes the following elements:

- A none repeating simple type element in which to set the group identifier.
- A repeating complex type into which to map the data from the matching inputs.

Group by

In the **General** tab of the properties page, you configure the **Group by** selection.

You can select one simple type element from the input data to the **Group** transform.

The value of the simple type element is used to collate occurrences of the repeating input.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Group** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

You can use the input connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Example

You can use the **Group** transform to map a single list of company employee records into a nested list of employees by department.

The input to the **Group** transform is the repeating array **EMPLOYEE**.

The output to the **Group** transform is the repeating array **Department**.

The schema file that contains the schema for the repeating array **EMPLOYEE** is the following:

```
<?xml version="1.0"?>
<schema xmlns="http://www.w3.org/2001/XMLSchema" xmlns:employee="http://www.ibm.com"
 targetNamespace="http://www.ibm.com">
    <element name="SQLResult">
        <complexType>
            <sequence>
                <element ref="employee:EMPLOYEE" minOccurs="0" maxOccurs="unbounded"/>
            </sequence>
        </complexType>
    </element>

    <element name="EMPLOYEE">
        <complexType>
            <sequence minOccurs="1" maxOccurs="1">
                <element ref="employee:NAME" minOccurs="1" maxOccurs="1"/>
                <element ref="employee:SALARY" minOccurs="1" maxOccurs="1"/>
                <element ref="employee:BONUS" minOccurs="1" maxOccurs="1"/>
                <element ref="employee:COMM" minOccurs="1" maxOccurs="1"/>
                <element ref="employee:DEPARTMENT" minOccurs="1" maxOccurs="1"/>
            </sequence>
        </complexType>
    </element>

    <element name="NAME" type="string"/>
    <element name="SALARY" type="string"/>
    <element name="BONUS" type="string"/>
    <element name="COMM" type="string"/>
    <element name="DEPARTMENT" type="string"/>
</schema>
```

The schema file that contains the schema for th repeating array **Department** is the following:

```
<?xml version="1.0"?>
```

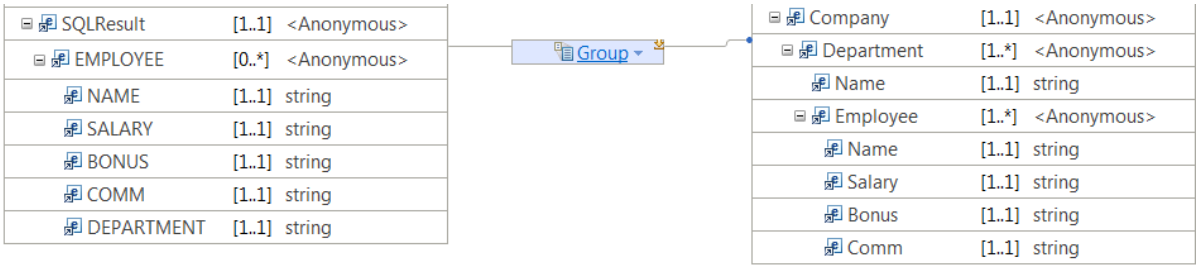
```
<schema xmlns="http://www.w3.org/2001/XMLSchema" xmlns:se="http://www.ibm.com"
 targetNamespace="http://www.ibm.com">
    <element name="Company">
        <complexType>
            <sequence>
                <element ref="se:Department" minOccurs="1" maxOccurs="unbounded"/>
            </sequence>
        </complexType>
    </element>

    <element name="Department">
        <complexType>
            <sequence minOccurs="1" maxOccurs="1">
                <element ref="se:Name" minOccurs="1" maxOccurs="1"/>
                <element ref="se:Employee" minOccurs="1" maxOccurs="unbounded"/>
            </sequence>
        </complexType>
    </element>

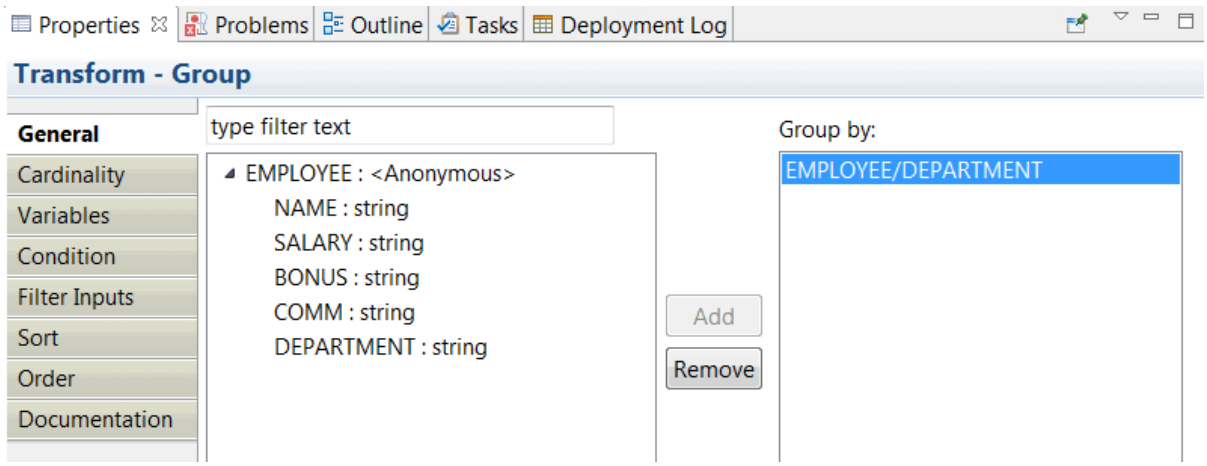
    <element name="Employee">
        <complexType>
            <sequence minOccurs="1" maxOccurs="1">
                <element ref="se:Name" minOccurs="1" maxOccurs="1"/>
                <element ref="se:Salary" minOccurs="1" maxOccurs="1"/>
                <element ref="se:Bonus" minOccurs="1" maxOccurs="1"/>
                <element ref="se:Comm" minOccurs="1" maxOccurs="1"/>
            </sequence>
        </complexType>
    </element>

    <element name="Name" type="string"/>
    <element name="Salary" type="string"/>
    <element name="Bonus" type="string"/>
    <element name="Comm" type="string"/>
</schema>
```

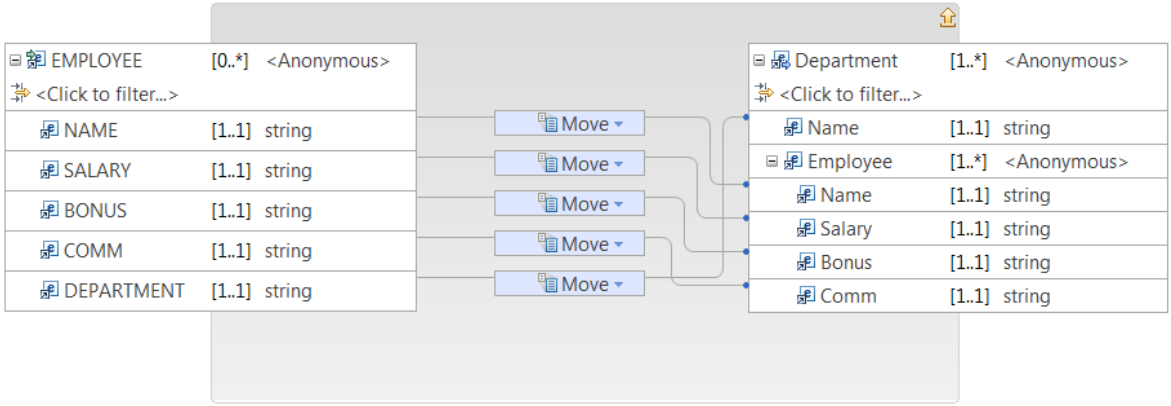
The following figure shows the map with a **Group** transform defined between **EMPLOYEE** and **Department**.



In the **General** tab of the **Properties** view for the **Group** transform, you select **DEPARTMENT:string**. Then, click **Add** to include it in the **Group by** selection. The value of **DEPARTMENT** is used to collate occurrences of **EMPLOYEE**.



Next, you open the nested map associated to the **Group** transform. You define the mappings to set the output elements of **Department**.



When you run the following input message:

```
<?xml version="1.0"?>
<employee:SQLResult xmlns:employee="http://www.ibm.com" xmlns:xsi="http://www.w3.org/2001/
XMLSchema-instance" xsi:schemaLocation="http://www.ibm.com Employee.xsd ">
  <employee:EMPLOYEE>
    <employee:NAME>SAM HIGH</employee:NAME>
    <employee:SALARY>52750.00</employee:SALARY>
    <employee:BONUS>1000.00</employee:BONUS>
    <employee:COMM>4220.00</employee:COMM>
    <employee:DEPARTMENT>DEVELOPMENT</employee:DEPARTMENT>
  </employee:EMPLOYEE>
  <employee:EMPLOYEE>
    <employee:NAME>SALLY TANGO</employee:NAME>
    <employee:SALARY>38250.00</employee:SALARY>
    <employee:BONUS>800.00</employee:BONUS>
    <employee:COMM>3060.00</employee:COMM>
    <employee:DEPARTMENT>HUMAN RESOURCE</employee:DEPARTMENT>
  </employee:EMPLOYEE>
  <employee:EMPLOYEE>
    <employee:NAME>JOHN SMITH</employee:NAME>
    <employee:SALARY>40175.00</employee:SALARY>
    <employee:BONUS>800.00</employee:BONUS>
    <employee:COMM>3214.00</employee:COMM>
    <employee:DEPARTMENT>DEVELOPMENT</employee:DEPARTMENT>
  </employee:EMPLOYEE>
</employee:SQLResult>
```

You get the following output message:

```
<io:Company xmlns:io="http://www.ibm.com">
<io:Department>
  <io:Name>DEVELOPMENT</io:Name>
  <io:Employee><io:Name>SAM HIGH</io:Name><io:Salary>52750.00</io:Salary><io:Bonus>1000.00</
io:Bonus><io:Comm>4220.00</io:Comm></io:Employee>
  <io:Employee><io:Name>JOHN SMITH</io:Name><io:Salary>40175.00</io:Salary><io:Bonus>800.00</
io:Bonus><io:Comm>3214.00</io:Comm></io:Employee>
</io:Department>
<io:Department>
   <io:Name>HUMAN RESOURCE</io:Name>
   <io:Employee><io:Name>SALLY TANGO</io:Name><io:Salary>38250.00</io:Salary><io:Bonus>800.00</
io:Bonus><io:Comm>3060.00</io:Comm></io:Employee>
</io:Department>
</io:Company>
```

If, Else if, and Else

The **If, Else if, and Else** transform enables you to control the flow of the mapping by setting conditions.

The **If, Else if and Else** transform operates as a group of conditional transforms. The condition is applied to the input element of the conditional transform. If the condition is satisfied, the transform that is nested within the conditional transform is run.

- For each conditional transform in the group, enter a condition in the **Condition** tab in the Properties view.

  You can define a condition expression that is an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising, XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.
- To change the order in which the conditions are evaluated, select the conditional group and click the **Order** tab and use the up and down arrows.
- Double-click the conditional transform (for example, **If**) to create the mapping that will execute for the condition.

The elements in the nested map must be mapped in order for the transform to run.

Insert
The **Insert** transform inserts a row to a database table.

Use the **Insert** transform to insert a row into a database table. For more information, see "Inserting data into a table" on page 1525.

The database server that is used during the creation of your **Insert** transform is specified in a database definition file (`.dbm` file) that you select from the Data Design project used to create the message map.

When your message map has been deployed to an integration server, and your message map is run, the database server that is used by the IBM App Connect Enterprise runtime component to process your **Insert** transform is specified by the JDBC Providers policy. The JDBC Provider policy name must have the same name as the database name that is specified in your **Insert** transform during development.

Join
You can use a **Join** transform to join elements from two or more inputs into an output element.

Overview

You provide a **Join expression** to determine which data to transform.

You define the mapping from the joined instances of the input arrays to an output target in the nested map. For more information, see "Using nested maps" on page 1371.

The **Join** transform implements an inner-join.

If you want to implement an outer-join, use the **For Each** transform with the option **Allow Empty input** enabled.

Inputs

The inputs to a **Join** transform can be repeating simple elements or complex type elements, which can be merged using nested transforms to create an output.

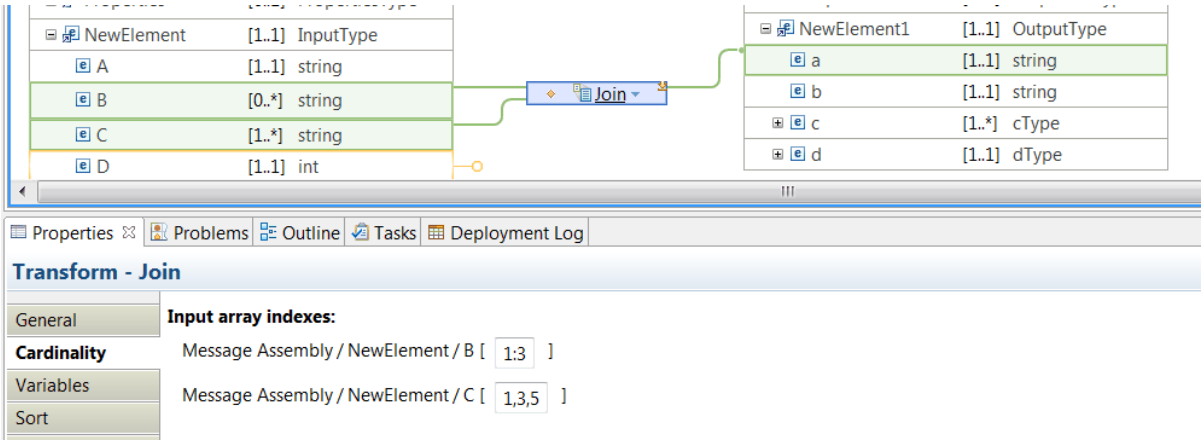
- You configure the inputs to a **Join** transform with primary connections.
- You must have at least 2 primary inputs to a **Join** transform.
- You can configure the **Cardinality** property page of each input to indicate which index of an input array to iterate over.
- You can configure the **Order** property page to define the order of iteration over the input elements.
- You can define a **Join expression** to specify the matching criteria for joining or filtering input repeating elements. The join expressions determines the size of the output element.

You can define additional inputs to the **Join** transform by using supplement connections. These inputs are passed unchanged to the nested map. You can use these inputs inside your nested map to define conditional expressions in the transforms that you define.

Cardinality

The **Cardinality** property determines the inputs participating in the join operation.

You configure the **Cardinality** property tab of a **Join** transform to define which indexes are used from each input array in the join operation. For more information, see “Selecting the indexes of input array elements” on page 1363.



Order of the inputs

By default, the order of the inputs to the **Join** transform is the order in which you wire the inputs.

You can modify the order by reordering the inputs in the **Order** tab of the transform properties.

Output

The output element can be a simple element or a complex type element that can be repeating or not repeating.

When your output element is a repeating element, the **Join expression** determines the size of the output element.

For example, if you have a repeating input element of size M, and a repeating input element of size N to a **Join** transform, the output element size is calculated as follows:

- If you click the option **Create Join expression based on index**, the size of the output element is the minimum value of M and N.
- If you do not define a **Join expression** or you do not select the option **Create Join expression based on index**, the size of the output element is *MxN*.
- If you define a **Join expression**, the size of the output element is determined by the expression.

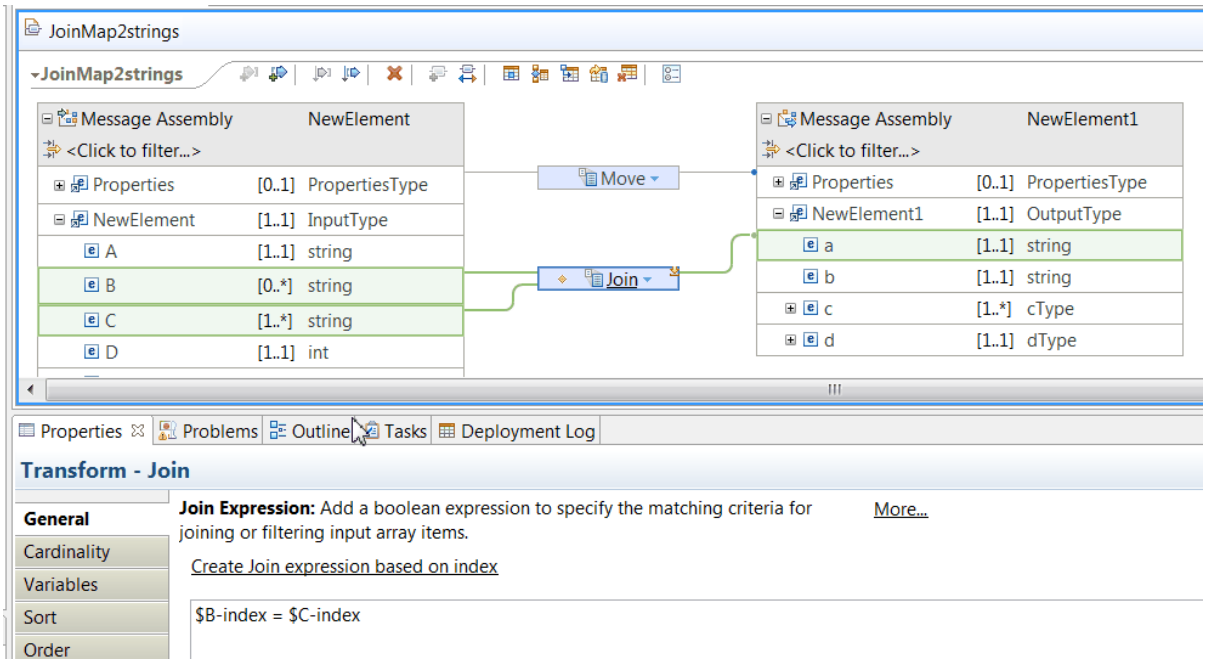
Example 1: To join the first element of the first array with the first element of the second array, you set a join condition that matches based on index. You click **Create Join expression based on index**.

Example 2: If you do not specify a **Join expression**, the join matches the first element of the first array with all elements of the second array, and then it matches the second element of the first array with all elements of the second array, and so on.

Join expression

You can define a **Join expression** to specify the matching criteria for joining or filtering input array elements. This expression is an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression comprising, XPath, Java and extension functions such as **mb:getUserDefinedProperty("propertyname")**.

- You can use content assist to create the expression. For more information, see "Using content assist (Mapping syntax)" on page 1443.
- You can select the option **Create Join expression based on index**. This option requires two repeatable inputs to create the Join expression.



For example, you can use **iib:getUserDefinedProperty("propertyname")** on a For Each filter to use a value that is not hard coded in the map, and you can also set dynamically via **CMP API**.

Local map

A **Local map** is a transform that provides a hierarchical view of element transforms in a message map. A **Local map** enables you to create a more efficient transformation because the nested mapping is executed by default if the primary input is available at run time.

Overview

You can use local maps to break up a large map into nested groups of mapping elements and process the complex elements of the whole data object.

Local maps are a partial view of a larger map, rather than separate files.

The local map does not transform data. You must specify transforms for the input and output elements in the nested map.

Inputs and outputs

A local map has at least one element as input (either a simple type or a complex type), which can contain nested elements. You can add more inputs to a local map, as supplementary, to allow extra simple type or complex type element data to be available in the nested mapping, or use them to provide a condition for when the nested mapping is executed.

The output can be either a single element or an array element, but it must be a complex type.

If you add another input as the primary input, the Graphical Data Mapping editor typically changes the transform type from **Local map** to a more applicable type. For example, when you add an extra simple element as a primary input to a local map that has an existing primary input, the Graphical Data Mapping editor changes the transform type to **Concat**.

When you connect a repeating input to a **Local map** transform, only the first instance of the array is processed. If you need to process multiple indexes of the array, you must use the **For Each** transform. For more information, see "For Each" on page 1320.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Local map** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

You can use the input connected with a primary connection to the transform. To add more inputs, or to provide a condition for when nested mapping is executed, you can define **Supplement** connections between input elements and the transform. If you do not provide a condition, and the primary input is optional in the schema model (`minOccurs=0`), the nested mapping of the local map is executed only if the primary input is available.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

Move
You can use the **Move** transform to copy data from one input element to one output element.

Overview

You can define the **Move** transform between single simple elements or between complex type elements.

You can only connect one input to the **Move** transform. You must use a primary connection to connect the input element to the transform.

You can use the **Move** transform between complex type input and output elements only if the input and output have the same type, or if the type of the input is derived from the type of output; for example, if the input element's type is USA`ddress` and the output type is A`ddress`.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Move** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

You can use the input connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

Normalize
The **Normalize** transform normalizes the input string by removing white space such as spaces, tabs, and returns, and moves the resulting normalized string to the output element.

Overview

For example, it can be used to remove multiple occurrences of white space characters before a comparison of data is done.

The **Normalize** transform is functionally equivalent to the XPath 2.0 `fn:normalize-space()` function. For more information about XPath functions, see the online document W3C XML Path Language (XPath) 2.0.

You can only connect one input to the **Normalize** transform. You must use a primary connection to connect the input element to the transform.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Normalize** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

You can use the input connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

Remove
You can use the **Remove** transform to delete an element from the Environment tree or to remove an element within an **Overrides** group.

Overview

For example, you can use the **Remove** transform to remove child elements from the target structure if you copy a complex structure from source to target.

The **Remove** transform does not have any inputs wired to the transform.

You can define a **Remove** transform on a simple, complex, or repeating output element.

The **Remove** transform is available in the list of available transforms when you define a transform on an element in the environment tree or when you define a transform on an element within an **Overrides** group.

Note: A **Remove** transform in an **Overrides** group cannot be used to remove a specific xsi:typed element; the **Remove** transform uses only the element name to identify the target element to remove.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **Remove** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

To add inputs to the transform, you can define **supplement** connections between input elements and the transform.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

Modifying repeating elements

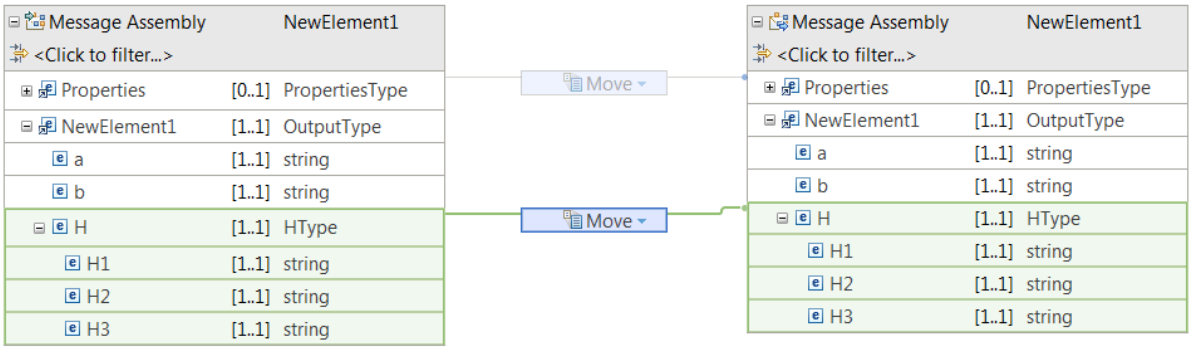
If you need to remove some elements of a repeating structure, use the **For Each** transform and define conditional expressions for each index to determine whether the element is moved or removed.

For more information, see "For Each" on page 1320.

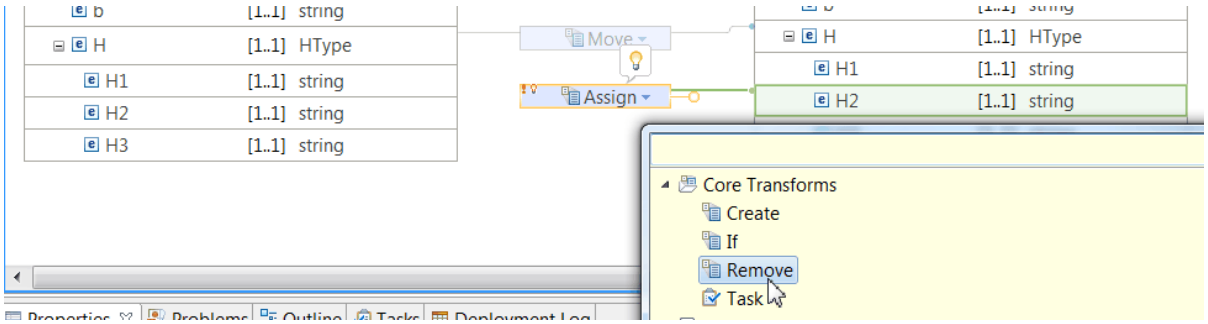
Example

This example shows how to copy an input structure to the output, and then delete one element from the output message structure.

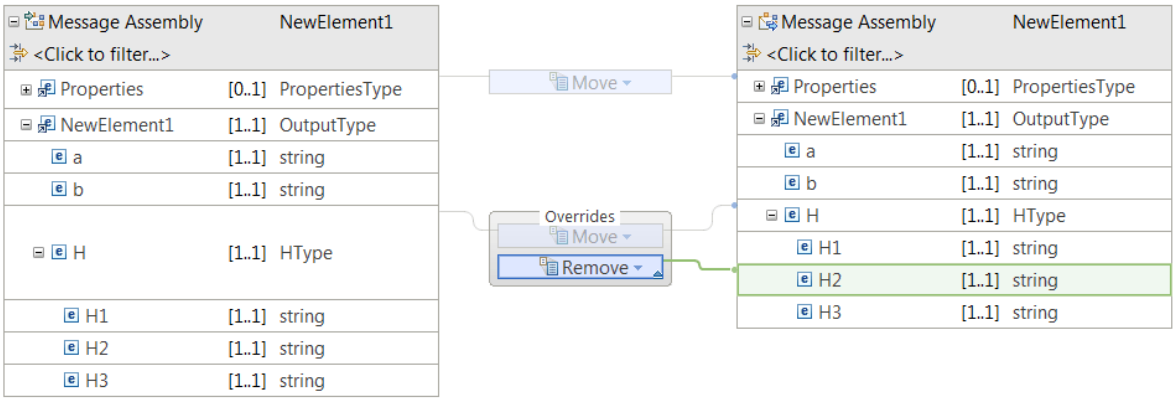
You define a map with a **Move** transform between the input element and the output element.



You click the element that you want to delete (**H2**) from the output structure, and then drag and drop the mouse onto the canvas. An **Assign** transform is added. You change the **Assign** transform to the **Remove** transform.



As soon as you select the **Remove** transform, the Graphical Data Mapping editor adds an **Overrides** function that groups the **Move** transform and the **Remove** transform. The **Overrides** function specifies that the input element **H** is copied over unchanged, and then element **H2** is deleted from the output structure.



Return

Use the **Return** transform to report the number of rows that are modified by a database transform.

The **Return** transform is called if the operation that is specified in the database transform is successful.

Use the **Return** transform in your message map to specify a nested mapping that is called if a database transform was completed successfully.

The **Return** transform provides an in-built input that provides an integer value of the number of rows that are modified by the related database transform:

Database transform	Name of input provided by Return transform	Description
Insert	NumberOfRowsInserted	The Return transform is called each time that an insert operation is successful, and reports the number of rows inserted as 1.
Update	NumberOfRowsUpdated	Number of rows updated depends on the WHERE clause
Delete	NumberOfRowsDeleted	Number of rows deleted depends on the WHERE clause

For more information, about database transforms, see “Mapping database content” on page 1523.

Select

Use the **Select** transform to retrieve data from rows in a database table, so that the data can be used in a message map.

For more information, see “Selecting data from a table” on page 1523.

When you design your message map in the IBM App Connect Enterprise Toolkit, the database server that is used during the creation of your **Select** transform is specified in the database definition file (`.dbm` file) that you selected from the Data Design project used to create the message map.

When your message map has been deployed to an integration server, and your message map is run, the database server that is used by the IBM App Connect Enterprise runtime component to process your **Select** transform is specified by the JDBC Providers policy. The JDBC Providers policy name must be the same name as the database name that is specified in your **Select** transform during development.

Submap
A **submap** enables you to use the same piece of mapping function in multiple graphical data maps.

Overview

A **submap** references another map. It calls or invokes a map from the same file or another map file, which can be stored in a library, an application, an integration service, or an Integration project.

When using submaps, consider the following points:

- A **submap** can provide callable mapping between global elements or global types from a message model.
- A **submap** cannot be used for local anonymous complex types. These must be mapped within the main map, for example, by a local map.
- You can place a submap in a project or in a library. Submaps must be placed in a project or library that is visible to the main map(s) that they are called from.

For more information, see "Creating a submap" on page 1386.

Inputs

You can connect one or more elements to the **Submap** transform with a primary connection or with a supplement connection.

- You can only use elements that are connected with a supplement connection to define conditional expressions.
- All primary inputs must have a global type.
- There is no restriction on the type of the elements that are connected with a supplement connection.

If a **Submap** has a single input that is repeating, the Graphical Data Mapping editor processes each instance that is included according to the **Cardinality** property.

If one and only one of the inputs to a **Submap** transform is repeatable, then all instances of the repeating input are processed. If you filter the indexes of the repeating input by configuring the **Cardinality** property, then only the instances that you configure are processed.

If there are multiple repeating inputs to a **Submap** transform, then you cannot use a **Submap** transform.

Define when the transform is applied at run time

You can define multiple connections between input elements and the **submap** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

You can use the inputs connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

Substring
In the Graphical Data Mapping editor, you can use the **Substring** transform to set the value of an output element to a substring of the original input value. You use this transform to extract a subset of characters that are separated by a delimiter based on a position that you indicate with an index.

Overview

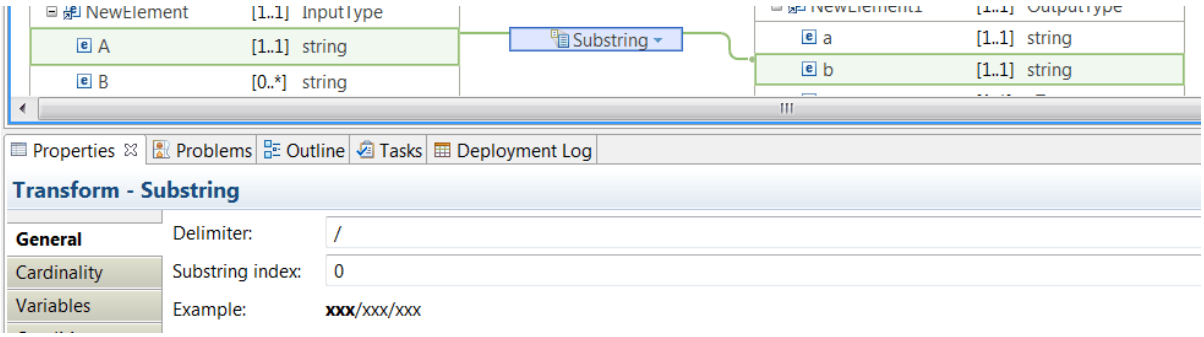
The **Substring** transform uses a delimiter and 0-based index to determine what text to extract from the incoming source string.

Based on the specified delimiter, the source string is divided into sections. The index is used to identify which section of the divided string you want to use.

For example, you can pass the following input string: `'123/124/125/126'`. You can configure the **Delimiter** property with the value `'/'`.

- If you set the **Substring index** property to `0`, the transform returns the value `'123'`.
- If you set the **Substring index** property to `1`, the transform returns the value `'124'`.
- If you set the **Substring index** property to `3`, the transform returns the value `'126'`.

By default, the **Substring index** has a value of 0, that indicates that the first section will be used.

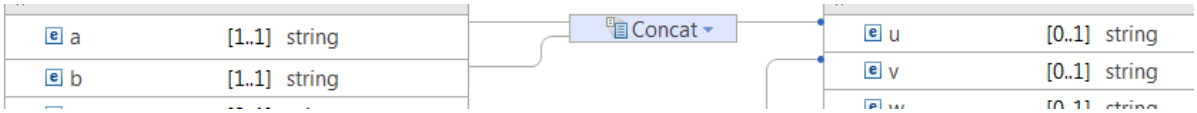


Inputs to the Substring transform

The **Substring** transform takes multiple input elements.

You wire one simple type input to the **Substring** transform as primary connection. This input contains the input value from which you need to extract part of it.

You can wire more inputs as supplementary connections. These other inputs are used to define the conditional expression that determines if a transform is applied.



Define when the transform is applied at run time

You can define multiple connections between input elements and the **Substring** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

For more information, see “Configuring the properties of a transform” on page 1431, “Defining an XPath conditional expression for a transform” on page 1433 and “Defining a Java conditional expression for a transform” on page 1439.

You can use the inputs connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Task
You can use the **Task** transform to indicate a manual task or point of concern that might need to be resolved before a message map can be used in your solution.

The **Task** transform can be connected to one or more inputs, and to a single output, to indicate the input and output elements that are required to resolve the point of concern.

Use the **General** property of a Task transform to specify the Task type:

Task type	Description
Error	Used to indicate a problem in your message map that must be resolved before the map is used in a solution. A **Task** transform of type **Error** is displayed in the Graphical Data Mapping editor, and in the **Problems** view of the Integration Development perspective. Your message map cannot be deployed if it contains one or more **Task** transforms of type **Error**.
Warning	Used to indicate an area of your message map that needs to be reviewed. A **Task** transform of type **Warning** is displayed in the Graphical Data Mapping editor, and in the **Problems** view of the Integration Development perspective. **Task** transforms of type **Warning** are ignored at run time.
Info	Used to contain a note or comment in your message map. A **Task** transform of type **Info** is displayed in the Graphical Data Mapping editor, and in the **Problems** view of the Integration Development perspective. **Task** transforms of type **Info** are ignored at run time.
To Do	Used to indicate an area of your message map that is incomplete. A **Task** transform of type **To Do** is displayed in the Graphical Data Mapping editor, and in the **Tasks** view of the Integration Development perspective. **Task** transforms of type **To Do** are ignored at run time.

Use the **Documentation** property of a **Task** transform to describe the details of your manual task or point of concern. The **Documentation** property can also contain a link to a related resource, for example a `.msgmap` file.

Using a Task transform when you convert a legacy message map

When you use the IBM App Connect Enterprise Toolkit to convert a legacy message map (`.msgmap` file) to a message map (`.map`) file, a **Task** transform is created in your new message map for each mapping structure that was not recreated by the conversion process. The **Documentation** property of a **Task** transform is used to describe the unconverted transform and, where possible, a suggested solution. For example:

```
This map transform was generated by conversion of the message mapping built in a previous
 version of the product.
The original transform from the converted file "example.msgmap_backup" was was
 "esql:concat('NativeError: ', esql:sqlnativeerror())".
The convert processing could not provide an equivalent transform. Reason: There is no supported
 corresponding XPath expression for esql:sqlnativeerror().
This map cannot be deployed and run until this 'Task' transform is re-implemented.
To re-implement this transform and remove the error marker on the map consider changing the
 'Task' transform into a <Custom XPath Transform>.
```

Update
The **Update** transform modifies one or more rows of data in a database table.

Use the **Update** transform to modify one or more rows of data that match a configured **Where** clause from a database table. Optionally, if no rows of data match your configured **Where** clause, the **Update** transform can insert a row of data. For more information, see “Updating data in a table” on page 1527.

The **Update** transform performs a single update SQL operation on the configured database server, so the inputs that you connect to your **Update** transform must provide a single set of data values. If you connect a repeating element to your **Update** transform, the Graphical Data Mapping editor moves the **Update** transform into a nested **For Each** transform.

The database server that is used during the creation of your **Update** transform is specified in a database definition file (`.dbm` file) that you select from the Data Design project used to create the map.

When your message map has been deployed to an integration server, and your message map is run, the database server that is used by the IBM App Connect Enterprise runtime component to process your **Update** transform is specified by a JDBC Providers policy. The JDBC Providers policy must have the same name as the database that is specified in your **Update** transform during development.

Built-in XPath transforms
In the Graphical Data Mapping editor, you can use built-in XPath functions to transform data.

Overview

The Graphical Data Mapping editor supports XPath functions that allow you to manipulate graphically string values, numeric values, date and time comparison, and more.

The XPath functions are grouped in the following categories:

- String functions
- Boolean functions
- Math functions
- Date and time functions
- QName functions
- Node functions
- List functions
- Diagnostic functions

For more information about XPath, see XPath tutorial or W3C XML Path Language (XPath) 2.0.

All XPath 2.0 functions are supported in the form `fn:<function_name>`.

For more information on the following XPath functions, see the following topics:

- “fn:concat” on page 1345
- “fn:string-join” on page 1348
- “fn:substring” on page 1352
- “fn:count” on page 1353
- “fn:sum” on page 1356

When you need to define complex XPath expressions, use the **Custom XPath** transform. For more information, see “Custom XPath” on page 1315.

Inputs versus arguments

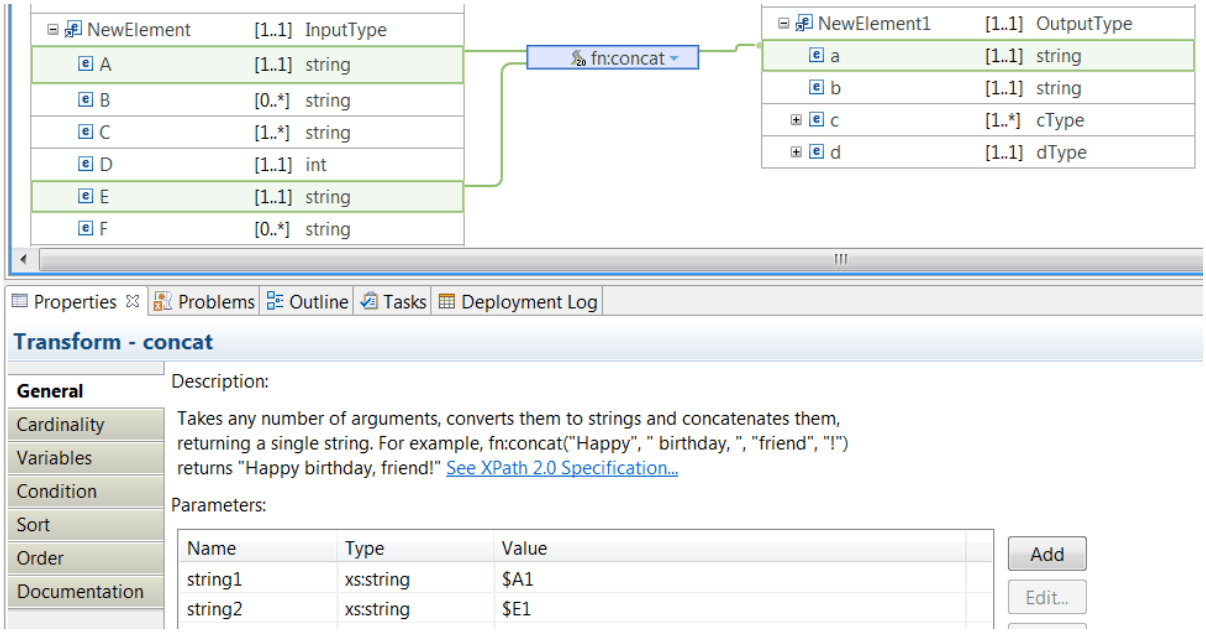
When you use an XPath transform, you must differentiate between inputs to the transform and arguments required to run the XPath function represented by the XPath transform.

Arguments are the data elements required in the calculation of an XPath function.

An argument can be a literal expression, a constant, an input element, a custom XPath expression, or a combination of multiple input elements.

You can have any number of inputs to an XPath transform. You use these inputs to define the arguments of the XPath function.

In the following figure, the XPath transform has two inputs. Each input is used as an argument of the **fn:concat** transform:

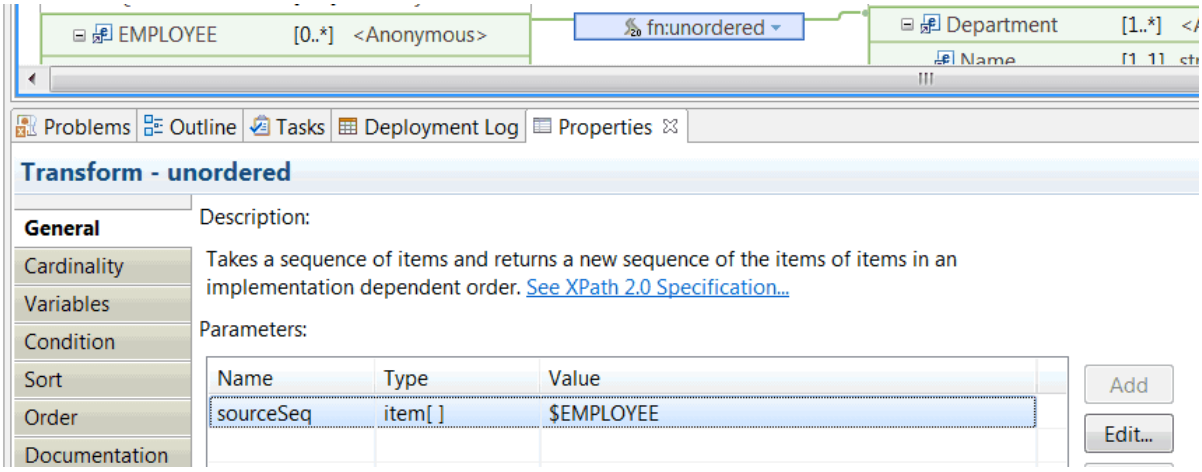


Modify the value of an input element before you apply the XPath function in a map

You can modify the value of an input element to an XPath function in the **Properties** page of the XPath transform.

You can define an XPath expression or a call to a static method on an imported Java class to modify its value. You can also create a complex expression comprising XPath, and Java.

In the **General** tab, you get the list of input elements to the XPath transform. For each element, the name, type and value are displayed.



To change the input value, you must select the element, and click **Edit**. Then you can enter the expression to modify the value.

Define when the transform is applied at run time

You can define multiple connections between input elements and an XPath transform. You can then use these input elements in a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

Alternatively, to define the conditional expression, you can call a static method on an imported Java class. You can also create a complex expression comprising XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

You configure the expression in the **Condition** tab that is available in the **Properties** page of the transform.

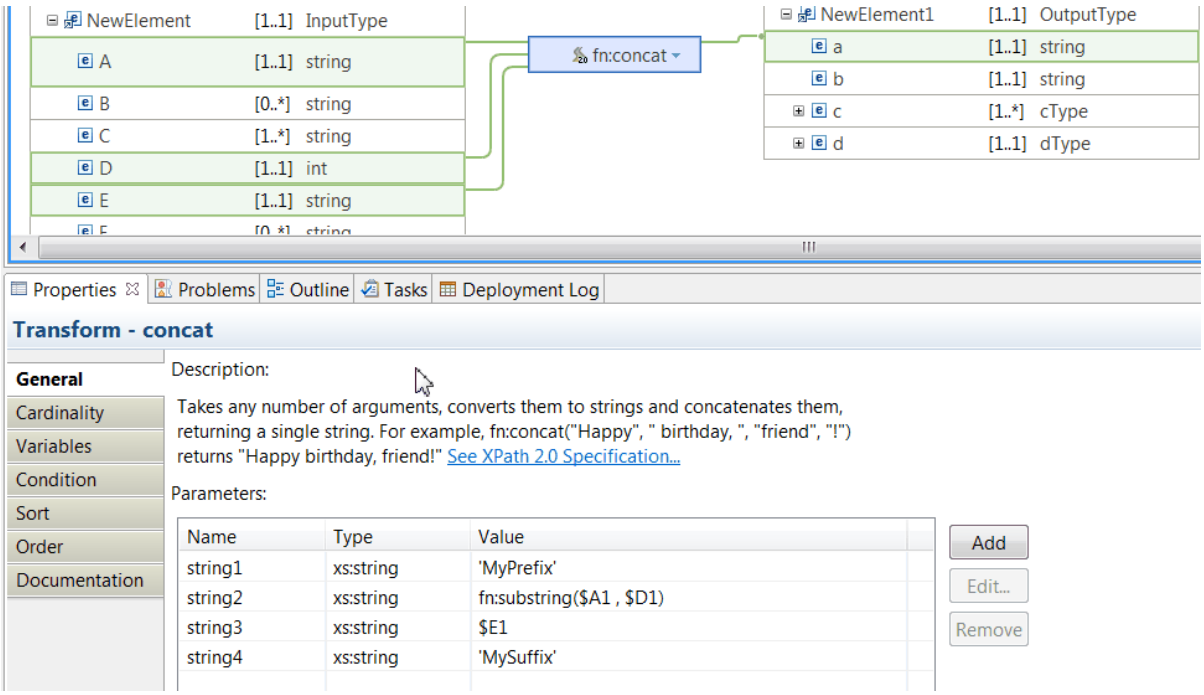
For more information, see "Configuring the properties of a transform" on page 1431, "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.

You can use the inputs connected with a primary connection to the transform. To add more inputs, you can define **supplement** connections between input elements and the transform.

Example

This example shows how to use the **fn:concat** transform to concatenate multiple input elements and set the value of a string element by using the **fn:concat** function.

The arguments to the XPath function include a prefix, two elements, and one suffix. One of the arguments is defined by an XPath function that requires data from two inputs. One of the arguments is set with data from an input. The prefix and the suffix are literals.



When you run the following message and transform the data with the **fn:concat** transform:

```
<NewElement>
  <A>My FieldA</A>
  <B>B1</B>
  <C>Field_1</C>
  <D>4</D>
  <E>FIELD_E</E>
</NewElement>
```

You obtain the following result:

```
<NewElement1>
    <a>MyPrefixFieldAFIELD_EMySuffix</a>
</NewElement1>
```

Troubleshooting

BIP3946E:

`BIP3946E: The map script generation for QName {1} has failed, with the following details: {2}`

You get **BIP3946E** when you try to deploy a map that contains an invalid XPath expression. Check the description provided by {2} to find out which expression is not a valid.

fn:concat
In the Graphical Data Mapping editor, you can use the **fn:concat** transform to create a string output element that is the result of concatenating simple input elements.

Overview

The XPath 2.0 function `fn:concat(arg1, arg2, ,,,)` takes two or more arguments, converts them to their string representation, and concatenates them, returning a single string.

The **fn:concat** transform is the representation of the **fn:concat** XPath function in the Graphical Data Mapping editor.

You can have any number of inputs to the **fn:concat** transform. These inputs are used to define the arguments of the **fn:concat** function.

For more information about XPath, see XPath tutorial or W3C XML Path Language (XPath) 2.0.

When to use the fn:concat transform

You can use **fn:concat** to concatenate input elements.

You can configure the arguments to the **fn:concat** transform to represent a prefix, a suffix, and delimiters.

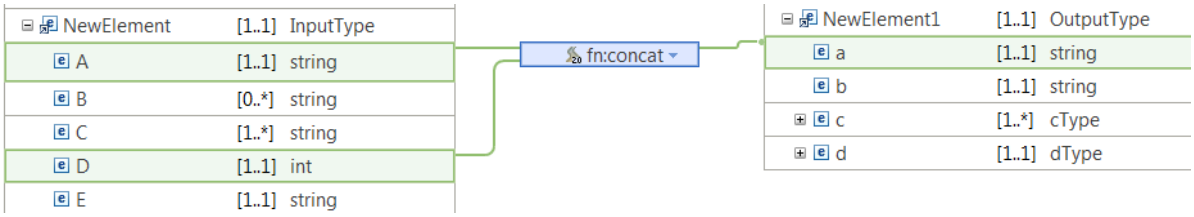
- You can use the first argument as the prefix.
- You can use the last argument as the suffix.
- You can insert a delimiter as an argument between any two arguments you want to delimit.

Inputs to the transform

You can connect simple elements to the **fn:concat** transform.

Simple input elements that are not of type **xs:string** will be cast to **xs:string**.

The following figure shows two inputs connected to the **fn:concat** transform:



Note: The Graphical Data Mapping editor does not display an error or a warning on a **fn:concat** transform when the input to the transform is not a single type element, or is repeatable.

- If the input XML has no more than one instance of the repeatable input, the **fn:concat** transform produces the expected result at run time.
- If the input XML has more than one instance of the repeatable input, the **fn:concat** transform results in a run time exception.

Arguments of the XPath function

The **fn:concat** function has two or more non-repeating arguments.

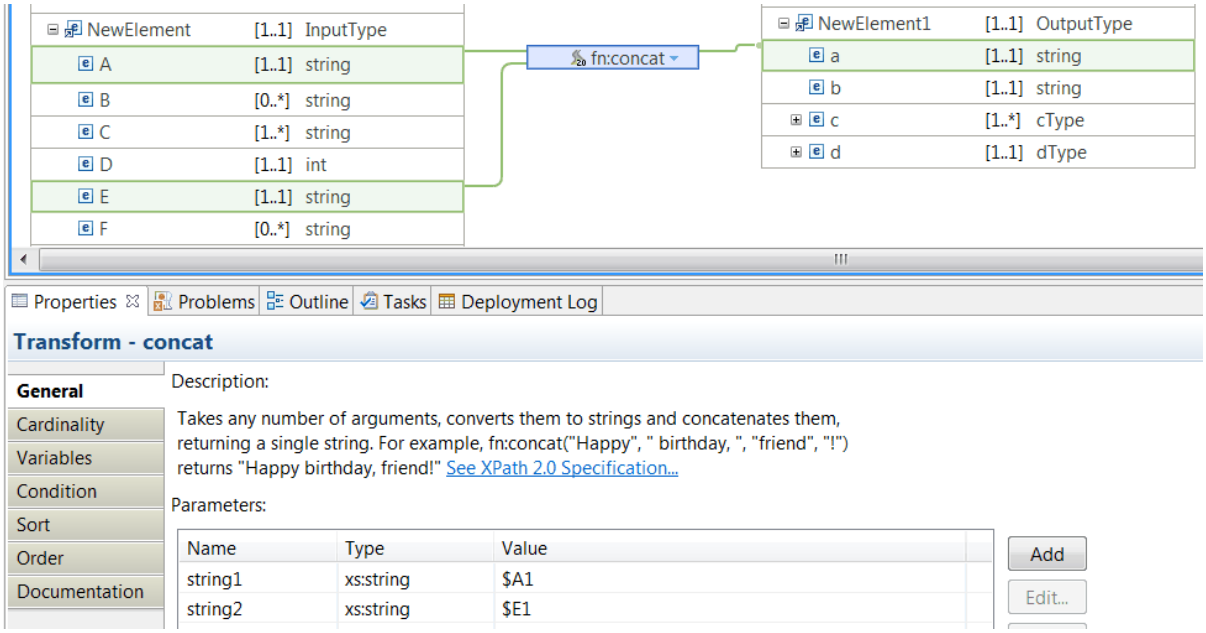
Note: A run time failure occurs complaining that a sequence is not valid if you do not ensure that each argument is non-repeating.

You define the number and the order of the arguments to the **fn:concat** function in the **General** tab of the **fn:concat** transform properties view.

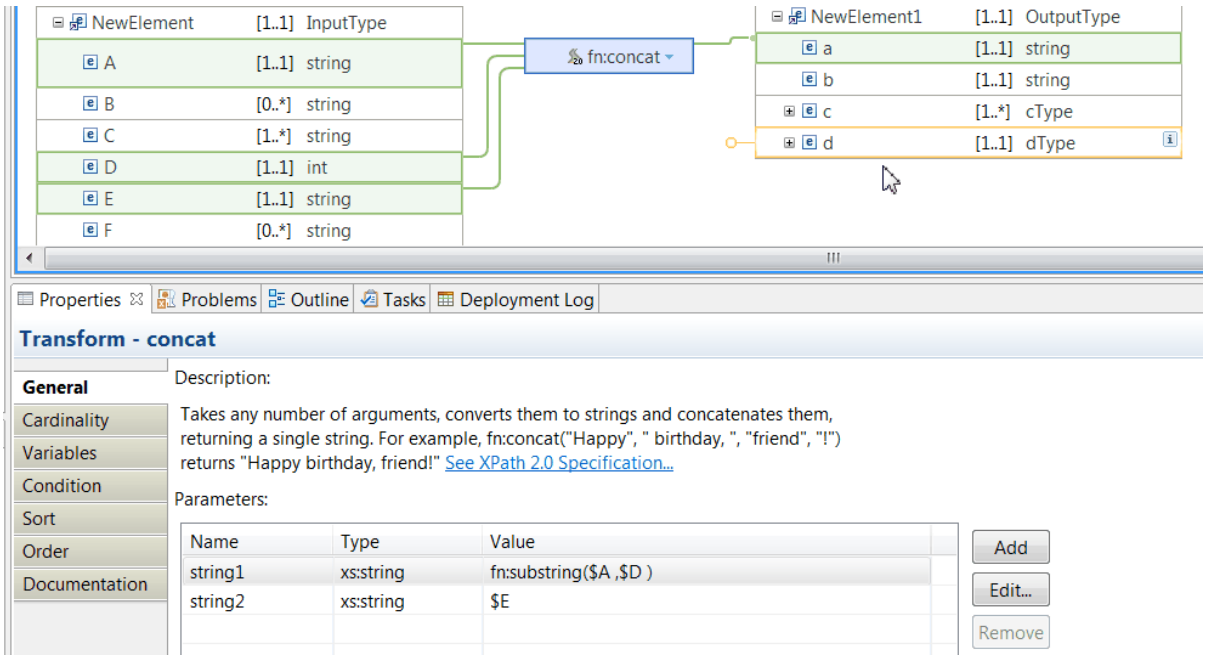
You can use the **Add** button on **General** tab to create additional arguments:

- You can add a literal value entered in single quotes.
- You can add a Custom XPath expression.

In the following figure, the **fn:concat** transform has two inputs. Each input is used as an argument of the **fn:concat** function:



In the following figure, the **fn:concat** transform has three inputs, whilst the **fn:concat** function only requires two arguments. Two of the inputs are used to define one of the arguments of the **fn:concat** transform:



Define a conditional expression

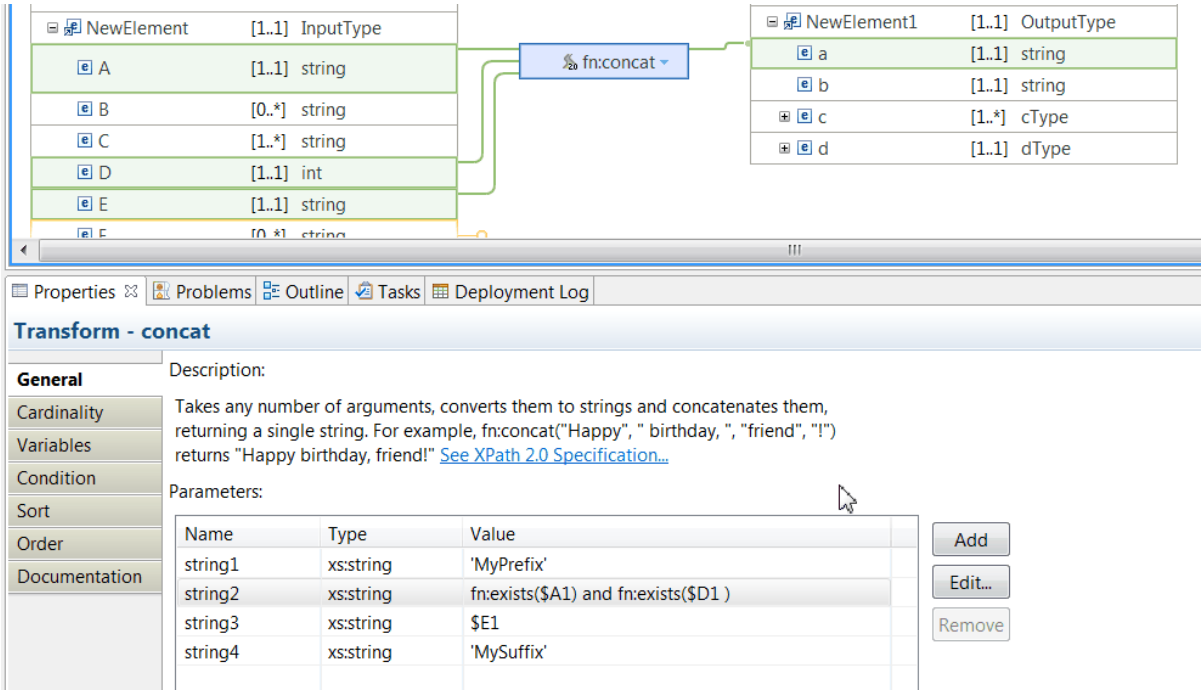
You can use any of the input elements to the **fn:concat** transform to define a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

For more information, see “Configuring the properties of a transform” on page 1431.

Example

This example shows how to use the **fn:concat** transform to concatenate multiple input elements and set the value of a string element by using the **fn:concat** function.

The arguments to the XPath function include a prefix, two elements, and one suffix. One of the arguments is set by an XPath function base on calculations from data from two inputs. One of the arguments is set with data from an input. The prefix and the suffix are literals.



When you run the following message and transform the data with the **fn:concat** transform:

```
<NewElement>
  <A>My FieldA</A>
  <B>B1</B>
  <C>Field_1</C>
  <D>4</D>
  <E>FIELD_E</E>
</NewElement>
```

You obtain the following result:

```
<NewElement1>
    <a>MyPrefixtrueFIELD_EMySuffix</a>
</NewElement1>
```

fn:string-join
In the Graphical Data Mapping editor, you can use the **fn:string-join** transform to create an output element that is the result of concatenating a sequence of input elements with a delimiter as optional.

Overview

The XPath 2.0 function `fn:string-join(arg1, arg2)` takes two arguments, converts them to their string representation, and concatenates them, returning a single string.

The **fn:string-join** transform is the representation of the **fn:string-join** XPath function in the Graphical Data Mapping editor.

You can have any number of inputs to the **fn:string-join** transform. These inputs can be used to define the arguments of the **fn:string-join** function.

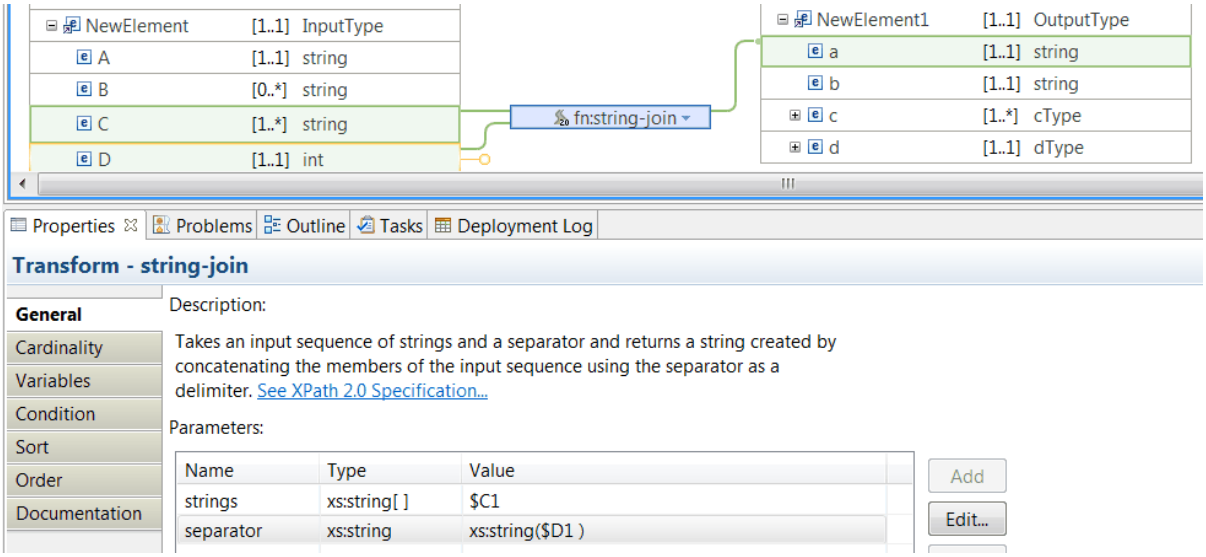
Inputs to the transform

You can connect one or more inputs to the **fn:string-join** transform. These inputs are used to define the arguments of the **fn:string-join** function.

- One of the primary inputs must be a repeatable simple element. This input is used to define the first argument of the **fn:string-join** function. It defines the sequence of elements that you want to concatenate.

  Note: When the type of the repeating elements is different from **xs:string**, the Graphical Data Mapping editor will cast the element to a **xs:string** type.
- One of the primary inputs can be a simple type element. This input is used to define the second argument of the **fn:string-join** function. It defines the delimiter used between the elements that you want to concatenate.

  Note: If the simple type is not of type **xs:string**, the transform will fail at run time with **BIP3945E**. Cast the element to a string if you want to use a non-string input element as your delimiter. For more information, see "Cast type (xs:type)" on page 1299.



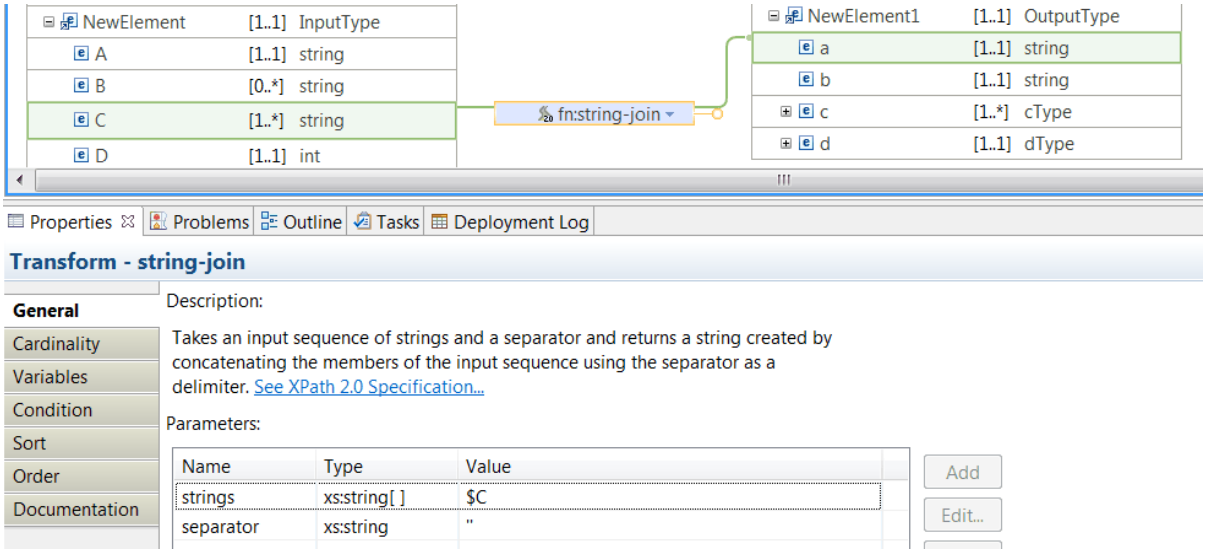
- More inputs can be connected to the **fn:string-join** transform. You can use these inputs as additional information to the transform. For example, you can use these inputs as arguments of the XPath expression that you can define in the **Condition** tab to determine whether the transform is applied at run time.

Arguments of the XPath function

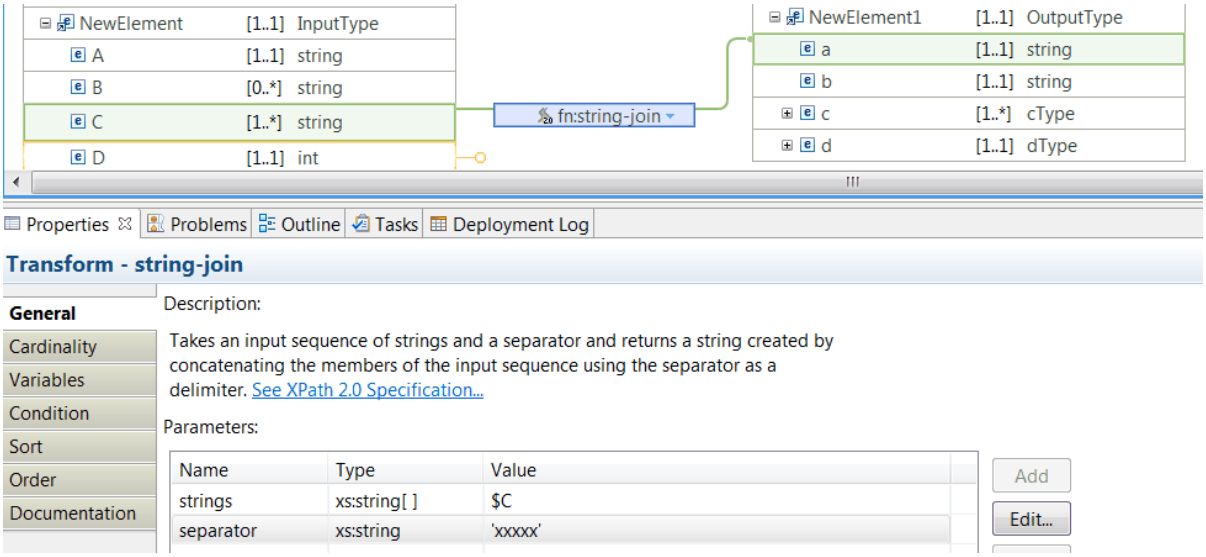
You define the arguments to the **fn:string-join** function in the **General** tab of the **fn:string-join** transform properties view.

- The first argument is a sequence of elements.
- The second argument is a delimiter. The delimiter is optional. If the separator defined for the **fn:string-join** function is a zero-length string, no delimiter is used.

In the following figure, the **fn:string-join** transform has one input. The input is used to define the first argument of the **fn:string-join** function. No delimiter is configured.



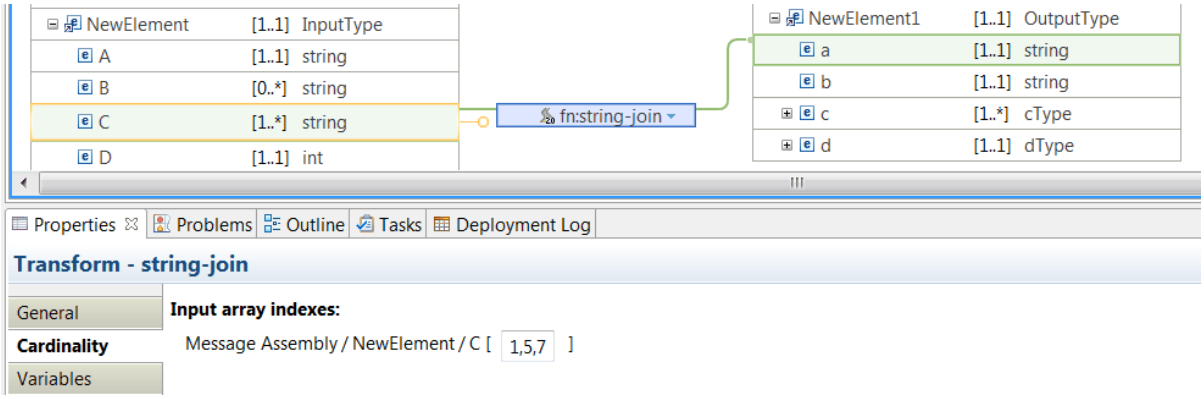
The following figure shows the **fn:string-join** transform with one repeating element as input, and a separator. To add the delimiter, you must select the **General** tab in the Properties view, click **Edit**, and then enter the value.



Cardinality

The **Cardinality** property determines the elements (also known as indexes) in the repeating input element that are processed by the **fn:string-join** transform.

You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see “Selecting the indexes of input array elements” on page 1363.



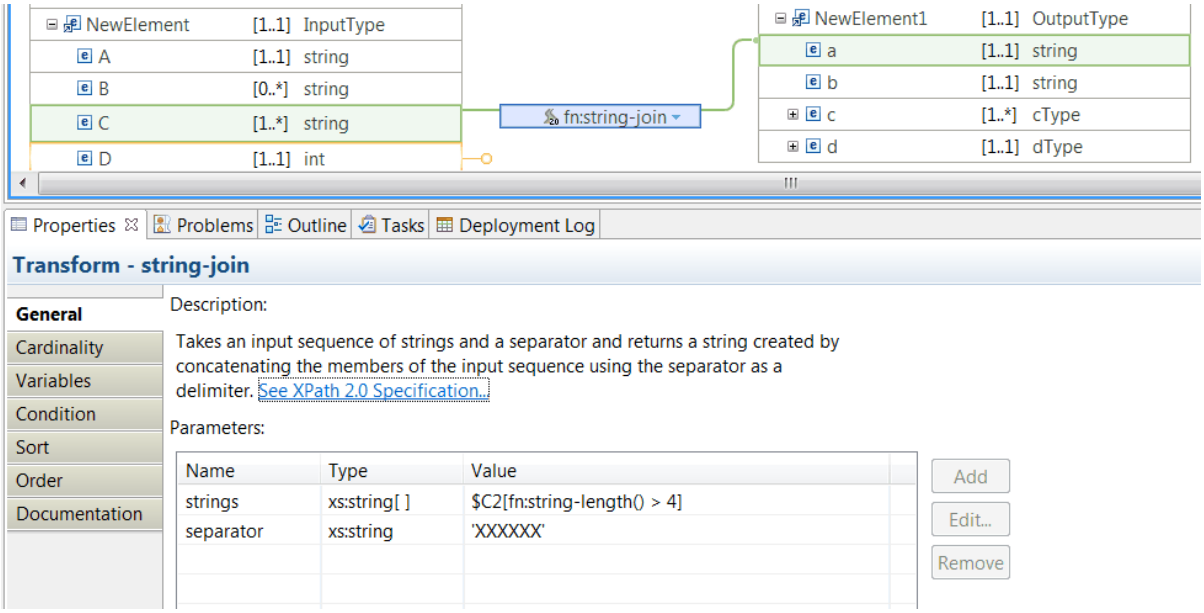
Control the instances to be concatenated

When the instances that you need to concatenate need to be calculated at run time based on a condition, you can filter dynamically the input indexes by defining a custom XPath conditional expression for the first argument named **strings** in the **General** tab. The expression determines which elements of the repeating structure are applied at run time.

For example, to calculate the value of the output element **a**, you must concatenate the elements in the repeating structure **C** whose length is greater than 4. You can use the following XPath expression:

```
$C2[fn:string-length() > 4]
```

Note: Always use content-assist to build your XPath expressions. You must use the element names used by the Graphical Data Mapping editor.



Define when the transform is applied at run time

You can use any of the input elements to the **fn:string-join** transform to define a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

For more information, see “Configuring the properties of a transform” on page 1431.

fn:substring
In the Graphical Data Mapping editor, you can use the **fn:substring** transform to set the value of an output element to a substring of the original input value. You must define the start position, and optionally, the number of characters that you need to extract.

Overview

The **fn:substring** XPath 2.0 function takes two arguments, an input string and a 1-based number, to return a part of the original string, beginning from the position indicated. You can also specify a third optional parameter as a number, to indicate the end position to compose the resulting string.

The following function call `fn:substring("12345", 2, 3)` returns `"234"`.

The following function call `fn:substring("12345", 2)` returns `"2345"`.

The `fn:substring-before()` and `fn:substring-after()` functions are variations of the `fn:substring()` function.

- Use the `fn:substring-before(arg1, arg2)` function when you need the part of arg1 that occurs before arg2 occurs in it. For example, `substring-before('1234567/CustomerID','/')` returns `1234567`.
- Use the `fn:substring-after(arg1, arg2)` function when you need the part of arg1 that occurs after arg2 occurs in it. For example, `substring-after('1234567/CustomerID','/')` returns `CustomerID`.

For more information about XPath, see XPath tutorial or W3C XML Path Language (XPath) 2.0.

Inputs to the transform

The **fn:substring** transform takes as input one simple type element. This element is used to define the first argument of the **fn:substring** function.

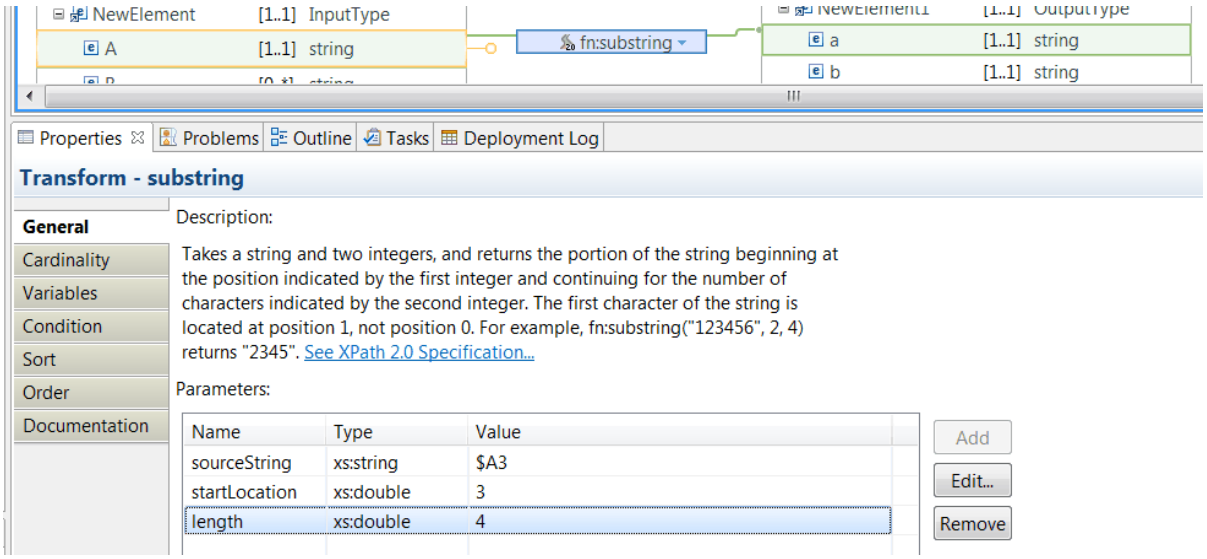
Note: If the simple type is not of type **xs:string**, the transform will fail at run time with **BIP3945E**. Cast the element to a string if you want to use a non-string input element. For more information, see “Cast type (xs:type)” on page 1299.

Arguments of the XPath function

You define the arguments to the **fn:substring** function in the **General** tab of the **fn:substring** transform properties view.

- The first argument is a string element. You can define a literal expression, a constant, an input element, or a custom XPath expression.
- The second argument is named **startLocation** and specifies the a start position.
- The third argument is named **length**, is optional, and specifies the number of characters that you need to select.

In the following figure, the **fn:substring** transform has one input. The input is used to define the first argument of the **fn:substring** function.



Define when the transform is applied at run time

You can use any of the input elements to the **fn:substring** transform to define a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

For more information, see "Configuring the properties of a transform" on page 1431.

fn:count

In the Graphical Data Mapping editor, you can use the **fn:count** transform to set the value of an output element to the total number of elements in the input element.

Overview

The XPath 2.0 function `fn:count((arg1, arg2,arg3, ...))` takes a list of elements and returns the total number of elements.

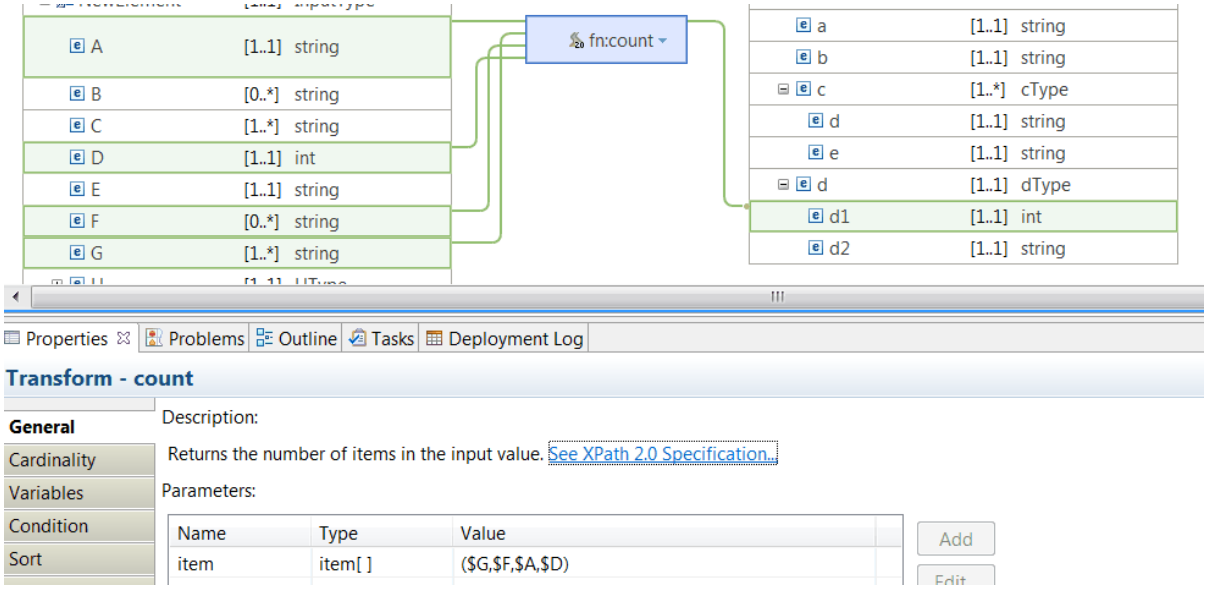
The **fn:count** transform is the representation of the **fn:count** XPath function in the Graphical Data Mapping editor.

You can have any number of inputs to the **fn:count** transform. These inputs can be used to define the arguments of the **fn:count** function.

Inputs to the transform

You can connect one or more inputs to the **fn:count** transform. These inputs are used to define the argument of the **fn:count** function.

In the following figure, there are 4 inputs to the **fn:count** transform.



When you run the following message, the value of **d1** is **4**.

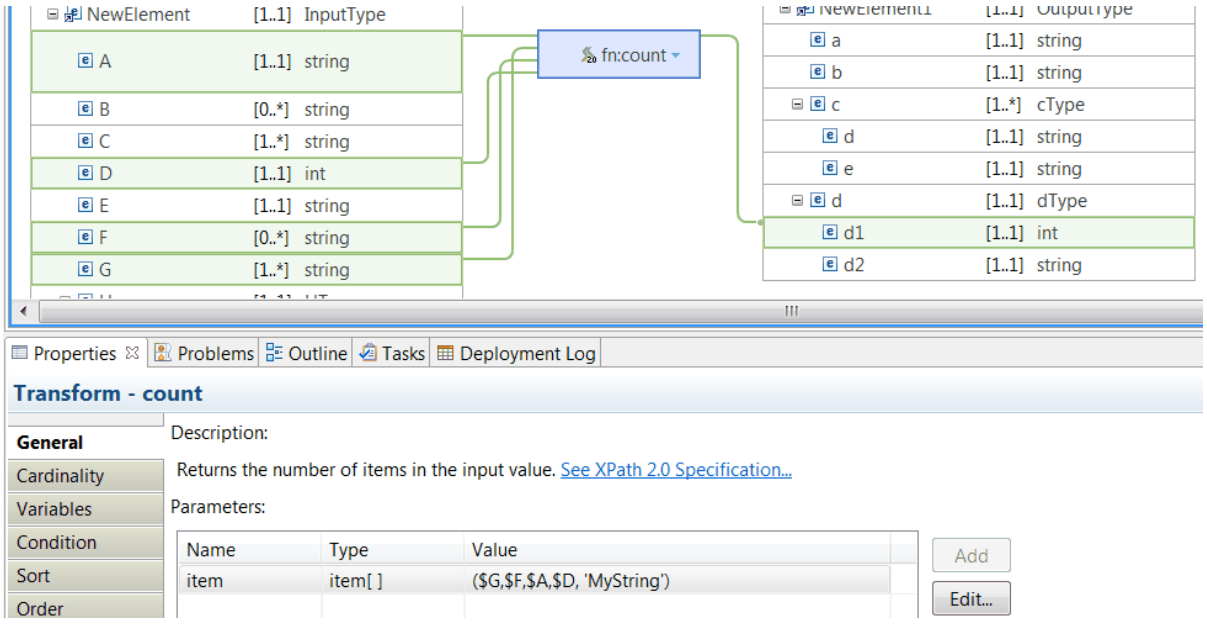
```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>10</A>
  <C>100</C>
  <C>1000</C>
  <C>10000</C>
  <D>1000</D>
  <E>112</E>
 </NewElement>
```

Arguments of the XPath function

You define the argument to the **fn:count** function in the **General** tab of the **fn:count** transform properties view.

You can define a literal expression, a constant, an input element, or a custom XPath expression as the argument.

In the following figure, there are 4 inputs to the **fn:count** transform. **A** is only considered if the string length is greater than 4. A literal expression has been added as an additional element in the argument.



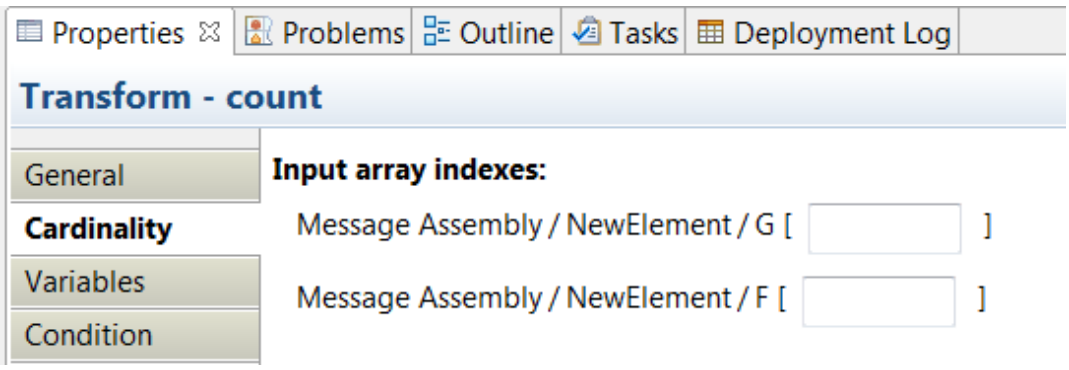
When you run the following message, the value of **d1** is **5**.

```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>10</A>
  <C>100</C>
  <C>1000</C>
  <C>10000</C>
  <D>1000</D>
  <E>112</E>
</NewElement>
```

Cardinality

The **Cardinality** property determines the elements (also known as indexes) in each repeating input element that is processed by the **fn:count** transform.

You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see “Selecting the indexes of input array elements” on page 1363.



Define when the transform is applied at run time

You can use any of the input elements to the **fn:count** transform to define a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied. You define this expression in the **Condition** tab of the tranform properties.

For more information, see “Configuring the properties of a transform” on page 1431.

fn:sum

In the Graphical Data Mapping editor, you can use the **fn:sum** transform to set the value of an output element to a numeric type that is the result of the sum of all the values in a sequence. You can also use the **fn:sum** transform to set the value of an output element to the sum of durations in a sequence.

Overview

You can use the XPath 2.0 function `fn:sum(arg1, arg2)` to sum numeric or duration values in a sequence.

The **fn:sum** transform is the representation of the **fn:sum** XPath function in the Graphical Data Mapping editor.

You can have any number of inputs to the **fn:sum** transform. These inputs can be used to define the arguments of the **fn:sum** function.

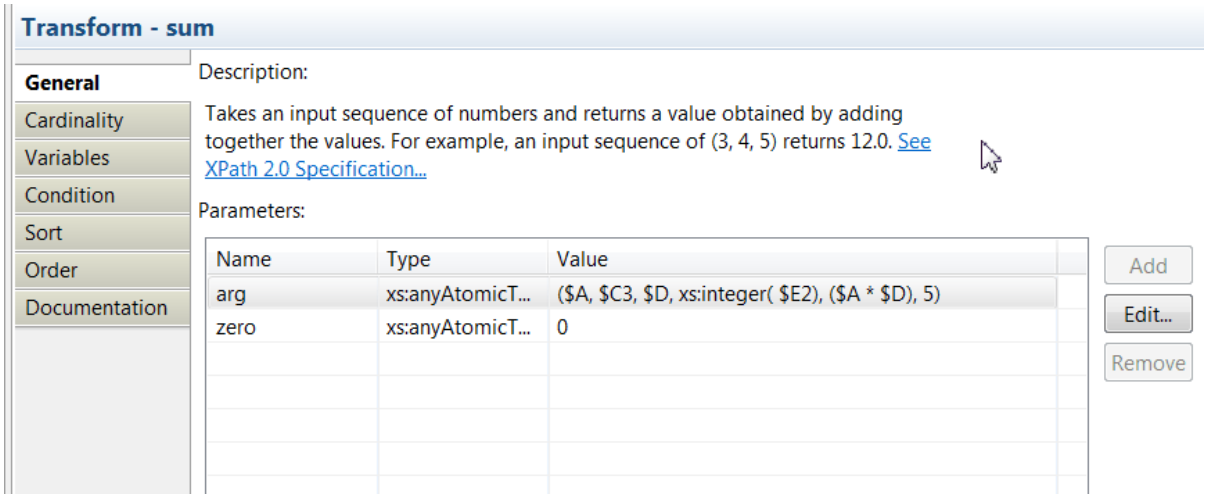
Inputs to the transform

You can connect one or more inputs to the **fn:sum** transform. These inputs are used to define the arguments of the **fn:sum** function.

Arguments of the XPath function

You define the two arguments to the **fn:sum** function in the **General** tab of the **fn:sum** transform properties view.

- The first argument (**arg**) contains any number of numeric and untyped values, or any number of duration values.
- The second argument (**zero**) contains the default value returned by **fn:sum** when the sequence is empty. You can set this value to the integer 0, a duration of zero seconds, or any other atomic value.



You must consider the following points when you define the arguments to the **fn:sum** function:

- Untyped values are cast to a double type element.
- You can edit the sequence specified for **arg** and then add literal values, cast untyped values, and add more values that are the result of arithmetic operations.
- If **arg** is an empty sequence, and **zero** is set, then **fn:sum** returns the value specified by **zero**.
- When you sum durations, you must ensure that all the elements in the sequence have the same type, that is, all values are of type **xs:yearMonthDuration** or all values are of type **xs:dayTimeDuration**.

Note: If an input is not of a numeric type such as **xs:int**, the transform will fail at run time. Cast the input element to a numeric type. For more information, see "Cast type (xs:type)" on page 1299.

Cardinality

The **Cardinality** property determines the elements (also known as indexes) in the repeating input element that are processed by the **fn:sum** transform.

You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see "Selecting the indexes of input array elements" on page 1363.

Define when the transform is applied at run time

You can use any of the input elements to the **fn:sum** transform to define a conditional expression that defines the condition under which the transform is applied. If the condition evaluates to **true**, the transform is applied.

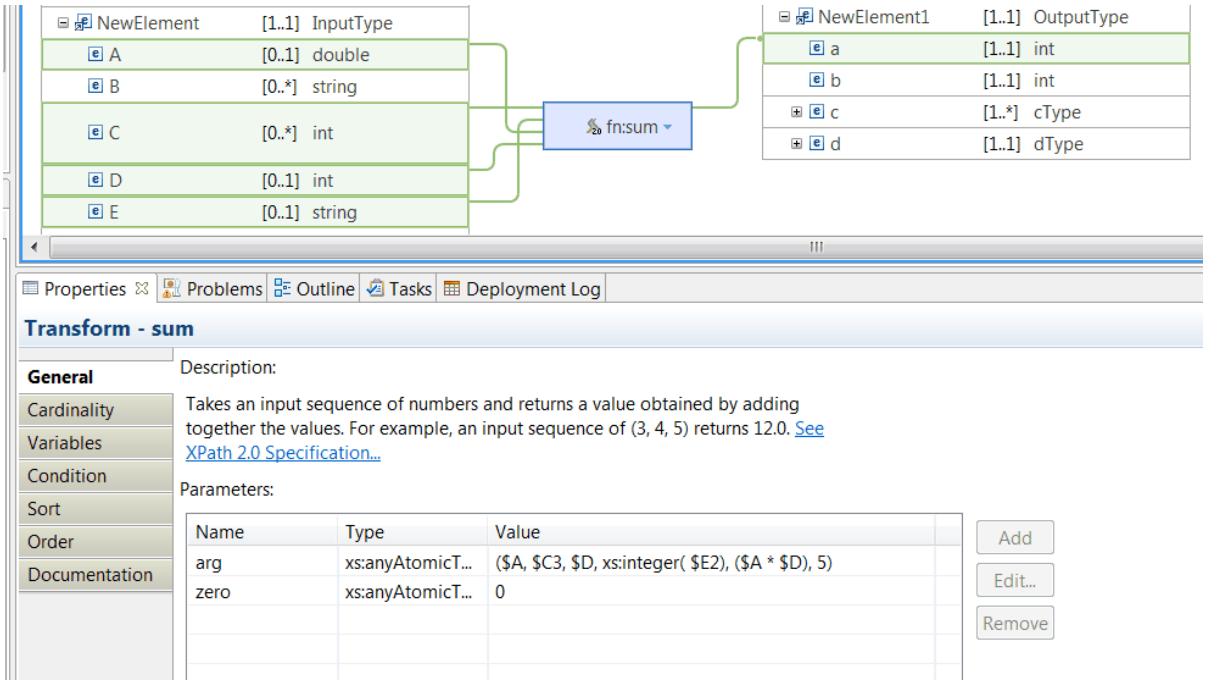
For more information, see "Configuring the properties of a transform" on page 1431.

Example: Calculate the value of a numeric output element

In the following figure, the **fn:sum** transform has four inputs and the **fn:sum** function has two arguments.

The input **E** is of type string and is cast to an integer type.

The second argument **zero** is set to the value of multiplying two input elements.



The **fn:sum** transform returns **11147** for the following input message:

```
<?xml version="1.0" encoding="UTF-8"?>
<NewElement>
  <A>10</A>
  <C>2</C>
  <C>10</C>
  <D>1000</D>
  <E>120</E>
</NewElement>
```

Choosing a transform to set the value of a simple type output element
You can use different transforms, such as the **Assign** transform, the **Create** transform, the **Move** transform, or the **xs:type** transform, to set the value of an output element.

Procedure

Complete the questionnaire to identify the transform that you can use to set the value of an output element:

1. Do you want to set the value to a fixed value?

   Use the **Assign** transform.
2. Do you want to initialize the output element, that is, do you want to create an empty structure?

   Use the **Create** transform to initialize a string output element or a hexBinary output element.
3. Do you want to create a nil output element?

   Use the **Create** transform and verify that the output element is defined as `nillable="true"` in the schema.
4. Do you want to set the output element as nil by using an input element with a value of nil?

   Use the **Move** transform. Verify that the input element is defined as `nillable="true"` in the schema. Ensure that the value of the input element is nil.
5. Do you want to set the output element to a default value?

   Use the **Create** transform and verify that the output element has a default value set in the schema.
6. Do you want to set the output element with input from a database column?

   Use the **Select** transform to obtain the database input value. Then, in the nested map that is associated with the **Select** transform, use the **Move** transform to set the value of the output element.
7. Do you want to set the value of the output element with the value of an input element? Do the input element and the output element have the same type associated? Do you want to cast the input value to the type of the output value?

   - When the input and output element have the same type, use the **Move** transform.
   - When the input and output element have different data types, use the **xs:type** transform.
8. Do you want to calculate the value of the output element by using the value of one or more input elements?

   To set an output element with a string data type or hexBinary data type, use any of the following transforms:

   - **Concat**
   - **Normalize**
   - **Append**
   - **Substring**
   - **fn:string-join**
   - **Custom XPath**
   - **Custom Java**
   - **Custom ESQL**

   To set up an output element with any other data type, use any of the following transforms:

   - Any supported XPath functions, for example, **fn:round**
   - **Custom XPath**
   - **Custom Java**
   - **Custom ESQL**

9. Do you want to apply the transform always? Do you want to apply the transform when a condition based on input data occurs?

   Define a conditional expression for the transform you choose. This expression determines when the transform is applied. For more information, see "Defining an XPath conditional expression for a transform" on page 1433.

Results

Table 53. Setting the value of a simple output element

	Number of input elements that are required to set the value of the output element	Transforms to set a string data type, or a hexBinary data type	Transforms to set other simple data types
Set the output element with a fixed value	0	**Assign**	**Assign**
Initialize the output element	0	**Create**	not valid option
Set the output element as nil	0	**Create** Condition: The output element must be defined as `nillable="true"` in the schema.	**Create** Condition: The output element must be defined as `nillable="true"` in the schema.
Set the output element as nil by using a nil input element	1	**Move** Condition: The input element must be defined as `nillable="true"` in the schema.	**Move** Condition: The input element must be defined as `nillable="true"` in the schema.
Set the output element with a default value	0	**Create** Condition: The output element must have a default value set in the schema.	**Create** Condition: The output element must have a default value set in the schema.
Set the output value from a database table column	1..N	**Select** transform to obtain the database input value and **Move** transform to set the value	**Select** transform to obtain the database input value and **Move** transform to set the value
Copy the value of the input element to the output element (both elements have the same data type)	1	**Move**	**Move**

Table 53. Setting the value of a simple output element (continued)

What to do next

Learn about the transforms. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Choosing a transform to set the value of a complex output element
You can use different transforms, such as **Move**, **Create**, **Assign**, to set the value of a complex output element.

Procedure

Complete the questionnaire to identify the transform that you can use to set the value of a complex output element:

1. Do you want to set the value to a fixed value?

   Use the **Assign** transform.
2. Do you want to initialize the output element, that is, do you want to create an empty structure?

   Use the **Create** transform.
3. Do you want to create a nil output element?

   Use the **Create** transform and verify that the output element is defined as `nillable="true"` in the schema.
4. Do you want to set the output element as nil by using an input element with a value of nil?

   Use the **Move** transform. Verify that the input element is defined as `nillable="true"` in the schema. Ensure that the value of the input element is nil.
5. Do you want to set the output element to a default value?

   Use the **Create** transform and verify that the output element has a default value set in the schema.
6. Do you want to set the output element with input from a database column?

   Use the **Select** transform to obtain the database input value. Then, in the nested map that is associated with the **Select** transform, use the **Move** transform to set the values of the output element.

7. Do you want to set the value of the output element with the value of an input element? Do the input element and the output element have the same type associated? Do you want to cast the input value to the type of the output value?
   - When the input and output element have the same type, use the **Move** transform.
   - When the input and output element have different data types, use the **xs:type** transform to set the value of each element.
8. Do you want to apply the transform always? Do you want to apply the transform when a condition based on input data occurs?

   Define a conditional expression for the transform you choose. This expression determines when the transform is applied. For more information, see "Defining an XPath conditional expression for a transform" on page 1433.

Results

Table 54. Setting the value of a complex output element

	Number of input elements that are required to set the value of the output element	**Transforms to set a complex type**
Set the output element with a fixed value	0	**Assign**
Initialize the output element	0	**Create**
Set the output element as nil	0	**Create** Condition: The output element is defined as `nillable="true"` in the schema.
Set the output element as nil by using a nil input element	1	**Move** Condition: The input element must be defined as `nillable="true"` in the schema.
Set the output element with a default value	0	**Create** Condition: The output element has a default value set in the schema.

Copy the value of the input element to the output element (both elements have the same data type)	1	**Move**
Copy the value of the input element to the output element (elements have different data types)	1	**xs:type**

What to do next

Learn about the transforms. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Choosing a transform to map repeating elements
In the Graphical Data Mapping editor, you can use the **For Each** transform, the **Append** transform, the **Join** transform, XPath functions, the **Custom XPath**, and the **Custom Java** transform to map input and output arrays. You can use any of these transforms to choose the set of the elements in the array that you want to transform, and place the result in an output array or single element.

About this task

The only way to control the order of populating an output array is by using the **Append** transform. You must provide input connections to the **Append** transform and set their order in the **Properties** page. For more information, see "Append" on page 1285.

Procedure

Choose one of the following transforms to map repeating elements:

1. When you have repeating elements as input and output to a transform, you can use the **For Each** transform to set the output array element.

   The **For Each** transform iterates over one input array element, which can be either a simple type or a complex type, and enters a nested mapping in which you can provide transforms to populate an instance of the output from the input. You can configure the cardinality to filter which instances to process based on index. Also, you can provide a Boolean expression which will be applied to each instance to determine if it will be mapped.

   
   Additionally, you can also set the **Allow empty input** option so that the Graphical Data Mapping editor enters the nested transform once when no matches occur. This can be used to implement an outer join by providing a supplementary input to the **For Each**.

   For more information, see "For Each" on page 1320.
2. When you have multiple inputs that are either simple type elements, complex type elements, or repeating elements from which you need to construct an array, you can use the **Append** transform to add instances to either a simple type output array or a complex type output array.

   For more information, see "Append" on page 1285.
3. When you have multiple inputs that are either simple type elements, complex type elements, or repeating elements as input to a transform, and you want to join these elements, you can use the **Join** transform to combine them into a single repeating output element. The output element can be an

array or a single element. You configure an expression to control the match conditions for the join. The Graphical Data Mapping editor provides a link to create a simple match by index expression.

For more information, see "Join" on page 1332.

4. You can use XPath functions to map from an array to a single element. For example, you can use **fn:string-join** to return a string created by concatenating multiple string arguments or **fn:sum** to return the sum of a repeating numeric element into a single element.

   For more information, see "Built-in XPath transforms" on page 1342.

5. When you want to map a particular instance from an array to a single output you can use a **Custom XPath** transform that has an XPath predicate expression to select a particular instance.

   For example, if you want to select the "Country" value from the instance of an array of "Address" elements that has a child element "Type" with the value "home", use the following form for your Custom XPath transform:

   ```
   $Address[Type = 'home']/Country
   ```

   Note: If you want to use an input element value to dynamically select an element of an array by index, you must ensure that your XPath predicate expression yields a singleton numeric value. For example, to select the "Country" value from the instance of an array of "Address" elements at the index that is specified by an input element "Counter" (that is defined as `xsd:int`), use the following form for your Custom XPath transform:

   ```
   $Address[fn:data($Counter)]/Country
   ```

   The `fn:data()` function is used to obtain the numeric value of the input element. If the "Counter" element is defined as `xsd:string` you must use the following form to explicitly cast the value to a numeric value:

   ```
   $Address[xs:int($Counter)]/Country
   ```

6. You can use a **Custom Java** transform to map an array by passing the array as an input or output parameter using a list of MbElement objects.

   For more information, see "Custom Java" on page 1312.

Selecting the indexes of input array elements

When you are transforming array elements in the Graphical Data Mapping editor, you can use the **Cardinality** page of the properties view to select the indexes of the input elements that you want the transform to operate over.

When you restrict the indexes of an input array, you reduce the number of indexes processed by the transform. This helps improve performance.

To specify the indexes, enter a value in the **Input array indexes** field of the Cardinality properties page for the transform.

The following table shows examples of the values that you can enter:

Table 55. Example values of input array indexes

Selected index elements	**Value in input array indexes field**
All indexes	* (or leave empty)
Only index 5	5
indexes 1 - 3	1:3
indexes 1, 3, and 5	1,3,5
indexes 2 and up	2:*
indexes 1, 3, 5 and up	1,3,5:*

Table 55. Example values of input array indexes (continued)	
Selected index elements	**Value in input array indexes field**
indexes 2 - 8, but not 5	2:4,6:8
All indexes except 5	1:4,6:*

The indexes are 1-based, which means that the first element of the array is referenced as 1, the second element as 2, and so on. If the cardinality field is left blank for a specified array, all indexes are taken. If you have multiple levels of nested array elements, blank cardinality fields imply that all indexes are taken. Therefore, if the input element to a transform is `A/B[]/C[]`, where B and C are arrays with no indexes specified, all indexes are taken. This means that all C's part of B[1], all C's part of B[2], all C's part of B[3], and so on, are taken.

Choosing a transform to concatenate input data
In the Graphical Data Mapping editor, you can use a **Concat** transform, a **Custom XPath** transform, or an XPath function to define a mapping operation that sets the value of an output element by concatenating input data.

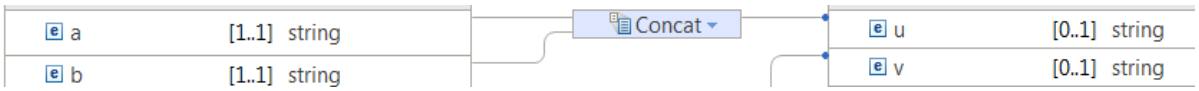
Procedure

Choose one of the following transforms to concatenate multiple input values and set the value of an output element:

- If your input elements are simple non-repeatable elements, and you want to create an output element that is the result of concatenating these input elements with a common delimiter, use the **Concat** transform. The delimiter is optional.

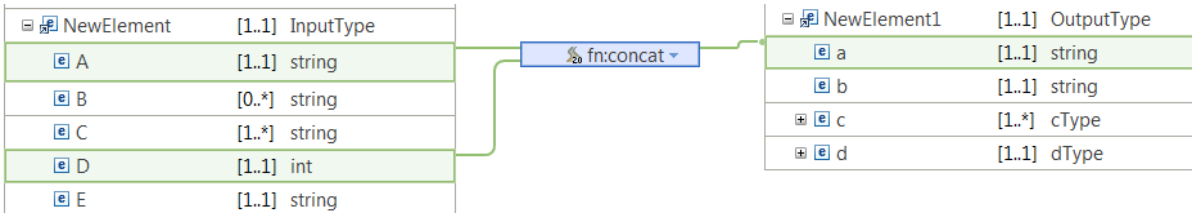
  The **Concat** transform concatenates two or more simple non-repeatable elements from the input into a single string value in the output. You can specify a constant to define a prefix, a suffix, and multiple delimiters.

  For more information, see "Concat" on page 1301.



- If your input elements are simple non-repeating elements, and you want to create an output element that is the result of concatenating these input elements by using an XPath expression with different delimiters, use the **fn:concat** transform. The delimiters are optional.

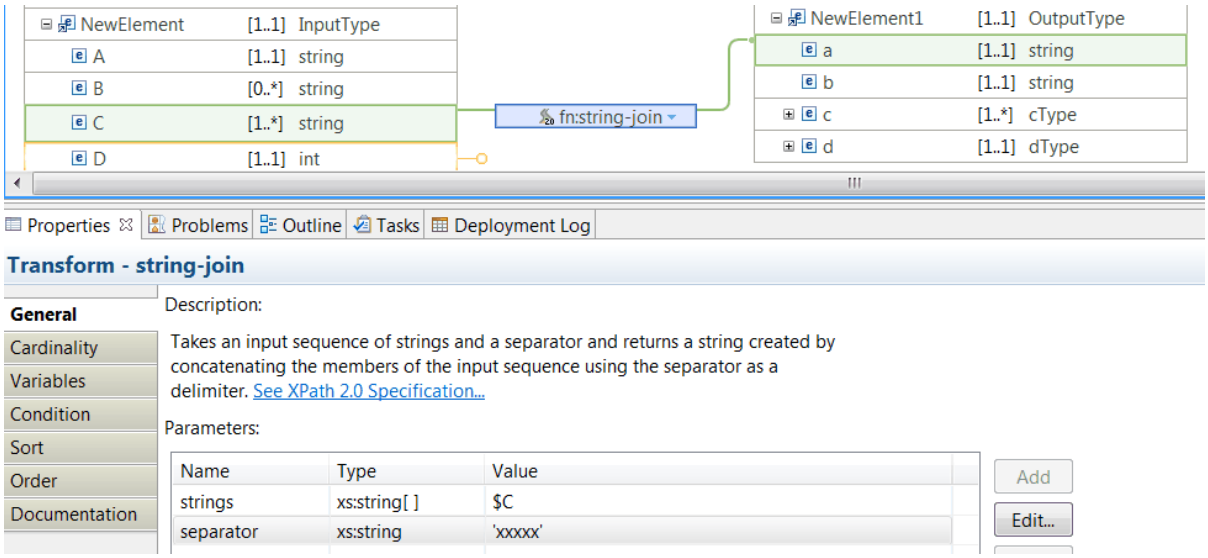
  For more information, see "fn:concat" on page 1345.



- If the input is a repeatable simple element, and you want to create an output element that is the result of concatenating the sequence of input elements with a delimiter as optional, use the **fn:string-join** transform.

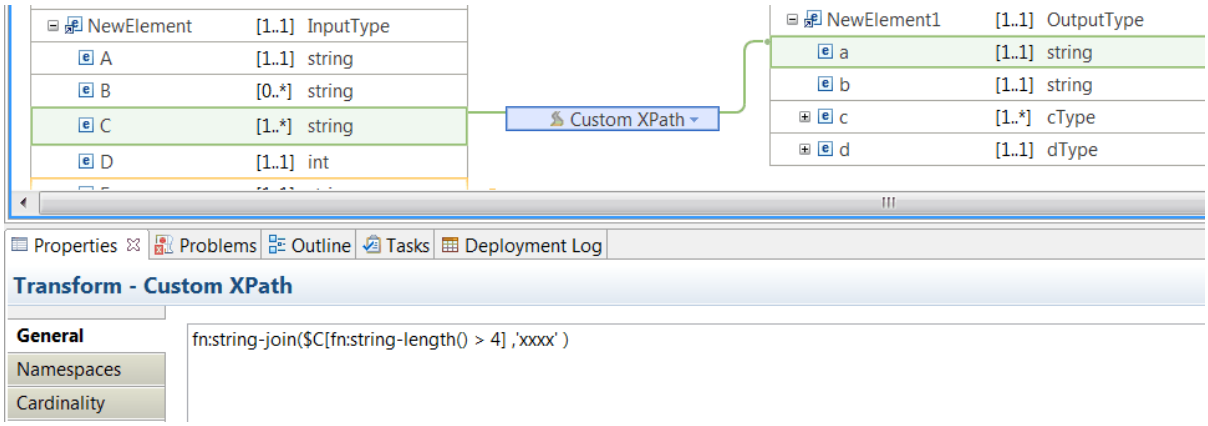
  For more information, see “fn:string-join” on page 1348.

  The following figure shows the **fn:string-join** transform:



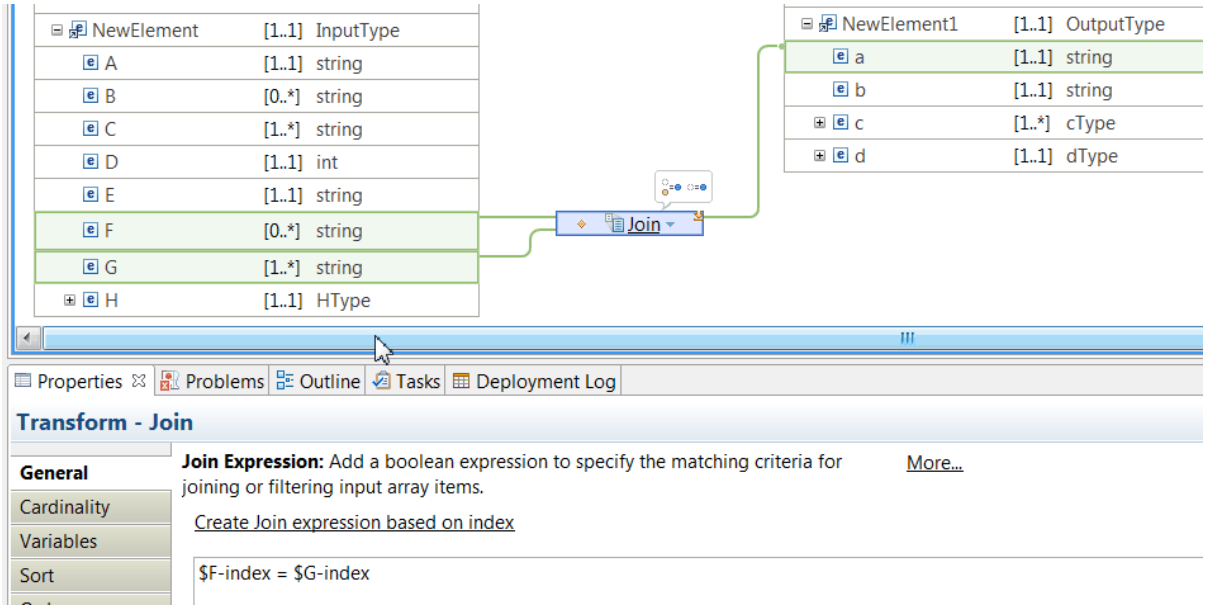
- Use the **Custom XPath** transform to define an XPath expression that concatenates multiple input elements into a simple output type.

  The following figure shows a **Custom XPath** transform that concatenates some input elements in the array into a string element:



- If you need to specify the matching criteria for joining or filtering input elements, use the **Join** transform. Then, define transforms between the input and output elements in the nested map associated to the **Join** transform.

  For more information, see "Join" on page 1332.



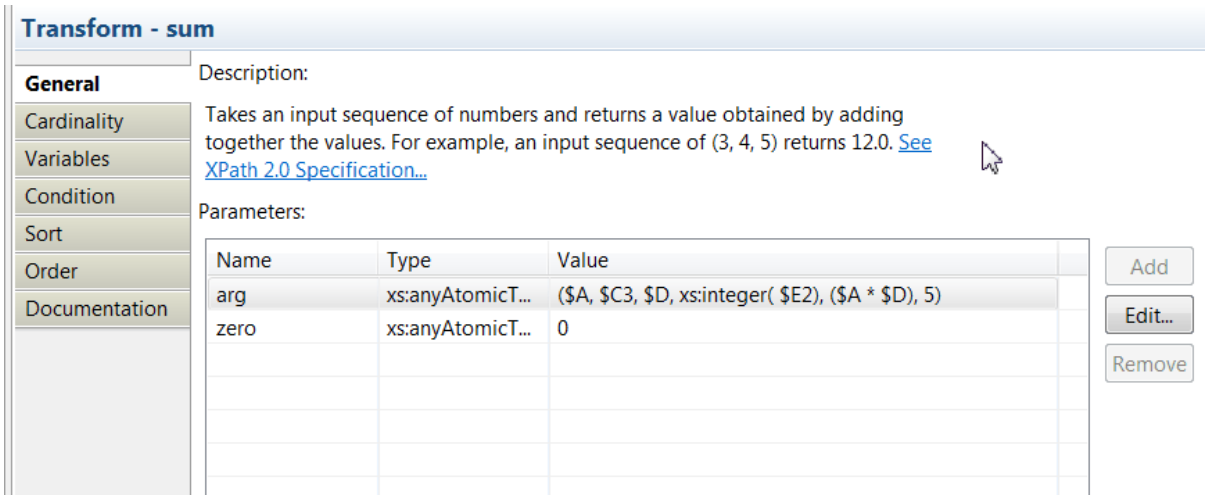
Choosing a transform to perform an arithmetic operation
In the Graphical Data Mapping editor, use the **fn:sum** or a **Custom XPath** transform to implement an arithmetic operation.

Procedure

Choose one of the following transforms to implement an arithmetic operation to set the value of an output element:

- Use the **fn:sum** transform to calculate the sum of the values of multiple input elements.

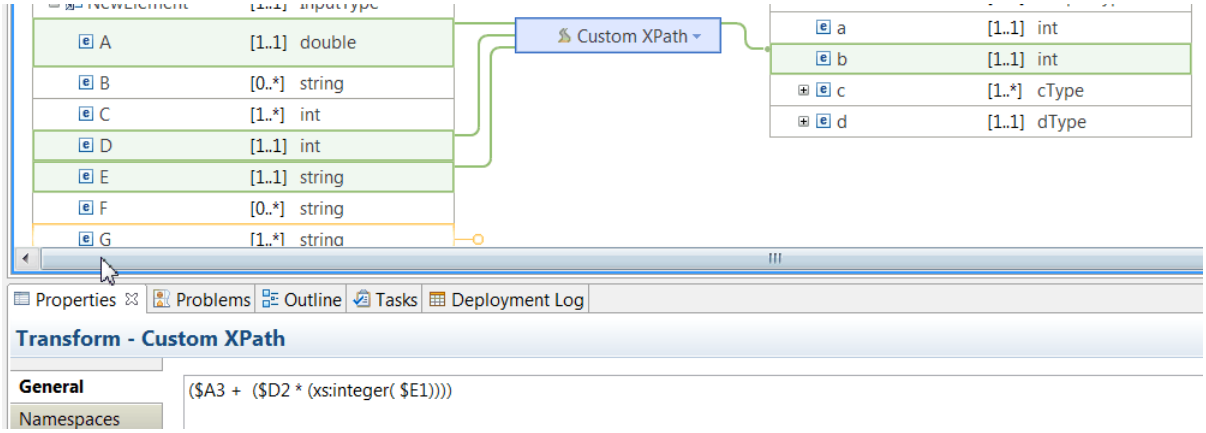
  For more information, see "fn:sum" on page 1356.



- Use the **Custom XPath** transform to implement any of the following arithmetic operations: addition (+), subtraction (-), multiplication (*), division (div), or any combination of these operations.

  Note: You can only use as arguments of an arithmetic operation non-repeating simple type input elements.

  For more information, see “Custom XPath” on page 1315.



Choosing a transform to define a conditional mapping
In the Graphical Data Mapping editor, you can define conditional transformations by using a transform or by defining a conditional expression in the transform.

Procedure

Choose any of the following options to configure a conditional mapping in your map:

1. Use the **If** transform, the **Else if** transform, and the **Else** transform to control the flow of the mapping.

   If, **Else if**, and **Else** operate as a group of conditional transforms. The condition is applied to the input element of the conditional transform. If the condition is satisfied, the nested transform within the conditional transform is run.
2. Use a **Custom Java** transform or a **Custom ESQL** transform to provide a condition function

   For more information, see “Custom Java” on page 1312 and “Custom ESQL” on page 1308.
3. Define a conditional expression in a transform to determine when the transform is applied bu configuring the **Condition** tab of the transform.

   For more information, see “Defining an XPath conditional expression for a transform” on page 1433 or “Defining a Java conditional expression for a transform” on page 1439.

   Note: If you use a condition to optionally create one or more child output elements within a complex element, check that the condition is on the transform targeting the whole complex element, not just a child. If the conditional transform only targets a child, the folder element within the complex element will be created in the output before the condition is evaluated.

What to do next

For more information about mapping transforms, see “Transform types in the Graphical Data Mapping editor” on page 1282.

Choosing a transform to map an input message to multiple output messages
You can create a map that takes a single input message and produces either multiple instances of an output message model, or one or more instances of different output message models.

About this task

When you create a map in the **New Message Map** wizard, you can only select a single input and a single output. However, you can use the **Add output** button in the Graphical Data Mapping editor to add additional outputs.

Note: You can only split an input message into multiple output messages in main maps. This is not valid in submaps.

Procedure

Choose any of the following options to split a message in your map:

- To produce multiple instances of a particular output message, you can use the **For Each** transform or the **Join** transform.

  A typical use of this function is message splitting, in which an input batch message is divided into individual record messages.

  When you run the map, a new message is propagated for each iteration of the **For Each** or **Join** transform.

  For more information, see "Splitting an input message into multiple output messages" on page 1503.
- To produce one or more instances of different output messages, you can use the **If/Else** transform.

  When you run the map, a new message is propagated for each conditional transform that is applied.

  For more information, see "Mapping an input message into different output messages" on page 1508.

Handling nulls in message maps
A message might contain fields that can carry a specific out-of-range value. This is distinct from the field being empty. Such values are termed *nil* or *null*, and the field is said to be *nillable* or *nullable*.

About this task

The logical message tree supports the concept of out-of-range values by using one of two techniques, depending on the data format:

1. For XML, the schema model allows for elements to be defined as nillable to indicate that they support an out-of-range `null` value. An XML element in a document is identified as being nilled, representing the null value, by having a **xsi:nil** attribute with the value **true**. The XMLNSC parser logical tree for a nilled element has an empty value and a child attribute set to **xsi:nil**, with the value **true**. For elements that are not defined as nillable, it is not possible to distinguish between having an empty value or the null value.
2. For other text and binary messages that are modeled with a DFDL schema or MRM message set, elements can also be defined as nillable to indicate that they support an out-of-range value. In the message bit stream, a reserved value is identified to indicate the nullable state. The DFDL and MRM parsers logical tree for a nilled element have the value set to the special value NULL.
3. For JSON messages, JSON objects and JSON arrays implicitly support the JSON null value to indicate that they support an out-of-range value. In JSON, data has a special value that is called `null` which can be set on any type of data including arrays, objects, number, and boolean types. In the Graphical Data Mapping editor, the JSON format supports null as a JSON value type for an object or an array. When a JSON message includes an object with a null value, the value in the message tree is set to NULL.

When you map nilled values, consider the behavior when you use the **Move** transform, **Custom Java**, or **Custom ESQL** to set a target.

The following table details the result when you map nilled values to different target types:

Source	Target (XML nillable)	Target (XML not nillable)	Target (Non-XML nillable)	Target (JSON object or JSON array)
Logical Message Tree XML nillable element	Target created as nilled, has xsi:nil attribute 'true', if source has xsi:nil attribute 'true'.	Target created with empty value.	Target created with NULL value, if source has xsi:nil attribute 'true'.	Target created with NULL value, if source has xsi:nil attribute 'true'.
Logical Message Tree XML element set to NULL	Target created with empty value. A Source XML having NULL value is not considered a nilled element.	Target created with empty value.	Target created with empty value. A Source XML having NULL value is not considered a nilled element.	Target created with NULL value.
Logical Message Tree non-XML	Target created as nilled. Target has xsi:nil attribute 'true', if source is NULL.	Target created with empty value.	Target created with NULL value, if source is NULL.	Target created with NULL value, if source is NULL.
Database nullable column	Target created as nilled. Target has xsi:nil attribute 'true', if source is SQL NULL.	Target created with empty value.	Target created with NULL value, if source is SQL NULL.	Target created with NULL value, if source is SQL NULL.
Custom ESQL	Target created as nilled. Target has xsi:nil attribute 'true', if return is ESQL NULL.	Target created with empty value.	Target created with NULL value, if return is ESQL NULL.	
Custom Java	Target created as nilled. Target has xsi:nil attribute 'true', if return is an MbElement with type set to "TYPE_UNKNOWN" and a value of "null" and a child element xsi:nil 'true'.	Target created with empty value.	Target created with value NULL, if return is an MbElement with type set to "TYPE_UNKNOWN" and a value of "null".	
Custom XPath expression: `iib:setNull()`	Target created as nilled. Target has xsi:nil attribute 'true', if source has xsi:nil attribute 'true'.	Target created with empty value.	Target created as nilled, has xsi:nil attribute 'true', if source has xsi:nil attribute 'true'.	Target created with JSON null value.

Accessing a user-defined policy from a graphical data map
Use the Graphical Data Mapping editor to access the properties of a user-defined policy in a static manner.

Before you begin

Complete the following tasks:

- Creating a message flow
- User Defined policy (UserDefined)

About this task

If you created a user-defined policy, and created properties for that policy, you can query those properties by using the MbPolicy.getPolicy call from a Custom Java transform in a message map.

Procedure

Complete the following steps to use Java in a Custom Java transform:

1. Create a Java class (for example, `MyPolicyAccessClass`) with the following static method:

   ```
   Static String getPolicyProperty(String policyProjectName, String propertyName)
   ```

2. Implement `getPolicyProperty` to look up the passed `policyProjectName` by using code such as in the following example.

   ```
   MbPolicy myPol = MbPolicy.getPolicy("UserDefined", policyProjectName);
   ```

3. Ensure that your method returns the value of the passed `propertyName` by using code such as in the following example.

   ```
   resultPropertyValue = myPol.getPropertyValueAsString(propertyName);
   ```

4. Create a message map.

   See “Creating message maps” on page 1378.

5. Add a Custom Java transform to the map.

   See “Mapping an element by using a Custom Java transform” on page 1496.

6. Set the following properties for the Custom Java transform.

   - Call the Java method `MyPolicyAccessClass.getPolicyProperty()`.
   - Set suitable values for the `policyProjectName` and `propertyName` parameters.

   You can map the returned `resultPropertyValue` from the output of the Custom Java transform.

Using Java in a message map
In the Graphical Data Mapping editor, you can use methods in a Java class to define a transformation, to define a conditional expression, or to change the value of an input parameter in another function.

About this task

The following guidelines apply when you use a Java class in a map:

- You can use static methods that return the appropriate type for the value of the output elements that they set.
- The values of the map input elements that are used as parameters of a static method must have the appropriate type.
- Do not define Java methods with data type overloading and then use the methods in a map. The map fails at run time with the following error: `IXJXE1039E: [ERR 0786] Multiple methods with the correct arity were found in the class '<class>' when attempting to`

```
evaluate a call to the Java extension function '{http://<class>;}<method>'
with arity of <N>.
```

- In a **Custom Java** transform, you can call Java methods that include **MbElement** data type arguments.
- When you define conditional expressions, you cannot use Java methods that include **MbElement** data type arguments.
- When you define conditional expressions, you can use Java methods that use the **DOM API**. For more information on the supported types, see "Custom Java" on page 1312.

Procedure

When you add a Java class to a map, you can use Java methods in any of the following situations:

- To use custom Java code in a Custom Java transform. For more information, see "Mapping an element by using a Custom Java transform" on page 1496 and "Processing complex or repeating elements in a Custom Java transform" on page 1498.
- To alter the value of an input argument to an XPath function.

  You alter the value in the **Properties** page of the XPath function. You can use content assist in the **Value** column that is available in the **General** tab to help you assign the elements of the source schema. For more information, see "Built-in XPath transforms" on page 1342
- To define a conditional expression. For more information, see "Defining a Java conditional expression for a transform" on page 1439.

  Note: To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a complex expression that includes XPath, Java, and any extension functions such as **iib:getUserDefinedProperty("propertyname")**.

What to do next

Deploy and test the message map. For more information, see "Troubleshooting a message map" on page 1587.

Using nested maps
You can edit some types of transforms, involving complex inputs and outputs, by entering a nested view in the Graphical Data Mapping editor.

About this task

Structural transforms control how nested elements are displayed in the Graphical Data Mapping editor. These transforms control the display of nested elements, but they do not affect the data. You can use In and Out arrow buttons and breadcrumb navigation for the nested transforms.

The following transforms can contain nested graphical data maps:

- Local map
- Join
- Append
- ForEach
- If, Else if, and Else
- Database Routine

The elements in a nested map must be mapped in order for the transform to run.

A **Local map** is a navigation aid that you use to view the map elements in a hierarchical way. A local map can have one primary input and multiple supplementary inputs, which can be either a simple type or a complex type. The output can be either a single element or an array element, but it must be a complex type. The local map does not transform data; you must specify transforms for the input and output elements in the nested map.

You can use the **Join** transform to join elements from two or more inputs. The inputs can be arrays or single elements, which can be merged using nested transforms to create a single output. The target element can be an array or single element but must be a complex type.

The **Append** transform iterates over multiple inputs in the specified order to append data. This transform takes multiple inputs of either simple or complex types. The output must be an array of either a simple type or a complex type.

The **For each** transform contains a nested map, and it iterates over one input array element (either a simple type or a complex type). The elements in the nested map must be mapped, otherwise the transform has no effect.

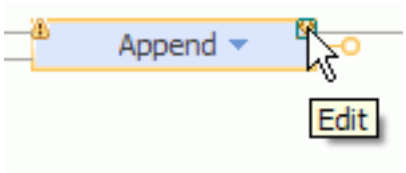
The **If**, **Else if**, and **Else** transforms enable you to control the flow of a mapping by setting conditions. If, Else if and Else operate as a group of conditional transforms, and the condition is applied to the input element of the conditional transform. If the condition is satisfied, the transform that is nested within the conditional transform is run.

The **Database Routine** transform contains a nested map to call a stored procedure or user-defined function from a database schema as input. Output from a **Database Routine** is optional, using the Return transform.

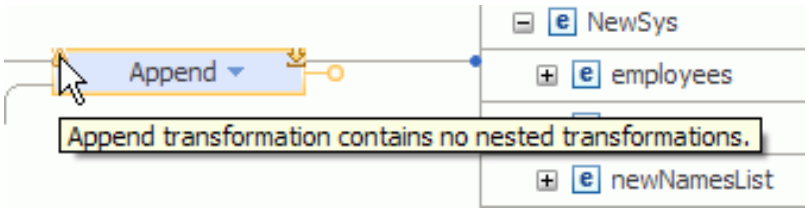
The following steps provide an example of how you can edit a nested map:

Procedure

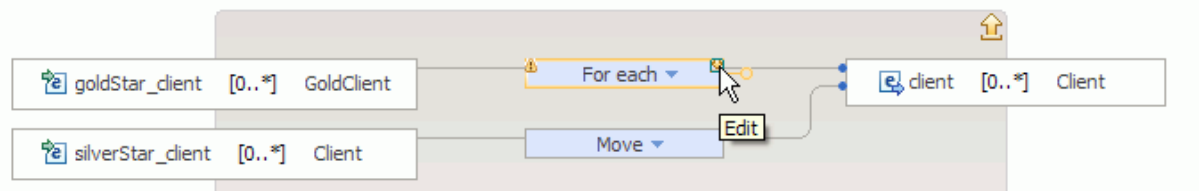
1. Some transforms, such as **Local map** and **Append**, contain nested maps. If a nested map exists, an **Edit** icon is shown on the transform. Click the **Edit** icon to edit the nested map.



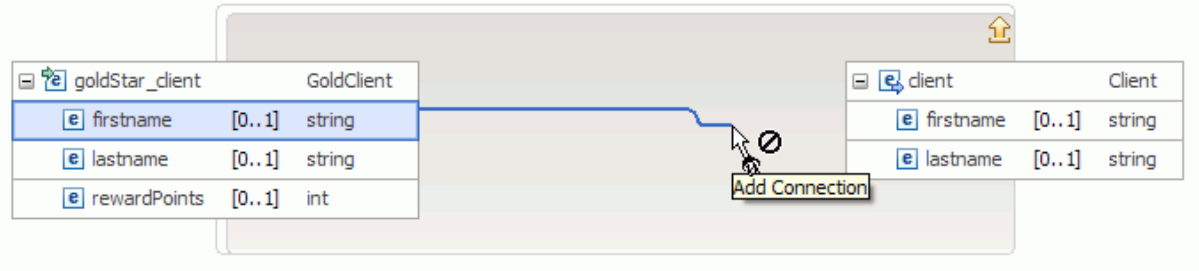
Nested maps must contain transforms, or else when the map is run, nothing happens. If a warning is displayed on the main map, you must edit the nested map.



2. When you open a nested map for some transforms such as **Append**, the nested map might also contain a nested map such as a **For each** transform:



In this case, you cannot create a mapping in the first nested map. Click **Edit** to go down another level and you can then create your mapping, as shown:



What to do next

For more information about mapping transforms, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Configuring your workspace mapping preferences

You can configure the Graphical Data Mapping editor preferences for mapping objects. You can also configure the keyboard commands that you can use when you develop message maps.

Procedure

Complete the following steps to configure your workspace:

- Optional: Configure the Graphical Data Mapping editor preferences for mapping objects. For more information, see "Setting mapping preferences for your workspace" on page 1373.

  You can set the options in the **Preferences** panel to specify the behavior of the Graphical Data Mapping editor and the mapping transforms in your workspace.
- Optional: Configure the keyboard mapping preferences in your workspace. For more information, see "Setting mapping keyboard preferences for your workspace" on page 1375.

  You can set your keyboard preferences in the Graphical Data Mapping editor by specifying your command choices in the workspace **Preferences** panel.

What to do next

Create a message map. For more information, see "Creating message maps" on page 1378.

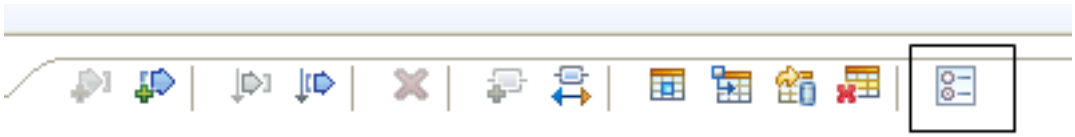
Setting mapping preferences for your workspace

You can set the options in the **Preferences** panel to specify the behavior of the Graphical Data Mapping editor and the mapping transforms in your workspace.

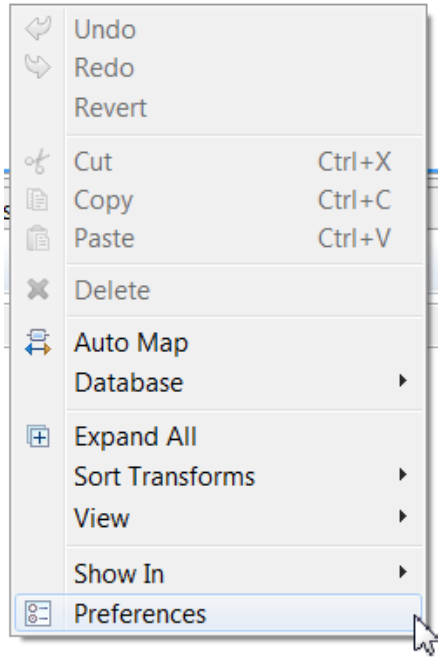
Procedure

Start the **Preferences** wizard by choosing one of the following options:

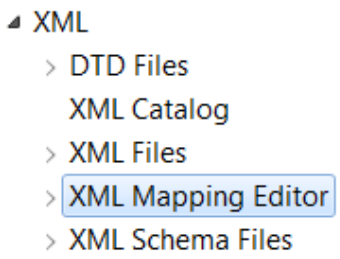
- Select the **Preferences** icon in the toolbar of the Graphical Data Mapping editor to set your preferences for the mapping.



- Right-click in the message map canvas and then select **Preferences** from the menu.

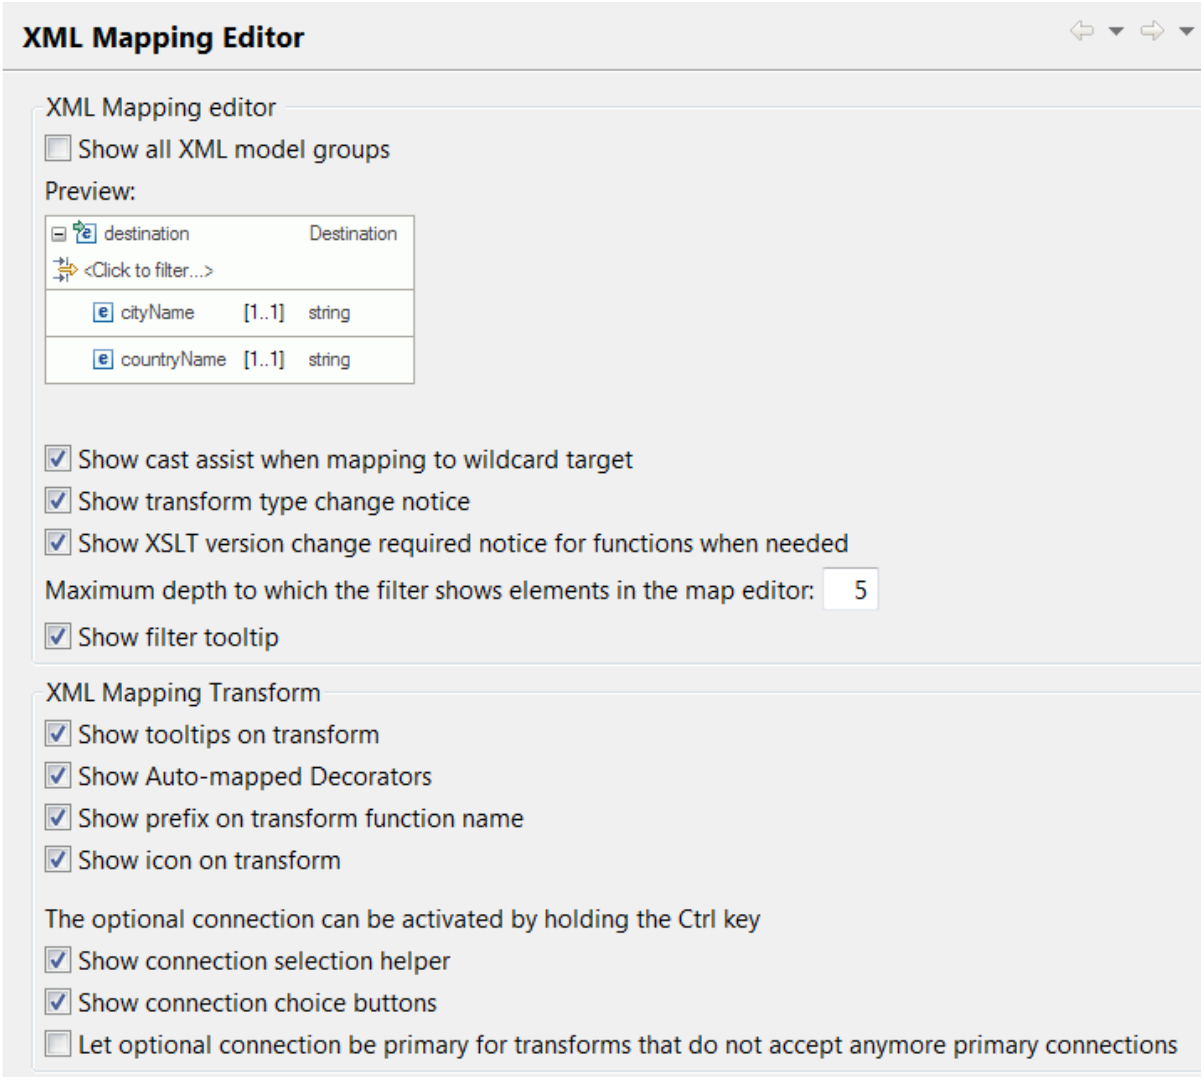


- Select **Window** > **Preferences** > **XML** > **XML Mapping Editor** in the main IBM App Connect Enterprise Toolkit menu.



Results

The **Preferences** wizard opens, and the **XML Mapping Editor** properties are displayed.



What to do next

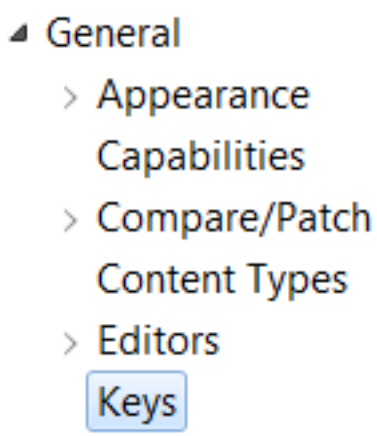
Create a message map. For more information, see “Creating message maps” on page 1378.

Setting mapping keyboard preferences for your workspace
You can set your keyboard preferences in the Graphical Data Mapping editor by specifying your choices in the workspace **Preferences** panel.

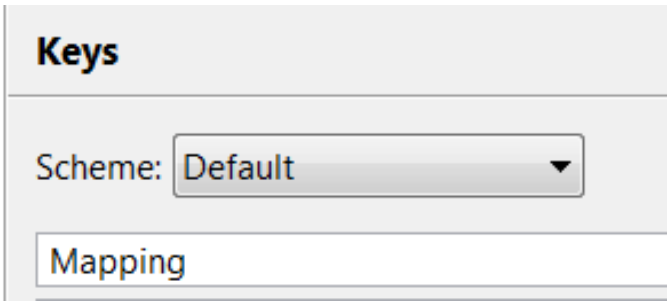
Procedure

Complete the following steps to change the default mapping keyboard commands, or to add new key combinations based on your usage specification:

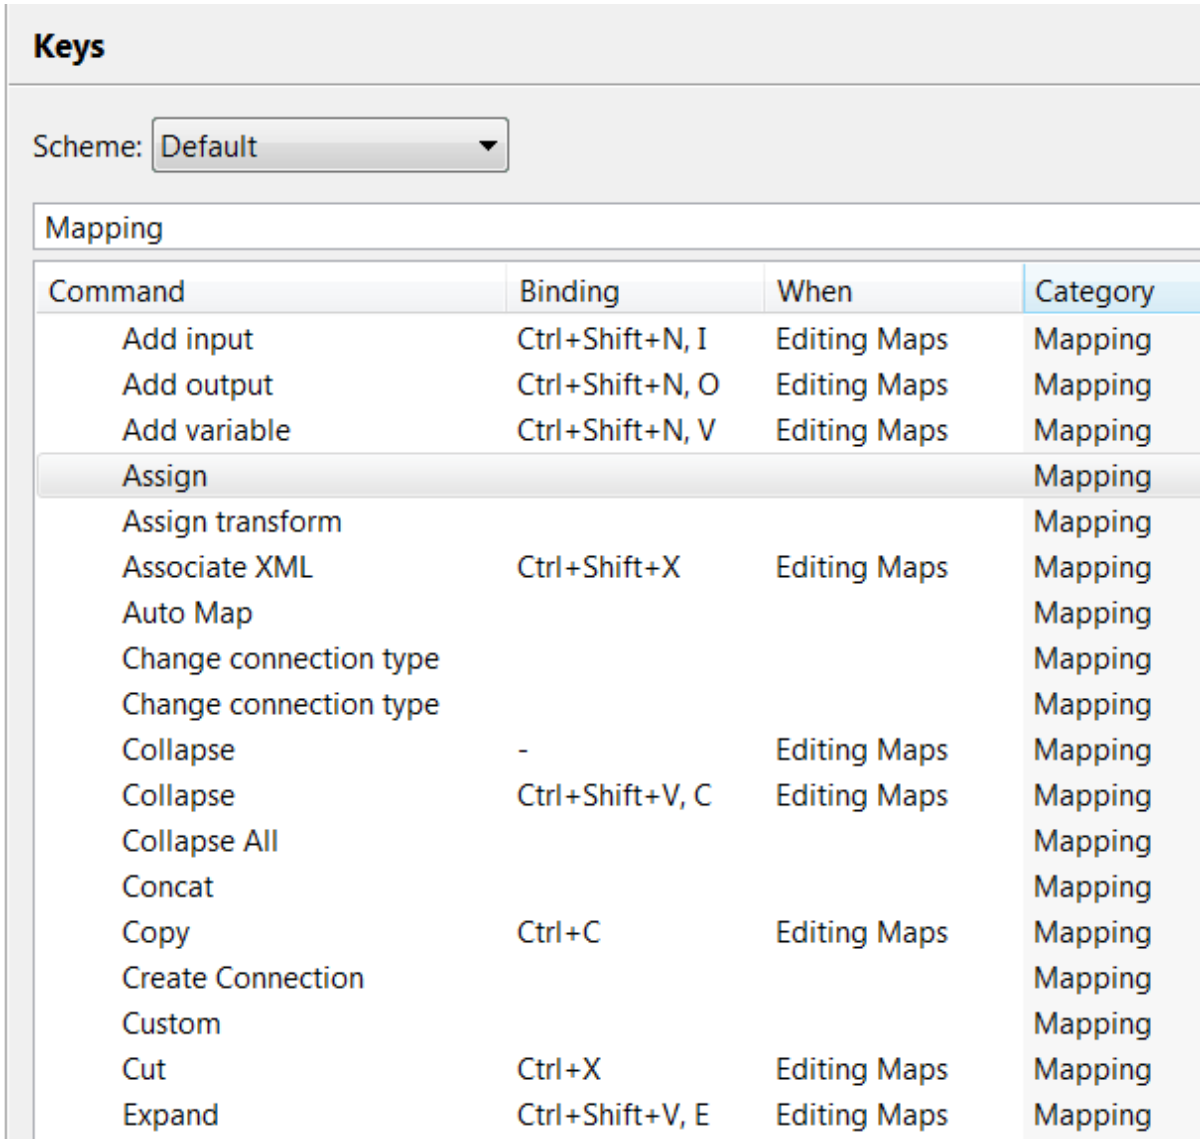
1. Select **Window** > **Preferences** > **General** > **Keys** in the main IBM App Connect Enterprise Toolkit menu.



2. Identify the entries that refer to mapping. Enter `Mapping` in the **type filter text** box.

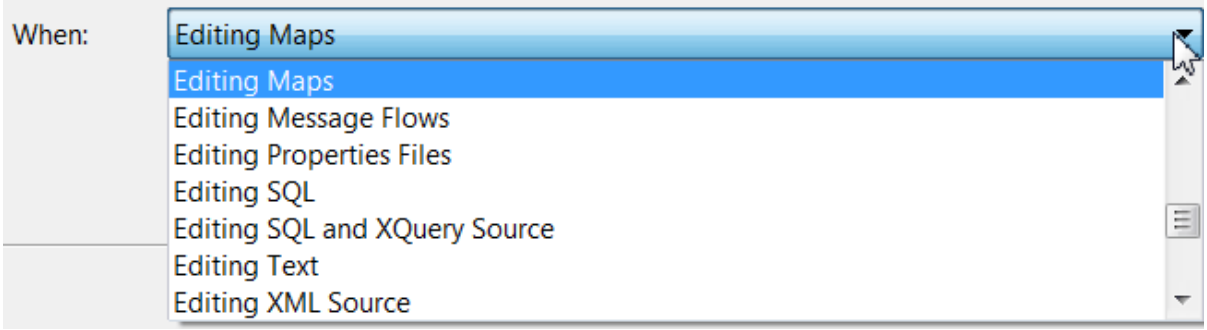


You can see the list of keys related to mapping.



3. Optional: Select a command, for example, **Assign**.

4. Optional: For each command, complete the following steps to define the key:
   a) Enter the key combination in **Binding**.
   b) Select `Editing Maps` in the field **When**.



Results

You have created a new key command for the **Assign** transform that you can use when you edit a message map in your workspace.

What to do next

Change or add new commands to specify key actions when using the Graphical Data Mapping editor.

Create a message map. For more information, see "Creating message maps" on page 1378.

Creating message maps

You can create a graphical data map, a message map, a submap, or a legacy message map to transform a message without the need to write code, providing a visual image of the transformation, and simplifying its implementation and ongoing maintenance.

About this task

A message map is the IBM App Connect Enterprise implementation of a graphical data map. It is based on XML schema and XPath 2.0 standards, with additional support for JSON schema draft 4 and Swagger 2.0. You can use a message map to graphically transform, route, and enrich a message, or implement a REST API. For more information, see "Implementing a REST API operation by using a message map" on page 1580. You can use a message map to modify data in a database system. You can use drag actions to make connections, select transforms, and build logic to transform your message data without programming.

A *submap* is a reusable form of graphical data map. Submaps enable you to use a set of mapping functions in multiple graphical data maps to transform a common set of elements in the input object to the output object. You can use a submap to reuse common data transformations. You can reuse submaps in other products that support graphical data maps.

Note: If you plan to reuse data transformations across different products, read "Guidelines for developing reusable graphical data mapping assets" on page 1273.

A *local map* is a subset of data transformations between input elements and output elements that are part of a graphical data map. You define a local map by creating a **Local map** transform in a message map. A local map is not an independent resource. There is no physical file associated with a local map. The scope of a local map is the message map. A local map is processed with the graphical data map. Local maps provide a way of breaking up a large graphical data map into nested groups of mapping elements. You can use local maps to simplify the overall graphical data map presentation. You can structure complex data transformations into nested groups that are easier to manage and implement.

A legacy message map is a message map that was created as a `.msgmap` file in earlier versions of WebSphere Message Broker (for example, in WebSphere Message Broker Version 7). In IBM App Connect Enterprise, you must convert your legacy message maps to `.map` files before you can deploy or modify

them. For more information, see “Using or converting legacy resources into message maps” on page 1588.

Procedure

Choose any of the following options to create a graphical data map:

- Create a message map to transform your messages graphically. For more information, see “Creating a message map” on page 1382.

  Use this type of map to create a graphical data map in IBM App Connect Enterprise. You can transform message assembly components, body data, and access a database to retrieve data or modify data, if needed.
- Create a graphical data map to share a map across different products that support the Graphical Data Mapping editor. For more information, see “Creating a graphical data map in the Eclipse editor” on page 1393.

  Use this type of map to create a graphical data map that you can use as a submap in IBM App Connect Enterprise, or that you can use as a main map in other products that support the Graphical Data Mapping editor. You can only transform the body of a message. You cannot access a database when you use this type of map to enrich a message or to modify database content.
- Create a submap to reuse common transformation logic. For more information, see “Creating a submap” on page 1386.

  Use this type of map to create a graphical data map that you can use as a submap in IBM App Connect Enterprise. You can only transform the body of a message. You can access a database to enrich a message or to modify database content.
- Create a local map to reduce complexity reading and managing graphical data maps. For more information, see “Creating a local map by using the Local map transform” on page 1391.

  Use this type of map to reduce the complexity of your maps and submaps. This type of map is local, and you cannot reuse it, unless you convert it to a submap.

Results

You can use the following table to identify the type of map that you must create when transforming data graphically in the Graphical Data Mapping editor:

Table 56. Types of map based on design requirements

	Recommended use	Type of resource	Supported in IBM App Connect Enterprise
Message map	Transform messages graphically	`.map` file	Yes
Submap	Reuse of common data transformations	`.map` file	Yes
Local map	Reduce complexity reading and managing a Message map	No file. It is embedded within a Message map	Yes
Graphical data map	Share graphical data maps across different software products	`.map` file	Yes

Table 56. Types of map based on design requirements (continued)			
	Recommended use	**Type of resource**	**Supported in IBM App Connect Enterprise**
Legacy message map	Solutions migrated from earlier versions of WebSphere Message Broker	`.msgmap` file	These files must be converted into `.map` files before they can be used in IBM App Connect Enterprise. (See note below.)

Note: Legacy message maps must be converted into `.map` message map format before they can be deployed or modified by IBM App Connect Enterprise.

You can see the message map in the **Application Development** view displayed under a **Maps** category, and organized by namespace.

What to do next

After you create a graphical data map, edit the map, and define transformations between the input message and the output message. For more information, see "Editing message maps" on page 1394.

Choosing the project structure when you create a message map
In IBM App Connect Enterprise, you can create a message map in an application project, a static library project, a shared library project, or an integration project.

About this task

You can use any of the following types of resources in a message map:

- XML schema models
- DFDL data models
- User-defined models
- ESQL routines
- Java code
- Submaps
- JSON schema files
- REST API swagger document

Many of these resources can be defined in the same project as the map or in a different one; however, for JSON schema and REST API swagger documents, the map must be in the same project container. When a resource is defined in a different project to the map, the project where the map is defined must reference it.

XML schema models and DFDL data models

When you define your message model by using a global XML schema or a DFDL model, consider the following rules:

- You can have the map and any schema definitions that are used in the map in the same project. The project can be a static library project, a shared library project, or an application project.
- You can have any schema definition that is used in the map in a static library project and the map in an application project.
- You can have any schema definition that is used in the map in a shared library project and the map in a different shared library project.

  Note: The XML schema files that are defined in the application project cannot access XML schema files that are defined in a shared library.

- You can have any schema definition that is used in the map in a shared library and the map in an application project.
- You can have any schema definition that is used in the map in a static library project and the map in an integration project.

User-defined models

When you use user-defined elements in your message model and you define these elements by using a global XML schema, consider the following rules:

- You can have the map and any schema definitions that are used in the map in the same project. The project can be a static library project, a shared library project, or an application project.
- You can have any schema definition that is used in the map in a static library project and the map in an application project.
- You can have any schema definition that is used in the map in a shared library project and the map in a different shared library project.
- You cannot have the schema definitions that are used in the map in a shared library and the map in an application project. The Graphical Data Mapping editor reports error **CWMSL209E** if you break this rule.
- You can have any schema definition that is used in the map in a static library project and the map in an integration project.

Submaps

When you use **submaps** in a message map, consider the following rules:

- You can have the map and submap in the same project. The project can be a static library project, a shared library project, or an application project.
- You can have a submap that is used in the map in a static library project and the map in an application project.
- You cannot have a submap that is used in the map in a shared library and the map in an application project. The Graphical Data Mapping editor reports error **CWMSL209E** if you break this rule.
- You can have a submap that is used in the map in a static library project and the map in an integration project.

Java code

When you define transformations in your map that use Java code, you can define a map in a static library project, a shared library project, an application project, or an integration project. You can define the Java code in one or more Java projects. Your map project must reference these Java projects.

Note: When the map uses Java code available in a shared library, you must create the map in the shared library project where the Java code is available.

ESQL routines

When you define transformations in your map that use ESQL code, consider the following rules:

- You can have the map and the ESQL code that is used in the map in the same project. The project can be a static library project, a shared library project, an application project, or an integration project.
- You can have the ESQL code in a static library project and the map in an application project, that references this static library.
- You can have the ESQL code in a shared library project and the map in a different shared library project that has a reference to it.

  Note:

  – When you store ESQL files in a shared library, you must place the ESQL files inside a schema that is not the default empty schema.

  – Each shared library can have one or more ESQL files in one or more ESQL schemas.

  – The schema in a shared library must be unique:

  - An application or a shared library cannot reference two shared libraries that have ESQL in the same schema.
  - An application with ESQL in schema A cannot reference a shared library with any ESQL in schema A.
- You can have the ESQL code in a static library project and the map in an integration project.

JSON schema and REST API Swagger models

When you define your message model by using JSON schema or REST API Swagger models, ensure that you are aware of the requirements specified in "JSON schema requirements for message maps" on page 1549.

Procedure

Choose one of the following project structures based on the resources that are used in the map if you want to update a map without redeploying your application:

- If the map includes XML schemas, DFDL models, or both, create the map and associated resources in one or more shared libraries. Reference the shared library project that contains the map from the application project.
- If the map includes XML schemas, DFDL models, and user-defined elements, create the map and the user-defined elements in the same shared library project. You can use the same or different shared library projects for the other resources. Reference the shared library project that contains the map from the application project.
- If the map includes XML schemas, DFDL models, and transformations that use ESQL code, create the map and the ESQL files in shared library projects. You can use the same or different shared library projects for the other resources. You must define the ESQL files within a schema. The schema names that are used by all the projects that contain ESQL files must be unique. Reference the shared library project that contains the map from the application project.
- If the map includes XML schemas, DFDL models, and transformations that use Java code, create the map in the shared library project where the Java code is available. Reference the Java project from the shared library project.
- If you want to map between different versions of an XML schema, where both versions might declare the same elements and types and cannot coexist in one application, you can build one shared library that contains version 1 of an XML schema file, and another shared library that contains version 2. You can then build a map that references the XML schema files in the shared libraries and maps between the two versions. At deployment time, separate models are built for each of the shared libraries. Therefore, no clash results from the duplicated elements and types.
- If the map includes JSON schema, create the map and JSON schema in a single shared library. Reference the shared library project that contains the map from the application project that contains the mapping node.
- If the map includes REST API, and optionally JSON schema (or both), create the map and JSON schema in the REST API project.

Creating a message map

You can create message maps either in the **Application Development** view of the IBM App Connect Enterprise Toolkit, or from a Mapping node in a message flow.

Before you begin

Before you create a message map, you must complete the following tasks:

1. Create an application, a library, an integration service, or an Integration project, as described in the following topics:
   - Creating an application
   - Creating a library
   - Creating an integration project
   - Creating a REST API. For information about the steps involved in completing this task, see “Implementing a REST API operation by using a message map” on page 1580 .
2. Create a message flow. For more information, see Creating a message flow.
3. Define the message flow content that includes a Mapping node. For more information, see Defining message flow content.

About this task

A message map is a graphical data map.

The physical representation of a message map is a `.map` file.

Procedure

You can use any of the following methods to start the New Message Map wizard and then create a message map:

- Create a message map in the **Application Development** view. For more information, see “Creating a message map in the Application Development view” on page 1383.
- Create a message map from a Mapping node in a message flow. For more information, see “Creating a message map from a Mapping node” on page 1385.

Results

A message map is created as a `.map` file.

In the **Application Development** view, the message map is displayed under a **Maps** category. Maps are organized by namespace.

What to do next

Edit the message map, and define transformations between the input message assembly and the output message assembly. For more information, see “Mapping input to output elements manually” on page 1418.

*Creating a message map in the **Application Development** view*
You can create a message map for use in your message flows in the **Application Development** view with messages as input and output objects. Data from database tables can also be used as input to the message map.

Before you begin

Before you create a message map, you must complete the following tasks:

1. Create an application, a library, an integration service, or an Integration project, as described in the following topics:
   - Creating an application
   - Creating a library
   - Creating an integration project
   - Creating a REST API. For information about the steps involved in completing this task, see “Implementing a REST API operation by using a message map” on page 1580 .

2. Create a message flow. For more information, see "Creating a message flow" on page 574.
3. Define the message flow content that includes a Mapping node. For more information, see "Defining message flow content" on page 614.

Procedure

To create a message map in the **Application Development** view, complete the following steps:

1. Choose one of the following options to start the New Message Map wizard:
   - In the IBM App Connect Enterprise Toolkit, click **File** > **New** > **Message Map**.
   - In the **Application Development** view, right-click the application, library, integration service, or Integration project where you want to create the message map. Then, click **New** > **Message Map**.

   The New Message Map wizard opens.
2. On the **Specify a new message map file** pane, select **Message map called by a message flow**.

   A message map is created that can be accessed from a Mapping node. A message map can contain components of a message body such as global elements and global types. A message map contains Properties, message headers, or the local environment.
3. Specify the **Container**, **Map name**, and broker schema for the message map. Click **Next**.

   If your message map is likely to be used by multiple solutions, store it in a shared library.
4. On the **Select map inputs and outputs** pane, select your input type:
   - If you want to use an XML, DFDL, or JSON schema-defined element, expand the list of available input objects, and select the input objects that you want to use as inputs to the message map.

     If necessary, use the **Filter map input names** field to filter what is shown in the list of available objects. Each object in the list is displayed in the form: `objectname {namespace}`.
   - If you want to use SOAP, JSON, or BLOB messages as input, expand **IBM supplied message models**, and select the message model type.
5. Select your mapping output type:
   - If you want to use an XML, DFDL, or JSON schema-defined element, expand the list of available output objects, and select the output objects that you want to use as outputs for the message map.

     If necessary, use the **Filter map output names** field to filter what is shown in the list of available objects. Each object in the list is displayed in the form: `objectname {namespace}`.
   - If you want to use SOAP, JSON, or BLOB messages as input, expand **IBM supplied message models**, and select the message model type.
6. Optional: If you are creating a **Message map called by a message flow node**, click **Next** to specify the **Output domain** for the message map.
7. Click **Finish** to create the message map.

Results

The new message map is created, and the Graphical Data Mapping editor opens with the selected sources and targets.

The message map is created as a `.map` file.

In the **Application Development** view, the message map is displayed under a **Maps** category. Maps are organized by namespace.

What to do next

Edit the message map, and define transformations between the input message assembly and the output message assembly. For more information, see "Editing message maps" on page 1394.

Creating a message map from a Mapping node
You can use a Mapping node to create a message map with messages as input and output objects. Data from database tables can also be used as input to the message map.

Before you begin

Before you create a message map, you must complete the following tasks:

1. Create an application, a library, an integration service, or an Integration project, as described in the following topics:
   - Creating an application
   - Creating a library
   - Creating an integration project
   - Creating a REST API. For information about the steps involved in completing this task, see "Implementing a REST API operation by using a message map" on page 1580 .
2. Create a message flow. For more information, see Creating a message flow.
3. Define the message flow content that includes a Mapping node. For more information, see Defining message flow content.

Procedure

To create a graphical data mapping (`.map`) file from a Mapping node:

1. In the Integration Development perspective, open your message flow.
2. Double-click a Mapping node that does not have a message map associated with it, or right-click the Mapping node and click **Open Map**.

   The New Message Map wizard opens.
3. On the **Specify a new message map file** pane, the type of message map that you want to create is selected as **Message map called by a message flow node**. This is a message map that can be accessed from a node.
4. Specify the **Container**, **Map name**, and **broker schema** for the message map, or use the values that have been entered for you by the wizard. Click **Next**.

   If your message map is likely to be used by multiple solutions, store it in a shared library. If you are using a JSON schema model, the container must be the shared library in which your JSON schema files are stored.
5. On the **Select map inputs and outputs** pane, select your input type:
   - If you want to use a DFDL, XML, or JSON schema-defined element, expand the list of available input objects, and select the input objects that you want to use as inputs to the message map.

     If necessary, use the **Filter map input names** field to filter what is shown in the list of available objects. Each object in the list is displayed in the form: `objectname {namespace}`.
   - If you want to use SOAP, BLOB, or JSON messages as input (and you have no JSON schema), expand **IBM supplied message models**, and select the message model type.
6. Select your mapping output type:
   - If you want to use a DFDL, XML, or JSON schema-defined element, expand the list of available output objects, and select the output objects that you want to use as outputs for the message map.

     If necessary, use the **Filter map output names** field to filter what is shown in the list of available objects. Each object in the list is displayed in the form: `objectname {namespace}`.
   - If you want to use SOAP, BLOB, or JSON messages as input, (and you have no JSON schema), expand **IBM supplied message models**, and select the message model type.
7. Optional: On the **Select the domain to create the output** pane, specify the **Output domain** for the message map (if it is not the same as the output type selected in step "6" on page 1385).
8. Click **Finish** to create the message map.

Results

The new message map is created, and the Graphical Data Mapping editor opens with the selected inputs and outputs.

A message map is created as a `.map` file.

In the **Application Development** view, the message map is displayed under a **Maps** category. Maps are organized by namespace.

What to do next

Edit the message map, and define transformations between the input message assembly and the output message assembly. For more information, see "Editing message maps" on page 1394.

Creating a submap
You can create a submap from scratch or after you define a **Submap** transform between an input object and an output object in a message map. You can also convert a local map into a submap.

About this task

You can use a submap to reuse common data transformations between input objects and output objects.

Procedure

Choose one of the following methods to create a submap:

- Create a submap from scratch.

  Use this method to create a common transformation between an input object and an output object.

  For more information, see "Creating a submap in the Application Development view" on page 1386.
- Create a submap by using the Graphical Data Mapping editor. For more information, see "Creating a submap by using the Submap transform" on page 1387.

  Use this method when you have a message map where you have identified a common transformation between an input object and an output object.
- Create a submap by converting a local map to a submap. For more information, see "Converting a local map into a submap" on page 1388.

  Use this method when you have a local map defined in your message map that you have identified as a common transformation between an input object and an output object.

What to do next

Edit the submap and define the transformation logic between the input and output elements in the submap. For more information, see "Specifying a transform (mapping operation)" on page 1430.

*Creating a submap in the **Application Development** view*
You can create a submap for use in your message flows in the **Application Development** view with messages as input and output objects. Data from database tables can also be used as input to the message map.

About this task

A submap enables you to use the same piece of mapping function in multiple message maps.

Procedure

Complete the following steps to create a submap in the **Application Development** view:

1. Choose one of the following options to start the New Message Map wizard:
   - In the IBM App Connect Enterprise Toolkit, click **File** > **New** > **Message Map**.
   - In the **Application Development** view, right-click the application, library, integration service, or Integration project where you want to create the message map. Then, click **New** > **Message Map**.

   The New Message Map wizard opens.
2. On the **Specify a new message map file** pane, select **Submap called by another map**.

   A submap is created that can be referenced from another message map. A submap can contain components of a message body such as global elements and global types. A submap does not contain Properties, message headers, or the local environment.
3. Specify the **Container**, **Map name**, and broker schema for the submap. Click **Next**.
4. On the **Select map inputs and outputs** pane, expand the list of available input objects, and select the input objects that you want to use as input to the submap.

   If necessary, use the **Filter map input names** field to filter what is shown in the list of available objects. Each object in the list is displayed in the form: `objectname {namespace}`.
5. Expand the list of available output objects, and select the output object that you want to use as output for the submap.

   If necessary, use the **Filter map output names** field to filter what is shown in the list of available objects. Each object in the list is displayed in the form: `objectname {namespace}`.
6. Click **Finish** to create the submap.

Results

The submap is created, and the Graphical Data Mapping editor opens with the selected sources and targets.

The submap is created as a `.map` file.

You can see the submap in the **Application Development** view displayed under a **Maps** category, and organized by namespace.

What to do next

Edit the submap, and define transformations between the input message assembly and the output message assembly. For more information, see “Editing message maps” on page 1394.

*Creating a submap by using the **Submap** transform*
Create a submap by using the Graphical Data Mapping editor. Create a submap by defining a **Submap** transform between an input object and an output object in a message map.

About this task

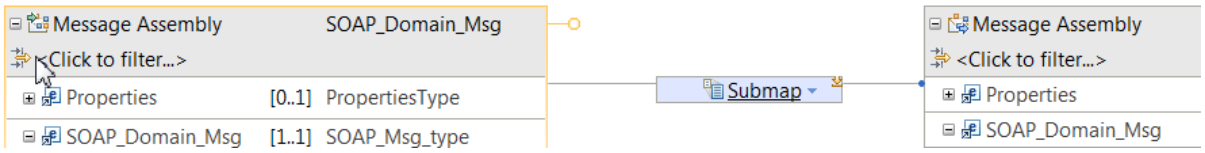
A submap enables you to use the same piece of mapping function in multiple message maps.

Procedure

Complete the following steps to create a submap:

1. Create a connection between global input and output elements in a message map, and then select the **Submap** transform on the connection:

   For example:



2. In the Properties view of the Submap transform, create a submap to use an existing submap:
   - To create a submap, click **New**. The New Message Map wizard opens.
   - Use an existing submap. Click **Browse**. A dialogue box will display the submaps that are available. Then, select a submap and click **OK**.
3. On the **Specify a new message map file** pane, the type of map that you want to create is selected as **Submap called by another map**. This is a message map that can be referenced from another message map. This is known as a submap and can contain components of a message body such as global elements and global types. A submap does not contain Properties, message headers, or the local environment tree. Click **Next**.
4. On the **Select map inputs and outputs** pane, the input and output objects of the submap have been pre-selected.
5. Click **Finish**.

   The new submap is displayed in the Graphical Data Mapping editor, and you can edit it in the same way that you would edit any graphical data map. For information about how to edit maps, see "Editing message maps" on page 1394.

Results

The new submap is displayed in the Graphical Data Mapping editor.

What to do next

Edit the submap. For more information, see "Editing message maps" on page 1394.

Converting a local map into a submap
Use the Graphical Data Mapping editor to convert a local map into a submap by using the **Refactor to submap** function.

About this task

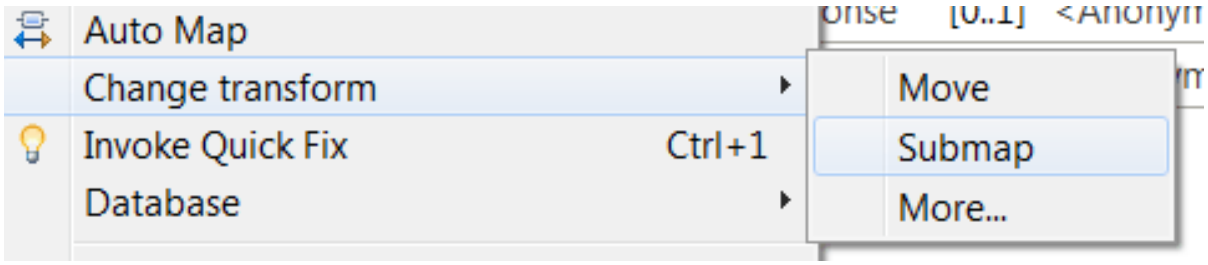
You can convert a local map into a submap so that the transformation logic can be reused by other graphical data maps.

To convert a local map into a submap, the following conditions must be true:

- The input and output elements to the local map must be global elements.
- There must be at least one transform configured in the local map.

If you want to convert a local map to an existing submap, you cannot use the **Refactor to submap** function. You must change the transform from a **Local map** transform to a **Submap** transform.

Note: If you have global elements defined as input and output objects to the local map, and you have not defined any transformations between the input and output objects, you cannot convert a local map into a submap. To create the submap, you can change the **Local map** transform for the **Submap** transform. The following figure shows the menu option that you can use to create a submap instead of a local map:



Procedure

To convert a local map into a submap, complete the following steps:

1. Right-click the **Local Map** transform in the graphical data map, and then select **Refactor to submap**.

   The following figure shows the menu that opens when you right-click the **Local map**

   transform:

   The New Message Map wizard opens.

2. On the **Specify a new message map file** pane, the type of map that you want to create is selected as **Submap called by another map**. This is a message map that can be referenced from another message map. This is known as a submap and can contain components of a message body such as global elements and global types. A submap does not contain Properties, message headers, or the LocalEnvironment. Click **Next**.
3. On the **Select map inputs and outputs** pane, the input and output objects of the submap have been pre-selected.
4. Click **Finish**.

   The new submap is displayed in the Graphical Data Mapping editor, and you can edit it in the same way that you would edit any graphical data map. For information about how to edit maps, see "Editing message maps" on page 1394.

Results

A submap is created, containing all the mappings from the local map.

What to do next

Edit the submap. For more information, see “Editing message maps” on page 1394.

Creating a message map programmatically
Use the Graphical Data Map Specification Language to create a message map programmatically.

About this task

The file `msl.xsd` provides the XML schema that describes the *Graphical Data Map Specification Language*, also known as **MSL**. This file is available in the Graphical Data Mapping component Version 1040, and later versions.

You can find the `msl.xsd` file inside the `com.ibm.msl.mapping.api_7.5.0.jar` jar file.

In IBM App Connect Enterprise, you can find the jar file in any of the following directories:

- In a Windows platform installation: `C:\Program Files\IBM\IIB\10.0.0.0\server\ct\lib\`
- In a Linux platform installation: *`install_dir`*`/iib-10.0.0.0/server/ct/lib/`

You can create a map programmatically when you have meta-data that defines the transformation logic that needs to be applied to an input message to produce the output. For example, you can write a JAXB based program that builds the map using JAXB classes generated from the provided MSL schema. The program reads XML data that defines the input elements to be mapped and the output elements.

Procedure

You must perform the following steps to programmatically generate a map file:

1. Create a template map in the Graphical Data Mapping editor.

   Deploy and test your template map in the run time to confirm that the message transformation is correct.
2. Inspect the MSL XML content in the template map.

   Use the MSL schema to identify the mapping constructs and the definition of the points of variation for the template map.
3. Develop the scripts and programs to generate the MSL XML for the new maps that you plan to generate programmatically.

   When you use a development approach based on JAXB, the bindings file `msl_jaxb_bindings.xml` available in the `com.ibm.msl.mapping.api_7.5.0.jar` file provides the minimal required bindings.
4. Validate the syntax of each generated map file (`.map`) against the provided MSL schema `msl.xsd`.
5. Import each generated map file into your development environment. Then, check that all the referenced resources, such as `xsd` files, are imported into the relevant project types. Ensure the relevant builder is invoked to semantically validate each generated map file. Also, check using the Graphical Data Mapping editor that the transforms in your generated map are correct and free of error and warnings.
6. Package and deploy into the run time your programmatically generated maps. Then, test your application to confirm that the message transformation is correct.

   Check that each generated map file is built into the relevant deployment artifact.

What to do next

Deploy and test the message map. For more information, see “Troubleshooting a message map” on page 1587.

*Creating a local map by using the **Local map** transform*
Create a local map by using the Graphical Data Mapping editor. Create a local map by defining a **Local map** transform between an input object and an output object in a message map.

About this task

You can use a local map to break up a large map into nested groups of mapping elements and process the complex elements of the whole data object.

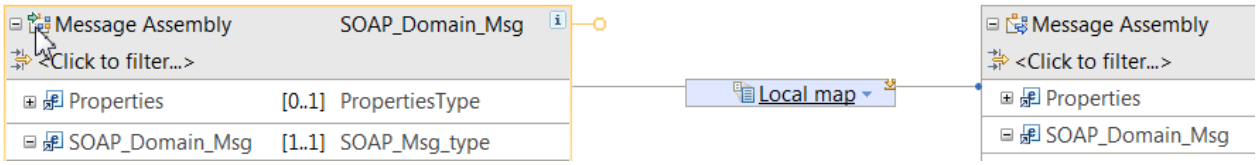
Local maps are a partial view of a larger map, rather than separate files.

A local map has only one element as input (either a simple type or a complex type), which can contain nested elements. The output can be either a single element or an array element, but it must be a complex type.

Procedure

Create a connection between one input element and one output element in a message map, and then select the **Local map** transform on the connection:

For example:



Results

The local map opens within the main map in the Graphical Data Mapping editor.

What to do next

Edit the local map. For more information, see “Editing message maps” on page 1394.

Converting a submap into a local map
You can use the Graphical Data Mapping editor to change a submap into a local map by using the **Refactor from submap** function.

About this task

You can customize the logic of a submap in a graphical data map, without altering the submap logic, by converting the submap into a local map.

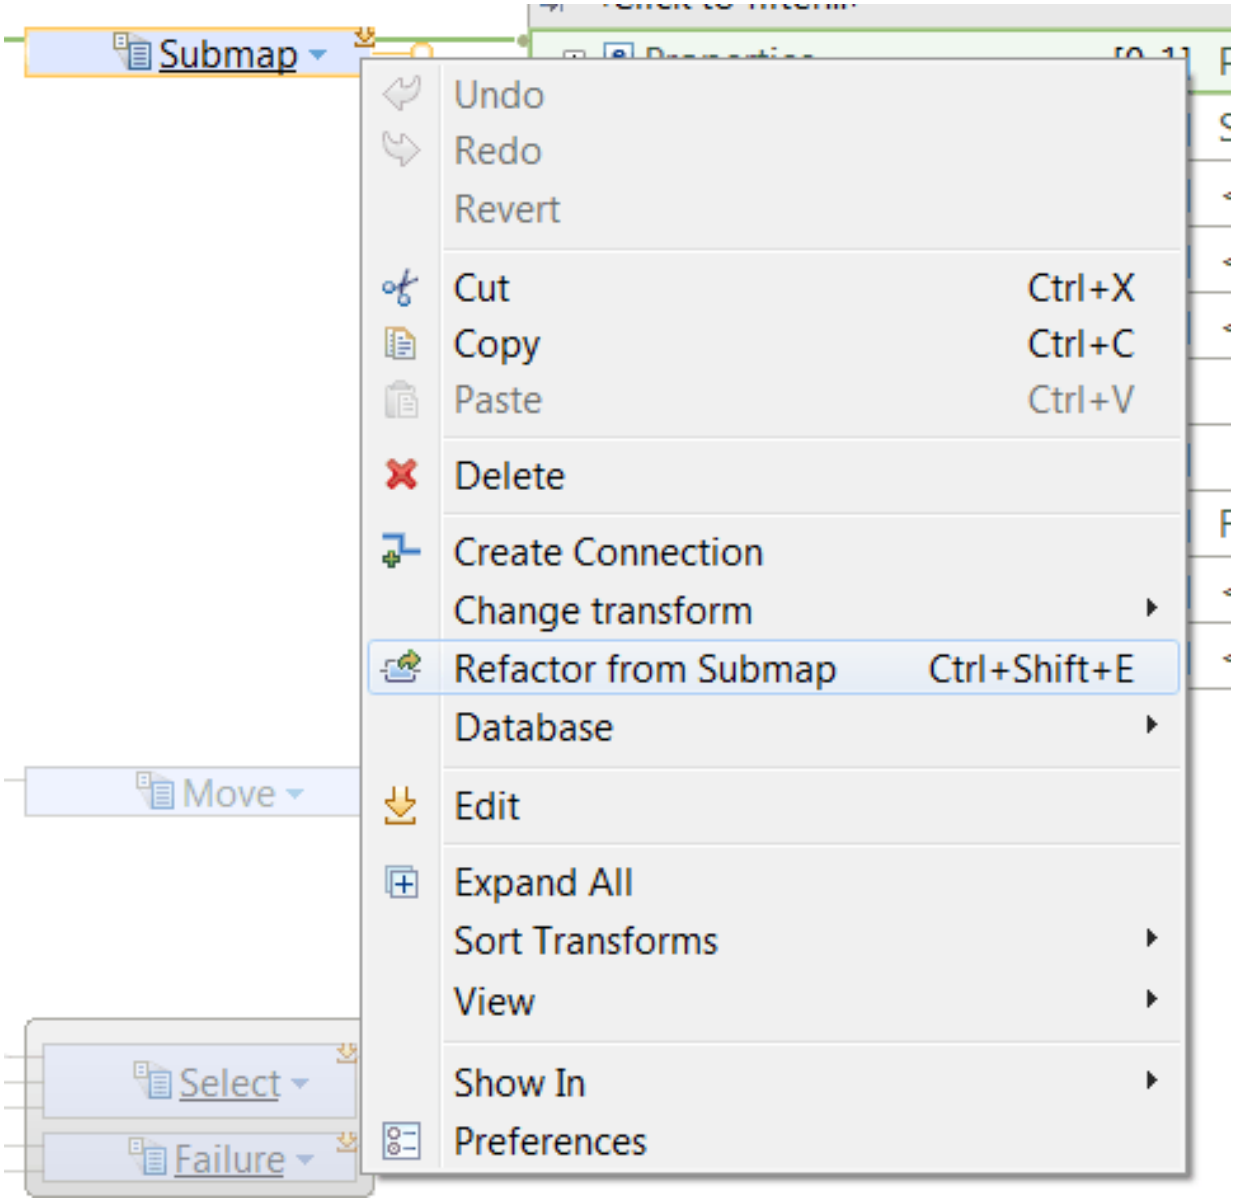
For example, you have a submap that contains common transformation logic that cannot be deleted. The submap is used by multiple graphical data maps. For one application, you need to specialize the submap, so rather than starting from scratch and creating a graphical data map, you can pull the submap logic into a main map by converting the submap to a local map. The action leaves the submap in place for ongoing use in other maps.

Procedure

To change a submap into local map, complete the following steps:

1. Right-click the Submap transform in the graphical data map, and then select **Refactor from submap**.

   The following figure shows the menu that opens when you right-click the **Submap** transform:



2. Optional: Delete the map file corresponding to the submap that you have converted to a local map if the submap is not being used anywhere else in your solutions. For more information, see "Deleting objects and transforms" on page 1444.

Results

A local map is created, containing all the mappings that were included in the original submap.

What to do next

Continue editing the graphical data map. For more information, see "Editing message maps" on page 1394.

Creating a graphical data map in the Eclipse editor
Create a graphical data map in the Eclipse editor to transform data graphically so that you can reuse it in other products that support graphical data maps.

Before you begin

Before you create a reusable message map, you must complete the following tasks:

1. Create an application, a library, an integration service, or an Integration project, as described in the following topics:
   - Creating an application
   - Creating a library
   - Creating an integration project
2. Create a message flow. For more information, see Creating a message flow.
3. Define the message flow content that includes a Mapping node. For more information, see Defining message flow content.

If you plan to reuse the graphical data map in other products, read "Guidelines for developing reusable graphical data mapping assets" on page 1273.

About this task

In IBM App Connect Enterprise, you can create a graphical data map as a reusable message map. You handle a graphical data map as a submap.

Procedure

To create a graphical data map in the Eclipse editor, complete the following steps:

1. Create a new graphical data map, by selecting **File** > **New** > **Other** > **XML** > **Data map**. Click **Next**.

   The New XML Mapping wizard opens.
2. Select the parent folder for the new graphical data map and specify a file name. By default the new file is called `NewMAP.map`. Click **Next**.

   The Input and Output Roots pane is displayed.
3. Select the input and output root files by clicking **Add** and then browsing to the required schema files.

   Note: If you choose not to select the input and output schemas at this point, you can select **Next**, and the Graphical Data Mapping editor is displayed with no input or output objects. You can then select your input and output objects in the Graphical Data Mapping editor by using the **Add an input object** and **Add an output object** icons.

   When you have specified your input and output objects, they are shown in the Graphical Data Mapping editor with the input object on the left side of the canvas, and the output object on the right side:
4. Click **Next**.
5. Click **Finish**.

What to do next

Edit the graphical data map, and define transformations between the input message and the output message. For more information, see "Editing message maps" on page 1394.

Editing message maps

You edit a message map in the Graphical Data Mapping editor.

Before you begin

Create a message map using the Graphical Data Mapping editor. For information about how to do this, see "Creating a message map" on page 1382.

About this task

In the Graphical Data Mapping editor, you create a map, you define the input and output message models to the map, and the transformations that must be applied to create the output message with values from the input elements. When your input or output message model includes an **xsd:any** element, you must qualify this extension point by using the **Cast** function or the **Add user defined** function prior to defining transforms.

You use the Graphical Data Mapping editor to map (or connect) elements of input objects to elements of output objects. Then, for each mapping, you can create a **transform**, which performs an action on the data of the input element and puts the result in the output element. The input objects are on the left side in the Graphical Data Mapping editor, and the output objects are on the right.

You can define XPath conditional expressions on a transform. This expression determines whether the transform is applied. Use content assist to set the required parameters of the expression. For more information, see "Using content assist (Mapping syntax)" on page 1443.

Procedure

You can do any of the following editing tasks in the Graphical Data Mapping editor:

1. Optional: Configure the general properties of a message map to define the Java, ESQL, and XSD resources that the map can refer to; to define your solution XML namespaces, and and to add any documentation. For more information, see "Configuring the general properties of a message map" on page 1395.
2. Redefine `xsd:any` elements in your message.
   a) Use the **Cast** function to redefine parts of the input or output model in a graphical data map by using a schema model. For more information, see "Mapping xsd:any on an input or output message" on page 1397. For more information, see "Mapping xsd:any on an input or output message" on page 1397.
   b) Use the **Add user defined** function to define dynamically the input and output message models when you do not have a schema model available for any of them. For more information, see "Defining user-defined elements" on page 1408.
3. Map the input and output elements in any of the following ways:
   a) Map elements manually. For more information, see "Mapping input to output elements manually" on page 1418.

      Use this method to select the input and output elements, create connections between them, and specify the required transforms.
   b) Map elements automatically. For more information, see "Mapping input to output elements automatically" on page 1421.

      Use the Auto map wizard (automap) to map elements by examining the names of input and output elements to create the mappings.
4. Specify a transform, also known as a mapping operation. For more information, see "Specifying a transform (mapping operation)" on page 1430.
5. Configure the properties of a transform. For more information, see "Configuring the properties of a transform" on page 1431.

6. Delete objects and transforms. For more information, see “Deleting objects and transforms” on page 1444.

What to do next

Configure the input and output message assembly in a message map by using the Graphical Data Mapping editor. For more information, see “Advanced editing in a message map” on page 1445.

Configuring the general properties of a message map
You can configure the general properties of a message map in the Graphical Data Mapping editor.

About this task

You can optionally configure the general properties of a message map:

- You can add documentation.
- You can configure prefixes for your XML namespaces.
- You can explicitly define references to Java, ESQL, and XSD resources that the map can refer. Note the Graphical Data Mapping editor will normally add these automatically while editing.

Procedure

Complete the following steps to configure the general properties of a map:

- Open the **Properties** tab of a map by using any of the following methods:
  - Select a map by focusing on the map canvas, rather than on an individual item in the map. Then, select the **Properties** tab.
  - Right-click the map canvas, and then select **Show in** > **Properties view**.

  - Use the appropriate keyboard combination, which, by default, is `Alt+Enter`.

    You can configure these shortcut keys by selecting **Window** > **Preferences** > **General** > **Keys**.

- In the **Properties** tab, add, modify, or remove resources:
  a) Select the **General** tab to view the namespace where the map is available.
  b) Select **Java Imports** to add or remove Java classes.

     If you add a Java call in the **General** tab of the **Properties** page of a **Custom Java** transform, an import is automatically added in the map to refer to the package qualified Java class, and a prefix based on the class name is added. All the **public static methods** in this Java class are then available in content-assist when building expressions in other transforms.

     If you only plan to use Java in XPath expressions on other transforms, you must first manually import the Java class into the map. You configure the **Java imports** tab in the **Properties** page of the map.

     For more information, see "Mapping an element by using a Custom Java transform" on page 1496.
  c) Optional: Select **ESQL Imports** to add or remove ESQL files that **Custom ESQL** transforms can refer to in the message map.

     When you include a **Custom ESQL** transform, an import is added to refer to the ESQL file, defining a prefix based on the file name. If you need to use custom ESQL only in condition or filter expressions, you can add ESQL imports to your ESQL file so that the applicable modules are available through content assist when you are composing an expression.
  d) Select **Scope** to add or remove XSD files that you can refer to in the message map.
  e) Select **Cast** to obtain the list of input and output wildcard elements that are cast to a specific type or global element in the message map. You can remove any entry that is not required anymore.
  f) Select **Namespaces** to add, edit, or remove user-defined namespaces in the message map.
  g) Select **Documentation** to provide a description of the message map, or other relevant usage notes.

What to do next

Continue editing the map, and define transformations between the input message and the output message. For more information, see "Editing message maps" on page 1394.

Adding input and output messages
Use the Graphical Data Mapping editor to add input and output messages to your message map.

Before you begin

Create a message map by using the Graphical Data Mapping editor. For more information, see "Creating a message map" on page 1382.

About this task

You can add an input object to your message map by using the **Add an input object** icon in the toolbar of the Graphical Data Mapping editor:

Note: In IBM App Connect Enterprise, you can only add one input object to a message map.

You can add an output object to your message map by using the **Add an output object** icon in the toolbar:

Note: In IBM App Connect Enterprise, you can only add one output object to a message map.

What to do next

When your message map contains all of the required input and output objects, create the connections between them, as described in "Adding connections between input and output elements" on page 1419.

Mapping xsd:any on an input or output message
You can use the **Cast** function to redefine parts of the input or output model in a message map. You can also use the **Add User-Defined** function to redefine dynamically parts of the input or output model.

In your integration solution, you can create a generic message model, which you can later redefine to a specific model, by using a wildcard, defined as `xsd:any`.

You can redefine an `xsd:any` element in any of the following ways:

- Using the **Cast** function. You can redefine an `xsd:any` element by specifying the specific complex or global type defined in a particular schema file.
- Using the **Add User-Defined** function. You can redefine an `xsd:any` element by specifying the specific complex or global type directly in the message map.
- Using a transform. You can define a transform, such as the **Submap** transform, and define the input and output `xsd:any` elements within the nested map of the transform.

Note: It is recommended to qualify an `xsd:any` element before you define any transforms in a main map. Alternatively, you can define a **Submap** between the `xsd:any` element and the output element, and then define the transforms within the nested map associated to the **Submap**.

For example, in IBM App Connect Enterprise, a SOAP message is a common example of a generic model in which you are required to define the business data being exchanged through the SOAP protocol. The predefined SOAP message format defines only the structure of the SOAP envelope and allows you to redefine the Header and Body content.

Note: The `xsd:any` input element cannot be involved in a transformation when it is contained within a cast item group. You can either create transformations on the cast elements or remove all associated cast elements to directly transform the `xsd:any`.

Qualify xsd:any parts of a schema-based message model by using the Cast function

You can define a wildcard in a schema-based message model as an `xsd:any` element to create a flexible message model that can be redefined later.

You use the **Cast** function to redefine parts of the input or output model in a message map.

For example, you might have a base type of `AddressType`, and two derived types of `USAddressType` and `CanadianAddressType`. Using the **Cast** function in the Graphical Data Mapping editor, you can cast `AddressType` to `CanadianAddressType`.

For more information, see "Casting elements in a message map" on page 1398.

Qualify xsd:any parts of a message model that does not have a schema by using the Add User-Defined function

You use the **Add User-Defined** function to redefine parts of the input or output model directly in a message map.

For more information, see "Defining user-defined elements" on page 1408.

Qualify xsd:any parts by using a Submap transform

You can use the **Submap** transform to qualify an `xsd:any` element defined on the input message assembly, the output message assembly, or both.

You must specify the input element type and the output element type using a global type in the referenced submap of the **Submap** transform.

You qualify the `xsd:any` elements in the nested map by defining the input and output elements.

Casting elements in a message map
In the Graphical Data Mapping editor, use the **Cast** function to redefine parts of the input or the output model in a message map. This function is also known as a **`mapping cast`**.

About this task

To create a flexible message model, you can define elements in your XML schema as wildcards, or you can provide an extension or derived type from a base type. In a JSON schema, you can use the "oneOf" or "anyOf" keywords to allow flexibility.

A *wildcard* is an element in your XML schema that is defined as `xsd:any`, `xsd:anyType`, or `xsd:anySimpleType`.

A message model schema might contain one or more wildcards. In addition, the model for the Message Assembly Environment, Local Environment, transport header folders, and SOAP and JSON domain messages, include wildcards, such as under the environment `Variables` folder, which allow you to define data specifically for the operation of your flow.

In the Graphical Data Mapping editor, you can redefine these wildcards by using the **Cast** function to select an element or type that is defined in a message model, such as an XML schema, DFDL schema, JSON schema, or Swagger document. For more information, see "Casting a wildcard defined as xsd:any into a specific type for a SOAP message" on page 1400 and "Configuring a generic type in the local environment tree by using the Cast function" on page 1466.

If you do not have a message model that provides a suitable element for casting, consider adding a user-defined element, as described in "Defining user-defined elements" on page 1408. When you have added a user-defined element, you can set its type from a global type in your message model, as described in "Defining the structure of a complex user-defined element" on page 1414.

When you apply a mapping cast, the choices that are available vary according to the type. The following choices are available for the specified type:

xsd:any
All global elements defined in the message models that are contained in the same application or referenced library, and are therefore visible to the map. This includes elements from XML, DFDL, and top-level objects and arrays in JSON schema.

xsd:anyType
All global types defined in the message models that are contained in the same application or referenced library, and are therefore visible to the map. This includes global types from XML, DFDL, and the types defined for top-level objects and arrays in JSON schema.

xsd:anySimpleType
All the standard XML types and any global type extensions for XML simple types defined in the XML message models that are contained in the same application or referenced library, and are therefore visible to the map.

<namespace>:<base XML schema type>
All the XML types that are defined as extensions or derived from this XML schema type.

JSON type defined with "oneOf" or "anyOf"
The JSON types defined in the `"oneOf"` or `"anyOf"` array.

If you are casting to an element or type that is derived from a JSON schema or Swagger document, see "JSON schema requirements for message maps" on page 1549.

You can use the **Cast** function to redefine a wildcard or base type multiple times. Each type that you cast appears under the wildcard or base type within a choice group.

To define transformations between subtypes of an XML data type, you can use extension or derived types. A *derived type* is a data type that is related to another data type known as the base type or super type. You can cast a base type to a derived type by using the **Cast** function. For more information, see "Casting an XML schema base type to a derived type or extension type" on page 1403.

When your input message or your output message is the IBM provided JSON domain object or JSON domain array message, you can redefine the **Data** element that is of type **anyType** by using the **Cast** function. For more information, see “Modeling a JSON message for use in a message map by using an equivalent XML schema model” on page 1572.

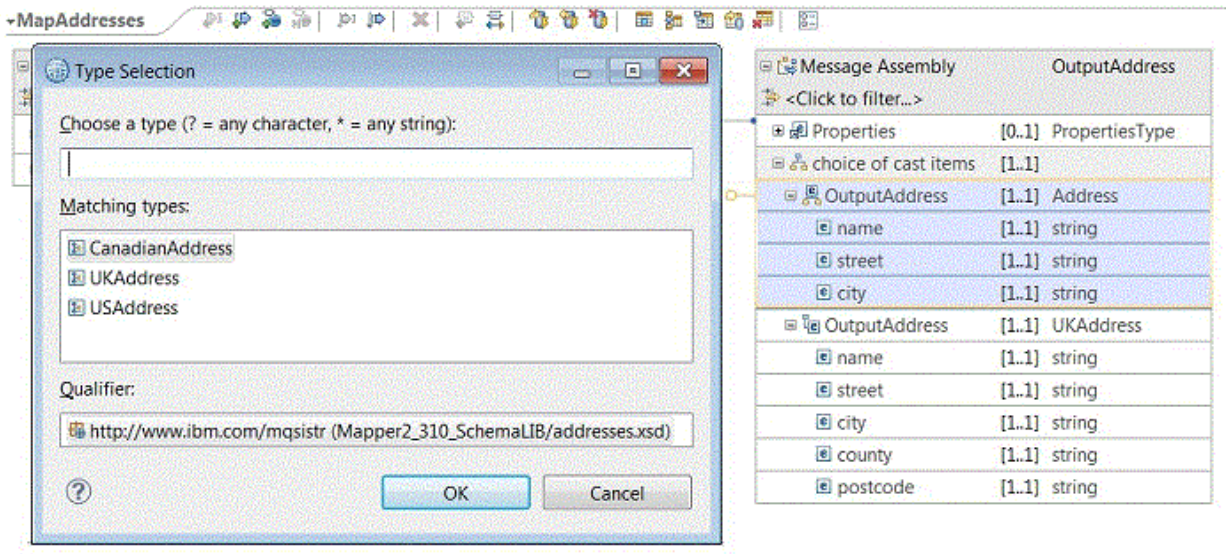
You can also use the JSON schema `"oneOf"` and `"anyOf"` keywords, to structure and combine more complex JSON schema. For more information, see “Casting with JSON schema types” on page 1405 and “JSON schema requirements for message maps” on page 1549.

Procedure

To redefine an element in your input or output model by using the **Cast** function, complete the following steps:

1. Open the map in the Graphical Data Mapping editor.
2. Right-click the element that you want to redefine, and select **Cast**.

   The **Type Selection** dialog opens:



3. Select the type that you want to cast to, and then click **OK**.

   The **Type Selection** dialog lists only those elements and types that are appropriate for the element that you want to cast, and that are contained in a referenced application or library. When you cast a base element, the **Type Selection** dialog lists only derived types.

   Note: In the following situations, **choice of cast items** contains more than one item:

   - You cast a wildcard input type to a specific schema type.
   - You cast a base schema input type to an extension or a restricted type.

   When applying XML extension or derived type schema type casts, the Graphical Data Mapping editor automatically applies an XPath expression to the mappings from these casts. At run time, the XPath expression checks the `xsi:type` attribute of the input element to determine which of the types is present in the input data. Then, only the mapping from the appropriate type is performed. The expression checks only the name of the type in each cast; the namespace is not considered. If **choice of cast items** includes types that have the same name but are in different namespaces, you must add your own conditional transform that checks the namespace and name part of the `xsi:type` attribute of the input data. When **choice of cast items** includes only a single type, the `xsi:type` attribute is not checked, and you must ensure that the input data presents only the single cast type.

Results

After you use the **Cast** function to qualify the type of the element that is defined with a wildcard, the type appears under the wildcard. You can define transformations between the input message and the output message. For more information, see "Specifying a transform (mapping operation)" on page 1430.

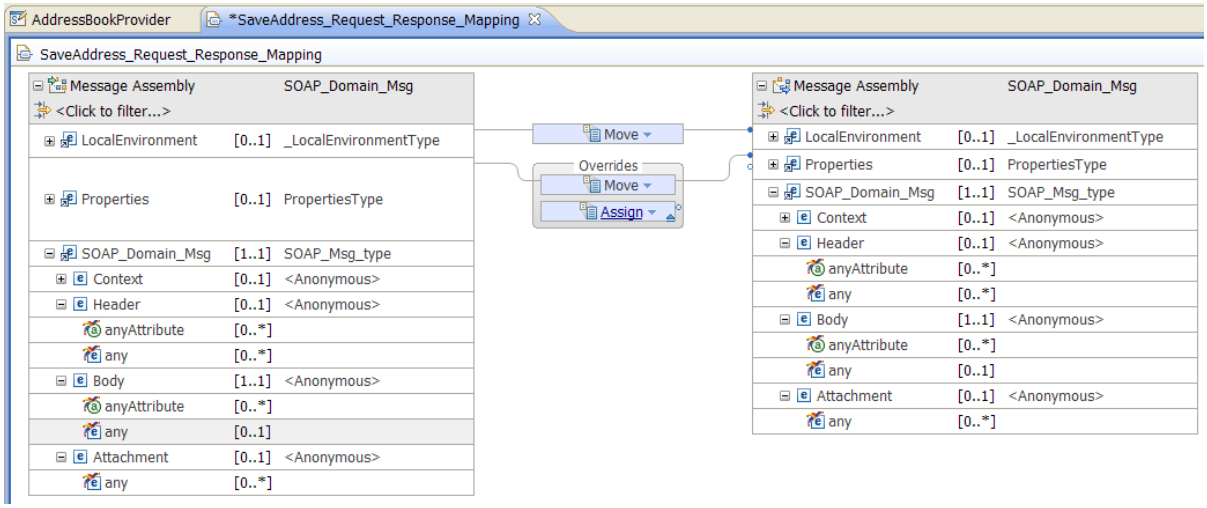
Casting a wildcard defined as xsd:any into a specific type for a SOAP message
You can use the **Cast** function to redefine a wildcard element, that is, an element with type *xsd:any*, into a specific type. Each type is described by a schema.

About this task

You can transform a SOAP message that is defined by using the predefined format **SOAP_Domain_Msg**. This message type contains a Header, a Body, and an Attachment part. Each part contains an element that is named **any** to represent a wildcard, that is, an element of type *xsd:any*. The Header and Body sections also include an element that is named **AnyAttribute**. You can cast elements and attributes included in any of these SOAP sections by using the **Cast** function.

Note: When you transform a SOAP message, you cast the Body wildcard on the input side to the type of the request message for the SOAP operation. On the output side, you cast the Body wildcard to the type of the response message for the SOAP operation.

The following figure shows the message map in the Graphical Mapping Data editor after you create a message map to transform a SOAP message:

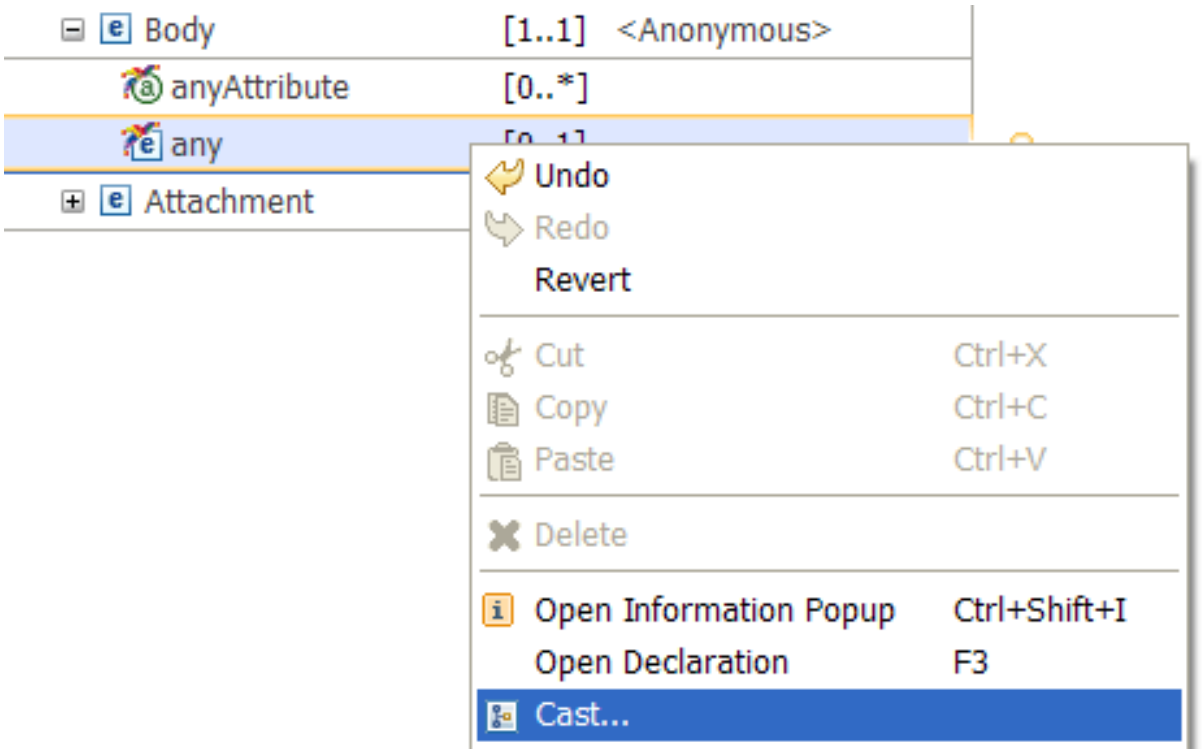


Procedure

To cast an element that is described as **any** or as **anyAttribute** in the message map, complete the following steps:

1. Right-click the element **any** or **anyAttribute** located in the section of your **SOAP_Domain_Msg** where you want to specify a type, and then select **Cast**.
   - To cast a SOAP header wildcard element, right-click **Header**, and then select **Cast**.
   - To cast a SOAP body wildcard element, right-click **Body**, and then select **Cast**.
   - To cast a SOAP attachment wildcard element, right-click **Attachment**, and then select **Cast**.

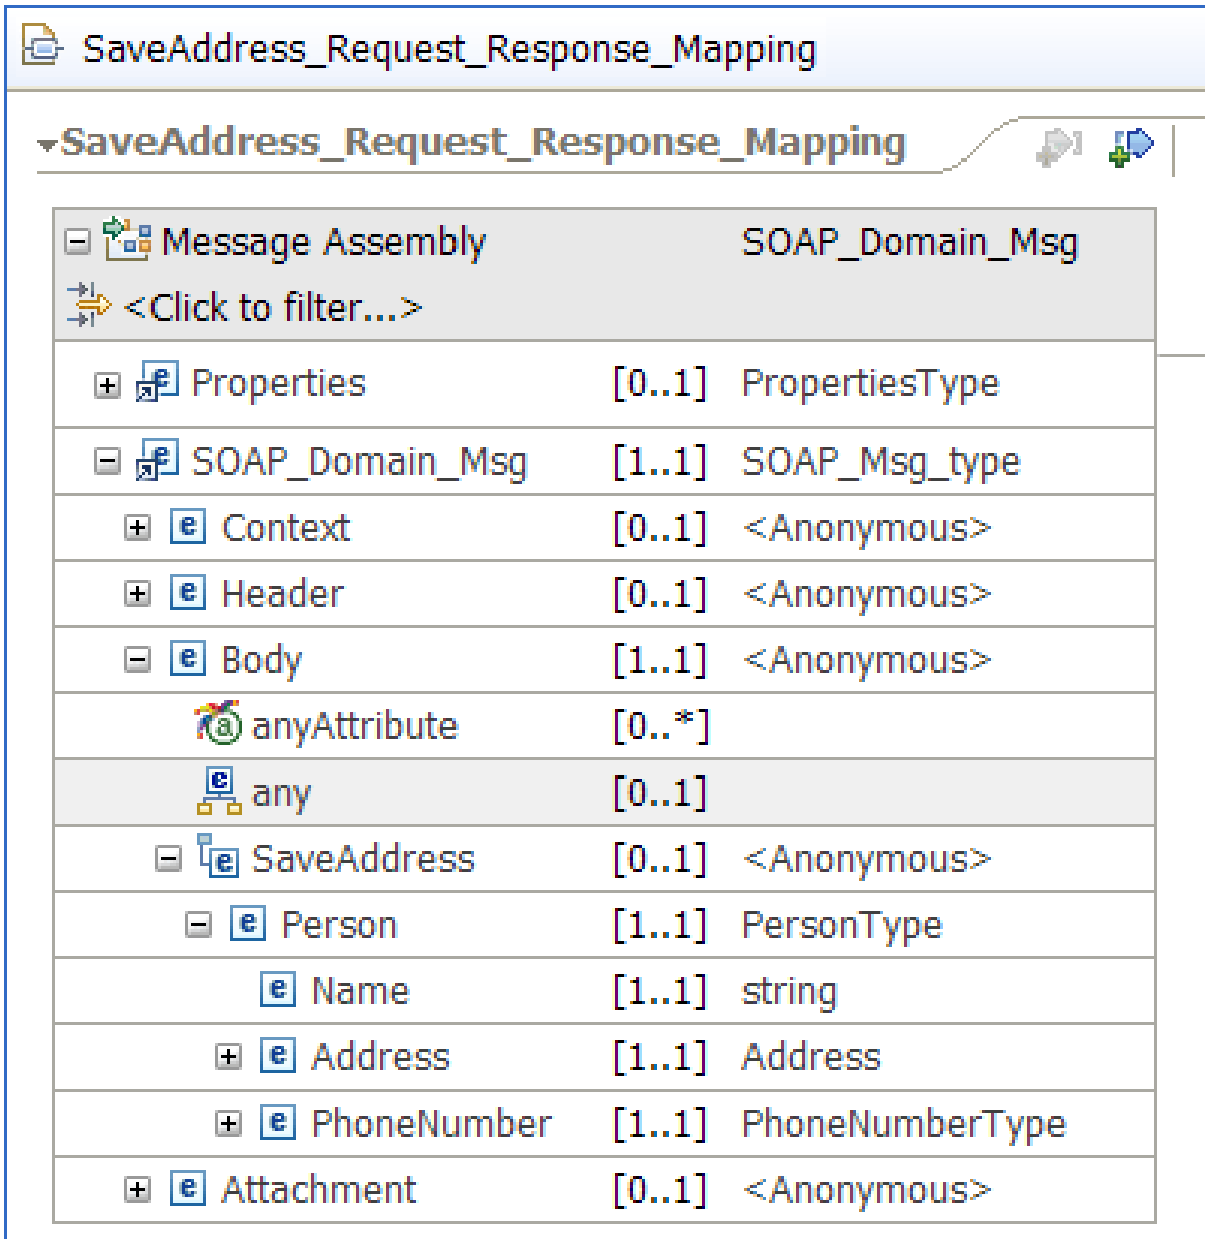
   For example, to cast the Body section, right-click **Body**, and then select **Cast**.



2. In the **Type Selection** window, select a type.

   The **Type Selection** window displays all the specific types that are available for selection. These types include the input and output elements that are defined in the WSDL file that describes your SOAP message.

   In the example, the element **any** of the **SOAP_Domain_Msg** Body is redefined to the complex element **SaveAddress**.



Results

A wildcard element is redefined to a specific type.

What to do next

Define transformations between the input message assembly and the output message assembly. For more information, see “Specifying a transform (mapping operation)” on page 1430.

Casting an XML schema base type to a derived type or extension type
In a message map, you can cast an XML schema base type to a derived type or extension type so that you can define transformations between subtypes of a data type.

Before you begin

- Model the schemas that correspond to the XML schema base type and the derived type.
- Cast an `xsd:any` element in your message map to an XML schema base type.

About this task

A *derived type* is a data type that is related to another data type known as the base type or super type.

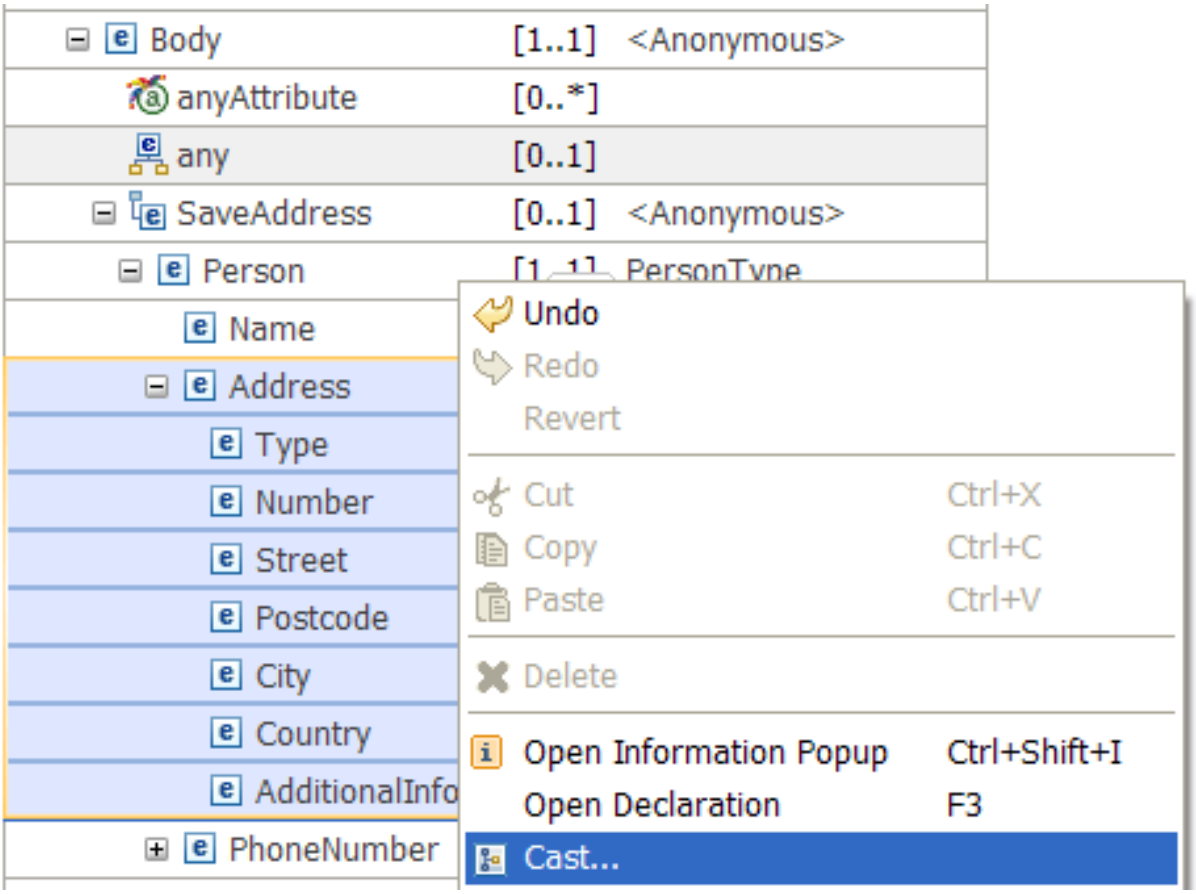
For example, **Address** is the XML schema base type, and **USAddress**, **CanadianAddress**, and **UKAddress** are derived types of **Address**.

Procedure

To cast an XML schema base type to a derived type, complete the following steps:

1. Select the XML schema base type.

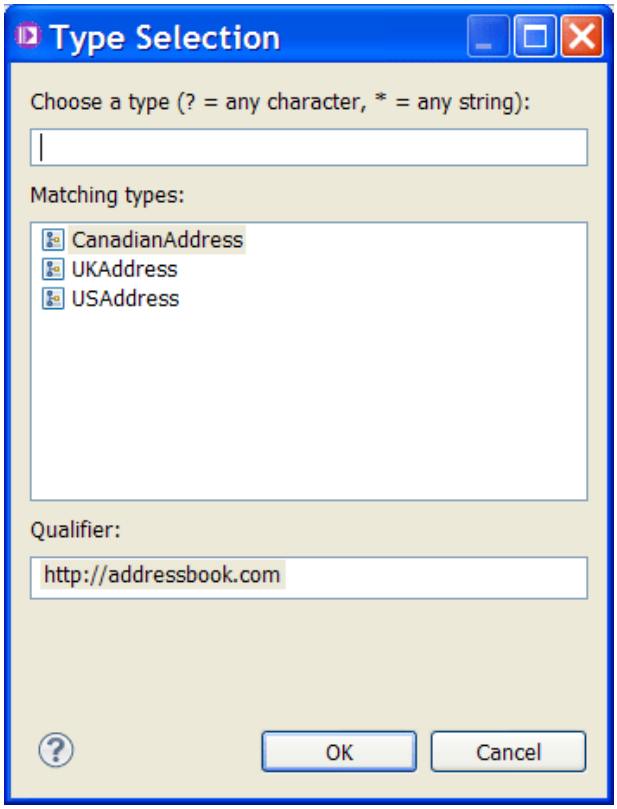
   For example, you can cast an `xsd:any` element to the **Address** XML schema base type.
2. Right-click the XML schema base type (**Address**), and then select **Cast**.



3. In the **Type Selection** window, choose a matching type, and then select **OK**.

   The options available correspond to specific address types in the schema model that are modeled by using **Address** as the XML schema base type.

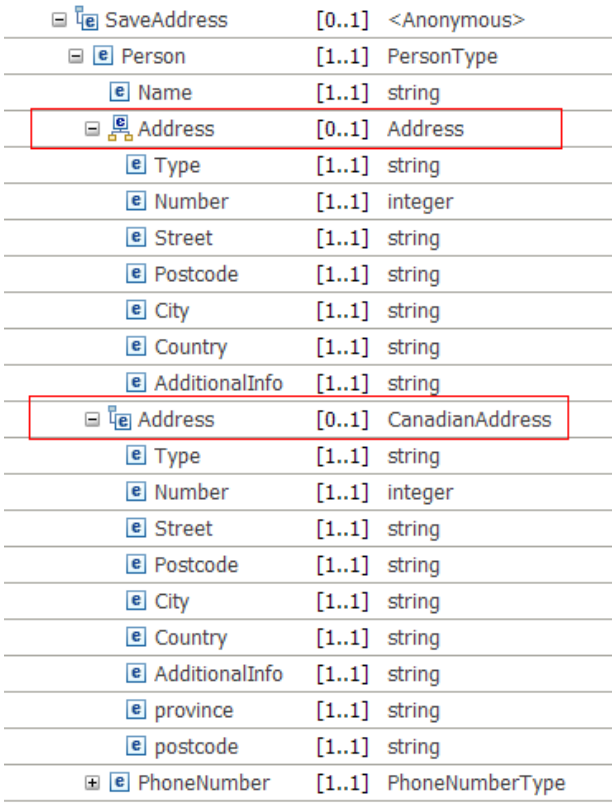
   The following figure shows the **Type Selection** window that you get:



Results

The message map contains two entries, one for the XML schema base type and a second one for the derived type.

In the example, one entry corresponds to the XML schema base type **Address**. The other entry corresponds to an Address with the derived type **CanadianAddress**.



What to do next

Define additional transformations between elements in the message map. For more information, see “Transform types in the Graphical Data Mapping editor” on page 1282.

Casting with JSON schema types
In a message map, you can use the cast function to define wildcards to a JSON data type, or extend a JSON type that is defined with the `"oneOf"` or `"anyOf"` keywords.

Before you begin

- Create a message map for your JSON data. For more information, see “Creating a message map” on page 1382.
- Ensure that you have a supported JSON schema model in the same container as your message map. For more information, see “JSON schema requirements for message maps” on page 1549.

About this task

You can use a mapping cast with JSON schema types when you want to use wildcards or combine complex JSON schema; for example:

- When your message model includes a wildcard. A wildcard is an element in your schema that is defined as `xsd:any` or `xsd:anyType`. The model for the Message Assembly Environment and Local Environment folders include wildcards (under the Variables folder, for example), which allow you to define data specifically for the operation of your flow.
- When a JSON schema includes the `"oneOf"` or `"anyOf"` keywords, to allow the flexibility to extend the content of a data type.

Procedure

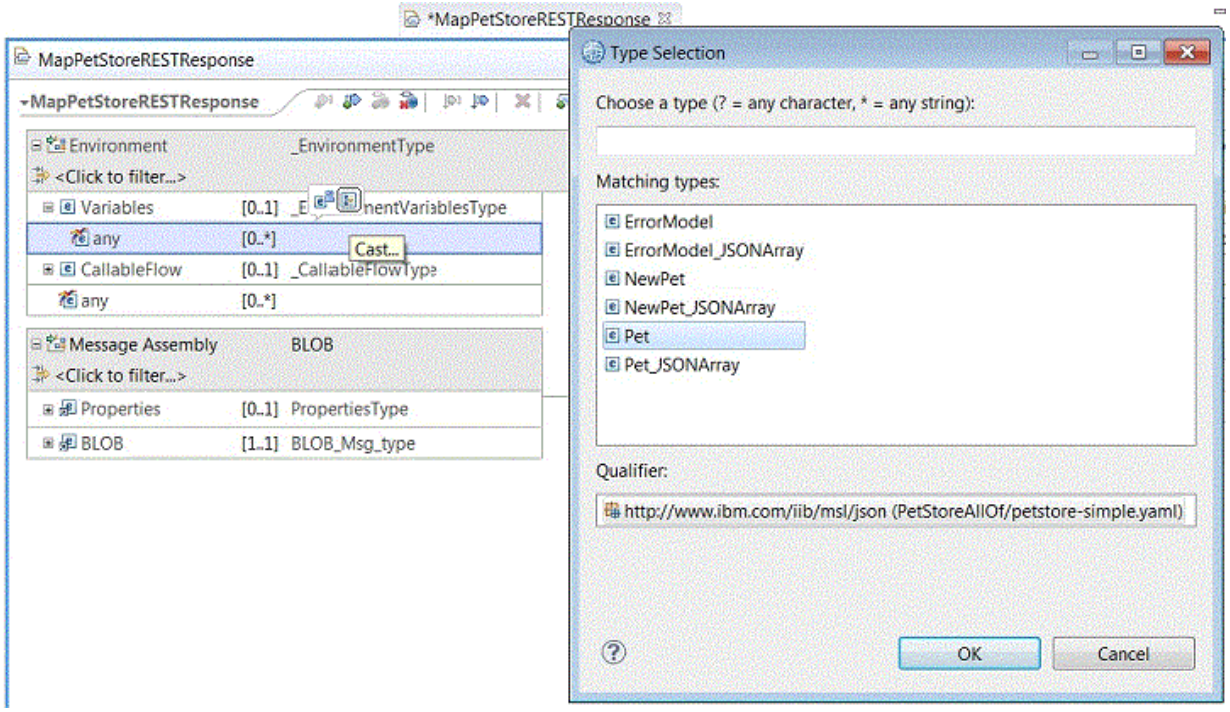
To cast a wildcard or a JSON schema type that includes the `"oneOf"` or `"anyOf"` keyword, complete the following steps:

1. Select the wildcard or JSON schema type that you want to use.
2. Right-click the wildcard or JSON schema type, and then select **Cast**.

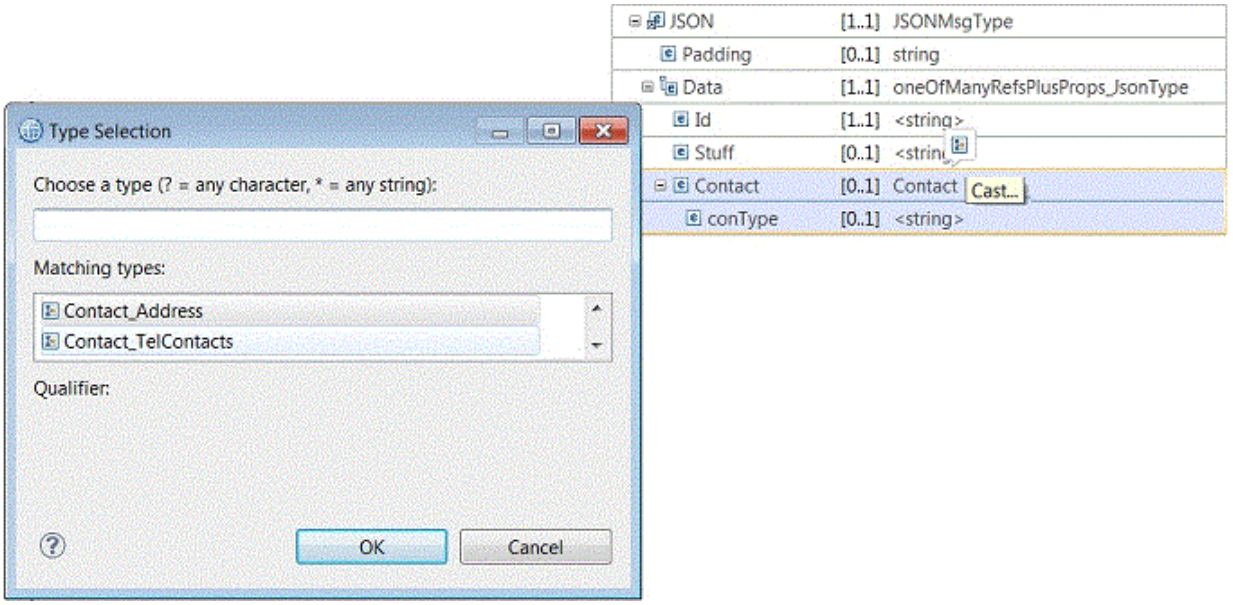
3. In the **Type Selection** window, choose the required type, and then select **OK**.

   The options depend on the JSON schema files that are available in the same project container as the message map and the item that is being cast.

   The following figure shows the **Type Selection** window that you might see when casting the environment tree `Variables` in a project container that contains a REST Swagger document used by a RESTRequest node:



The following figure shows the **Type Selection** window that you might see when casting a JSON type `Contact` that is defined using the JSON keyword `"oneOf"`, which extends the type as either an address or telephone contact:



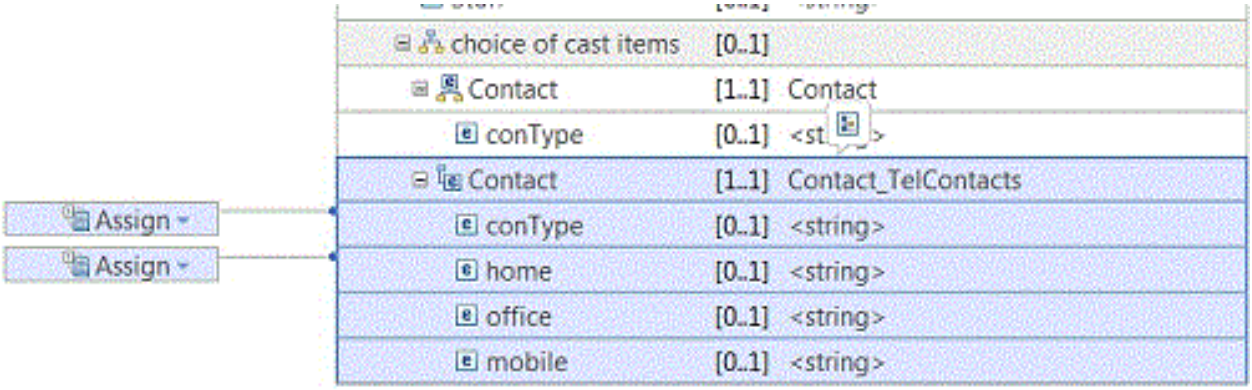
For example:

```
"Contact" : {
     "properties": {
             "conType": {
```

```
                    "type": "string"
                }
        },
         "oneOf": [
{"type": "null"},
{"$ref":"#/definitions/Address"},
{"$ref":"#/definitions/TelContacts"}
                  ]
}
```

Results

The message map contains a `choice of cast items` group, including the type that you have picked for the cast action; you can now complete mappings to the data members of that type. For example:



What to do next

Define additional transformations between elements in the message map. For more information, see “Transform types in the Graphical Data Mapping editor” on page 1282.

Defining user-defined elements
You can add, reuse, rename, transform, and delete a user-defined element directly into your message map during the development phase.

About this task

A *user-defined element* is an element that you can add directly into a message map to define the data of an extension point, which is shown as **any** or **anyAttribute** in the map.

You can add user-defined elements to define extension points in any of the following message assembly components:

- The local environment tree variables folder
- The message body
- `xsd:any` elements in your message body
- The Environment tree
- The transport headers that include extension points such as MQRFH2

You can also use user-defined elements to define a JSON message, and a SOAP or XML message that has an **xsd:any**.

You can add any of the following types of user-defined elements:

- Simple type user-defined elements
- Complex type elements
- Repeatable user-defined elements

When you add a user-defined element, you must consider the following behavior:

- You can define a simple type user-defined element or a complex user-defined element in the input message assembly or in the output message assembly.
- You can include simple type attributes, simple type elements, complex type elements, and repeatable elements in a user-defined complex type element.
- You can define user-defined attributes within a complex user-defined element.
- You can set the type of a user-defined element or attribute from an existing global type definition. You can use any available message models, XML schemas, or DFDL schemas. For more information, see "Choosing the project structure when you create a message map" on page 1380.

JSON elements are defined as nillable by default to allow the JSON null value. The Graphical Data Mapping editor creates all JSON user-defined elements as nillable.

Note: Be aware of the following limitations:

- The Graphical Data Mapping editor does not create any other type of user-defined element as nillable. For this reason, if you use the **Add User-Defined** function to add XML elements, they cannot be defined as nillable. If you need nillable XML elements, you must define a schema model for them.
- You cannot use user-defined elements as the input or output of a submap.

When you use the Graphical Data Mapping editor to transform a JSON message, ensure that the JSON element names that you define by using the **Add User-Defined** function are valid according to the XML rules for naming elements. JSON allows a wider range of characters than XML, for example a JSON object might include the **@** character. However, the Graphical Data Mapping editor allows element names that are valid in XML or XPath.

Procedure

You can do any of the following actions with user-defined elements:

- Create a user-defined element by using the **Add User-Defined** function. For more information, see "Adding and renaming a user-defined element" on page 1410.
  - You can create a simple or a complex user-defined type. For more information, see "Defining the structure of a complex user-defined element" on page 1414.
  - You can rename a user-defined element.
  - You can set the cardinality. For more information, see "Configuring the cardinality of a user-defined element" on page 1412.
- Reuse multiple times a user-defined element. For more information, see "Reusing a user-defined element in a message map" on page 1415.
- Specify transforms where a user-defined element can be an input element to the transform, or an output element. For more information, see "Specifying a transform (mapping operation)" on page 1430.
- Delete a user-defined element. For more information, see "Deleting a user-defined element" on page 1417.

What to do next

After you add your input and output objects, create the connections between them, and specify your transforms, you can test your message map. For more information, see "Troubleshooting a message map" on page 1587.

Adding and renaming a user-defined element
You can add a user-defined element by using the **Add User-Defined** function. You can add simple type or complex type user-defined elements.

Procedure

To create a user-defined element, complete the following steps:

1. Select the extension point **any** under which you want to add a user-defined element.
2. Select **Add User-Defined**. You can choose any of the following methods:
   - Right-click the element any. A menu appears. Select the **Add User-Defined** function.

   - Select the **Add User-Defined** function by selecting the **Add User-Defined** icon  that is available on top of the field.

   An element is added under the **any** field.

   The default type of a new created user-defined element is **string**.
3. Click the user-defined element, and then enter the name of the element.

   If the user-defined element name exists in multiple places, you are prompted to select an action that determines whether to reuse or rename an existing user-defined element in multiple places in the map.

4. Specify the user-defined element type. Complete the following steps:
   a) Click the type of the user-defined element.
   b) Select the type of the user-defined element.

      Note: The default type is **string**.

      - To configure a simple type, choose from any of the following values:
        - Boolean
        - date
        - dateTime
        - decimal
        - double
        - duration
        - float
        - hexBinary
        - int
        - long
        - string
        - time
      - To configure a complex type, choose **<Anonymous>**.
      - To configure a JSON array, choose **JSONArray_Default**.
      - To set the type by using a global XML schema, choose **Browse**, and select the type. You can set the type to an XML schema or to a DFDL schema.

        When you define the user-defined element type by using a global XML schema, the following rules apply:

        - You can have the map and any schema definitions that are used in the map in the same project. The project can be a static library project, a shared library project, or an application project.
        - You can have any schema definition that is used in the map in a static library project and the map in an application project.
        - You can have any schema definition that is used in the map in a shared library project and the map in a different shared library project.
        - You cannot have the schema definitions that are used in the map in a shared library and the map in an application project. The Graphical Data Mapping editor reports error **CWMSL209E** if you break this rule.

        Note: You can get error **CWMSL209E** when the type of the user-defined element references an unresolved schema. To resolve this problem, add the schema in the Scope tab of the map **Properties** view, or add the dependency to the map container project. Then, reselect the type.
5. When you add elements to a complex user-defined element, you define the cardinality for each child element that you add. The cardinality defaults to **Minimum occurrence** and **Maximum occurrence** of 1. For more information, see "Configuring the cardinality of a user-defined element" on page 1412.

   Note: You cannot change the cardinality for user-defined elements that are within the choice group that is created for you when you define elements at the level of the **xsd:any** wildcard. The cardinality is determined by the cardinality set on the **xsd:any**.

What to do next

- If you add a simple type user-defined element, edit the message map, and define transformations between the input message assembly and the output message assembly. For more information, see "Specifying a transform (mapping operation)" on page 1430.

- If you add a complex type user-defined element, define its complex structure by using the **Add User-Defined** function. For more information, see "Defining the structure of a complex user-defined element" on page 1414.
- If you add a JSON array, define its structure by using the **Add User-Defined** function. For more information, see "Graphically modeling a JSON array in a message map" on page 1560.

Configuring the cardinality of a user-defined element
In a message map, you can set the cardinality of user-defined elements except for JSON arrays and elements that are defined at the **xsd:any** level.

About this task

In the Graphical Data Mapping editor, when you define your message data with user-defined elements, you must comply with the following rules:

- The Graphical Data Mapping editor sets the cardinality for elements that are defined at the **xsd:any** level based on the internal model of the **xsd:any**.
- You can configure the cardinality of user-defined elements in the **Properties** page of the element.
- You cannot set the cardinality of elements that are defined at the **xsd:any** level because their value is defined by the cardinality set in the message model that provided the **xsd:any**. Typically, models define the **xsd:any** cardinality as **Minimum occurrence** = `0` and **Maximum occurrence** = unbounded so that user-defined elements defined at the**xsd:any** level can optionally exist, and optionally repeat. The predefined JSON and SOAP message models use this approach.
- You can change the cardinality of a user-defined element of type **<Anonymous>** that is not defined at the **xsd:any** level.
- You can change the cardinality of any child user-defined element that describes a user-defined element of type **<Anonymous>**.
- If you set the type of a simple user-defined element with an external message model, you cannot change the cardinality of the element in the **Properties** page. The cardinality of this element is set from the schema model that you reference.
- If you set the type of a complex user-defined element with an external message model, you cannot change the cardinality of its children in the **Property** pages. The cardinality of these elements is set from the schema model that you reference.
- In a JSON message, the following rules apply for JSON arrays:
  - You cannot change the cardinality of a user-defined element of type **JSON array** that defines a JSON array in the root of a JSON array message.
  - You cannot change the cardinality of **Item** in a JSON array.
  - If you change the type of **Item** to **<Anonymous>**, you can change the cardinality of any child elements, including JSON array elements.

The cardinality represents the number of occurrences of an element. You can define an element as mandatory, optional, or repeating. You set the cardinality of an element by configuring the **Minimum occurrence** and the **Maximum occurrence** properties.

- An *optional* element has **Minimum occurrence** set to `0`. An optional element can be omitted from the message.
- A *repeating* element has **Maximum occurrence**> 1 to indicate a bounded number of repeats, or **Maximum occurrence**=unbounded to indicate an unlimited number of repeats. A repeating element occurs more than once in the message, and all the occurrences must appear together without any other elements between them.

Procedure

In the **Properties** page of a user-defined element, complete the following steps to set its cardinality if the element is not defined at the **xsd:any** level, and the element is a child of a user-defined element:

- Check whether the default cardinality of a user-defined element meets your message model requirements or not.

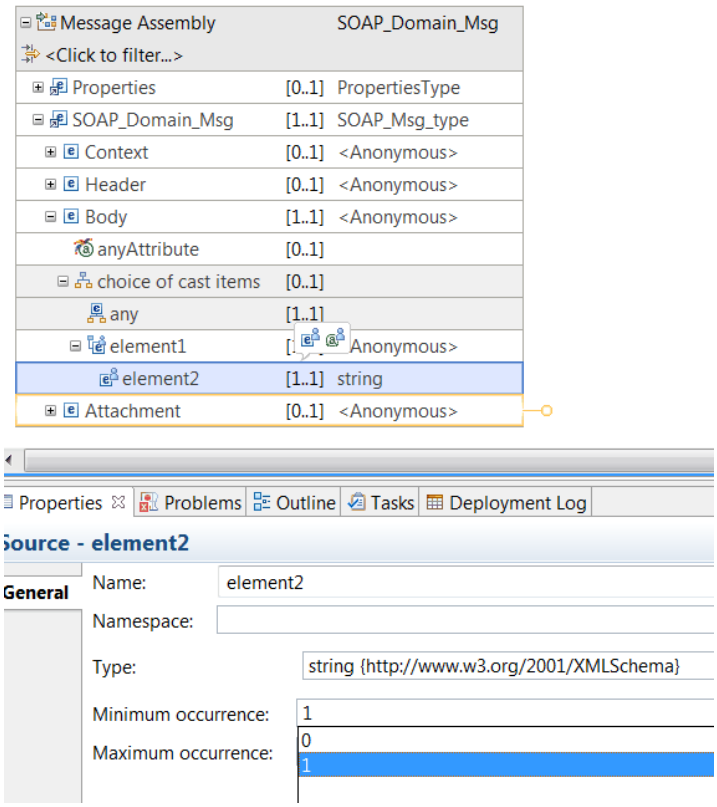
  The Graphical Data Mapping editor sets the cardinality of user-defined elements to **1:1**, that is, any user-defined element must be present exactly once.

  - **Maximum occurrence** = 1
  - **Minimum occurrence** = 1
- Set the cardinality of any user-defined element that you add below the **xsd:any** level if your data does not match the default configuration.
  - Set the **Minimum occurrence** to 0 or 1.
  - Set the **Maximum occurrence** to 0, 1, or unbounded.

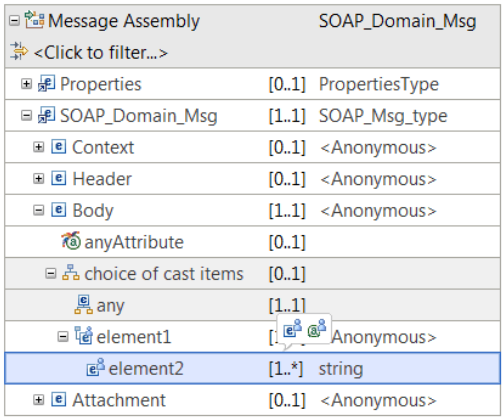
Example

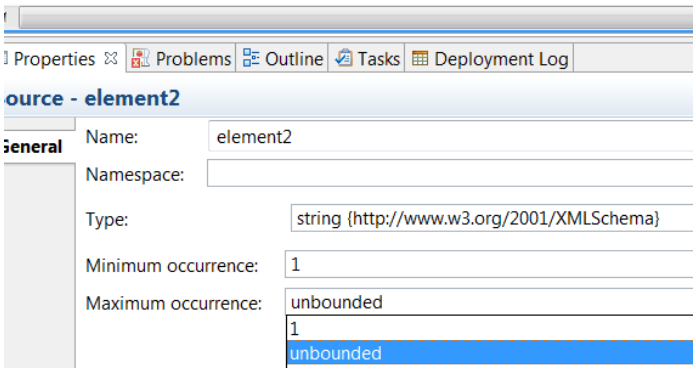
When you have a simple or complex user-defined element that is not defined at the **xsd:any** level, you can configure the cardinality of the element. The following figure shows an input SOAP message with a user-defined element named *element2*. You create this element by using the **Add User-Defined** function.

To change the default value of **Minimum occurrence**, open the **Properties** page of the element, and select 0 or 1.



To change the default value of **Maximum occurrence**, open the **Properties** page of the element, and select 0, 1, unbounded, or enter a number as required.





What to do next

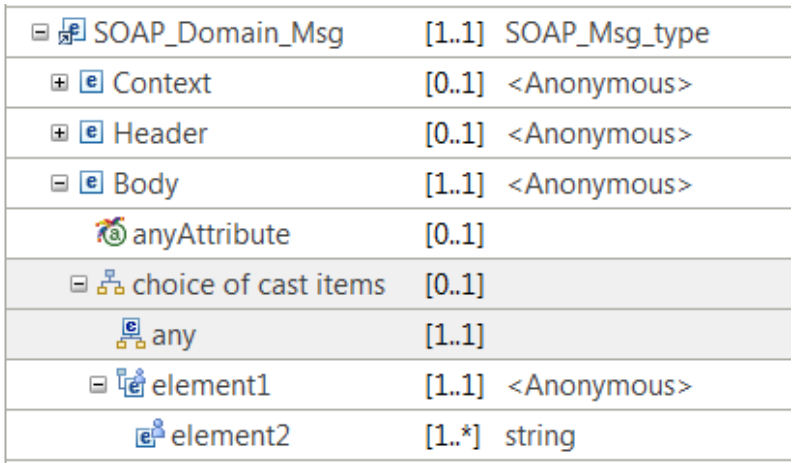
Construct the transforms to map the data you model. For more information, see "Choosing a transform to map repeating elements" on page 1362 or "Specifying a transform (mapping operation)" on page 1430.

Defining the structure of a complex user-defined element

You can define the structure of a complex type by using the **Add Element** function. You can reorder the position of elements in your complex structure. You can also use global types such as XML schemas, DFDL schemas, JSON schemas, and Swagger documents to set the type of user-defined elements.

Before you begin

In a message map, add a user-defined element with **<Anonymous>** type to your input or output assembly. For more information, see "Adding and renaming a user-defined element" on page 1410.



About this task

You can define a complex user-defined element in the input message assembly or in the output message assembly.

- You can include simple type attributes, simple type elements, complex type elements, and repeatable elements in a user-defined complex type element.
- You can set the type of a user-defined element to a global complex type defined in an XML schema, DFDL schema, JSON schema, or Swagger document.

To set the cardinality of a complex user-defined type, you must differentiate whether the type is based on a global type or not.

- When you set the type to a global type, you can configure the cardinality only through an XML schema or DFDL schema.
- When you add elements to a complex user-defined element, you define the cardinality for each child element that you add. The cardinality defaults to **Minimum occurrence** and **Maximum occurrence** of 1. For more information, see "Configuring the cardinality of a user-defined element" on page 1412.

  Note: You cannot change the cardinality in the Graphical Data Mapping editor for user-defined elements that are within the choice group that is created for you when you define elements at the level of the **xsd:any** wildcard. The cardinality is determined by the cardinality set on the **xsd:any**.

Procedure

Complete the following steps to define the structure of a complex element:

- Right-click the complex user-defined element, and select **Add Child Element** from the context menu.

  You can define simple type elements and complex type elements.
- Specify the type of the element. Click the type of the element and choose one of the XML simple types, or select **Browse** to set the type from a global complex type from an XML schema, a DFDL schema, or a JSON schema or Swagger document that is in the same project container as the map. If you are casting to a type that is derived from a JSON schema or Swagger document, see "JSON schema requirements for message maps" on page 1549 for more information.
- Modify the location of an element in your structure. Right-click the element that you want to move, and choose **Move down** to move down an element or **Move up** to move up an element.
- Specify the cardinality of the element. Configure in the element **Properties** tab a value for the properties **Minimum occurrences** and **Maximum occurrences**. For more information, see "Configuring the cardinality of a user-defined element" on page 1412.
- Repeat the previous steps to define all the elements.

What to do next

Edit the message map, and define transformations between the input message assembly and the output message assembly. For more information, see "Specifying a transform (mapping operation)" on page 1430.

Reusing a user-defined element in a message map

You can reuse multiple times a user-defined element that you have modeled in the input message assembly or in the output message assembly. All instances of the reused user-defined element must be of the same type.

About this task

You can reuse user-defined elements in the same message map or in a different message map.

To reuse a user-defined element in multiple maps, you can define the user-defined element in a submap. Alternatively, you can copy and paste the user-defined element between maps. When you copy a user-

defined element, you must maintain in multiple places any changes you make to the user-defined element.

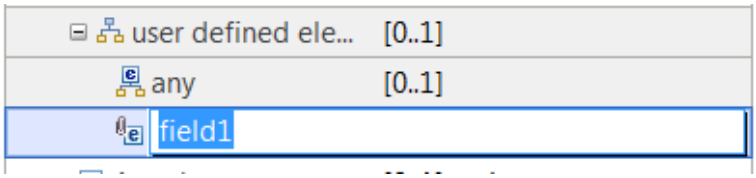
Procedure

Complete the following steps to copy into the output message assembly a user-defined element that is defined in the input message assembly:

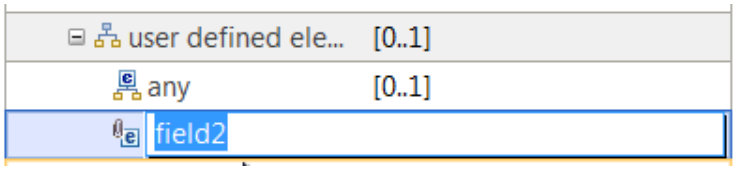
1. Add a user-defined element to your input message assembly. For more information, see "Adding and renaming a user-defined element" on page 1410.

   You can select the **Add User-Defined** function to add an element.

   A user-defined element is added. In this example, the user-defined element name is `field1`.



2. Add another user-defined element. In this example, you add a user-defined element on the output message assembly. The element name is `field2`, which is the next available generic name for user-defined elements.



3. Rename `field2` to **field1**.

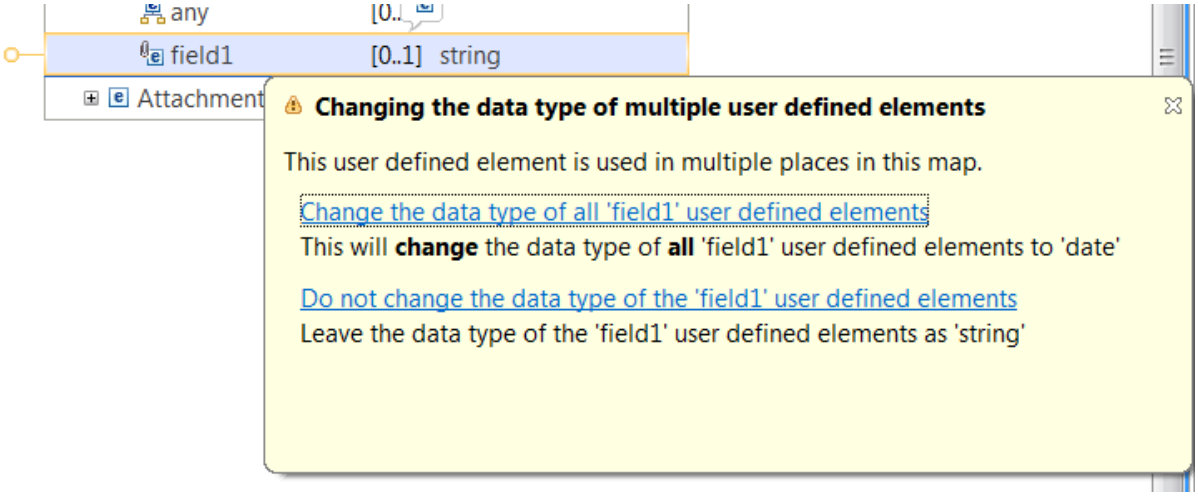
   If the user-defined element name exists, you are prompted to select an action that determines whether to reuse or rename an existing user-defined element in multiple places in the map. You can choose any of the following actions:

   - Select `Change the name of all element1 user defined elements.` to change the name of all user-defined elements with that name in the map. The element *element1* is the name of the existing user-defined element.
   - Select `Change the name of only this element1 user defined element.` to change the name of only this user-defined element. The element *element1* is the name of the existing user-defined element.
   - Select `Do not change the name of this element1 user defined element.` to leave the name unchanged.

4. Optional: When you change the type of an element that is reused multiple times, you must specify whether all elements with the same name are updated to the new type. You can choose from any of the following options:

   - Change the data type of all the user-defined elements with the same name to a new type.
   - Do not change the data type for all the user-defined elements with the same name.

     Note: If you want to change the type of only one instance, you must change the name of the user-defined element and define it with the new type. You cannot have a user-defined element with two distinct types.



What to do next

Edit the message map, and define transformations between the input message assembly and the output message assembly. For more information, see “Mapping input to output elements manually” on page 1418.

Deleting a user-defined element
You can delete a user-defined element by using the **Delete** function from the menu options. Alternatively, you can use the **Delete** key or the **Delete** icon in the Graphical Data Mapping editor button bar.

About this task

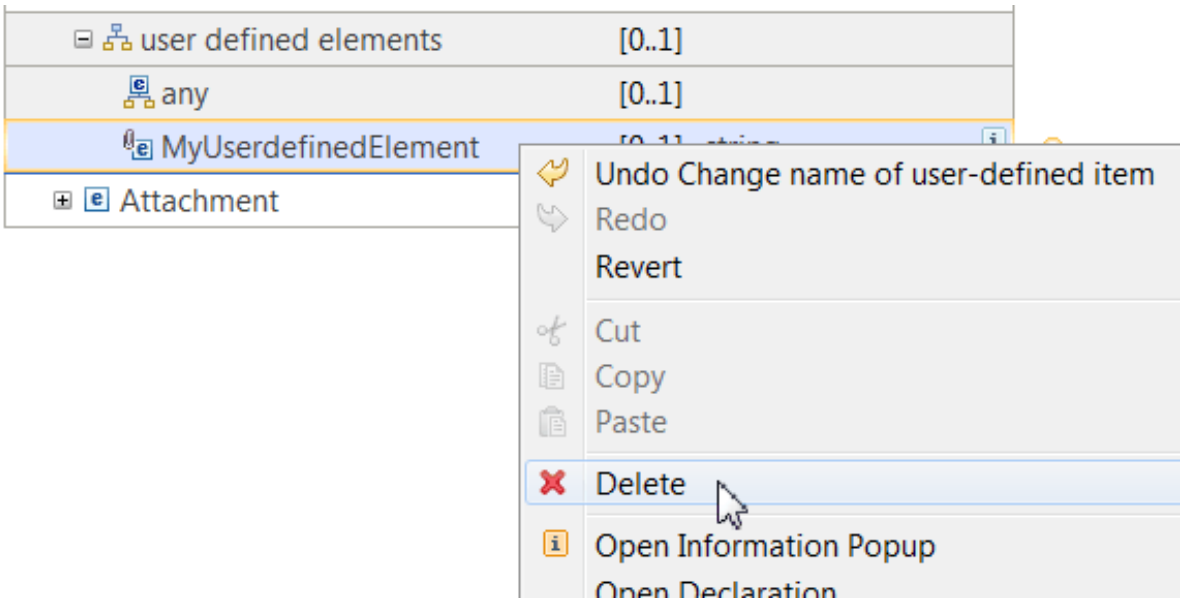
You can reuse a user-defined element in multiple locations in your input message assembly or your output message assembly if they are of the same type. However, you can only delete one user-defined element entry, that is the entry that you select for deletion. The rest of instances where the user-defined element is defined remain intact.

Procedure

Complete the following steps to delete a user-defined element:

1. Identify the user-defined element that you want to delete in the input message assembly or the output message assembly.
2. Right-click the element.

   A menu appears.



3. Select the **Delete** function and click **OK**.

What to do next

Continue editing the message map, and define transformations between the input message assembly and the output message assembly. For more information, see "Specifying a transform (mapping operation)" on page 1430.

Mapping input to output elements manually
Use the Graphical Data Mapping editor to map from input to output elements.

Before you begin

- Create a message map by using the Graphical Data Mapping editor. For more information, see "Creating a message map" on page 1382.
- Add input and output objects to a message map. For more information, see "Adding input and output messages" on page 1396.

About this task

Note: You can also use the Graphical Data Mapping editor to map automatically from input to output elements. For more information, see "Mapping input to output elements automatically" on page 1421.

Procedure

To create manually the mappings between elements in a message map, complete the following tasks:

1. Add connections between the input and output objects. For more information, see "Adding connections between input and output elements" on page 1419.
2. Optional: Connect multiple input elements to a transform. For more information, see "Connecting multiple input elements to a transform" on page 1420.

3. Create the transforms. If the transform that you have selected is a type that is part of a nested transform (for example, Local map, Join, If), you must enter into that nested map and complete the transformation in it. For more information, see "Specifying a transform (mapping operation)" on page 1430.
4. Set the properties for the transforms (for example, Condition, Cardinality, or Order).

What to do next

When you have added your input and output objects, created the connections between them, and specified your transforms, you can test your message map. For more information, see "Troubleshooting a message map" on page 1587.

Adding connections between input and output elements
Use the Graphical Data Mapping editor to create connections between the input and output objects in your message map.

Before you begin

- Read the following concept topics:
  - "Graphical Mapping overview" on page 1264
- Create a message map by using the Graphical Data Mapping editor. For more information, see "Creating a message map" on page 1382.
- Add input and output objects to your message map. For more information, see "Adding input and output messages" on page 1396.

Procedure

You can create a connection in a message map by using one of the following methods:

- Move the cursor anywhere over the required element in the input object, then click and drag the connection over the required output element and drop. You can also create the connection from the opposite direction, by dragging the connection from the output element to the input element. You can also use the grab handle that appears when you hover over an element to click and drag the connection.

  Note: When you drag and drop a connection from an input element to an output element, a transform is added automatically. To add the transform, you must drop the connection above the lowest point of the input and output message. If you use this method in a nested map, you must drop the connection above the lowest point of the shaded area.

  you must drop above the bottom of the shaded area"
- Select the appropriate input or output object and right-click to display the menu, then select **Quick Link**. An outline view of the opposite data structure is displayed; if the **Quick Link** action is invoked on an input object, a quick outline view of the output data structure is shown, and if the action is invoked on an output object, a quick outline view of the input data structure is shown. You can then use the quick outline view and its built-in filter to find and select the required element. When you have selected the required element, a transform is created in the Graphical Data Mapping editor.
- Select the required input element and right-click to display the menu, then select **Add Connection**. This method allows you to carry out other actions in the editor that require the use of mouse clicks (such as expanding output elements, or using the scroll bars) while a transform is being created.
- Some transformations, such as the **Assign** transform, require a connection to an output object, but not to an input object. You can create these transformations either by invoking the **Add Connection** action, or by clicking anywhere on the output object or on its **grab handle** icon and then dragging the connection onto the empty space between the input and output objects.

What to do next

When you have created the connection between your input and output objects, select the required transform as described in "Specifying a transform (mapping operation)" on page 1430.

Connecting multiple input elements to a transform
To make additional input data available to a transform, you can add additional connections. You must define the connection type as either **Primary** or **Supplement**. A **Primary** connection controls the type and outcome of the transform. A **Supplement** connection does not change the type of the transform; it can be used to provide additional input to the transform, or in an optional condition on the transform.

Before you begin

- Read the following concept topics:
  - "Graphical Mapping overview" on page 1264
- Create a message map by using the Graphical Data Mapping editor. For more information, see "Creating a message map" on page 1382.
- Add input and output objects to your message map. For more information, see "Adding input and output messages" on page 1396.

About this task

When you create additional input connections to a transform, you must choose the connection type.

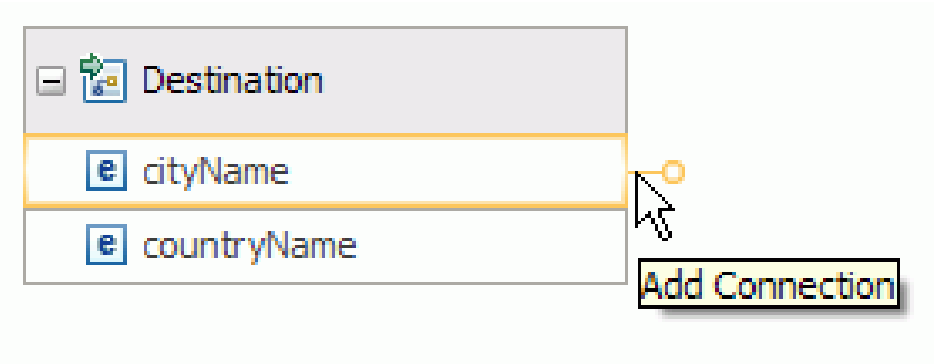
- *Primary connection*: You define a **Primary** connection when you need to control the type and outcome of the transform..
- *Supplement connection*: You define a **Supplement** connection to provide additional input to the transform, or to be used in an optional condition on the transform.

You can also change the preferences of the Graphical Data Mapping editor. You can set the **Let optional connection be primary for transforms that do not accept anymore primary connections** preference.

Procedure

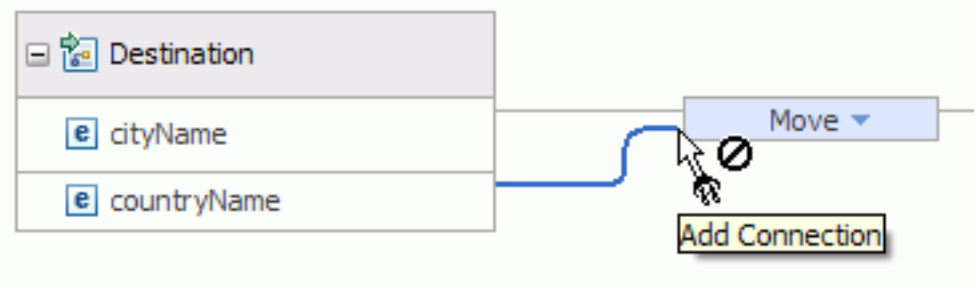
The following steps show how to connect multiple input elements to a transform by using the drag and drop method:

1. Move your cursor to the element of the input object that you want to map:



2. Click anywhere in the input element, or on its **grab handle** icon , and drag the connection to the output element. A connection is created between the two elements, and a transform is assigned, based on the number and type of input elements.

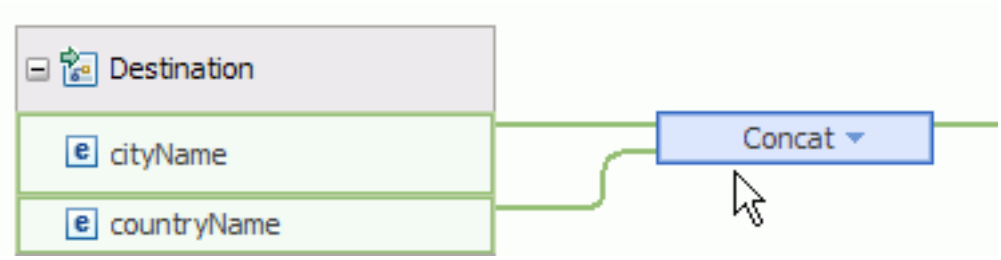
3. Create a new connection between a second input element and the transform.



When you define an additional connection between a second input element to an existing transform in your message map, you are prompted to specify if the connection is a primary connection or if it is a secondary connection (also known as a supplement connection).

4. Specify the type of the new connection as either a primary connection or a secondary connection (Supplement). If you specify a primary connection, the default transform changes to one that allows multiple primary inputs, such as Local Map, Concat, or Join.

For example:



If you choose **supplement connection**, the transform type is not changed and the additional connection is available to use within the transform. For example, you could use its value in a condition expression, or for nested transforms, such as **For each**, **Join**, or **Local map**. The additional input now appears as an extra source on the left side within the nested mapping.

What to do next

When you have created the connection between your input and output objects, select the required transform as described in "Specifying a transform (mapping operation)" on page 1430.

Mapping input to output elements automatically
Use the Auto map wizard (automap) to automatically create **Move** transforms from input to output elements based on some correlation of the names of input and output elements to create mappings.

About this task

You can use Auto map as a quick fix when you create a **Local map** or another nested mapping, and a warning or error marker is displayed to prompt you to complete the nested mapping.

Procedure

The following steps describe how to map from input to output elements by using the Auto map wizard:

1. In the Graphical Data Mapping editor, select the input and output elements that you want to map.
   - If you make no selections, the entire input and output objects in the current mapping level are processed by the Auto map wizard.
   - You can select groups of simple elements or complex elements. For complex elements, the descendants of the selected complex element can be mapped.
2. Click the Auto map icon.

   The Auto map wizard opens.
3. Choose the appropriate **Mapping scope** option:
   - **Map all simple descendants of the selected elements**. This option maps the descendants of the input element to the descendants of the output element that match each other; this option is selected by default. Optionally, select **Group transforms into nested maps**. For more information about using nested maps, see "Grouping transforms into nested maps" on page 1441.
   - **Map the immediate children of the selected elements**. This option maps only the immediate child elements of the input element to the immediate child elements of the output element that match each other.
4. Specify how names are matched in the **Name Matching Options** section.
   a) Select the **Case sensitive** option to set whether you want to match the case sensitivity of the name. This option is not selected by default.
   b) Select the **Alphanumeric characters (Letters and digits only)** option to exclude special characters (for example & and -) from the name. This option is selected by default.

   These two options are independent of each other, and you can select their values separately.
5. In the **Mapping Criteria** section, specify the mapping criteria for the matches between the input and output element names:
   - **Create transforms when the names of inputs and outputs are the same**. This option matches items of the same name, and is selected by default.

     Whether the two names are considered to be the same, depends on your selections for **Case sensitive** and **Alphanumeric characters (Letters and digits only)**. For example, if you use the default options for **Case sensitive** and **Alphanumeric characters (Letters and digits only)**, GIVEN_NAME and GivenName are considered to be a match. However, if you select **Case sensitive** and **Alphanumeric characters (Letters and digits only)**, the two names are considered to be identical only if they contain the same alphanumeric characters in the same order, and the characters are of the same case.

     For more information, see "Mapping by same name" on page 1423.
   - **Create transforms when the names of inputs and outputs are more similar than**. With this option, you can specify how similar two names must be to create a mapping between them by varying the result from zero to 100 percent. The result is displayed and the default value is 60; see "Examples of similarity values" on page 1425 for some examples of how similar words are matched to one another.

     For more information, see "Mapping by similar name" on page 1424.
   - **Create transforms when the input and output names are matched to synonyms defined in a file**. With this option, you can create mappings for word pairs that are defined in a synonym file. A synonym file is a flat text file with file extension `.txt` or `.csv`. For further information about

creating a synonym file from a Microsoft Excel spreadsheet, see “Creating and using a synonym file” on page 1428.

For more information about the synonym file, see “Format of the synonym file” on page 1425. For information about the methods that are used to match synonyms in a synonym file, see “Algorithm used to match synonyms” on page 1428.

If the input and output names that you are using satisfy more than one of the following options, the order in which names are matched is:

a. Same

b. Synonym

c. Similar

Any output that is matched during an earlier step is excluded from name matching in a later step.

6. Click **Finish** to start the auto mapping, or click **Next** to view a summary of the transforms that were found and to choose the transforms that you want to create. You can clear matches that are defined on the **summary** page.

   Sometimes an input might match to more than one output; use the summary page to review and choose which mappings to create.

   The auto mapping is performed, and the selected matched input and output elements are mapped through **Move** transforms. Each auto mapped **Move** transform is annotated to indicate that it was created as a result of auto mapping. Hover the mouse or right-click the annotated transform to accept or reject the automatically created transforms.

Mapping by same name

Learn about the rules that apply when you select the **Create transforms when the names of inputs and outputs are the same** option in Auto map (automap).

About this task

When you select **Create transforms when the names of inputs and outputs are the same**, the following rules apply:

1. Any output field that has a fixed value is excluded in name matching. Any output that is already mapped, or under a container that is already mapped, is excluded from name matching.
2. If an input and an output have the same name, it is a match, regardless of the kind of, and XSD type of, the input and output. An element, a database column, or an attribute can all form a match if their names are the same.
3. XML namespaces are excluded from name matching. Therefore, `abc:something` and `xyz:something` are considered the same, as are `{http://www.abc.com}:something` and `{http://www.xyz.com}:something`.
4. When multiple inputs have the `same` name as one output, one mapping is created.

   However, if you have multiple inputs with the same name as one output and you choose to map by the same name (or similar name) **and** to match descendants, an attempt is made first to match by path and name. If a match is found, one transform is made, and no further matches are considered.
5. When a single input has the same name as multiple outputs, multiple mappings are created, each for one input and one output.

   However, if you have a single input with the same name as multiple outputs and you choose to map by the same name (or similar name) **and** to match descendants, an attempt is made first to match by path and name. If a match is found, one transform is made, and no further matches are considered.

6. When you select the **Map all simple descendants of the selected elements** option, the following steps are taken to match names:

   a. Compare the relative path and item name of the selected input and output

   b. Compare the item name without relative path

   For example, assume you have the following input and output items:

   - **Input:**

   ```
   OldPurchaseOrder
     items
      item
       partNum
     partNum
   ```

   - **Output:**

   ```
   NewPurchaseOrder
     items
      item
       partNum
     resource
      partNum
   ```

   If you select **Create transforms when the names of inputs and outputs are the same** when you have the inputs and outputs shown above, the relative paths of all the items are:

   - Relative paths of the input items:

   ```
   items/item/partNum
   partNum
   ```

   - Relative paths of the output items:

   ```
   items/item/partNum
   resources/partNum
   ```

   During step a) `items/item/partNum` and `items/item/partNum` are matched.

   During step b) `partNum` and `resources/partNum` are matched.

   Inputs and outputs matched in a previous step are ignored in later steps.

   When you select the **Map the immediate children of the selected elements** option, the only step taken to match names is to compare the item name without the relative path.

Mapping by similar name
Learn about the rules that apply when you select the **Create transforms when the names of inputs and outputs are more similar than** option in Auto map (automap).

About this task

When you select **Create transforms when the names of inputs and outputs are more similar than**, the following rules apply:

1. Fixed value outputs and mapped outputs are excluded in name matching.
2. The *similarity* test is done using the name of an element, a database column, or an attribute regardless of its type. If an input and an output have the same name, it is a match, regardless of the kind of, and XSD type of, the input and output. An element, a database column, or an attribute can all form a match if their names are the same.
3. The similarity test applies in the same way to case sensitivity and alphanumeric characters as for **Mapping by same name**.
4. Namespace or namespace prefixes do not participate in the similarity test. XML namespaces are excluded from name matching. Therefore, `abc:something` and `xyz:something` are considered the same, as are `{http://www.abc.com}:something` and `{http://www.xyz.com}:something`.

5. When multiple inputs have the same name as one output, one mapping is created. However, if you have multiple inputs with the same name as one output and you choose to map by the same name (or similar name) **and** to match descendants, an attempt is made first to match by path and name. If a match is found, one transform is made, and no further matches are considered.
6. When you select **Map all simple descendants of the selected elements**, the following steps are taken to match names.

   Inputs and outputs matched in a previous step are ignored in later steps:

   a. Compare the relative path and item name of the selected input and output
   b. Compare the item names without relative path
   c. Compare similar item names without relative path

   When you select the **Map the immediate children of the selected elements** option, the only step taken to match names is to compare similar item names without the relative path.
7. You can select the similarity threshold for two words to be considered similar.
8. You cannot use any other similarity algorithm.

Examples of similarity values
The following table lists words that are similar to one another, together with their similarity value, as a percentage:

Word1	**Word2**	**Similarity value %**
catalog	catalogue	85
anasthesia	anaesthesia	84
recognize	recognise	75
color	colour	66
theater	theatre	66
tire	tyre	33
intro	introduction	53
abbr	abbreviation	42
name	fullname	60
firstname	fullname	40
id	identification	14
NCName	Non colonized name	40
USA	United States of America	0
faq	frequently asked questions	0

Format of the synonym file
The Auto map (automap) facility allows you to create mappings between specific inputs and outputs by putting the names of the inputs and outputs in a file called the synonym file.

Synonyms, in the context of the synonym file, are groups of words that represent mappings that you want to create.

File type

A synonym file can reside anywhere in your file system, only if the encoding used in the synonym file is the same as that used by the Eclipse Toolkit system.

However, if the synonym file uses a specific encoding that is, or might be, different from the encoding of the Eclipse Toolkit, the file must reside in a project in the IBM App Connect Enterprise Toolkit.

If the synonym file is created outside the IBM App Connect Enterprise Toolkit, and uses a specific encoding, save the file under an IBM App Connect Enterprise Toolkit project and click **Refresh** to make the file visible in the navigator.

The synonym file uses Tab-separated or comma-separated files only. If you have written your mapping requirement in any external application, for example, Microsoft Word or Microsoft Excel, you must export the relevant data in a format that the synonym file supports.

Item names in the file

A synonym file contains the names of items to be mapped, without the path to the item or the namespace of the item.

For example, if you want to map `partNum` to `partNumber` in the following XML, you must put `partNum` in the synonym file, not `item/partNum`, `items/item/partNum`, or `purchaseOrder/items/item/partNum`.

```
<po:purchaseOrder xmlns:po="http://www.ibm.com">
 <items>
    <item>
         <partnum>100-abc</partnum>
         <productName>Acme Integrator</productName>
         <quantity>22</quantity>
         <USPrice>100.99</USPrice>
         <po:comment>Acme Integrator</po:comment>
         <shipDate>2008-12-01</shipDate>
    </item>
 </items>
</po:purchaseOrder>
```

Synonyms in the file can:

- Be case sensitive or not case sensitive
- Contain the entire mapping item name
- Have non-alphanumeric characters removed

Rows in the synonym file

In the synonym file, each row represents one group of names to be mapped between each other and each row must contain at least two names. Names within a row are separated by commas in `.csv` files, and by Tab characters in `.txt` files.

A synonym file can contain an optional special row at the top. This top row contains key words **Input**, **Output**, or **Input_Output**, separated by the same delimiter used in the remainder of the file. The top row is used to indicate whether the synonyms are to be used to match names in mapping the input or the output:

- If the first word in the top row is **Output**, the first name only, in each subsequent row is searched in the mapping output for name matching.
- If the second word in the top row is **Input**, the second name only, in each subsequent row is searched in the mapping input for name matching.
- If the third word in the top row is **Input_Output**, the third name only, in each subsequent row is searched in both the mapping input and mapping output for name matching.

The top row must not contain fewer key words than the maximum number of names in any row in the file.

If the top row contains any word other than **Input**, **Output**, or **Input_Output**, the top row is ignored and it is assumed that the top row is missing. If you omit the optional top row, every name in the synonym file is considered to be **Input_Output**; that is, any name found either in the mapping input or in the mapping output is matched.

If a synonym file contains two rows:

```
car               automobile
automobile        vehicle
```

car and *vehicle* are not considered to be synonyms.

In order to make all three words synonyms, your synonym file can have either of the following structures:

- One row with all three words -

```
car          automobile          vehicle
```

- Three rows -

```
car          autombile
automobile   vehicle
car          vehicle
```

Special characters

You can write synonym files manually, or export them from another application; for example, Microsoft Excel.

Item names in synonym files reflect the application domain and do not have to match exactly the names in the XML schema or the relational database column.

For example, a synonym file might contain the row:

```
         summer       l'été
```

As `l'été` does not conform to the XML NCName format, you could name the element `l_été`. If all the alphanumeric characters in the synonym file match those in the schema, you can use the file with the option **Alphanumeric characters (Letters and digits only)**.

Many mapping requirements are written in Microsoft Excel, and cells in a Microsoft Excel file might contain specific characters like double quotation marks, space, new line, comma, and so on. When such a Microsoft Excel file is saved as a Tab-separated or comma-separated file, they contain additional double quotation marks.

Two groups of synonyms in a synonym file are delimited either by a Line Feed (LF) character, or Line Feed followed by a Carriage Return (LFCR). A Carriage Return (CR) character by itself does not end a group of synonyms.

Leading and trailing space characters adjacent to the delimiter (comma or Tab character) are ignored. Blank rows, or rows that contain only space characters, are permitted and ignored in a synonym file.

Different editors might inject different space characters into a synonym file; spaces are not used to delimit synonyms, and spaces are ignored unless they are inside double quotation marks.

If a synonym contains a comma, a double quotation mark, a carriage return, or a leading or trailing space that is significant, the synonym must be enclosed in double quotation marks. A double quotation mark within a synonym is escaped with another double quotation mark. For example:

```
        "comma,separated"
        "double""quote"
          "with<CR>
           newline"
          "  spaces   "
```

When the synonym file is read by the Graphical Data Mapping editor, the double quotation marks at the beginning and end of the synonym are removed and the following data is stored in the synonym table:

```
        comma,separated
        double"quote
          with<CR>newline
            spaces
```

The Graphical Data Mapping editor reads a synonym file containing these special characters correctly, and you should select the **Alphanumeric characters (Letters and digits only)** option when using the synonym file.

Algorithm used to match synonyms
The way in which synonyms are matched by the Auto map (automap) function, to create mappings between specific inputs and outputs, follows a set of rules.

1. Fixed value outputs and mapped outputs are excluded in name matching. Any output field that has a fixed value is excluded in name matching. Any output that is already mapped, or under a container that is already mapped, is excluded from name matching.
2. The synonym matching is done by using the name of an element, a database column, or an attribute regardless of its type. If an input and an output have the same name, it is a match, regardless of the kind of, and XSD type of, the input and output. An element, a database column, or an attribute can all form a match if their names are the same.
3. The synonym matching of alphanumeric characters is not case-sensitive, and is identical to that used in "Mapping input to output elements automatically" on page 1421.
4. Namespace or namespace prefixes do not participate in synonym matching. XML namespaces are excluded from name matching. Therefore, `abc:something` and `xyz:something` are considered the same, as are `{http://www.abc.com}:something` and `{http://www.xyz.com}:something`.
5. When multiple inputs have the `same` name as one output, one mapping is created. However, if you have multiple inputs with the same name as one output and you choose to map by the same name (or similar name) **and** to match descendants, an attempt is made first to match by path and name. If a match is found, one transform is made, and no further matches are considered.
6. If an input and an output have the `same` name, they are not considered a match under the option for synonyms. If you require a mapping for same-name inputs and outputs, you must also select the **Create transforms when the names of inputs and outputs are the same** option.
7. In addition to mapping synonyms, you might want to create mappings for some, but not all, same-name inputs and outputs. In this case, you have two options:
   - Clear **Create transforms when the names of inputs and outputs are the same**, and include the same-name inputs and outputs in the synonym file
   - Select **Create transforms when the names of inputs and outputs are the same**, and clear the unwanted mappings on the second page of the wizard.
8. When you select the **Map all simple descendants of the selected elements** option together with both same name and synonym mapping options, the following steps are taken to match names:
   - Compare the relative path and item name of the selected input and output
   - Compare the item name without relative path
   - Compare the item name without relative path to synonym

   Inputs and outputs matched in a previous step do not participate in later steps.
9. When you select the **Map the immediate children of the selected elements** option together with both same name and synonym mapping options, the following steps are taken to match names:
   a. Compare the item name without relative path
   b. Compare the item name without relative path to synonym

   Inputs and outputs matched in a previous step do not participate in later steps.

Creating and using a synonym file
You can use a synonym file to configure automatic mapping of input to output elements in the Auto map wizard (automap). You can use either a Tab delimited `.txt` file or a comma delimited `.csv` synonym file.

You can create a synonym file manually or generate a synonym file from the information that is contained in a Microsoft Excel spreadsheet.

Procedure

Complete the following steps to configure Auto map to use a synonym file that is created from the information that is contained in a Microsoft Excel spreadsheet:

1. Optional: Create a synonym file where the original mapping requirement is written in Microsoft Excel. The following set of instructions describe how to create a synonym file where the original mapping requirement is written in Microsoft Excel. If your original requirement is written in a table in Word, you must copy and paste the table into Microsoft Excel before you begin.
   a) Select the section of the Microsoft Excel spreadsheet that you require.
   For example, if you have a Product that you want to map to a Part number, select that section of the spreadsheet.
   b) Remove all columns from the spreadsheet, except the ones that contain the input field name and the output field name.
   You might have to edit some of the cells. For example, if your mapping instruction includes the phrase `based on`, remove this phrase.
   c) If the input or output fields contain paths, remove the paths to leave only the short names of the item.

   However, it is helpful to sort the column before you remove the paths. Sorted path names can indicate which is the best input or output to select when you start the action. If all the interested inputs or outputs start with the same path prefix, you might consider selecting the lowest input (or output) node in the tree, which has that common path prefix.
   d) Remove all rows that do not have an input field name and an output field name.
   For example, if you have an obsolete product that no longer has a part number and you have `n/a` in the input, remove that row.
   e) Select the **Save As** function in Microsoft Excel to save the spreadsheet into a format that is supported by IBM App Connect Enterprise Toolkit.

   You can use either a Tab delimited `.txt` file or a comma delimited `.csv` file. A comma delimited file can be opened with Microsoft Excel. The file can also be opened in a text editor.
2. Create the mappings by using the synonym file. Select the options in the Auto map wizard that match your requirements.
   For example, select the default options of **Map all simple descendants of the selected elements** and **Alphanumeric characters (Letters and digits only)**.

   When you choose these options, select **Create transforms when the input and output names are matched to synonyms defined in a file**.

   If you want to map same-name inputs to outputs, and the synonym file does not contain rows with those names (for example a row with **car,car**), select the **Create transforms when the names of inputs and outputs are the same** option, in addition to the **Create transforms when the input and output names are matched to synonyms defined in a file** option.

   You can select both **Create transforms when the names of inputs and outputs are the same** and **Create transforms when the names of inputs and outputs are more similar than**, in addition to **Create transforms when the input and output names are matched to synonyms defined in a file**, if your synonym file does not contain a row **color,color** and you want to map between them.
3. Click **Finish**.

Selecting matches
Use the Auto map wizard (automap) to select the mappings that you want to create.

About this task

When you have specified how you require the names to be matched on the initial panel of the Auto map wizard, and have selected **Next**, you see a panel that displays all the matches found.

You can now select the options that you require:

Procedure

1. Select a row in the **Transform Outputs** column that you want to change.
   Selecting a folder tree node results in the entire tree branch being selected or not selected.
2. Click **Edit** to start the **Select Transform Input** dialog.
3. To select a transform output, select the appropriate tree node check box.
   Conversely, to remove a mapping output, clear the appropriate tree node check box.
4. Ensure that you have selected only the number of matches that you require.
   The third column displays the number of transform inputs selected for each transform output. The cell has a value greater than one when the input of a transform contains several elements of certain names under various containers, and the input names match to the same output name.
5. Click **Finish** to complete the mapping process, or click **Back** to change the matches that you have set up.
   When you click **Finish**, you obtain a warning message if either, or both, of the following conditions apply:
   a. More than a few inputs to map to the same output.
   b. Many outputs for which you want to create mappings.

Specifying a transform (mapping operation)
Specify a transform, a cast function, or an XPath function between two or more elements by selecting from the list of available mapping operations that are shown on the connection.

Before you begin

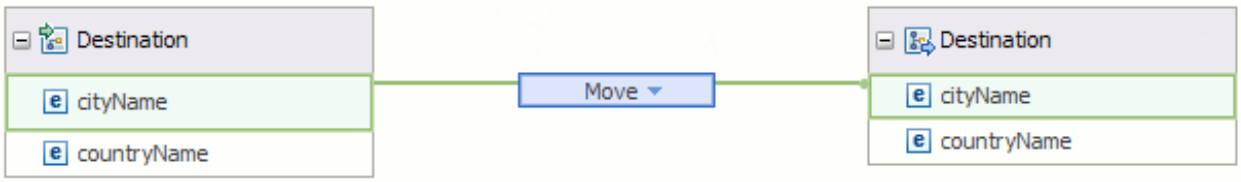
Learn about the different mapping operations. For more information, see "Transforms (Mapping operations)" on page 1280.

About this task

In the Graphical Data Mapping editor, you can use transforms, cast functions, and XPath 2.0 functions to run different actions on input data and move the result to the output element. You choose the appropriate mapping operation that is based on the result that you want to achieve.

When you create a connection between two or more elements, a transform is assigned, based on the number and type of input elements. You can then change the transform by choosing from a list of available transforms. If a particular transform type is not shown in the list, that transform is not valid for your input and output elements.

For example:



Note: Transforms that require multiple inputs such as **ForEach**, **Join**, or **Append** are not available in the list of available transforms until you wire two inputs to the transform.

Note: When you drag and drop a connection from an input element to an output element, a transform is added automatically. To add the transform, you must drop the connection above the lowest point of the

input and output message. If you use this method in a nested map, you must drop the connection above the bottom of the shaded area.

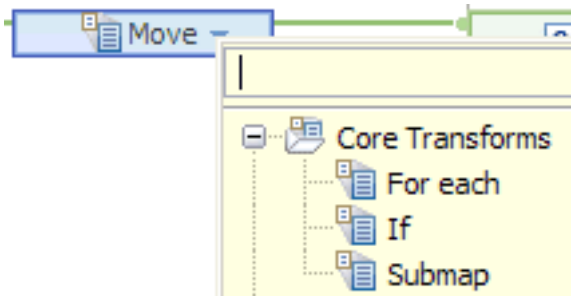
When you have a list of valid transform types, choose the appropriate transform:

- If you have a single array as input, with the same array type as output, and you want to move all elements to the output, use **Move**.
- If you have a single array as input, and you want to iterate over each element in the array (for example, you might want to remove some elements) use the **ForEach** transform and set the cardinality options.
- If you have multiple input elements, you can use the **Append** or the **Join** transforms. If you use the **Append** transform, the number of output elements is the total of the input elements. If you use **Join** transform, the number of output elements depends on the user expression added to specify the matching criteria for joining or filtering input items.

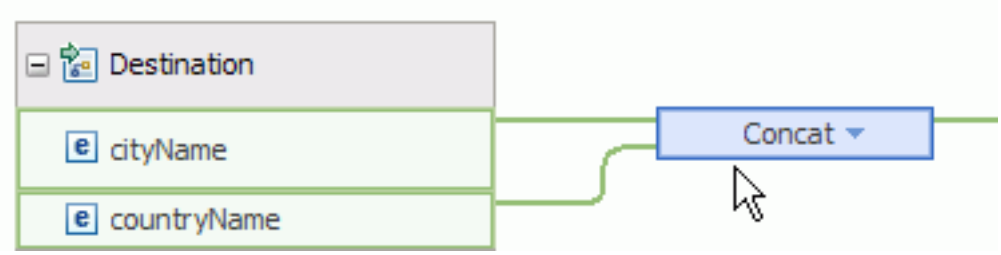
The following steps show how to change the transform that is selected, and also how to add more elements:

Procedure

1. Change the transform by clicking the arrow in the transform box, and selecting from the list of available transforms.
   For example:



2. If you create more primary connections between an input element and the transform, the transform type changes to one that allows multiple primary inputs, such as **Local Map**, **Concat**, or **Join**.
   For example:



What to do next

Configure the properties of the transform. For more information, see “Configuring the properties of a transform” on page 1431.

Configuring the properties of a transform
Configure the properties of a transform to set the value of an output element; define a conditional expression that determines whether the transform is applied; define the indexes to use when the input

element is a repeating structure; or reorder the way in which inputs to a transform are handled by the Graphical Data Mapping editor.

Procedure

Complete the following steps to configure the general properties of a transform:

- Open the **Properties** view of a transform by using any of the following methods:
  - Select a transform. Then, select the **Properties** tab.
  - Right-click the transform, and then select **Show in** > **Properties view**.
  - When the map is in full vie, select `Alt+Enter`.

    You can configure these keyboard shortcuts by selecting **Window** > **Preferences** > **General** > **Keys**.

  Note: You can detach the **Properties** view from the map. This is very useful if you have a secondary workstation screen. In one workstation screen you can see the map, and in the other you can see the properties map.
- In the **Properties** tab, add, modify, or remove resources:
  - Select **Cardinality** to select the indexes of the input and output elements that you want this transform to operate over. For more information, see "Selecting the indexes of input array elements" on page 1363.
  - Select **Variables** to list the names of the input elements that are connected to the transform. Select **Edit** to change the name of a variable.

    Note: When you change the name of a variable, the new name is the one you see when you use content-assist to create your expressions.
  - Select **Condition** to define the XPath expression that must be evaluated against the input element before the transform is applied. If the condition evaluates to **true**, the transform is applied. For more information, see "Defining an XPath conditional expression for a transform" on page 1433 and "Defining a Java conditional expression for a transform" on page 1439.
  - Select **Filter** to define an expression that must be evaluated against each element on a repeating input element before the transform is applied. If the condition evaluates to **true**, the transform is applied for each input.
  - Select **Sort** to sort the inputs to the transform by ascending order, descending order, case order, or data order. Then, complete the following steps:

    1. Select **Sort the inputs to this transform**.
    2. Add elements to the **Sort by** column.
    3. Select a sort method.

    Note: The element or elements that are used to provide the sort must provide a singular, scalar value. If you nest sorts, each sort uses the original input data value for the sort element. Specifically, the outer sort cannot use the result of a nested sort.
  - Select **Order** to display the order of input connections to a transform. You can reorder them.
  - Select **Documentation** to provide a description of the transform, or other relevant usage notes.

What to do next

Deploy and test the message map. For more information, see "Troubleshooting a message map" on page 1587.

Defining an XPath conditional expression for a transform
You can define an XPath expression to set the conditional expression that determines whether a transform is applied in a message map. When the XPath expression evaluates to true, the transform is applied.

About this task

When you define an XPath expression, you use the variable names of input elements. The value of an input element has an *effective Boolean value*.

The effective Boolean value is false for the following input elements:

- The input element is Boolean and its value is `false`.
- The input element is a sequence, and the sequence is empty.
- The input element is string and its value is the empty string `""`.
- The input element is a float or a decimal and the value is `NaN (not a number)`.
- The input element is of a numeric type and its value is `0`.

In any of these cases, the XPath expression can be formed from just the variable name that represents the input element.

You can also get a Boolean result from defining expressions that use variable names that represent inputs and constant values and any of the following operators :

- Logical operators such as `and`, `or`, `not`.
- Comparison operators such as =, `!=`, <, >, <=, >=.

Note: Always use content assist to select the variable name of the input elements that you use to define the XPath expressions. If you do not use content assist, you may be using an incorrect element name and your map will fail at run time.

Note: XPath 1.0 functions are valid XPath 2.0 expressions. You can use the XPath Expression Builder to generate simple XPath 1.0 expressions.

Note: If you define a conditional expression for a transform, and then realize that the condition is identical for other transforms in the map, change the transform to an **If** transform. The conditional expression remains unchanged.

Procedure

Complete any of the following steps to set a conditional expression in a transform:

- For non-repeating elements, select the **Condition** property in the **Properties** tab, and enter an XPath expression.
- For repeating elements, select the **Filter Inputs** property in the **Properties** tab, and enter an XPath expression that will be applied to each instance of the repeating element.

  For more information, see “Defining an XPath conditional expression for a structural transform (ForEach)” on page 1437.

Results

The input element is evaluated against the condition. If the condition evaluates to true, the transform is applied to the input element.

Example

The following examples show how to define simple XPath conditional expression for a transform when you have non-repeating elements:

Example: XPath expression to check a Boolean input element

This example shows how to define the XPath expression for a Boolean element so that it evaluates to true. The expression depends on the value of the Boolean element.

The XML schema for the element is the following:

```
<element name="IsEmployee" type="boolean"></element>
```

When the value of a Boolean element is set to **false**, the XPath expression that you define is the following:

```
fn:not($IsEmployee)
```

When the value of the Boolean element is set to **true**, the XPath expression that you define is the following:

```
$IsEmployee=fn:true()
```

The $IsEmployee expression on its own tests if the element exists and always evaluates to true if the element exists regardless of what value it is set to.

Example: XPath expression to check if the value of a numerical input element is greater than a constant value

This example shows how to define an XPath expression that evaluates to true when the value of a numerical element is greater than 200.

The XML schema for the element is the following:

```
<element name="BusinessUnit" type="int" ></element>
```

The XPath expression that you define is the following:

```
$BusinessUnit > 200
```

Example: XPath expression to check if a numerical input element has a specific value

This example shows how to define an XPath expression that evaluates to true when the numerical input element has a value of `0`.

The XML schema for the element is the following:

```
<element name="QtyBooks" type="int" ></element>
```

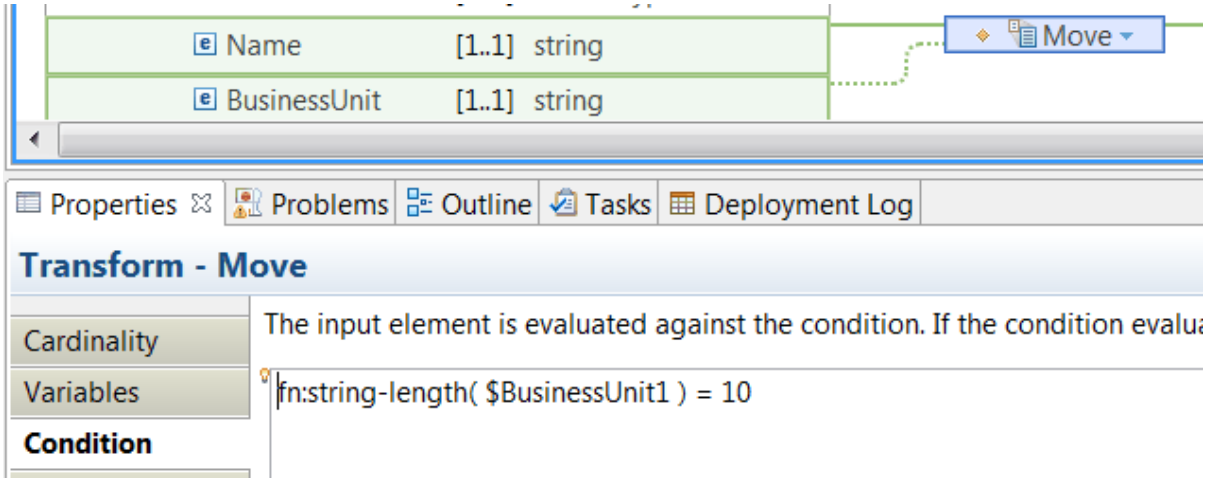
The XPath expression that you define is the following:

```
$QtyBooks = 0
```

Example: XPath expression to check the string length of an input element

This example shows how to define an XPath expression that evaluates to true when the length of a string is 10.

- The **Move** transform has a primary connection wired from the element **Name**.
- The **Move** transform has a secondary connection wired from the element **BusinessUnit**. This connection is supplementary because this element is not used to calculate the value of the output element.
- The **Move** transform should only execute if the length of the element **BusinessUnit** is `10`.



The XML schema for the elements are the following:

```
<element name="Name" type="string" ></element>
```

```
<element name="BusinessUnit" type="string" ></element>
```

The XPath expression that you define is the following:

```
fn:string-length($BusinessUnit) = 10
```

Example: XPath expression to check if a string input element is set to the empty string

This example shows how to define an XPath expression that evaluates to true when a string element is empty.

To define an XPath expression that checks if a string element is empty, you must use the operator `!=`.

The XML schema for the element is the following:

```
<element name="Name" type="string" ></element>
```

The XPath expression that you define is the following:

```
$Name != ''
```

Example: XPath expression to check if a repeating element is empty

This example shows how to define an XPath expression that evaluates to true when a repeating element, which is referred to as a sequence, is empty.

The effective Boolean value of an empty sequence is false. You could use `fn:not($Address)`, but it is easier to understand if you use `fn:empty()`.

The XPath function **fn:empty()** evaluates to `true` if a sequence is empty.

The XML schema for the element is the following:

```
<xsd:element form="qualified" name="Address" type="mqsistr:Address"
maxOccurs="unbounded" minOccurs="0" />
```

The XPath expression that you define is the following:

```
fn:empty($Address)
```

Example: XPath expression to check if an optional input element is present

This example shows how to define an XPath expression that evaluates to true when an optional element is present.

Use the `fn:exists` XPath function if the input element is a boolean. Otherwise, you can use the effective Boolean value.

The XML schema for the element is the following:

```
<element name="BookName" type="string" maxOccurs="unbounded" minOccurs="0" ></
element>
```

The XPath expression that you define is the following:

```
$BookName
```

Example: XPath expression to check if a complex input element has no content, that is, it is empty

To determine whether a complex element is empty, you must check for the presence of child elements or attributes.

Testing the effective Boolean value of elements or attributes that are present in a complex type will yield true. You can use the `fn:not` XPath function to invert a boolean.

The `fn:not` function accepts a sequence of items. The value that this function returns is true if any of the arguments is either a single Boolean value false, a zero-length string, the number 0 or NaN, or the empty sequence. Otherwise, it returns false.

This example shows how to define an XPath expression that evaluates to true when the complex input element has no children.

The XML schema for the elements are the following:

```
<complexType name="Address">
    <sequence>
 <element name="Type" type="string"/>
 <element name="Number" type="integer"/>
 <element name="Street" type="string"/>
 <element name="Postcode" type="string"/>
 <element name="City" type="string" />
 <element name="Country" type="string"/>
 <element name="AdditionalInfo" type="string"/>
    </sequence>
</complexType>
```

The XPath expression that you define to check for child elements being present in a complex element is the following:

```
fn:not($Address/* )
```

The XPath expression that you define to check for attributes being present in a complex element is the following:

```
fn:not($Address/@* )
```

The XPath expression that you define to check for elements and attributes being present in a complex element is the following:

```
fn:not($Address/*) and fn:not($Address/@* )
```

What to do next

Deploy and test the message map. For more information, see “Troubleshooting a message map” on page 1587.

Defining an XPath conditional expression for a structural transform (ForEach)
Configure the **Filter Inputs** section in the **Properties** view of the **ForEach** transform to define the conditional expression that determines whether the transform is applied in a message map.

About this task

The **ForEach** transform can only have one **primary** input connection. Additional connections to the **ForEach** transform must be of type **Supplement**.

Procedure

Complete the following steps to define a conditional expression on a **ForEach** transform:

- Select **Allow empty input** if you want the **ForEach** transform to execute at least one.

  If you select this option, the transformations that you define in the **ForEach** transform nested map will execute once regardless of the conditional expression.
- Define the XPath expression that determines whether the **ForEach** transform is applied in the map.

  Note: Always use content assist to select the name of the input elements that you use to define the XPath expressions.

  The conditional expression applies to all the indexes that you configure in the **Cardinality** tab of the **ForEach** transform properties view.

Results

The input element is evaluated against the condition. If the condition evaluates to true, the transform is applied to the input element.

Example

This example shows how to define an XPath expression that checks the value of a string element:

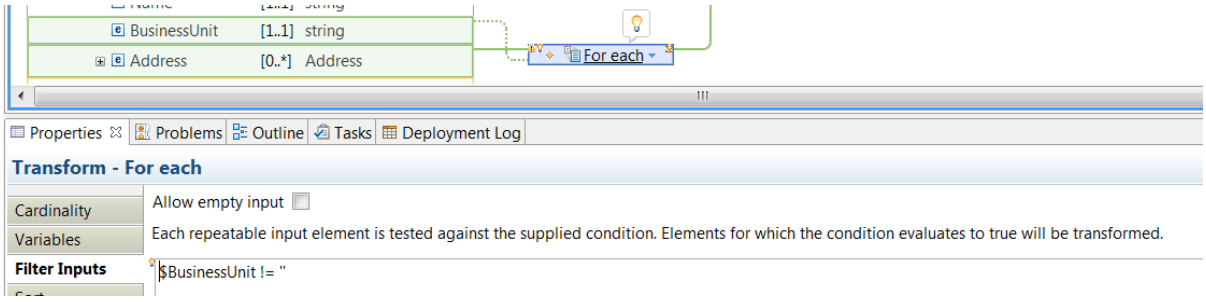
- The **ForEach** transform has a primary connection wired from the repeating element **Address**.
- The **ForEach** transform has a secondary connection wired from the mandatory element **BusinessUnit**. This element can be set to nil. This element is not used to calculate the value of the output element.
- The **ForEach** transform should only execute if the **BusinessUnit** element is not empty.

The XML schema for the mandatory element is the following:

```
<element name="BusinessUnit" type="string" nillable="true"></element>
```

The XML schema for the repeating element is the following:

```
<xsd:element form="qualified" name="Address" type="mqsistr:Address"
maxOccurs="unbounded" minOccurs="0" />
```



The XPath expression that you define is the following:

```
$BusinessUnit != ''
```

What to do next

Deploy and test the message map. For more information, see "Troubleshooting a message map" on page 1587.

Choosing an XPath conditional expression that tests for a nil value in a transform
Use the XPath functions **fn:empty**, **fn:nilled**, or **fn:exists** to test if an output element is set to nil. You can use these functions to define conditional expressions in a transform.

About this task

For example, you can use **fn:empty**, **fn:nilled**, or **fn:exists** as part of conditional expression that determines if a transform is applied. You can also use these transforms as part of the conditional expressions that you set in an **IF** transform.

Procedure

- Choose any of the following XPath functions to determine the state of a source element:

XPath function	Usage	Source element	Output
fn:empty	Tests whether a set of elements is empty	A single XML or non-XML element that is present and nilled	false
fn:empty	Tests whether a set of elements is empty	A NULL value in a logical tree	false
fn:empty	Tests whether a set of elements is empty	A missing element, not present in the logical tree	true
fn:nilled	Tests whether an element is nilled	A nillable XML element	true only if the xsi:nil attribute is present and set to 'true' in the logical tree
fn:nilled	Tests whether an element is nilled	A nillable non-XML element	true only if the value in the logical tree is NULL
fn:exists	Tests whether an element exists	A single XML or non-XML element	true if the element is present in the logical tree, regardless of the nillable and nilled state
fn:exists	Tests whether an element exists	A NULL value in a logical tree	true
fn:exists	Tests whether an element exists	A missing element, not present in the logical tree	false

Example

This example shows an XPath expression that checks if an input element is nilled.

The XPath expression evaluates to true when an input element is not set to nil.

Use the `fn:nilled` XPath function to test whether the value of an input element has the `xsi:nil` attribute set.

Note: An XML element that has the `xsi:nil` attribute set is considered to be present.

The XML schema for the element is the following:

```
<element name="BookName" type="string" nillable="true" ></element>
```

The XPath expression that you define is the following:

```
fn:nilled( $BookName)
```

Defining a Java conditional expression for a transform
You can use a Java method to set the conditional expression that determines whether a transform is applied in a message map.

About this task

To define the conditional expression, you can define an XPath expression or a call to a static method on an imported Java class. You can also create a compound (nested) expression that includes XPath, Java and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

Note: When you define a Java conditional expression, the following rules apply:

- You can use Java methods that only use standard Java types.
- You cannot use Java methods that include **MbElement** data type arguments.
- You can use Java methods that use the **DOM API**. For more information on the supported types, see "Custom Java" on page 1312.

Note: If you define a conditional expression for a transform, and then realize that the condition is identical for other transforms in the map, change the transform to an **If** transform. The conditional expression remains unchanged, and the transform is moved within the nested level of the **If** transform. Then, place all of the transforms that depend on the same condition in the **If** nested mapping.

Procedure

Complete the following steps to set a conditional expression in a transform:

1. Create a message map.

   When you use Java code in a map, you can define the map in a static library project, a shared library project, an application project, or an integration project. You can define the Java code in one or more Java projects. Your map project must reference these Java projects. For more information, see Adding a project to an application, integration service, or library

   Note: When the map uses Java code available in a shared library, you must create the map in the shared library project where the Java code is available.

   For more information, see "Creating message maps" on page 1378.
2. Create a Java project.

   For more information, see Creating a Java project.
3. Create Java object classes.

   The Java class that you provide to the map must have static methods that return Boolean values.

   For example, the following Java method might be used to define a conditional expression on a transform:

```
public static boolean lessThanHund(BigDecimal val) {
  if ( val.intValueExact() < 100 )
   return true;
```

```
  return false;
}
```

4. Ensure that the Java project the class is in is referenced by the project that contains the map.

   Before you create a reference to a Java project, ensure that the Java class is available in a Java project in your workspace.

   a. In the **Application development** page, right-click the project where the map is defined.

   b. Select **Managed included projects**.

   c. Select the Java project, and then click **OK**.

5. Make the Java class visible anywhere in the map. Unless you have already used a method from the Java class in a Custom Java transform elsewhere in the map, you must manually create an import for the class. To manually import the Java class, you must configure the **Java imports** tab in the **Properties** page of the map:

   a) Select **Add**.

   b) Click **Browse**.

   c) In the **Select entries** field, enter the name of the Java package that contains the Java class.

      Note: You must start typing the name of your Java package before you can see any classes to choose from in the **Select entries** field.

   d) Select a Java class.

   e) Click **OK**.

   f) Enter a unique value in the **Prefix** field.

   Note: If the Java project that contains the Java class does not build in Eclipse, then the Java class is not visible anywhere in the map. You must resolve all the Java errors before you can configure the **Java imports** tab in the **Properties** page of the map. You can see the errors in the **Problems** tab.

   When you add a Java call in the **General** tab of the **Properties** page of a **Custom Java** transform in your map, an import is automatically added in the map to refer to the package qualified Java class, and a prefix based on the class name is added. All the **public static methods** in this Java class are then available in content assist when building expressions in other transforms. If you want to use this class, you can skip this step.

6. For non-repeating elements, select the **Condition** property in the **Properties** tab, and enter a Java method.

   Note: Always use content assist to select the variable name of the input elements that you use to define the expressions. If you do not use content assist, you might be using an incorrect element name and your map fails at run time.

   You can identify the Java method in content assist by using the prefix. For example, in the following figure the prefix is **Conditionals** and the method is **lessThanHund()**:

   ```
   Conditionals:lessThanHund( $element11)
   ```

   
   Note: If the input element being used to provide a value for a Java method is not of the correct type, you can use a type cast function, for example **xs:int($var)**, to set the required type. For more information, see "Cast type (xs:type)" on page 1299.
7. For repeating elements, select the **Filter Inputs** property in the **Properties** tab, and enter a Java method that is applied to each instance of the repeating element.

Results

If the Java method returns true, the transform is applied to the input element.

Example

You can call the following Java method when you define a conditional expression in a map:

```
public static boolean evalNodeCondition(Node inputNode, String hasChildNamePrefixed)
    { boolean result = false;
      if ( inputNode != null ) {
            Node fcn = inputNode.getFirstChild();
            if ( fcn != null ) { result = fcn.getLocalName().startsWith(hasChildNamePrefixed);
            }
     }
return result;
```

What to do next

Deploy and test the message map. For more information, see "Troubleshooting a message map" on page 1587.

Grouping transforms into nested maps
Use the **Group transforms into nested maps** property to nest the transforms in a new **Local map** transform. The local map provides a way of displaying parts of a larger message map, enabling you to view the message map elements in a hierarchical way.

About this task

When the **Group transforms into nested maps** property is selected, the Auto map wizard (automap) attempts to place new transforms inside new message map transforms.

The Auto map wizard recursively analyzes the input and output elements of the new transforms, searching for a common input ancestor and a common output ancestor. If a common input ancestor is found for the input elements, and a common output ancestor is found for the output elements, a new **Local map** transform is created between them. Inside the new local map, when no more common ancestors can be found, the new transforms are created at this level. If there are still some common ancestors at a given level, the process is repeated.

For example, a map might contain the following input:

```
SomeInput
--Resources
---field1
---field2
---field3
---field4
```

and the following output:

```
SomeOutput
---Items
----field1
----field2
----field3
----field4
```

If the **Group transforms into nested maps** property is not selected, the Auto map wizard creates transforms between the input and output elements `field1`, `field2`, `field3`, and `field4` at the current level of the map.

However, if the **Group transforms into nested maps** property is selected, the Auto map wizard creates a **Local map** transform between `SomeInput/Resources` and `SomeOutput/Items` at the current level of the map, and then creates transforms between the input and output elements `field1`, `field2`, `field3`, and `field4` inside the local map.

Moving transforms into a local map or a submap
In the Graphical Data Mapping editor, you can group transforms into a local map or submap to enhance readability and maintenance of the message map. You can re-factor a local map to a submap to enable reuse of mappings of global complex types in multiple maps.

About this task

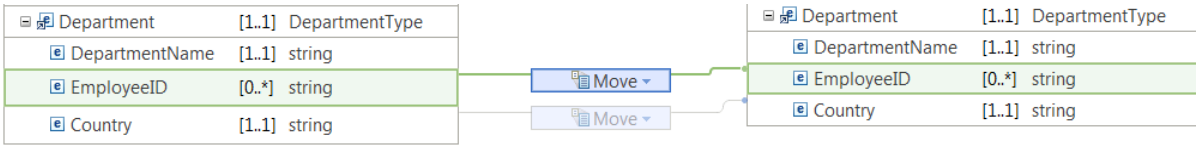
You can use a **Quick Fix** to move one or more transforms inside a local map or submap.

Your map has one or more transforms that are defined between child elements of an input and an output complex element. Then, you decide to change the design of your map, and move these transforms into a local map or into a submap.

Procedure

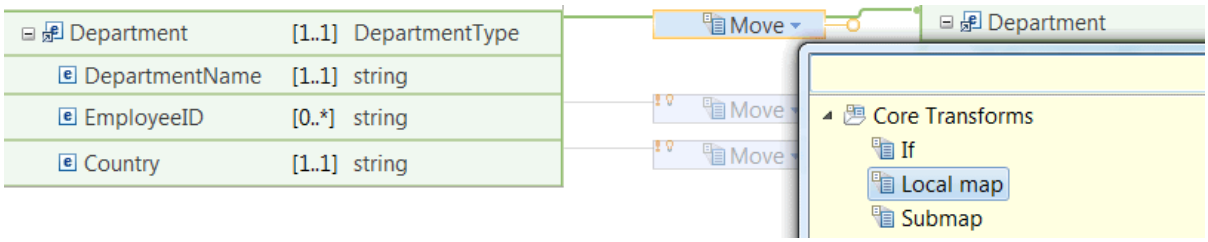
You must complete the following steps to move one or more transforms into a local map or submap:

1. Create a map with a complex input element and a complex output element.
2. Define transforms between the input and output child elements.



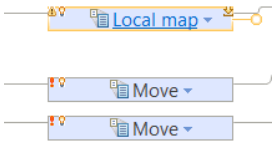
3. Change map design to group part of the transforms in a local map or submap.
4. Wire a **Move** transform from the source folder to the target folder.

5. Change the **Move** transform to a **Local map** transform or **Submap** transform.

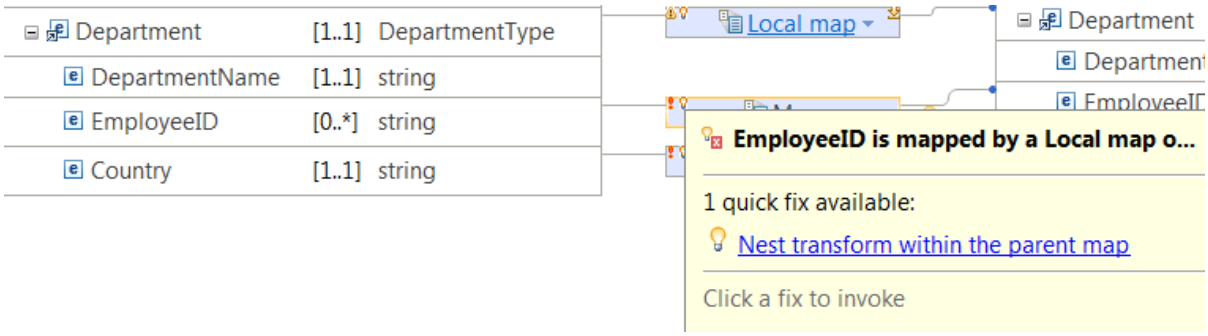


The Graphical Data Mapping editor displays an error marker on each child field mapping. This error indicates that the element is also mapped at the parent level.

The Graphical Data Mapping editor offers a **Quik Fix** on each transform to move the transform inside the local map or submap.



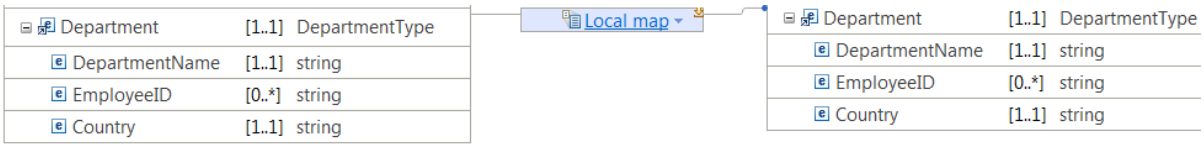
6. Click the **Quick Fix** associated to each of the transforms that you want to move inside the local map or submap. Then, click **Nest transform within the parent map**.



The local transform moves inside the local map. The Graphical Data Mapping editor automatically re-factors the map.

Results

The transforms, that initially were defined at the main level, are now located inside the local map or submap.



What to do next

Deploy the message map and verify that the output message is valid. For more information, see “Troubleshooting a message map” on page 1587.

Using content assist (Mapping syntax)
Use content assist to find the variable names for input and output objects, database elements, and paths.

Press **Ctrl+Spacebar** to display content assist, and use it to help you build your XPath statements and mapping expressions. Content assist provides the variable names that you need to use to reference

elements in your XPath statements and expressions. The variable name assigned for the same element can vary between uses in different transforms, so always use content assist to obtain the correct variable name. Avoid copying and pasting expressions that include variable names.

You can use content assist for the following tasks:

- Making comparisons
- Performing arithmetic
- Creating complex conditions

The comparison operators are:

= (equals)
!= (not equals)
> (greater than)
>= (greater than or equal)
< (less than)
<= (less than or equals)

The arithmetic operators are:

+ (plus)
- (minus)
* (multiply)
div (divide)

For information about XPath syntax, see W3C XML Path Language (XPath) 2.0.

Conditional operators (`or` and `and`) are supported; these are case-sensitive.

The following objects can be mapped:

- Message elements (defined in the schema for the input and output)
- Message assembly, comprising the properties tree and optionally the LocalEnvironment and transport headers
- Data from database tables

Database objects with names that do not conform to the XML NCName format

Some database objects have names that do not conform to the XML NCName format (for example, the name contains characters like #, or $). If the database object name is used in SQL (for example, in the `where` clause of the **Select** transform), no action is required. If the database object is used in XPath (for example, in a Custom transform or a condition), use content assist, which adds the appropriate XPath-compliant expression.

Deleting objects and transforms
You can delete input objects, output objects, and transforms from a message map by using the Graphical Data Mapping editor.

Procedure

- To delete an input object or an output object from a message map, choose any of the following methods:
  - Select the appropriate object in the Graphical Data Mapping editor, and then click the **Delete selected elements** icon in the toolbar.
  - Select the object and then either press the delete key **Del**, or right-click and select **Delete** from the menu.

  You can delete multiple elements at the same time by marking them by using **Ctrl + click**, and then clicking the **Delete selected elements** icon.

- To delete a transform from a graphical data map, choose any of the following methods:
  - Select the transform and press the delete key (**Del**).
  - Select the transform, right-click on the transform, and then select **Delete** from the menu.

What to do next

Continue editing the map, and define transformations between the input message and the output message. For more information, see "Editing message maps" on page 1394.

Advanced editing in a message map

You can configure the input and output message assembly in a message map by using the Graphical Data Mapping editor.

Procedure

- Configure the general properties of the input and output message assembly by using the Graphical Data Mapping editor. For more information, see "Configuring the properties of the input and the output message assembly to a message map" on page 1445.
- Optional: Configure the message assembly to include any of the following components: the Properties tree, one or more message tree headers, the message tree body, and the local environment tree. For more information, see "Configuring the message map to include message assembly components" on page 1447.

  In IBM App Connect Enterprise, the message assembly is the internal representation of a message. When you transform a message, you might need access to elements in a message assembly component or you might need to modify some of these elements in your message map.
- Transform transport headers. For more information, see "Mapping transport headers" on page 1461.
- Transform elements in the Properties tree by using transforms such as the **Move** transform to copy a value, or the **Assign** transform to set a value of an element. You can also use elements in the Properties tree as input data to your transformations. For more information, see "Mapping the Properties tree" on page 1463.
- Update, delete, or create data in the local environment tree. You can use the environment tree as input data to your transformations. For more information, see "Mapping data in the local environment tree" on page 1464.
- Update, delete, or create data in the environment tree. You can use the environment tree as input data to your transformations. For more information, see "Mapping the environment tree" on page 1471.
- Configure a database to map or modify database content. For more information, see "Adding database definitions to the IBM App Connect Enterprise Toolkit" on page 1474.
- Use a Mapping node to access properties that are associated with the message flow that contains the node. For more information, "Accessing user-defined properties from a Mapping node" on page 1479.

What to do next

Configure mapping transforms in your message map. For more information, see "Choosing a transform to set the value of a simple type output element" on page 1358.

Configuring the properties of the input and the output message assembly to a message map

You can configure the general properties of the input and output message assembly in a message map by using the Graphical Data Mapping editor.

About this task

The input and output message assembly properties are located within the **General** tab. They provide information that is displayed for information only, and cannot be modified. In addition, you can configure

the message assembly components that you might require to define your data transformations, and the message domain that defines the serializer to convert the logical tree structure into a bit stream.

Procedure

Complete the following steps to configure the general properties of the input and output message assembly to a message map:

- Configure the source message assembly components:
  a) Select the input message assembly in the map, and then select the **Properties** tab.

     You can see the **Source - Message Assembly** properties:

  b) Add or remove message assembly components to the message map source message assembly.

     For more information, see "Customizing a message map to include a message assembly component" on page 1458.

- Configure the target message assembly components:
  a) Select an output message assembly in the map, and then select the **Properties** tab.

     You can see the **Target - Message Assembly** properties:

  b) Specify the **Output domain**. This property defined the parser used to create the output message.
  c) Add or remove message assembly components to the message map target message assembly.

     For more information, see "Customizing a message map to include a message assembly component" on page 1458.

What to do next

Define the map transformations, For more information, see "Specifying a transform (mapping operation)" on page 1430.

Configuring the message map to include message assembly components
In IBM App Connect Enterprise, the message assembly is the internal representation of a message. When you transform a message, you might need access to elements in a message assembly component or you might need to modify some of these elements in your message map. You can configure a message map to include the following message assembly components: the Environment tree, the message tree Properties tree, message tree headers, the message tree body, and the local environment tree.

About this task

When a message arrives to an application or to an integration service, it is received by an input node that you have configured in a message flow. Before the message can be processed by the message flow, the message must be interpreted by one or more parsers that create a logical tree representation from the bit stream of the message data. The logical tree is also known as the message assembly. The tree format contains identical content to the bit stream from which it is created, but it is easier to manipulate in the message flow.

Procedure

To include message assembly components into your message map, complete the following steps:

1. Identify the message assembly components that you need to add to your message map. For more information, see "Choosing message assembly components to include in a message map" on page 1448.

   You may need to include the local environment tree to use information provided in a variable or you may need to add a header to access transport specific information.

   You can store information in the environment tree while the message passes through the message flow. You might need to use data passed in the environment tree to calculate the value of output elements in a message map. You might need to use data from the environment tree to determine whether a transform should be applied.
2. Identify whether you need to initialize, delete, or transform elements in components of the message tree or in the local environment tree. For more information, see "Choosing a mapping action" on page 1450.

   You can add different parts of the message tree to the map input, to the map output, or to both. You can also add the local environment tree. Depending on how you add a message assembly component, this component can be deleted, initialized, or transformed.
3. Configure the message map to include a message assembly component. For more information, see "Customizing a message map to include a message assembly component" on page 1458.

   To customize your message map to include more message assembly components, you must add message assembly components to the input message and to the output message, and then define transforms between them.
4. Configure the message map to include the environment tree.

   For more information about mapping the environment tree, see "Mapping the environment tree" on page 1471.

Results

You now have a message map that includes the message assembly components that you need to complete your message transformation.

What to do next

Define transforms between other message assembly components that you have included. For more information, see "Specifying a transform (mapping operation)" on page 1430.

Choosing message assembly components to include in a message map
You can add the message tree components, that is, the Properties tree, the headers, and the message body into a message map. You can also add the local environment tree into a message map, and the Environment tree.

About this task

In IBM App Connect Enterprise, the logical tree structure is the internal representation of a message. The logical tree structure is created by the parser when the message is received by an input node. It is also known as the Message tree and makes up part of the message assembly. The message assembly consists of four trees:

- Message tree: This tree includes the Properties folder, the message body, and headers.
- Environment tree
- Local environment tree: This tree includes multiple destination folders, and a variables folder.
- Exception list tree

When you create a message map, the Properties folder and the message body are automatically included in your Graphical Data Mapping editor.

Note: You can remove the properties folder and the message body in the message map if you only want to modify the local environment tree. This will accelerate your message transformation since the message properties and the message body will be copied over without the need to bring them into the transformation engine.

You cannot add the exception list tree to the message map. The exception list is included automatically, and the entire contents of the input exception list is retained in the output.

Procedure

Choose one or more message assembly components to include in a message map:

- **Header folders**: You can add one or more headers to a message map, in addition to the Properties folder and the message body.

  When an input message is received by an input node, the input node invokes the correct parser for each header, and includes in the message tree the corresponding headers. You can then access these headers by using message maps.

  The message tree always includes the following components:

  – All the headers that are present in the message.
  – The message body.
  – The Properties folder. The Properties folder (sometimes referred as the Properties tree) is the first element of the message tree and holds information about the characteristics of the message. When the input node receives the input message, it creates and completes the Properties folder.

  If you need to access information available in an element of a header or if you need to modify it, then you must add the header to the message map. For more information, see “Mapping transport headers” on page 1461.

- **Local environment tree**: You can add the local environment tree to the message map. The local environment is divided into two parts:
  - Standard folders that are automatically defined for each of the destination folders available in IBM App Connect Enterprise.
  - A variables folder that is added automatically. You can use the **Cast** function to include a variable into your message map. You can add variables by using the **Add User Defined** function.

  The local environment tree stores variables that can be referred to and updated by message processing nodes that occur later in the message flow.

  You can also use the local environment tree to define where a message is sent. The destination can be internal or external to the message flow.

  IBM App Connect Enterprise also stores information in the local environment tree in some circumstances, and references it to access destination values that you might have set.

  If you need to access information available in an element of the variables folder or if you need to modify a variable, then you must add each individual variable to the message map. For more information, see "Configuring a generic type in the local environment tree by using the Cast function" on page 1466.
- You can add the environment tree to the input message assembly of the message map.

  If you do not include the environment tree in the input message assembly, the entire contents of the environment tree are retained in the output.

  If you add the environment tree, you can define both its content and structure by using the **Add User Defined** function.

  Note: The environment tree differs from the local environment tree in that a single instance of it is maintained throughout the message flow.

Results

The following table summarizes the message assembly tree folders that you can include into your message map:

Table 57. Message assembly trees that can be included in a message map

Message assembly trees	Folders in a message assembly tree	Can be configured in a message map as an input to the map and as an output to the map?	Status in a message map
Message tree	Properties folder	Yes	Required
Message tree	Header folders	Yes	Optional
Message tree	Message body	Yes **Note:** You must cast parts of the SOAP message body to be able to define transforms between its input and output elements.	Required
Local environment tree	Variables folder	Yes (You must cast a variable to define transforms between its input and output elements.)	Optional
Local environment tree	Destination folders	Yes	Optional

Table 57. Message assembly trees that can be included in a message map (continued)			
Message assembly trees	**Folders in a message assembly tree**	**Can be configured in a message map as an input to the map and as an output to the map?**	**Status in a message map**
Environment tree		Yes	Optional
Exception list tree		No	

What to do next

Identify the configuration of the different message assembly components. For more information, see "Choosing a mapping action" on page 1450.

Choosing a mapping action
You can add different parts of the message tree to the map input, to the map output, or to both. You can also add the local environment tree. Depending on how you add a message assembly component, this component can be deleted, initialized, or transformed.

Procedure

Identify the action that you want to achieve in your message map to find out how to add a message assembly component into the message map:

- To copy a message assembly component unchanged, do not include the component in the message map.

  The mapping engine copies the local environment tree and any other headers and folders from input to output, unchanged, when they are not included in the message map.

  The mapping engine handles the following components as independent units of transformation:

  – The properties tree in the message tree
  – The message body in the message tree
  – Each header structure in the message tree. For example, the MQMD is treated as one unit, the MQRFH2 header is considered an independent unit, and so on.
  – The local environment tree

  If any of these units is not included in the message map, the mapping engine copies their contents unchanged.

  Note: If the only transform that you define between an input map component and an output map component is the **Move** transform so that the component is copied over without any modification, you are recommended to remove the component from the message map. The map transformation will be more efficient since the mapping engine will only focus on the structures that do require change.
- To read elements of a message assembly component, add the component to the input message assembly only. The Mapping node passes it through unchanged
- To modify all the elements of a message assembly component, add the component such as the local environment tree to the input message assembly and to the output message assembly. Then, define transforms between each of its elements.
- To modify some elements of a message assembly component, add the component such as the local environment tree to the input message assembly and to the output message assembly. Define a **Move** transform for the entire component, that is, at folder level, and then specific transforms for each of the elements that you want to transform within an **Override** function. For more information, see "Transforming some elements of a message assembly component by using the Override function" on page 1453.

- To initialize a message assembly component, that is, to create a new message assembly component in your output message, add the message assembly component only to the output message assembly. For more information, see "Initializing a message assembly component in the output message" on page 1458.
- To add a message assembly component, add the message assembly component to the output message assembly and populate at least one field. The Mapping node creates a new output structure containing the results of your transformations.
- To delete a message assembly component from the input message, add the message assembly component to the output message assembly and do not set any field. For more information, see "Deleting a message assembly component from the output message" on page 1457.

Results

The following table summarizes the mapping engine behavior when you add the local environment tree to your message map. The same behavior applies when you add any of the header folders, such as the **MQ headers** > **MQMD** folder, to your message map.

Table 58. Mapping engine behavior when adding the local environment to a message map for transformation

Input element	Output element	Transform defined between the input element and the output element	Mapper behavior
Local environment tree	Local environment tree	A transform operation such as **Move** is defined between the input local environment tree and the output local environment tree. Additional transforms are defined between some elements of the local environment tree within an **Override** function to change the value of those elements.	The input local environment tree is copied into the output local environment tree. The elements whose transforms are defined within the **Override** function have output values different from the input values based on the transformation. The elements outside the **Override** function maintain the same values in the output local environment tree.

Table 58. Mapping engine behavior when adding the local environment to a message map for transformation (continued)

Input element	Output element	Transform defined between the input element and the output element	Mapper behavior
Elements from other message assembly components, database elements whose values are obtained by doing a database read, or a combination of both	Local environment tree	A **Move** transform is defined between each parent input message assembly structure and its corresponding output message assembly structure. Additional transforms are defined between input elements and the output local environment tree. **Note:** If you do not define the **Move** transform between an input and an output message assembly structure from which you use values to set the local environment output elements, then you will lose the message assembly structure in the output message, although your map will perform the transformation correctly.	Each input message assembly structure is copied into its corresponding output message assembly structure. The output local environment variables are defined as per the additional transforms using values from the input elements.
Local environment tree	Local environment tree	None	Delete the original local environment tree. An empty local environment tree is created for the output message.
Local environment tree	None	None	Delete the original local environment tree. An empty local environment tree is created for the output message.
None	Local environment tree	None	Delete the original local environment tree. An empty local environment tree is created for the output message. You might populate some of the fields by using transforms between other input map components such as the message body and the new local environment structure.

Table 58. Mapping engine behavior when adding the local environment to a message map for transformation (continued)

Input element	Output element	Transform defined between the input element and the output element	Mapper behavior
Local environment tree	Local environment tree	A transform operation such as **Move** can be defined between one element from the input local environment tree and one element from the output local environment tree. The rest of the local environment elements do not have transforms defined that specify how to move the input value to the output value.	The output local environment tree is initialized and only the element that has the transform defined has a non default value set.
Local environment tree	Local environment tree	A transform operation such as **Move** is defined between the input local environment tree and the output local environment tree.	The input local environment tree is copied into the output local environment tree.

What to do next

Configure the message map to include the local environment tree or a message header. For more information, see "Customizing a message map to include a message assembly component" on page 1458.

*Transforming some elements of a message assembly component by using the **Override** function*
You can use the **Move** transform to copy a complex type from the input message to the output message, while updating some of the child elements in the complex type by using the **Override** function. A message assembly component is described by a complex data structure.

About this task

Note: You can only use the **Override** function to include **Move** transforms and **Assign** transforms.

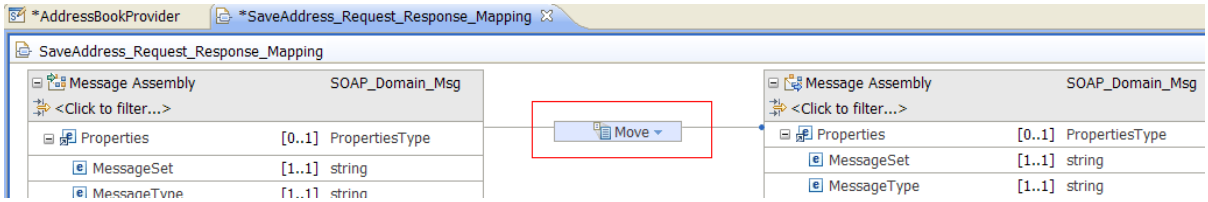
Procedure

When you want to modify only some fields of a message assembly component, complete the following steps to transform the message assembly component:

1. Required: Define a **Move** transform to copy the input message component into the output message component, that is, to copy an input complex data structure into an output complex data structure.

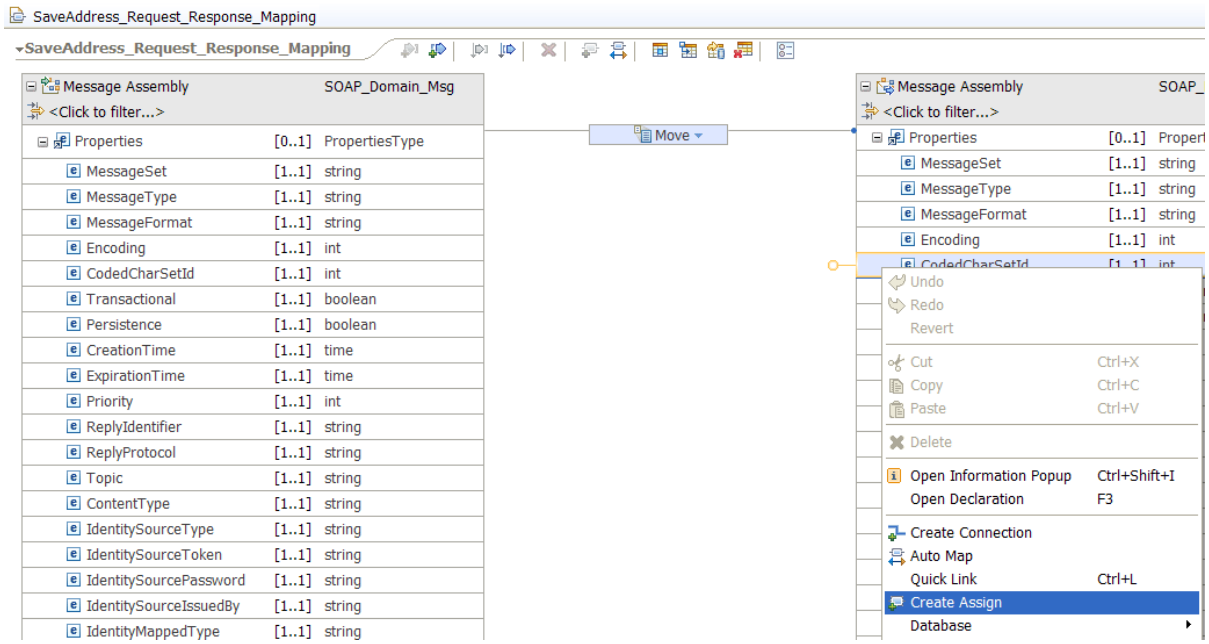
   For example, the Properties tree has a **Move** transform defined automatically when you create a message map so that all elements in the Properties tree are copied to the output Properties tree

structure. If you transform elements in the Local Environment tree, you must manually define the **Move** transform.

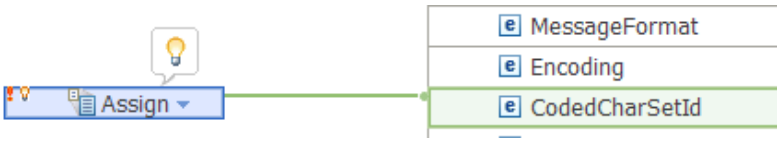


2. Add additional transforms between the input and output elements in the message assembly component.

   For example, you need to change the encoding for the output message. You assign a different value to the **Encoding** element in the properties tree. Right-click the **Encoding** element, and then select the menu option **Create Assign**.

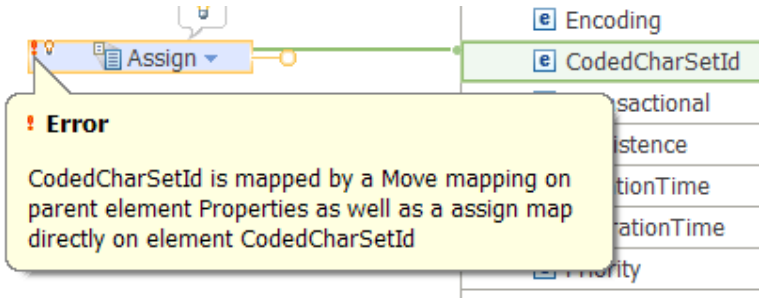


The **Assign** transform is defined and connected to the **Encoding** element in the output Properties tree.



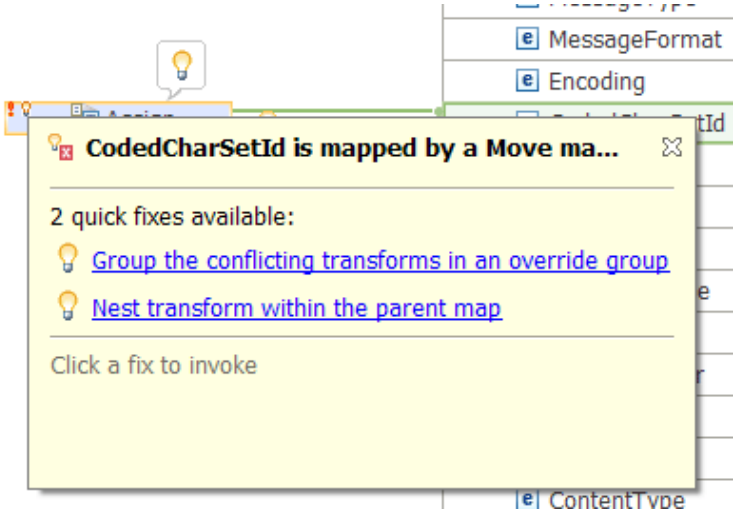
You get the following icons on the top left hand side of the transform:

- An **Error** icon represented with a red exclamation mark. You can ignore this error and continue. You get the error because you have defined two transformations on an element and this is not allowed. By using the **Override** function, you fix the problem.

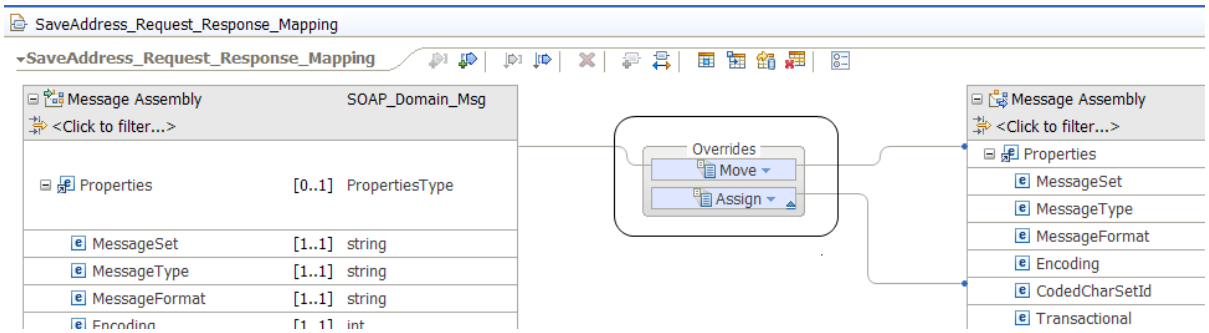


- A **suggestion** icon represented by a yellow light bulb.

  When you hover over the icon, you get the following pop-up window:



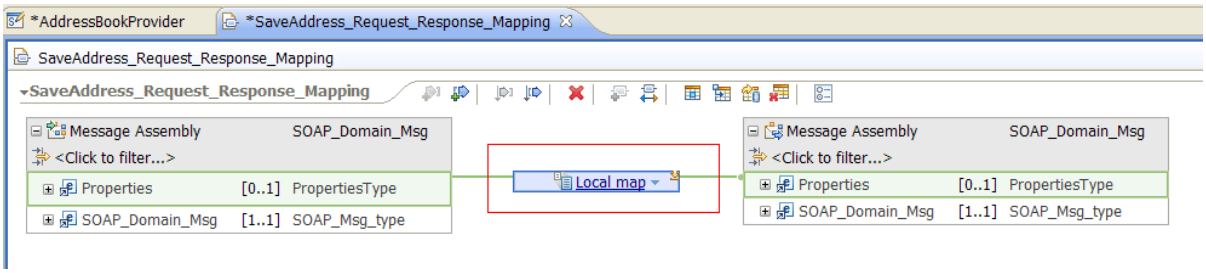
3. When you hover over the yellow light bulb, choose **Group the conflicting transforms in an override group**. This option is the recommended approach and allows you to maintain visibility of the transforms you have defined in the main transformation map.



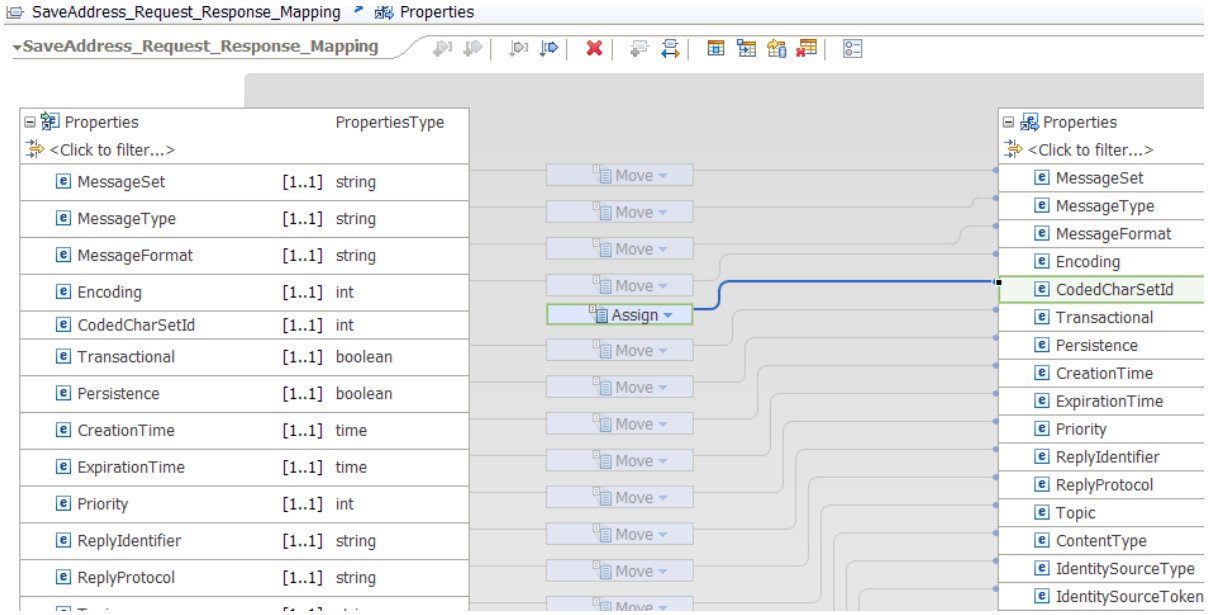
Results

You have transformed elements of a message assembly component by using the **Override** function.

Note: If you choose **Nest transforms within the parent map**, a **Local map** transform is defined between the input Properties tree and the output Properties tree.



The local map that is created contains a **Move** transform per element, with the exception of the **Encoding** element that has an **Assign** transform.



What to do next

Configure the message map body parts. For more information, see “Mapping input to output elements manually” on page 1418 or “Mapping input to output elements automatically” on page 1421.

Deleting a message assembly component from the output message
To delete a message assembly component from the output message, add the message assembly component to the output message and ensure that there are no mappings to it.

About this task

You cannot delete the Environment tree. You can only use the **Remove** transform to explicitly remove elements within the Environment tree.

Procedure

To delete a message assembly component from the output message, complete any of the following steps:

- To delete the local environment tree, add the local environment tree to the output message, and do not set any fields.
- To delete the Properties tree, delete the **Move** transform between the input properties tree and the output properties tree.
- To delete a header, add the transport header folder to the output message, and do not set any fields.
- To delete a message body from the output message, add the message body to the output message, and do not set any fields.

What to do next

Configure the message map body parts. For more information, see “Mapping input to output elements manually” on page 1418 or “Mapping input to output elements automatically” on page 1421.

Initializing a message assembly component in the output message
To initialize a message assembly component in the output message, you add the message assembly component to the output message only. The input values are ignored. You define new values for the elements in the output message assembly structure.

About this task

When you initialize a message assembly structure, you ignore the incoming values and define new values on the output message assembly.

Procedure

To initialize different message assembly components, complete the following steps:

- Add the message assembly component to the output message assembly only.
  - To initialize the local environment tree, add the local environment tree to the output message only.
  - To initialize the Properties tree, delete the **Move** transform between the input properties tree and the output properties tree.
  - To initialize a header, add the transport header folder to the output message only.

  For more information, see "Customizing a message map to include a message assembly component" on page 1458.
- Use mapping transforms to set values for the elements in the new structure.

What to do next

Configure the message map body parts. For more information, see "Mapping input to output elements manually" on page 1418 or "Mapping input to output elements automatically" on page 1421.

Customizing a message map to include a message assembly component
To customize your message map to include more message assembly components, you must add message assembly components to the input message and to the output message, and then define transforms between them.

Before you begin

Check whether you need additional message assembly components to transform your input message. For more information, see "Choosing a mapping action" on page 1450.

About this task

You configure additional message assembly components for a message map in the Graphical Data Mapping editor.

Note: The Environment tree is configured differently. For more information, see "Mapping the environment tree" on page 1471.

By default, when a message map is created, the only message assembly component that is configured automatically is the Properties tree. The input Properties tree is connected to the output Properties tree with a **Move** transform.

Procedure

To add a message assembly component in a message map, complete the following steps:

1. Open the message map in the Graphical Data Mapping editor.

2. Add a message assembly component such as the local environment tree to the input message.
   - Method 1:

     Right-click the input or output message assembly. Then, select **Add or remove headers and folders**.
   - Method 2:

     a. Select **Message Assembly** .

     b. In the Properties view, select the **General** tab.

     c. Click **Properties**.

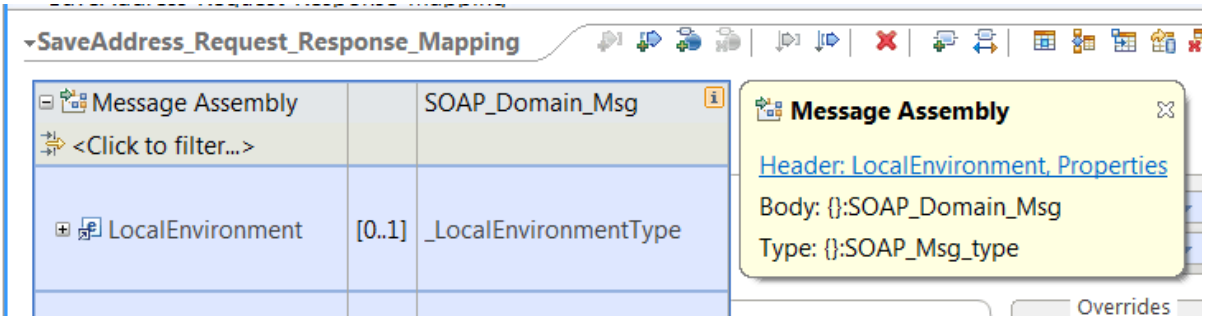
     Note: If you have other structures included in your message assembly, the option that you can click includes all the different message assembly components that you have currently selected.

For example, if you had the Properties tree and the local environment tree selected, you click **LocalEnvironment, Properties**.

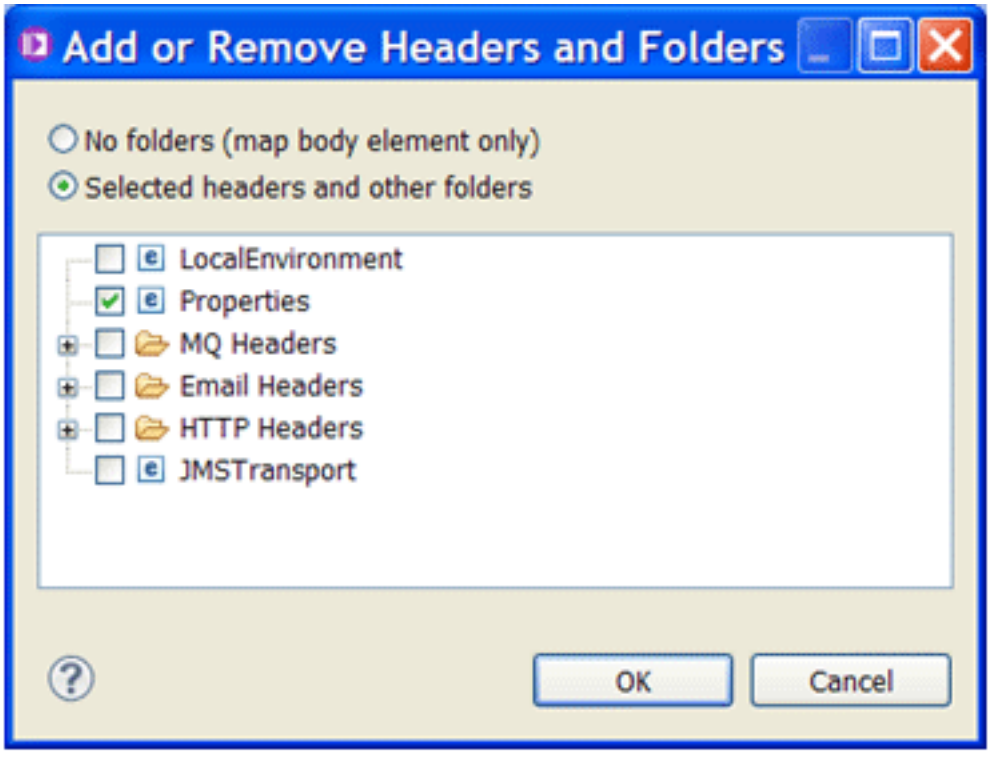
- Method 3:

  a. Select the information icon located by the input message body type.

  b. Select **Header: Properties**.



3. In the **Add or Remove Headers and Folders** window, select one or more message assembly components, and then click OK.



What to do next

Define transforms between the input message assembly and the output message assembly. Depending on the data that you want to transform from the added header or folder, it might be necessary to first

define the content of a generic element, such as the Local Environment Variables folder, by using Mapping casts or adding user-defined functions. For more information, see “Mapping data in the local environment tree” on page 1464.

Mapping transport headers
Use the Graphical Data Mapping editor to transform transport headers.

About this task

When you create a top level message map, only the Properties folder is initially included in the map, and a default transformation from input to output properties is created in a local map. You can then use the Message Assembly properties page in the Graphical Data Mapping editor to modify the transport headers that you might include in the map.

Depending on how you add a transport header to a message map, the component can be deleted, initialized, or transformed:

- To pass unchanged a transport header, do not add it to the message map.
- To read elements from a transport header, add it only to the input message assembly of the message map. The Mapping node passes it through unchanged.
- To modify elements in a transport header, add it to input message assembly and to the output message assembly, and provide transforms to copy and modify the header. The Mapping node deletes the input transport header, and creates a new output transport header containing the result of your transformations.
- To add a transport header to your message, add the header to the output message assembly and populate at least one field. The Mapping node creates a new output transport header containing the results of your transformations.
- To delete a transport header, add it to the output message assembly and do not set any field at all. The Mapping node deletes the transport header from the output message.
- MQ Headers

  MQMD
  MQCFH header with root element MQPCF
  MQCIH
  MQDLH
  MQIIH
  MQMDE
  MQRFH
  MQRFH header with MQRFH2 or MQRFH2C parser
  MQRMH
  MQSAPH
  MQWIH
  SMQ_BMH
- Email Headers

  EmailOutputHeader
- HTTP Headers

  HTTPInputHeader
  HTTPReplyHeader
  HTTPRequestHeader
  HTTPResponseHeader
- JMSTransport

Procedure

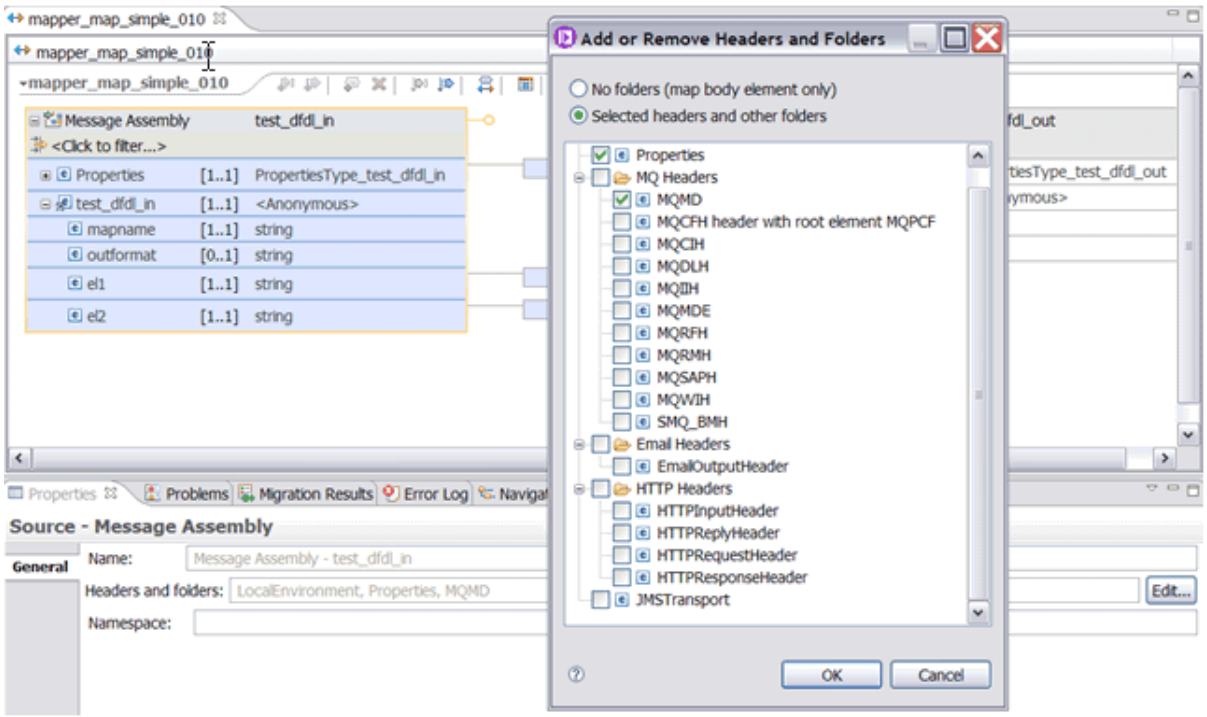
Complete the following steps to transform data in a transport header by using a message map:

1. Decide whether you need a transport header in the input message assembly, the output message assembly, or both. You may want to copy, initialize, or modify elements of a transport header. For more information, see “Choosing a mapping action” on page 1450.

   Note: The Mapping node copies the transport headers from input to output, unchanged, when they are not included in the message map.

2. Add a transport header to the input message assembly, the output message assembly, or both. For more information, see “Customizing a message map to include a message assembly component” on page 1458.

   For example, select **MQMD** to include MQMD headers in the input message assembly of the message map:



3. Optional: Define a **Move** transform between the input transport header and the output transport header to copy all the input values onto the output values.

   Note: If you need to modify only some fields in a transport header, you can use a **Move** transform to copy the transport header unchanged, and then use the **Override** function to modify the elements you must update. For more information, see “Applying mapping overrides” on page 1513.

   You can do this in any of the following ways:

   - In the message map, right-click a transport header on the input message assembly, and select **Add Connection**. Move the mouse to the output local transport header, and click the transport header to define the **Move** transform.
   - In the message map, right-click a transport header on the input message assembly, and select **Quick Link**. A new window appears where you can select a transport header as the output element. Use this option when you have a long list of output elements. You can filter the list in Quick link too.

4. Define transforms between the input transport header and the output transport header. For more information, see “Specifying a transform (mapping operation)” on page 1430 and “Transform types in the Graphical Data Mapping editor” on page 1282.

What to do next

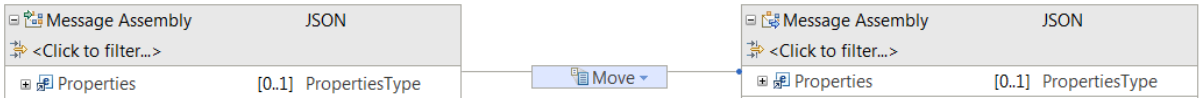
Define additional transformations between other elements in the message map. For more information about the available transforms, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Mapping the Properties tree
In a message map, you can transform elements in the Properties tree by using transforms such as the **Move** transform to copy a value, or the **Assign** transform to set a value of an element. You can also use elements in the Properties tree as input data to your transformations.

About this task

The Properties tree holds information about the characteristics of the message. For more information, see Message tree structure.

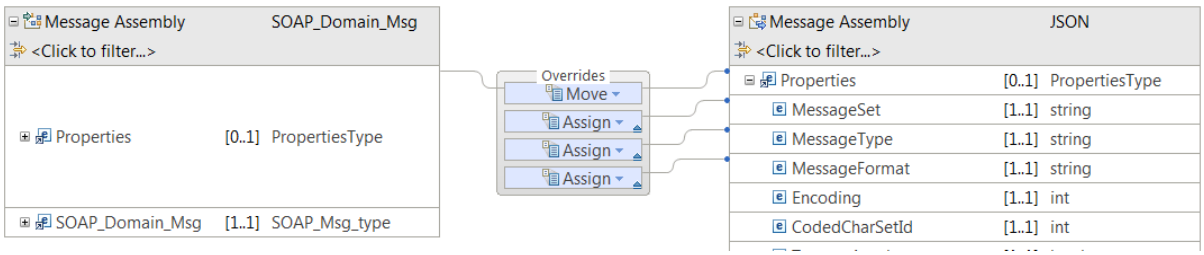
By default, when you create a new map, the Graphical Data Mapping editor includes the Properties tree in the input assembly and in the output message assembly. Depending on the output domain, it can define transforms to update some output elements. Then, copies all the unchanged elements from the input Properties tree to the output Properties tree. If the input and output messages are in the same domain, the transform is a **Move** transform that copies all elements unchanged.



Note: If your mapping does not have any requirements to make changes to the output Properties tree, remove the Properties tree from the output message assembly. The Mapping node will propagate the Properties tree unchanged. If you are also not reading any values from the Properties tree, you can remove the Properties tree from the input message assembly.

When you map messages between unlike domains, it might be necessary to set the **MessageSet**, the **MessageType**, and the **MessageFormat** elements in the output Properties tree. The fields that need setting are dependent on the target parser associated with the output message domain. When you create a new map, the Graphical Data Mapping editor will place a **Move with Overrides** transform group with **Assign** transforms that set default values for these elements in the output.

For example, if the target domain is JSON and the source is SOAP, the Graphical Data Mapping editor defines an **Override** to reset the **MessageSet**, the **MessageType**, and the **MessageFormat**, and move unchanged the rest of the Properties tree elements from input to output.



Note: When you map to a message in the SOAP domain and you have used the **Cast** function to qualify the **xsd:any** in the SOAP Body to a message type defined by a message set format, you must set the **MessageSet**, the **MessageType**, and the **MessageFormat** properties to the values for that message set in the Properties tree.

Procedure

You can complete any of the following mapping tasks when you add the Properties tree to a message map:

1. Use Property elements to define conditional expressions that determine if a transform can be applied anywhere in the map. For more information, see “Defining an XPath conditional expression for a transform” on page 1433.
2. Use the **Assign** transform to set a fixed value without the use of input data.
3. Use transforms to calculate or set the value of an output message element from the value of elements in the Properties tree.

   For example, you can use the **Move** transform to copy an input element value to the output element.
4. Use transforms to calculate the value of a Properties tree element based on the value of elements available in other parts of the message.
5. Use the value of elements defined in the Properties tree to insert, update, or delete data in a database. You can also use the value of a Property element in the definition of a **Where** clause of a **Select** transform.
   - Use the transform **Insert** to add new data to one or more tables in a database.
   - Use the transform **Delete** to delete data in one or more tables in a database.
   - Use the transform **Update** to update data in one or more tables in a database.
   - Use the **Database Routine** transform to update, insert, or delete data in a database by using store procedures.

What to do next

1. Define transforms in the message map to set the value of the output elements. For more information, see “Specifying a transform (mapping operation)” on page 1430.
2. Deploy the map and verify that the output message is valid. For more information, see “Deploying message maps” on page 1585.

Mapping data in the local environment tree
Use the Graphical Data Mapping editor to transform data graphically in the local environment tree.

Before you begin

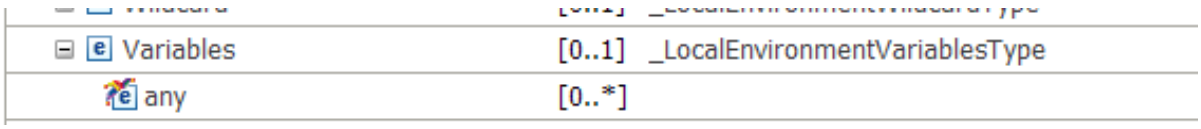
Create a message map. For more information, see “Creating a message map” on page 1382.

About this task

The local environment tree is a part of the logical message tree in which you can store information while the message flow processes the message. You use the local environment tree to store variables that can be referred to and updated by message processing nodes that occur later in the message flow. You can also use the local environment tree to define destinations (that are internal or external to the message flow) to which a message is sent.

When you add the local environment tree to a message map, you must provide transforms for all of its elements so that the input values of each element are not lost. You can copy the input field unchanged or modified by a transform. Many IBM App Connect Enterprise nodes depend on information in the local environment tree being copied along the message flow.

The variables folder in the local environment tree is defined as *xsd:any*. When you add the local environment tree, you can see the structure of the destination folders with all its elements, and a **Variables** folder with a single element defined with a generic type.



You manually define the elements that are included in the **Variables** folder by using the **Cast** or **Add User Defined** functions. There is no predefined structure for the **Variables** folder. Each message flow node has

an input and an output local environment tree. There is a **Variables** folder in the input local environment tree and a **Variables** folder in the output local environment tree.

Note: You should not access attributes or other non-element field types in the local environment tree. The data in the local environment tree is stored by using a generic parser and does not have specific field types set, (see "XMLNSC: Using field types" on page 533). In particular, if you copy data from an XMLNSC tree into the local environment tree, the field type that defines the element or attribute type is not preserved. If you model the data to be an attribute, the map attempts to access the data by using an XPath expression that matches data elements that have the field type that is specified in the XMLNSC tree, and so the data is not read.

When you create a top level message map, only the Properties folder is initially included in the map, and a default transformation from input to output properties is created in a local map.

You can then use the Message Assembly properties page in the Graphical Data Mapping editor to modify the message assembly components transformed in the map and include the local environment folders in the mapping. For more information, see "Customizing a message map to include a message assembly component" on page 1458.

Procedure

Complete the following steps to transform data in the local environment tree by using a message map:

1. Decide whether you need the local environment tree in the input message assembly, the output message assembly, or both. You may want to copy, initialize, or modify LocalEnvironment elements. For more information, see "Choosing a mapping action" on page 1450.

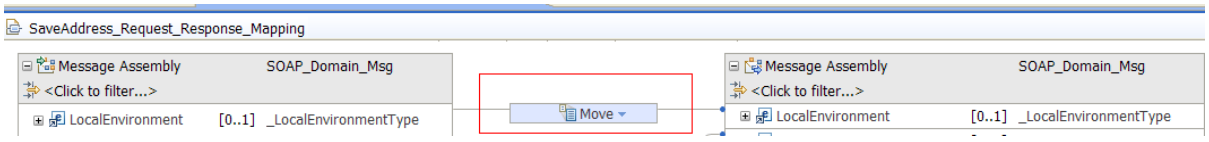
   Note: The Mapping node copies the LocalEnvironment tree from input to output, unchanged, when they are not included in the message map.
2. Add the local environment to the input message assembly, the output message assembly, or both. For more information, see "Customizing a message map to include a message assembly component" on page 1458.
3. Optional: Define a **Move** transform between the input local environment tree and the output local environment tree to copy all the input values onto the output values. Create a connection between the input local environment tree and the output local environment tree.

   Note: If you need to modify only some fields in the local environment tree, you can use a **Move** transform to copy the local environment tree unchanged, and then use the **Override** function to modify the elements you must update. For more information, see "Applying mapping overrides" on page 1513.

   You can do this in any of the following ways:

   - In the message map, right-click **LocalEnvironment** on the input message assembly, and select **Add Connection**. Move the mouse to the output local environment tree, and click **LocalEnvironment** to define the **Move** transform.
   - In the message map, right-click **LocalEnvironment** on the input message assembly, and select **Quick Link**. A new window appears where you can select the output element **LocalEnvironment**. Use this option when you have a long list of output elements. You can filter the list in Quick link too.

   The following figure shows graphically how the **Move** transform is defined between the input local environment tree and the output local environment tree.



4. Optional: Define the **Variables** folder in the local environment tree. The **Variables** folder contains an `xsd:any` element, that you can redefine by using a **Cast** function and a schema file describing the

variables. Alternatively, you can use the **Add User Defined** function to define dynamically the variables that you require in the message map.

- Define the **Variables** folder in the local environment tree by using the **Cast** function. For more information, see "Configuring a generic type in the local environment tree by using the Cast function" on page 1466.
- Define the **Variables** folder in the local environment tree by using the **Add User Defined** function. For more information, see "Configuring a generic type in the local environment tree by using the Add User-Defined function" on page 1470.

5. Define transforms between the input local environment tree and the output local environment tree. For more information, see "Specifying a transform (mapping operation)" on page 1430 and "Transform types in the Graphical Data Mapping editor" on page 1282.

   You must provide transforms to copy or modify all fields that are required on the output. Many message flow nodes depend on information in LocalEnvironment being copied along the message flow. If you need to modify only some fields, use a `Move` transform to copy LocalEnvironment and then use the `Override` function to modify the elements you must update. For more information, see "Applying mapping overrides" on page 1513.

Configuring a generic type in the local environment tree by using the Cast function
You can use the **Cast** function to define variables in a message map that are defined in the local environment tree, such as in the **Variables** folder.

About this task

Sometimes you need to use information that is passed in a generic type variable in the local environment or other part of the message assembly. For example, you might need to calculate the output value of a different element in the message body that is based on a value provided by a preceding node in the local environment variables folder, as shown in the following example:

```
LocalEnvironment.Variables.value_name
```

In this example, `Variables` is a generic element, and you must define the required elements in it for each *value_name*. You can also set values in the output local environment, `Destination.`*`specific_node`*, to override the behavior of a following node. For example:

- For routing in the message flow, the map could set:

  ```
  LocalEnvironment.Destination.RouterList.DestinationData[1].labelName
  ```

- To set a parameter to issue a REST request:

  ```
  LocalEnvironment.Destination.REST.Parameters.parameter_name
  ```

  In this case, `Parameters` is a generic element, and you must define the required elements in it for each *parameter_name*.

- To set an order in a filter, to be used by a LoopBack request:

  ```
  LocalEnvironment.Destination.Loopback.Request.filter.order[1].name
  ```

  In this case, the order is a generic element, and you must define the required elements in it for each *name*.

Procedure

To configure the local environment tree **Variables** or other generic element, so that you can use its elements as part of your transformations, complete the following steps:

1. If you already have the required element defined in a message model, such as an XML schema, DFDL schema, JSON schema, or Swagger document, omit this step and go to step 2; otherwise, complete this step to create a model to define your data.

   Create a schema file in your application, integration service, or library to define the elements of the local environment tree **Variables** folder and their type:

   - In the **Application Development** view, select **New** > **Message Model** > **Other XML**. Click **Next**.
   - Select **Create an empty XML schema file, I will model my data using the XML schema editor**, and then click **Next**.

   - Create an XSD file ***YourLExsdFileName*.xsd**, where *YourLExsdFileName* is the name of the file that contains the local environment variables folder message model. Then, click **Finish**.

   - The XSD file opens in a new tab where you use the XML Schema editor to define your variables and their types.

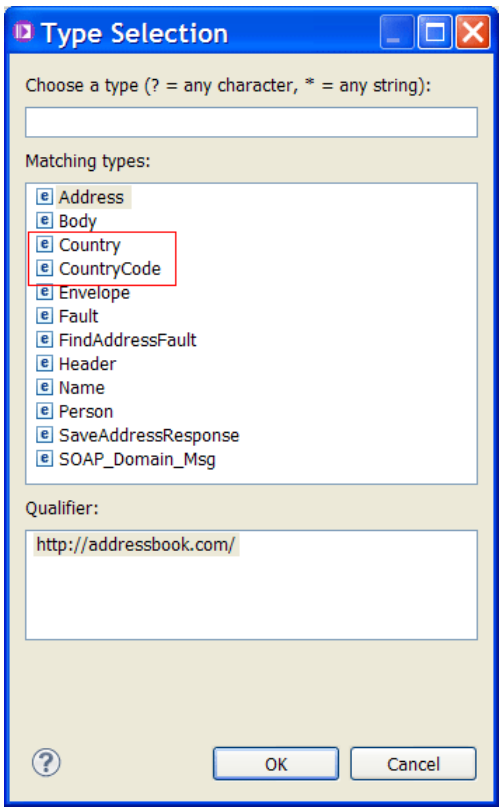
     For example, you can define the following schema:

```
<?xml version="1.0" encoding="UTF-8"?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema">
       <xsd:element name="Country"  type="xsd:string"/>
       <xsd:element name="CountryCode"  type="xsd:integer"/>
</xsd:schema>
```

     Note: You can define the local environment variables in a message flow node by using ESQL or Java. Namespaces is not defined. For this reason, the schema is also defined without a namespace declaration.

2. Use the **Cast** function to define the local environment variables in the message map so they are visible under the **Variables** folder in the map. Complete the following steps to cast the **any** element to a variable and its type in the output local environment tree:
   - Right-click the **any** element, and then select **Cast**.

   - In the **Type Selection** window, select a type, for example **Country**, and then click **OK**.



Note: Do not cast to an XML type that uses attributes. The data in the local environment tree is stored by using a generic parser and does not have specific field types set, (see "XMLNSC: Using field types" on page 533). In particular, if you copy data from an XMLNSC tree into the local environment tree, the field type that defines the element or attribute type is not preserved. If you model the data to be an attribute, the map attempts to access the data by using an XPath expression that matches data elements that have the field type that is specified in the XMLNSC tree, and so the data is not read.

Results

You have defined one local environment variable that can be used by other message flow nodes in your message flow for routing or filtering.

You can see the element **Country** under the local environment **Variables** folder in the message map.

Variables	[0..1]	_LocalEnvironmentVariablesType
any	[0..*]	
Country	[0..*]	string

Example

Another example:

If you set in an ESQL compute node two simple fields within the **Variables** folder of the Local Environment tree by using the following code:

```
SET Outputlocal environment.Variables.dec = 10.1;
SET Outputlocal environment.Variables.str = 'Some text';
```

To access these fields in a Mapping node by using the **Cast** function, you must create a schema file in your integration solution to define the elements and their type. Note that since the ESQL is not using any namespace to qualify these elements, the schema is also defined without a namespace declaration:

```
<?xml version="1.0" encoding="UTF-8"?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema">
       <xsd:element name="dec"  type="xsd:decimal"/>
       <xsd:element name="str"  type="xsd:string"/>
</xsd:schema>
```

Once the schema file is saved, you can then select the any element under the Variables section in the Local Environment tree, and use the context menu action **Cast** to add a Mapping cast for each of the elements "dec" and "str" that are required in the message map. For more information, see "Mapping xsd:any on an input or output message" on page 1397.

What to do next

Define transforms between the input local environment tree and the output local environment tree. For more information, see "Specifying a transform (mapping operation)" on page 1430 and "Transform types in the Graphical Data Mapping editor" on page 1282.

Configuring a generic type in the local environment tree by using the Add User-Defined function
You can use the **Add User-Defined** function to define variables in a message map that are defined in the local environment tree, such as in the **Variables** folder.

About this task

Sometimes you need to use information that is passed in a generic type variable in the local environment or other part of the message assembly. For example, you might need to calculate the output value of a different element in the message body that is based on a value provided by a preceding node in the local environment variables folder, as shown in the following example:

```
LocalEnvironment.Variables.value_name
```

In this example, `Variables` is a generic element, and you must define the required elements in it for each *value_name*. You can also set values in the output local environment, `Destination.`*`specific_node`*, to override the behavior of a following node. For example:

- For routing in the message flow, the map could set:

  ```
  LocalEnvironment.Destination.RouterList.DestinationData[1].labelName
  ```

- To set a parameter to issue a REST request:

  ```
  LocalEnvironment.Destination.REST.Parameters.parameter_name
  ```

  In this case, `Parameters` is a generic element, and you must define the required elements in it for each *parameter_name*.

- To set an order in a filter, to be used by a LoopBack request:

  ```
  LocalEnvironment.Destination.Loopback.Request.filter.order[1].name
  ```

  In this case, the order is a generic element, and you must define the required elements in it for each *name*.

Procedure

To configure the local environment tree **Variables** or other generic element, so that you can use its elements as part of your transformations, complete the following steps:

1. Identify the variables that you must add in your message map under the **Variables** folder.

2. Use the **Add User-Defined** function to define one by one each variable in the message map. For more information, see “Adding and renaming a user-defined element” on page 1410.
3. Select the type for each user-defined variable. For more information, see “Defining the structure of a complex user-defined element” on page 1414.

Results

You have a message assembly structure that includes the local environment tree, and its **Variables** folder includes an any element, and other elements.

What to do next

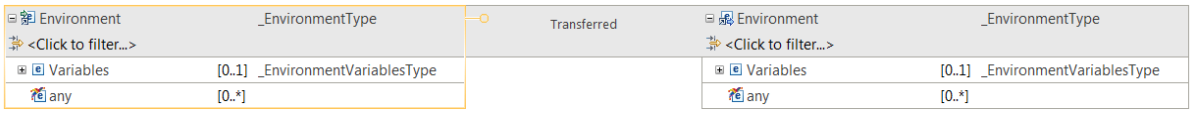
Define transforms between the input local environment tree and the output local environment tree. For more information, see “Specifying a transform (mapping operation)” on page 1430 and “Transform types in the Graphical Data Mapping editor” on page 1282.

Mapping the environment tree
In a message map, you can update, delete, or create data in the environment tree **Variables** folder. You can use the environment tree as input data to your transformations.

About this task

The environment tree is a single global set of data that is available to all nodes in a message flow. The Mapping node accesses the single instance of the environment tree at both the input and output side of the map.

The Graphical Data Mapping editor displays the environment tree by showing the same component on the input and in the output connected via a banner to highlight the fact that it is a single global object.



In the Graphical Data Mapping editor, you can add the environment tree to the input message assembly of a message map or to the output message assembly of a message map.

- When you add the environment tree to the input message assembly, you automatically get the environment tree included in the output message assembly.
- When you add the environment tree to the output message assembly, you automatically get the environment tree included in the input message assembly.
- When you define the content of the environment tree, changes are automatically applied to both the input and the output message assembly.

To add the environment tree, select the icon  in the Graphical Data Mapping editor toolbar.

Alternatively, you can right-click anywhere in the map and select **Add environment mapping**.

To remove the environment tree, select the icon  in the Graphical Data Mapping editor toolbar. Alternatively, you can right-click anywhere in the map and select **Remove environment mapping**.

Note: When you use the environment tree in your integration solutions, you should create your own information in the provided folder called **Variables**.

You define the structure of the environment tree by using the **Add User-Defined** function or the **Cast** function. For more information, see “Adding and renaming a user-defined element” on page 1410 or “Casting elements in a message map” on page 1398.

The following rules apply when you map the environment tree in the Graphical Data Mapping editor:

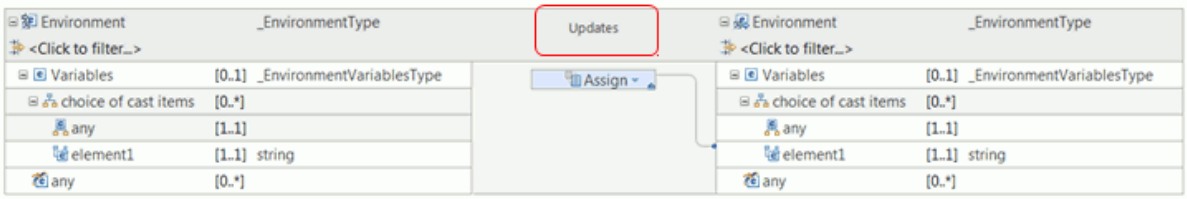
- If you do not include the environment tree in your message map, the entire contents of the environment tree are retained unchanged.
- If you only need to read and update the environment tree, you define a map that only contains the Environment tree.
- If you only need to read from the input assembly and update the environment tree, you define a map that includes the input message assembly and the environment tree.
- If you only need to read from the environment tree and build a new output message, you define a map that includes the output message assembly and the environment tree. You can optionally update the environment tree.
- If you have multiple output message assemblies, or the output message assembly is propagated multiple times, for example when you split an input message with a repeating structure into multiple messages, the environment tree will only be mapped once.
- You cannot wire an output message assembly and the environment tree to a transform that allows multiple outputs, that is, an **If** transform, a **For each** transform, and any of the database transforms. When you need to populate both Environment and the output message assembly, you must have two instances of the transform.

When you add for the first time the environment tree in your message map, the entire contents of the environment tree are retained unchanged. This is indicated visually in the banner with the word **Transferred** located between the input and the output environment structures.

If you include the environment tree in your message map, then the entire contents of the input environment tree are retained in the output environment tree, subject to any modifications that you make in the map.

- Any element present in the environment tree that is not transformed in the map remains unmodified.

  Note: Yon only need to define the elements that you need to map to or from the environment tree. All other elements that might be present in environment tree will remain and be transferred unmodified by the map. You can use the **Remove** transform to delete data from the environment tree.
- When you add transformations that modify the environment tree, there will be a visual change to indicate that the environment tree will be updated after being transferred. As soon as you modify an element in the environment tree, the word **Transferred** changes to **Updates**.



- When you define a transform to modify an element in the environment tree, the value of the input element is not transferred. The outcome of the transform determines the existence, state, and content of the element in the environment tree output element.

Note: For each element in the environment tree, you cannot have different transforms that use the element as a both a source and a target.

Procedure

You can complete any of the following mapping tasks when you add the environment tree to a message map:

1. Use Environment elements to define conditional expressions that determine if a transform can be applied. For more information, see "Defining an XPath conditional expression for a transform" on page 1433.
2. Use the value of elements defined in the **Variables** folder of the environment tree to calculate or set the value of an output message element. Use the value of elements from other parts of the message to calculate the value of an environment tree element.
   - Use the **Assign** transform to set a fixed value without the use of input data.
   - Use the **Create** transform to create an empty element, or a nil element without the use of input data.
   - Use the **Move** transform to copy an input element value to the output element.
   - Use the **If** transform, a custom transform, or the **XPath** transform to define the condition that determines the value of an output element.
   - Use the **Append** transform, the **Group** transform, the **ForEach** transform, the **Join** transform, a custom transform, or the **XPath** transform to set the value of a repeating element.
   - Use the **Select** transform or the **Database Routine** transform to set the value with data available in a database system.
   - Use the **xs:type** transforms to cast the value of a simple input element to a specific data type.
   - Use the **fn:type** transforms to set the value by using XPATH 2.0 functions.

   In the same map, you cannot access and update an element in the environment tree. For example, you cannot define a **Move** transform and an **Assign** transform to the same environment element in a map. Maps do not allow you to control the order of transforms. In this example, you cannot control whether the access or the update of the element occurred first. You will get an error if you access and update an element in the environment tree in the same map.

   Note: You can define a custom transform, **Custom XPath**, **Custom Java**, or **Custom ESQL**, to read the value of an environment element, and then increment its value. The Graphical Data Mapping editor reads the environment variable first, and then updates its value. For example, you can use it to implement a counter action.

   The following transforms are not permitted in environment tree mappings:

   - **Local Map** transform.
   - **Submap** transform.

   When you use a **Custom ESQL** transform or a **Custom Java** transform to modify the environment tree in a message map, check that the transform does not make modifications to environment data that might conflict with other transforms in the map.

   If you use a mapping to add a child to a complex element which already exists in the environment tree, it will be added as the last child.

   If you wish to modify a child element of an existing repeating parent, you should iterate over each parent using the **ForEach** transform, and include child mappings.

   If you need to read and update an element of the Environment tree, you must use two sequential Mapping nodes.

3. Use the value of elements defined in the **Variables** folder of the environment tree to insert, update, or delete data in a database. You can also use the value of an environment element in the definition of a **Where** clause of a **Select** transform.
   - Use the transform **Insert** to add new data to one or more tables in a database.
   - Use the transform **Delete** to delete data in one or more tables in a database.
   - Use the transform **Update** to update data in one or more tables in a database.
   - Use the **Database Routine** transform to update, insert, or delete data in a database by using stored procedures.

4. Use the **Remove** transform to remove elements from the environment tree.

   You do not need to define a **Move** transform between the input and the output environment structures, data will be retained. If you want to remove data from the environment tree, you can use the **Remove** transform. For more information, see "Remove" on page 1336.

What to do next

Define transforms in the message map to set the value of the output elements. For more information, see "Specifying a transform (mapping operation)" on page 1430.

Adding database definitions to the IBM App Connect Enterprise Toolkit
You must have a database definition (`.dbm` file), contained in a data design project, to create database mappings by using the Mapping node.

About this task

A database definition file holds the physical data model that details all the database resources, such as the schema, the tables, and other resources, that you need access to.

If you can connect to your database server by using the IBM App Connect Enterprise Toolkit, you can create a database definition when you create your database mapping. For more information, see "Mapping database content" on page 1523.

If you cannot connect to your database server by using the IBM App Connect Enterprise Toolkit, you must create a database definition file from scratch before you can create your database mapping. For more information, see "Creating a database definition from scratch" on page 1478.

You can also use database definitions in other nodes, such as the Compute node, to validate references to database sources and tables. You must include a data design project in an application, or reference it from an Integration project, before you can use the database definitions that the data design project contains.

Database definition files in the IBM App Connect Enterprise Toolkit are not automatically updated. If you modify your database, you must re-create the database definition files.

The following topics describe how to add a database definition to the IBM App Connect Enterprise Toolkit:

- "Creating a data design project" on page 1474
- Creating a database definition by using the **New Database Definition File** wizard to connect to a database server.
- Create a database definition from scratch when it is not possible to connect to the database server by using the IBM App Connect Enterprise Toolkit.
- "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475
- "Creating a database definition from scratch" on page 1478

Creating a data design project
Create a data design project to contain your database definition files.

About this task

A data design project is a specialized type of project where you store database definition files that hold information about database resources.

To create a data design project in the Integration Development perspective, complete the following steps:

Procedure

1. Click **File** > **New** > **Other**.
   A window opens in which you can select a wizard.
2. Expand **Data**, select **Data Design Project**, and click **Next**.
   The **New Data Design Project** wizard opens.
3. Enter a name for your data design project, and then click **Finish**.
   The **Open associated perspective** dialog is displayed.
4. Click **No**.
   Your data design project is created, and is displayed in the **Application Development** view, under **Independent resources**.

What to do next

After you create a data design project, you can complete the following tasks:

- Create a database definition by using the **New Database Definition File** wizard to connect to a database server; see "Creating a database definition (.dbm file) by using the New Database Definition File wizard" on page 1475.
- Create a database definition from scratch when it is not possible to connect to the database server by using the IBM App Connect Enterprise Toolkit; see "Creating a database definition from scratch" on page 1478.
- Include your data design project in an application; see Adding a project to an application, integration project, or library.
- Reference your data design project from an Integration project; see Referencing resources in other libraries.

*Creating a database definition (`.dbm` file) by using the **New Database Definition File** wizard*

Use the **New Database Definition File** wizard to add database definitions to the IBM App Connect Enterprise Toolkit.

Before you begin

Note: Your database server must be configured to listen on a static port; dynamic ports are not supported with the **New Database Definition File** wizard. Contact your database administrator for information on how to verify port configuration.

About this task

A database definition file holds the physical data model that details all the database resources, such as the schema, the tables, and other resources, that you need access to.

If you can connect to your database server by using the IBM App Connect Enterprise Toolkit, you can create a database definition (`.dbm` file) when you create your database mapping. For more information, see "Mapping database content" on page 1523.

If you cannot connect to your database server by using the IBM App Connect Enterprise Toolkit, you must create a database definition file from scratch before you can create your database mapping. For more information, see "Creating a database definition from scratch" on page 1478.

You can also use database definitions in other nodes, such as the Compute node, to validate references to database sources and tables. You must include a data design project in an application, or reference it from an Integration project, before you can use the database definitions that your data design project contains.

Database definition files in the IBM App Connect Enterprise Toolkit are not automatically updated. If you modify your database, you must re-create the database definition files.

Complete the following steps to create a database definition (`.dbm` file) by using the **New Database Definition File** wizard:

Procedure

1. Click **File** > **New** > **Database Definition**.

   The **New Database Definition File** wizard is displayed.
2. Select an existing data design project, or click **New** to create a data design project.
3. From the **Database** drop-down list, select the type of database that you want to model and, if applicable, select the **Version**. Click **Next**.

   Important: Ensure that you select a database from the list that is supported by IBM App Connect Enterprise; you can use this wizard in a shell-share environment with other Rational products that support other databases or versions. For a list of databases supported by IBM App Connect Enterprise, see IBM App Connect Enterprise requirements.

   If your database is supported by IBM App Connect Enterprise, but is not included in the list of selectable databases, you might need to create a database definition from scratch; see "Creating a database definition from scratch" on page 1478.

   When using specific database servers, you might need to set the paths of your JDBC JAR files before you can use them with the **New Database Definition File** wizard. To set the paths of your JDBC JAR files:

   a) Click **Window** > **Preferences**.

      The **Preferences** window opens.

   b) Expand **Data ManagementConnectivityDriver Definitions**.

   c) In the **Driver Definitions** pane, select the database server that you want to connect to, and click **Edit...**.

      The **Edit Driver Definition** window opens.

   d) Select the **JAR List** tab, and click **Add JAR/Zip...**.

   e) Browse to the JDBC JAR file that was supplied with your database product, select the JAR file, and then click **Open**.

      The **Edit Driver Definition** window closes.

   f) In the **Preferences** window, click **OK** to close the window, and return to the **New Database Definition File** wizard.
4. Select a connection to use from the list of existing connections, or click **New** to create a database connection.

   If you select to use an existing connection, the existing database definition is overwritten.

5. If you selected to create a connection:
   a) Optional: If you want to enter a custom value for the *Connection Name*, clear **Use default naming convention**.
   b) Enter values for the Connection to the database, for example, *Database name*, *Host name* and *Port number*.
   c) Enter values for the *User ID* and *Password* to connect to the database.

      Click **Test Connection** to verify the settings that you selected for your database. The default Port number for a DB2 database is 50000.
   d) Click **Next**.

      If your data design project already contains a database definition for the database that you selected, and you want to overwrite this database definition, click **Yes** in the **Confirm file overwrite** window.

      Tip: If you cannot connect to your database by using the **New Database Definition File**, you might need to create you database definition from scratch; see "Creating a database definition from scratch" on page 1478.
6. Alternatively, if you selected to use an existing connection:
   a) To overwrite the existing database definition, click **Yes** in the **Confirm file overwrite** dialog.
   b) Enter values for the *User ID* and *Password* to connect to the database, and then click **Next**.
7. Select one or more database schemas from the list and click **Next**.

   When you create a database definition for use in a graphical data map called from a Mapping node, the database schema name that is displayed in the map is the one that you select here, but might be overridden by the corresponding JDBC Providers policy.
8. Select the elements that you require on the **Database Elements** page.

   You can select any option, in addition to **Tables**, on the **Database Elements** page.
   a) Select **Views** to see all the database views in the **Data Project Explorer**
   b) Select **Routines** to add stored procedures and user-defined functions to the database definition file.

   If you select additional options, the database definition files that you create contain more information than the Compute, Database, or Mapping nodes require.
9. Click **Finish**.

Results

A new database definition (`.dbm` file) is added to your data design project. If you opened the **New Database Definition File** wizard while creating a database transform in the graphical data mapping editor, you are returned to the database transform wizard.

What to do next

Before you can use your database definition in a messaging solution, you must complete one of the following tasks:

- Include your data design project in an application; see Adding a project to an application, integration service, or library.
- Reference your data design project from an Integration project; see Referencing resources in other libraries.
- Create a corresponding JDBC Providers policy; see JDBC Providers policy (JDBCProviders).

Creating a database definition from scratch
You can create a database definition (`.dbm` file) from scratch. A database definition is required to create database mappings.

Before you begin

- You must have created a data design project; see "Creating a data design project" on page 1474

About this task

A database definition file holds the physical data model that details all the database resources, such as the schema, the tables, and other resources, that you need access to.

You must have a database definition (`.dbm` file) contained in a data design project before you can create database mappings. You can also use database definitions in other nodes, such as the Compute node, to validate references to database sources and tables. You must include a data design project in an application, or reference it from an Integration project, before you can use the database definitions that your data design project contains.

Database definition files in the IBM App Connect Enterprise Toolkit are not automatically updated. If you modify your database, you must re-create the database definition files.

Complete the following steps to create a database definition (`.dbm` file) from scratch:

Procedure

1. Click **File** > **New** > **Other**.
   A window opens in which you can select a wizard.
2. Expand **Data**, select **Physical Data Model**, and click **Next**.
   The **New Physical Data Model** wizard opens.
3. Next to the *Destination folder* field, click **Browse...**.
   A window opens in which you can select a parent folder for your database definition.
4. Select a data design project from the list, and then click **OK**.

   Important: Ensure that you select a data design project as the parent folder for your database definition. Database definitions must be contained in a data design project before you can use them in your IBM App Connect Enterprise messaging solutions.
5. In the *File name* field, enter a name to represent the database that you want to model. You do not need to select the **Database** or **Version**.

   Important: Create a database definition only if your database is supported by IBM App Connect Enterprise.

   For a list of databases supported by IBM App Connect Enterprise, see IBM App Connect Enterprise requirements.
6. Select **Create from template**, then click **Next**.
7. In the **Templates** pane, select **Empty Physical Data Model**, then click **Finish**.
   Your empty database definition is created, is displayed in the Data Project Explorer view, and is opened in the **Physical Data Model** editor.
8. If the Data Project Explorer view is not open in your IBM App Connect Enterprise Toolkit, open it:
   a) Click **Window** > **Show View** > **Other**.
      A window opens in which you can select a view.
   b) Expand **Data Management**, select **Data Project Explorer**, and click **OK**.
      The **Data Project Explorer** view opens.
9. In the Data Project Explorer view, expand your database definition and select **Database**.
   The database properties are displayed in the Properties view.

10. In the Properties view, select the **General** tab. In the *Name* field, enter the name of your database.

    If you use this database definition with the Graphical Data Mapping editor, the *Name* is displayed as the name of the data source, and is used when creating the JDBC Providers policy for the IBM App Connect Enterprise runtime connection.
11. In the Data Project Explorer view, select **Schema**.

    The database schema properties are displayed in the Properties view.
12. In the Properties view, select the **General** tab. In the *Name* field, enter the name of your database schema.

    Database schemas are used only by the Mapping node, and only when calling a graphical data map that contains a database transform. For more information about mapping database content, see "Mapping database content" on page 1523.
13. In the Data Project Explorer view, right-click **Schema** and select **Add Data Object** > **Table**.

    A **Table** is created, and is displayed under your **Schema** in the Data Project Explorer view.
14. Define the columns in your **Table**:
    a) In the Data Project Explorer view, right-click your **Table**, and select **Add Data Object** > **Column**.

       A **Column** is created, and is displayed under your **Table** in the Data Project Explorer view.
    b) Enter a name for your **Column**.
    c) In the Properties view, select the **Type** tab to define the attributes of your column.
15. Repeat steps "13" on page 1479 through "14" on page 1479 for each table in your database, and then save your database definition.
16. Save your database definition, and close the **Physical Data Model** editor.

What to do next

Before you can use your database definition in a messaging solution, you must complete one of the following tasks:

- Include your data design project in an application; see Adding a project to an application, integration service, or library.
- Reference your data design project from an Integration project; see Referencing resources in other libraries.

Accessing user-defined properties from a Mapping node

You can use a Mapping node to access properties that are associated with the message flow that contains the node.

About this task

To access these properties from a Mapping node, call the function `iib:getUserDefinedProperty('propertyname')` from a **Custom XPath** transform. The function returns a string that contains the property value, regardless of the original type of the property.

Note: In IBM Integration Bus Version 10, the function `mb:getUserDefinedProperty('propertyname')` is deprecated. If you try to use this function, you get the following message: `The function mb:getUserDefinedProperty in XPath mb:getUserDefinedProperty('UDP1') is deprecated. Use the corresponding "iib:" function instead.`

Procedure

To access user-defined properties from a Mapping node, complete the following steps:

1. Right-click the element for which you want to set the value by using a user-defined property, and click **Add Assign**.
2. Click the down arrow on the transform and change the **Assign** transform to a **Custom XPath** transform.

3. In the **General** tab of the **Properties** page for the **Custom XPath** transform, enter the following text:

```
iib:getUserDefinedProperty('property_name')
```

where *property_name* is the name of your user-defined property.

Results

You set the value of your element to a user-defined property. Now you can provide a value for the user-defined property dynamically by using the Integration API or a BAR file override.

Setting the value of an output element by using a transform or a function

Use the Graphical Data Mapping editor to set the value of an output element by using an expression, a transform, or a function.

About this task

You can use a function or a transform to set the value of an output element, either by connecting the output element with an input element and then specifying a transform on the connection between them, or by specifying a transform directly on the output element. For information about creating connections and specifying transforms, see "Editing message maps" on page 1394.

For information about all the functions and transforms that are available, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Transforms that support conditional control such as the **If** transform can use XPath 2.0 expressions, or invoke Java or ESQL functions.

Procedure

You can use any of the following mapping operations to map graphically your data in the Graphical Data Mapping editor

- **Core mapping transforms**: You can use built-in structural and functional mapping operations, which enable you to graphically construct the required message transformations to build the output message. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.
- **Custom transforms**: You can use custom transformations to build your own XPath 2.0, Java, or ESQL functions, which can be invoked to perform specialized transformations within the message map. For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.
  - Custom Java transform. For more information, see "Custom Java" on page 1312.
  - Custom XPath transform. For more information, see "Custom XPath" on page 1315.
  - Custom ESQL transform. For more information, see "Custom ESQL" on page 1308.
- **XPath functions** (`fn:`*`functionName`*): You can use XPath 1.0 and XPath 2.0 functions to transform data in a message map. For more information about XPath, see the online document W3C XML Path Language (XPath) 2.0.

  Note: XPath 1.0 functions are valid XPath 2.0 expressions. You can use the XPath Expression Builder to generate simple XPath 1.0 expressions.
- **Database transforms**:
  - You can use the **Select** transform to query one or more database tables, and retrieve data that you can use in the message map to set output element values, define conditions, or use as input to build

other transforms conditions. Database tables can be set as additional outputs of a message map. For more information, see “Selecting data from a table” on page 1523.

– You can use a **database routine** transform to call a stored procedure or user-defined function from a database, and retrieve data that you can use in the message map to set output element values, define conditions, or use as input to build other transforms conditions.

  Note: For information about the support for stored procedures, see “Support for stored procedures” on page 1318.

What to do next

Define transformations to set the value of output elements in your output message:

- Use the **Assign** transform to set the value of an output element to a constant. For more information, see “Setting the value of an output element to a simple data type” on page 1481.
- Use any of the **xs:type** transforms to cast the value of a simple type input element and set the value of a simple type output element. For more information, see “Setting the value of an output element with a explicit data type” on page 1483.
- Use the **Create** transform to set the value of an output element that is defined as a simple type or as part of a complex data type. You use the default or the fixed value defined in the schema for that element. For more information, see “Setting the value of a simple output element to a default or fixed value” on page 1485.
- Use the **Assign** transform or the **Create** transform to create an empty output element defined as a string or as a hexBinary element. For more information, see “Creating an empty output element” on page 1489.
- Use the **Create** transform, the **Move** transform, the **Custom Java** transform, the **Custom ESQL** transform, or the return value of a database to create a null output element. For more information, see “Creating a nil output element” on page 1487.
- Use the `fn:nilled` XPath function, and the `fn:exists` XPath function to define conditional expressions that determine whether an input element is nilled, or is present. For more information, see “Choosing an XPath conditional expression that tests for a nil value in a transform ” on page 1438.
- Use the `fn:empty` XPath function to define conditional expressions that determine whether an input element is empty. For more information, see “Creating an empty output element” on page 1489.

Setting the value of an output element to a simple data type
In the Graphical Data Mapping editor, use the **Assign** transform to set the value of an output element to a constant.

About this task

You cannot use the value of an input element to set the value of an output element in an **Assign** transform.

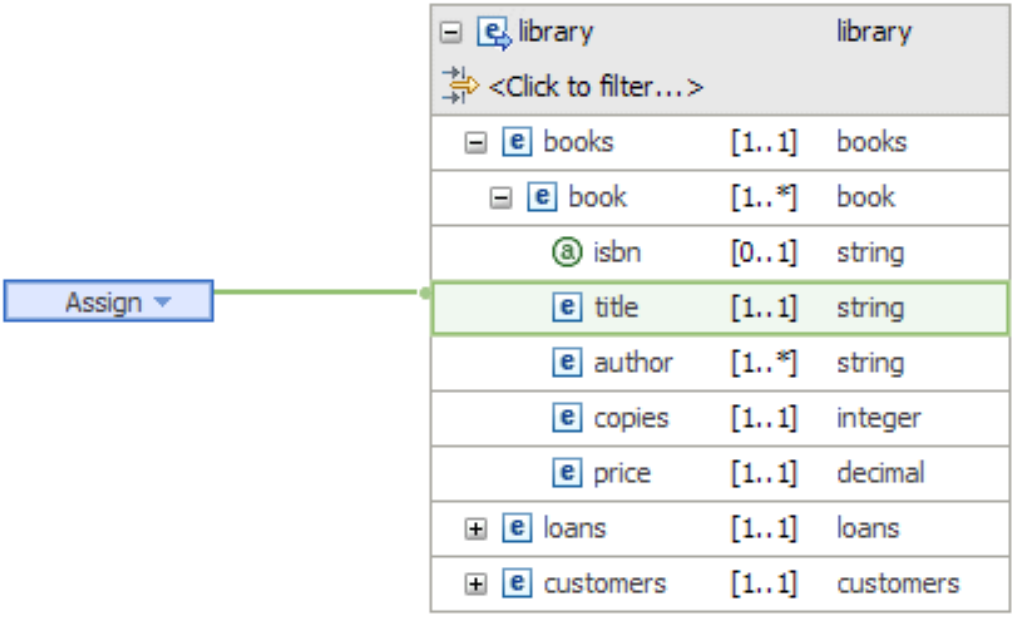
However, you can define **supplement** connections between input elements and the **Assign** transform. You can then use these input elements in a conditional expression that defines the condition under which the transform should be applied.

The output element is set to a constant value.

Procedure

Complete the following steps to set the value of an output element to a constant:

1. Create an **Assign** transform for the output element, by using either of the following methods:
   - Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, an **Assign** transform is created.
   - Right-click the output element and then select **Create Assign**.

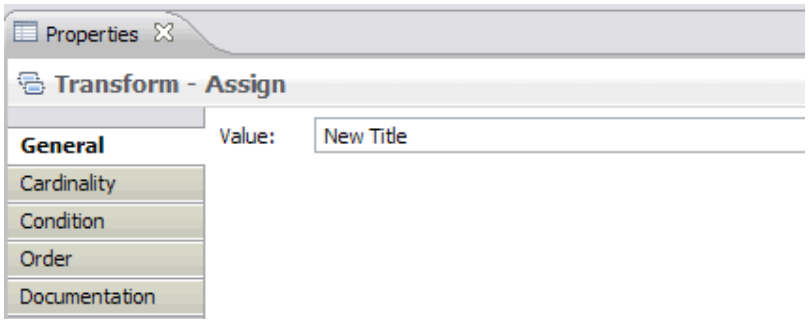


2. Enter the required constant into the **Value** field in the Properties panel for the **Assign**.

   The constant value can be any simple data type value.

   Note: Do not enclose string literals in single or double quotes; enter the required text in the entry field without quotes.

   The following figure shows the Properties view of the **Assign** transform:



Results

If you do not specify a value, an empty element is created.

By default, the following values are set for an output element when you use the **Assign** transform:

*Table 59. Default values set by using the **Assign** transform*

Type	Default value
string	Empty string
dateTime	`2002-01-01T11:00:00`

*Table 59. Default values set by using the **Assign** transform (continued)*	
Type	**Default value**
boolean	`false`
decimal	`0.0`
double	`0.0`
hexBinary	`00`
long	`0`
duration	`P1Y`
time	`00:00:00`
date	`2002-01-01`

Setting the value of an output element with a explicit data type
In the Graphical Data Mapping editor, you can use any of the **xs:type** transforms to cast the value of a simple type input element and set the value of a simple type output element.

About this task

For example, you want to assign a value with a specific data type to a target element that is defined as `xs:anySimpleType`. You can use the **xs:type** transform.

You can have zero or more input elements to an **xs:type** transform. However, you can only cast one value for an output element by using an **xs:type** transform. If the mapping for the **xs:type** transform has more than one input, any input that is not referenced by the argument of the **xs:type** transform will be ignored.

You can use the input elements to build a conditional expression that determines if the **xs:type** transform is applied or not.

You must choose the **xs:type** transform according to the output element data type. For example, if you have an output element with a boolean data type, you must choose **xs:boolean** transform.

You can use any of the following `xs:any` transforms:

- **xs:NOTATION**: This function takes a primitive and casts it as notation.
- **xs:Qname**: This function takes a primitive and casts it as Qname.
- **xs:anyURI**: This function takes a primitive and casts it as anyURI.
- **xs:base64Binary**: This function takes a primitive and casts it as base64Binary.
- **xs:boolean**: This function takes a primitive and casts it as boolean.

  You can use any of the following values: `true` or `false`.
- **xs:dateTime**: This function takes a primitive and casts it as dateTime.
- **xs:date**: This function takes a primitive and casts it as date.
- **xs:dayTimeDuration**: This function takes a primitive and casts it as dayTimeduration.
- **xs:decimal**: This function takes a primitive and casts it as decimal.
- **xs:double**: This function takes a primitive and casts it as double.
- **xs:float**: This function takes a primitive and casts it as float.
- **xs:gDay**: This function takes a primitive and casts it as gDay.
- **xs:gMonthDay**: This function takes a primitive and casts it as gMonthDay.
- **xs:gMonth**: This function takes a primitive and casts it as gMonth.
- **xs:gYearMonth**: This function takes a primitive and casts it as gYearMonth.

- **xs:gYear**: This function takes a primitive and casts it as gYear.
- **xs:hexBinary**: This function takes a primitive and casts it as hexBinary.
- **xs:integer**: This function takes a primitive and casts it as integer.
- **xs:int**: This function takes a primitive and casts it as signed 32-bit integer.
- **xs:string**: This function takes a primitive and casts it as string.
- **xs:time**: This function takes a primitive and casts it as time.
- **xs:yearMonthDuration**: This function takes a primitive and casts it as yearMonthDuration.

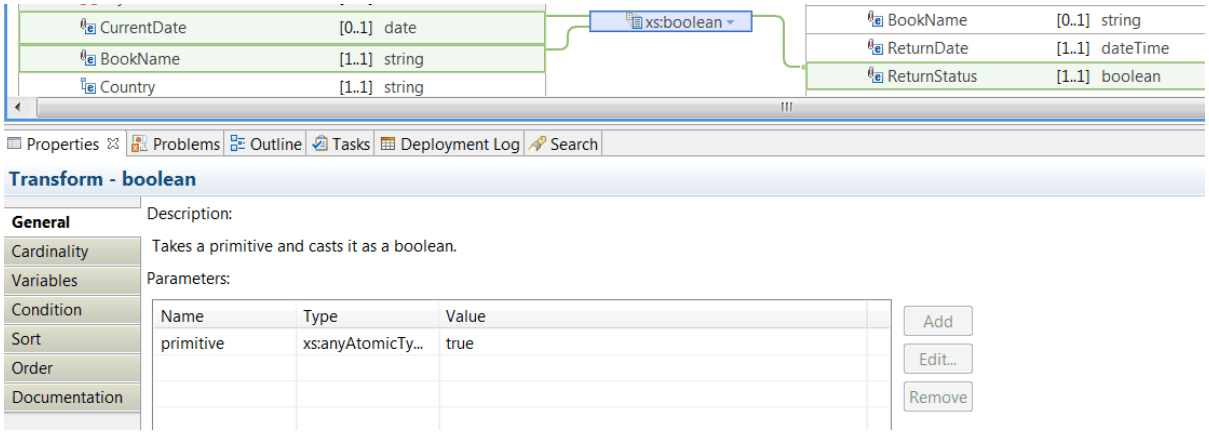
Procedure

Complete the following steps to set the value of a output element by using an **xs:type** transform:

1. Add an **xs:type** transform, for example, an **xs:boolean** transform, to set the value of the output element, by using either of the following methods:
   a) Create an **Assign** transform by using either of the following methods:
      - Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, an **Assign** transform is created.
      - Right-click the output element and then select **Create Assign**.

   b) Use the drop-down, and select **Cast Function** > **xs:boolean**.
2. Enter `true` into the **Value** field in the Properties panel for the **xs:boolean** transform.

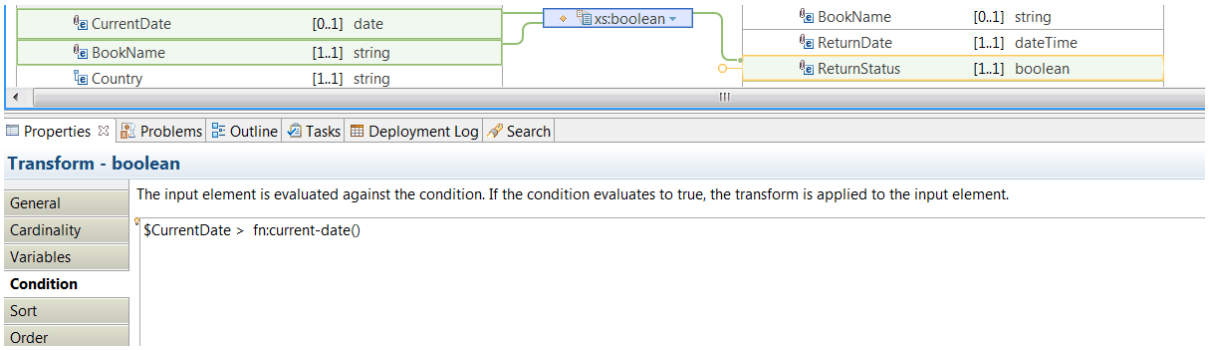
   You can set the value to `true` or `false`.



3. Optional: Define a conditional expression to control when the transform should be applied .

   You define a conditional expression by using an XPath expression.

   For example, to evaluate the transform, the current date has to be a date after the date specified in the element **CurrentDate**.



Setting the value of a simple output element to a default or fixed value
In the Graphical Data Mapping editor, use the **Create** transform to set the value of a simple output element. You use the default or the fixed value defined in the schema for that element.

About this task

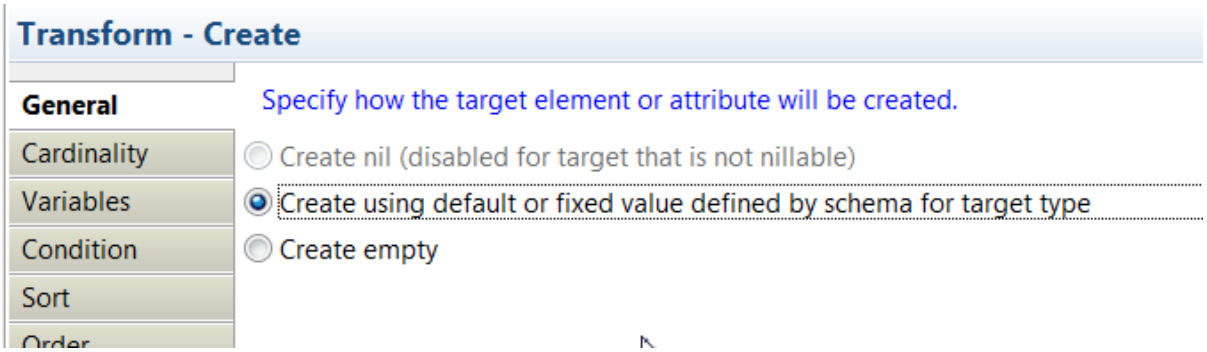
The **Create** transform creates an output element without the use of input data.

Note: You can only set the value of a simple output element to its default or fixed value when the schema includes a default value or a fixed value for the element.

Procedure

Complete the following steps to create a simple output element with its default or fixed value:

- Create an **Assign** transform by using either of the following methods:
  a) Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, an **Assign** transform is created.
  b) Right-click the output element and then select **Create Assign**.
- Use the drop-down, and select **Core transforms** > **Create**.
- In the Properties panel, select the **General** tab. Then, select **Create using default or fixed value defined by schema for target type**.



Setting the value of a simple type element included in a complex type output structure to a default or fixed value
In the Graphical Data Mapping editor, use the **Create** transform to set the value of an output element that is defined as part of a complex data type. You use the default or the fixed value defined in the schema for that element.

About this task

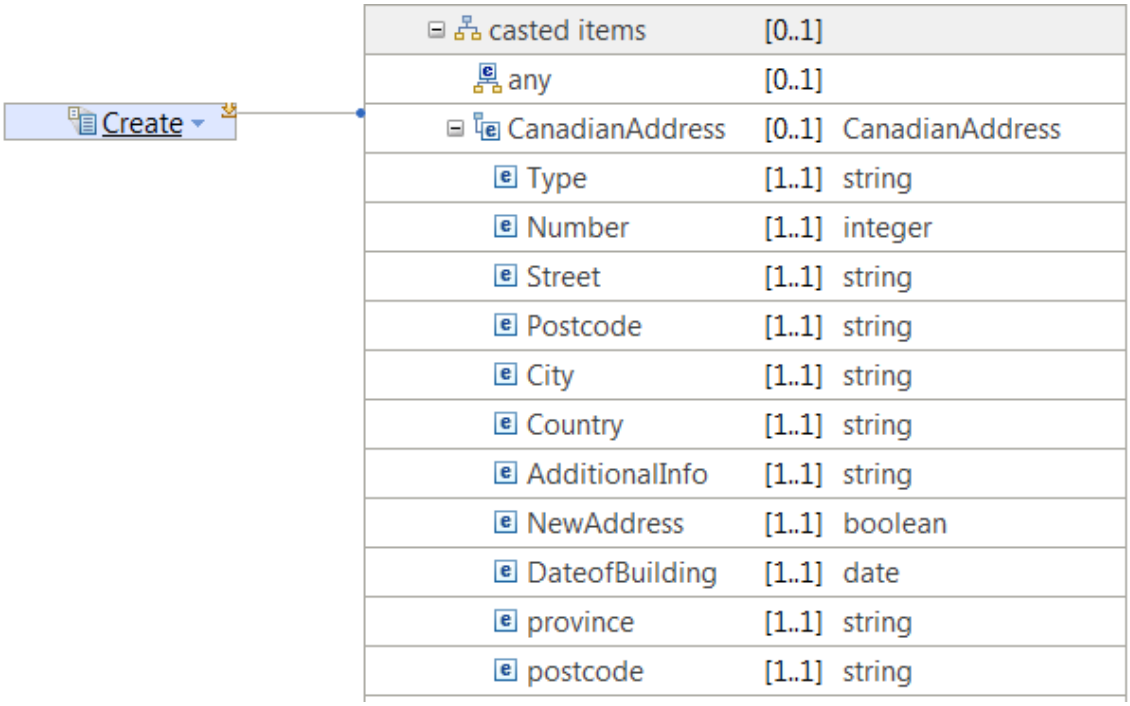
The **Create** transform creates an output element without the use of input data.

Note: You can only set the value of a simple output element to its default or fixed value when the schema includes a default value or a fixed value for the element.

Procedure

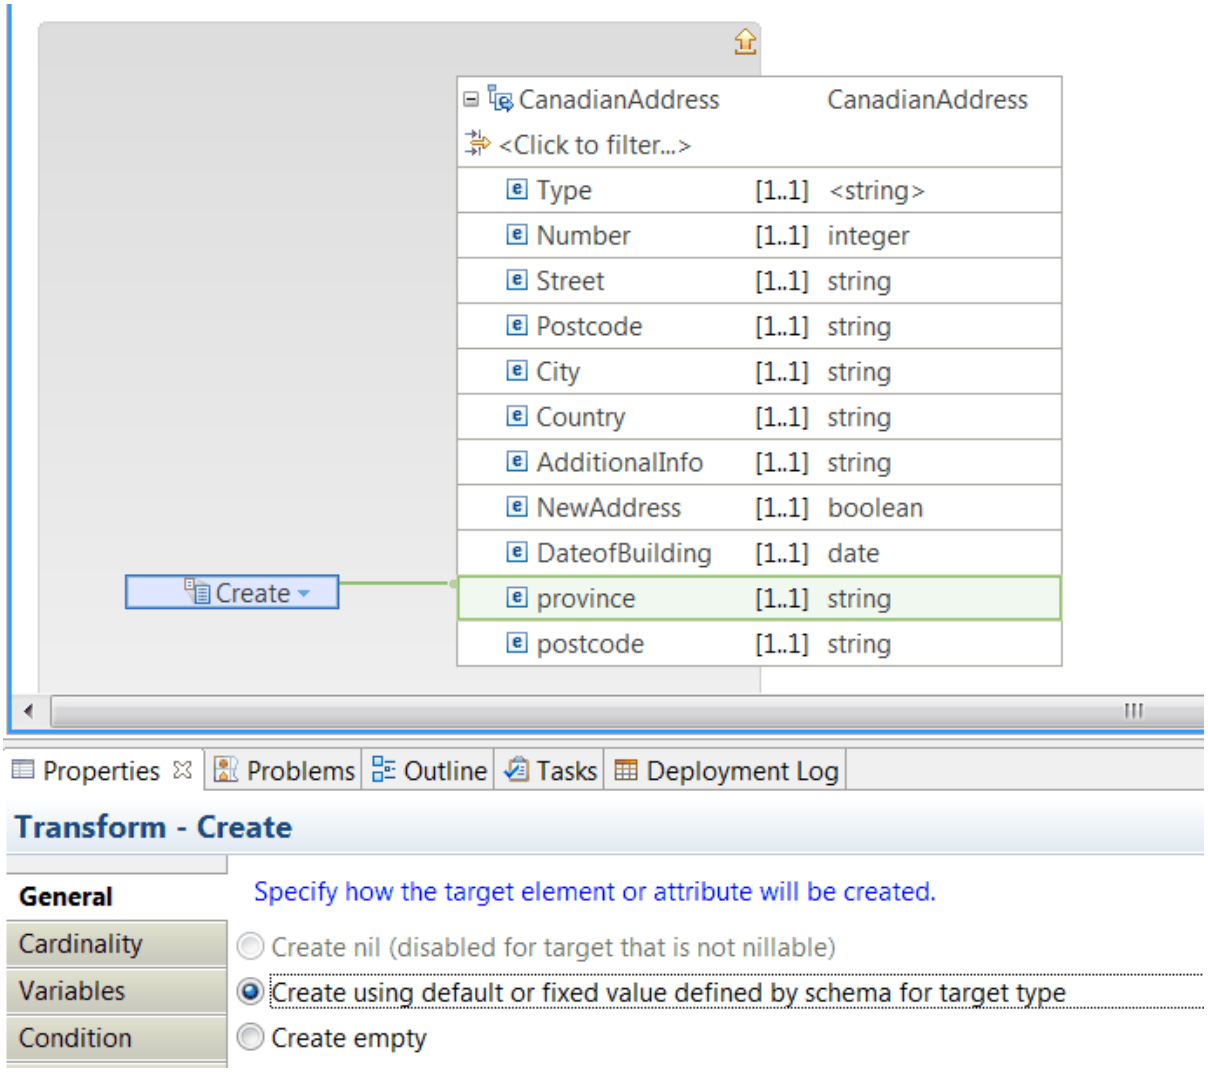
Complete the following steps to create a simple type element included in a complex type output structure with its default or fixed value:

- Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, a **Create** transform is created.



- Open the nested map associated to the **Create** transform. You can define how each target element or attribute will be created within the complex element. For more information, see "Setting the value of a simple output element to a default or fixed value" on page 1485.

  You can use in the **Create** transform nested map more **Create** transforms, **Assign** transforms, or any other mapping transforms that do not require an input. You can use this method to populate as many fields as required in the complex output structure.



Creating a nil output element
In the Graphical Data Mapping editor, you can use the **Create** transform, the **Move** transform, the **Custom Java** transform, the **Custom ESQL** transform, or the return value of a database to create a nil output element.

Before you begin

When you map null values, consider the Graphical Data Mapping editor behavior. For more information, see "Handling nulls in message maps" on page 1368.

Procedure

Choose any of the following methods to create a nil output element:

- Use the **Create** transform. Create a nil element without the use of input data.
- Use the **Move** transform. Copy an input element that is nil to an output nil element.

- Use the **Custom Java** transform.

  The Java method that you implement must return an MbElement that is nil.
- Use the **Custom ESQL** transform. Your ESQL code must return a NULL value.
- Use the database transform, and **Move** a nullable column to an output nillable element.
- Use a **Custom XPath** transform with the function `iib:nullValue()` to set an XMLNSC element to `nil`, a JSON object to NULL, and a JSON array to NULL.

Example

Example: Use the Create transform to create a simple type output element as nil

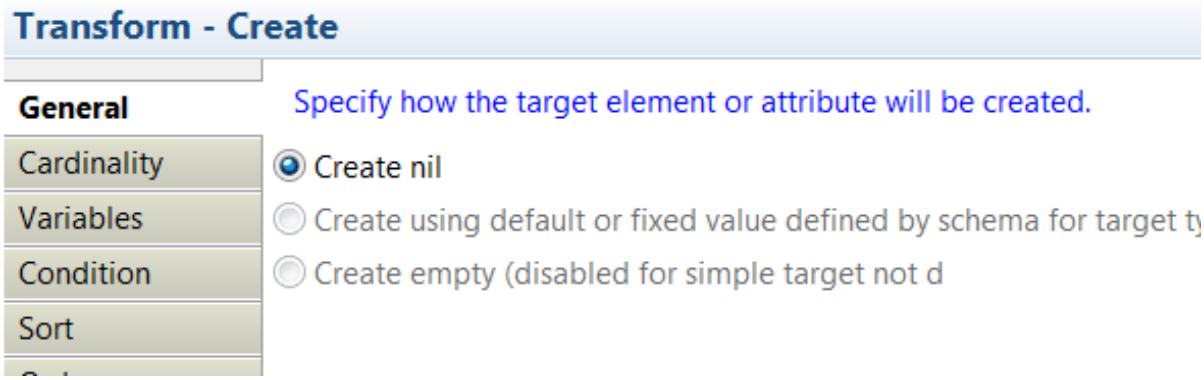
This example shows how to use the **Create** transform to create a simple type output element as nil in the Graphical Data Mapping editor.

You can use the **Create** transform to create an output element with `xsi:nil="true"`, also called a nil element, without the use of input data.

Note: The option to create a nil element is available only when the output element is nillable.

Complete the following steps to create a simple nil output element:

1. Add a **Create** transform to set the value of the output element.
   a. Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, an **Assign** transform is created.
   b. Select the drop-down, and select **Core transforms** > **Create**.
2. In the Properties panel, select the **General** tab. Then, select **Create nil**.



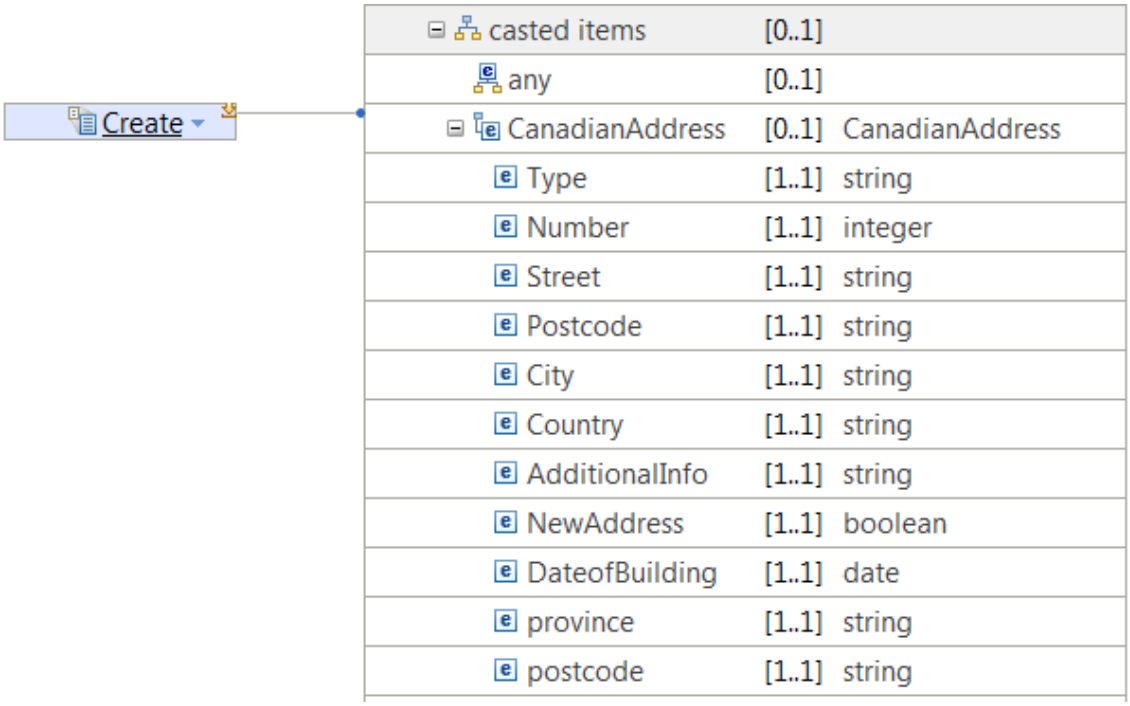
Example: Use the Create transform to create a complex type output element as nil

This example shows how to use the **Create** transform to create a complex type output element as nil in the Graphical Data Mapping editor.

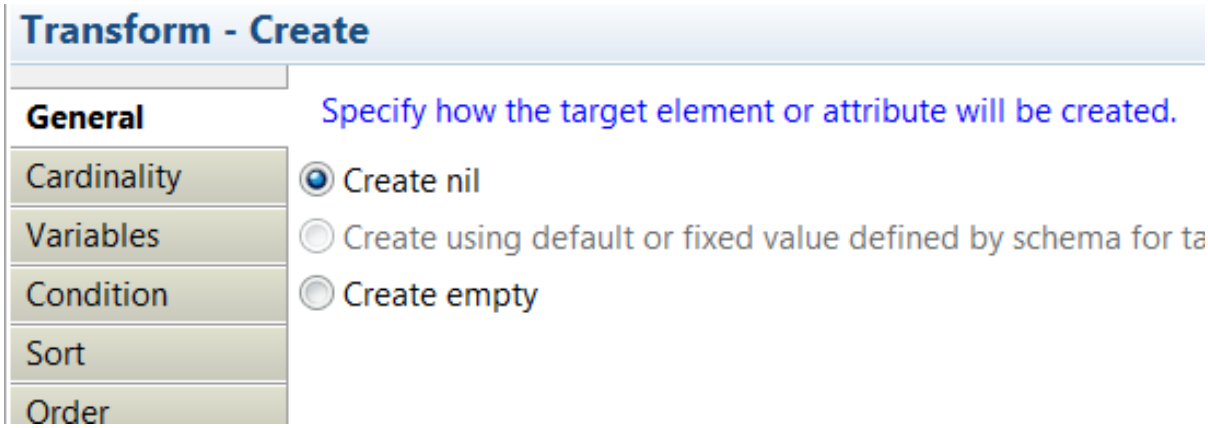
Note: The option to create a nil element is available only when the output element is nillable.

Note: The **Create** transform has a nested map, however, you cannot create or assign fields within a complex nil output element. You will get the following error: `Cannot create or assign fields within nil target. To allow mapping, change parent Create transform to create empty instead of nil.`

1. Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, a **Create** transform is created.



2. In the Properties panel, select the **General** tab. Then, select **Create nil**.



Creating an empty output element
In the Graphical Data Mapping editor, you can use the **Assign** transform or the **Create** transform to create an empty output element defined as a string or as a hexBinary element when you have no source to copy from.

About this task

You can define an empty output element when the following conditions are met:

- The data type of the element is string or hexBinary.
- The element is not nillable.

Procedure

Choose any of the following methods to create an empty output element:

1. Use the **Assign** transform to create an empty output element. For more information, see “Initializing an output element by using the Assign transform” on page 1490.
2. Use the **Create** transform to create a simple or complex empty output element. For more information, see “Initializing a simple or complex output element by using the Create transform” on page 1491.

Results

The following table lists the data types and the transforms that you can use to create an output element:

Table 60. List of transform types that you can use to create an empty element

Data type	**Valid transforms**
Simple data types: string, hexBinary	Assign, Create
Complex data types	Create

*Initializing an output element by using the **Assign** transform*
In the Graphical Data Mapping editor, use the **Assign** transform to create an empty output element.

About this task

There is no input element to an **Assign** transform.

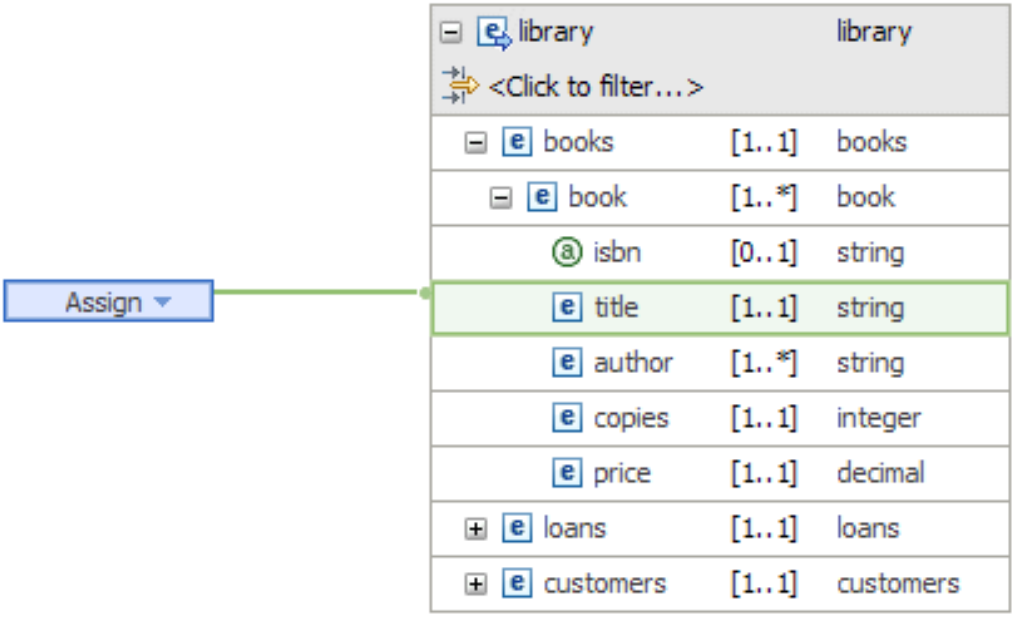
You can only create an empty output element for the following output element data types:

- string
- hexBinary

Procedure

Complete the following steps create an empty output element:

1. Create an **Assign** transform for the output element, by using either of the following methods:
   - Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, an **Assign** transform is created.
   - Right-click the output element and then select **Create Assign**.



2. Do not specify a value in the **Value** field in the Properties panel for the **Assign** transform.

*Initializing a simple or complex output element by using the **Create** transform*
In the Graphical Data Mapping editor, use the **Create** transform to create a simple or complex empty output element.

About this task

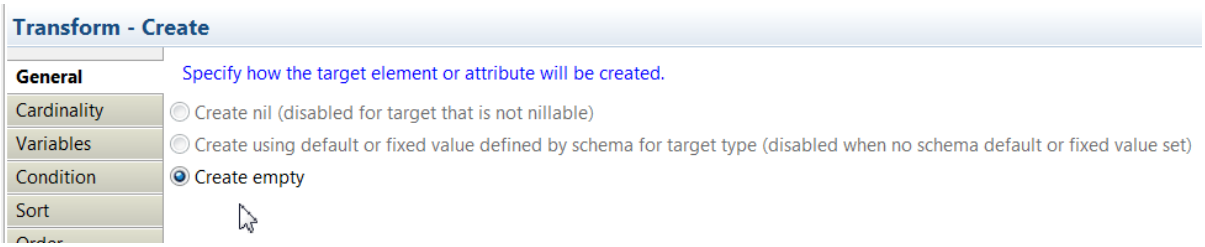
The **Create** transform creates an output element without the use of input data. You can create either simple or complex type output elements.

You can create a simple empty output element for elements defined as string or hexBinary.

Procedure

Complete the following steps to create a simple or complex empty output element:

- For simple type output elements, complete the following steps:
  a) Add a **Create** transform to set the value of the output element, by using either of the following methods:
     – Create an **Assign** transform by using either of the following methods:
       - Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, an **Assign** transform is created.
       - Right-click the output element and then select **Create Assign**.
     – Use the drop-down, and select **Core transforms** > **Create**.
  b) In the Properties panel, select the **General** tab. Then, select **Create empty**.



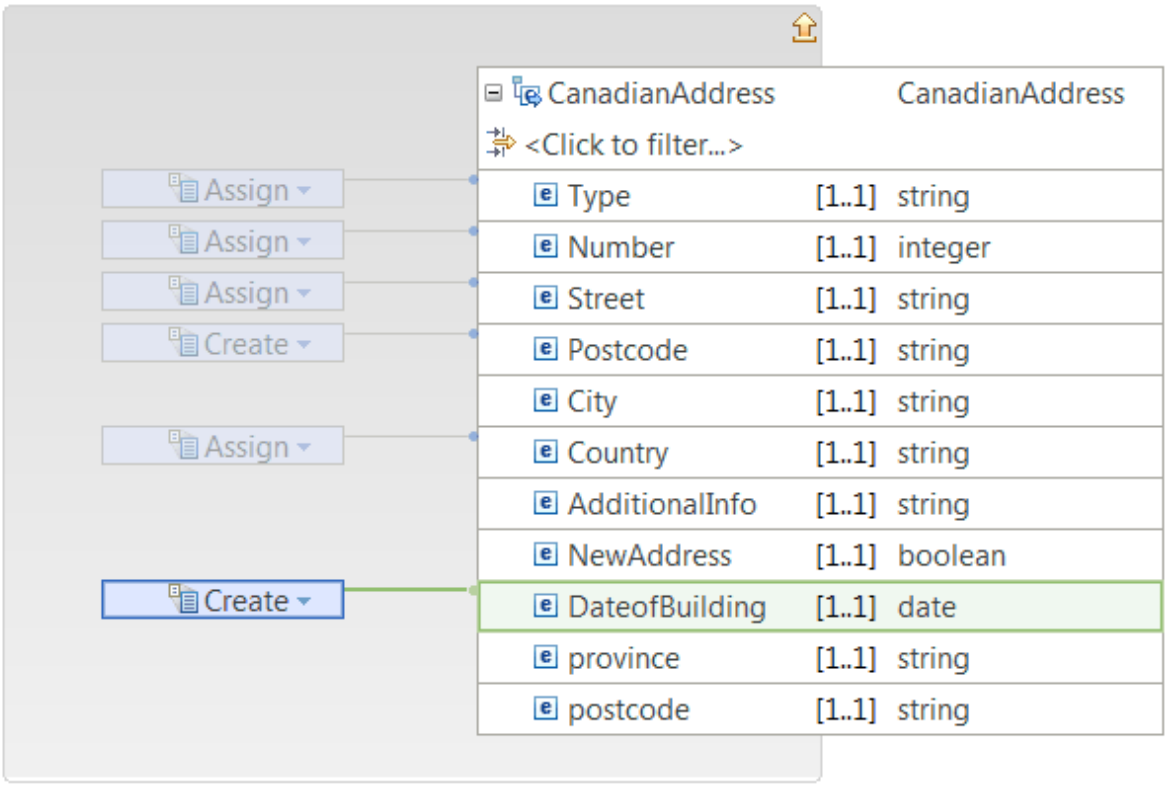
- For complex type output elements, complete the following steps:
  a) Click the output element and drag the connector towards the input elements, releasing the connector onto a blank part of the canvas. When you release the connector, a **Create** transform is created.

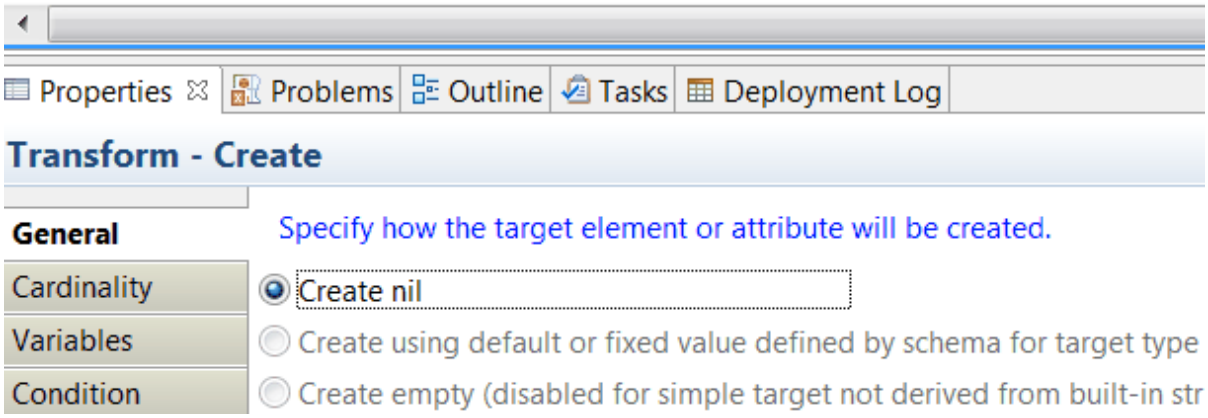
  b) In the Properties panel, select the **General** tab. Then, select **Create empty**.

  c) Optional: Open the nested map associated to the **Create** transform. You can define how each target element or attribute will be created in a complex element.

  You can use the **Create** transform to create an empty complex output element. then, you can enter the **Create** transform nested map and use more **Create** transforms, **Assign** transforms, or any other

mapping transforms that do not require an input. You can use this method to populate as many fields as required in the complex output structure.





Checking whether the value of an input element exists, or is null

You can use the `fn:exists` XPath function, and the `fn:nilled` XPath function to define conditional expressions that determine whether an input element is present, or is null.

About this task

You can define conditional expressions in a transform to determine whether the transform should be applied or not in your message map.

For example, you might decide not to apply a transform if the input value is null.

You can use the following XPath functions to define conditional expressions in a transform:

- Use the `fn:nilled` XPath function to test whether the value of an input element has the `xsi:nil` attribute set.

- Use the `fn:exists` XPath function to test whether the value of an input element is present.

  Note: An XML element that has the `xsi:nil` attribute set is considered to be present.

Procedure

Take the following steps to define a conditional expression in a **Move** transform that determines whether the transform is applied or not. The transform applies if the element exists, and is not null.

1. Create a **Move** transform between an input element and an output element.
2. In the Properties view, under **Condition**, enter an XPath expression to define the conditional expression that must evaluate to true for the transform to be applied.

```
fn:exists($BookName) and (fn:nilled( $BookName) = false)
```

Checking whether the value of an input element is empty

Use appropriate expressions to test for empty input values, depending on whether the element is a simple or complex type.

About this task

You can define conditional expressions in a transform to determine whether the transform is applied or not in your message map. For example, you might decide not to apply a transform if the input value is empty.

For simple string types, you can test whether the element is empty by comparing with the empty string `''` (two single quotation marks). For example, to check whether a string element that is represented by the variable name `str` is empty, use the following expression:

```
$str = ''
```

If the element is also nillable, use the following expression:

```
(fn:nilled( $elementName) = false)  and $str = ''
```

Other simple types have no natural empty value. For example, with numerical type elements the value must always contain a minimum set of valid digits. In this case, you might consider a particular value to be empty, and so test for that value. To check whether a number element that is represented by the variable name `num` has a zero value, use the following expression:

```
$num = 0
```

To determine whether a complex element is empty, check for child elements or attributes. For example, to check a complex element that is represented by the variable name `comp`, use the following expression:

```
fn:not( $comp/* or $comp/@* )
```

If the complex element allows mixed content, check for text content as well.

```
fn:not( $comp/text() or  $nodes/* or $nodes/@* )
```

Procedure

Take the following steps to define a conditional expression on a **Move** transform between a source and target string element. The expression ensures that the transform is not applied if the input data is an empty string.

1. Create a **Move** transform between an input element and an output element.

2. In the Properties view, under **Condition**, use content assist (Ctrl+Space) to enter the appropriate XPath expression.
   For example, assuming the variable name for the input is `str`:

```
$str = ''
```

Mapping an element by using a Custom Java transform

In the Graphical Data Mapping editor, you can use a method in a Java class to set the value of an output element. You can use the Custom Java transform to invoke a Java method, optionally passing one or more values to its parameters.

Procedure

Complete the following steps to use Java in a Custom Java transform:

1. Create a message map.

   When you use Java code in a map, you can define the map in a static library project, a shared library project, an application project, or an integration project. You can define the Java code in one or more Java projects. Your map project must reference these Java projects. For more information, see Adding a project to an application, integration service, or library.

   Note: When the map uses Java code available in a shared library, you must create the map in the shared library project where the Java code is available.

   For more information, see “Creating message maps” on page 1378.
2. Add a Custom Java transform to the map, and connect an input and output:
   - The input and output elements must be child elements; you cannot use a Custom Java transform to map a root element of a message.
   - Ensure that the input elements provide simple data values, and the output element has a data value set by the invoked Java method.
   - If you want to map complex or repeating elements in a Custom Java transform, see “Processing complex or repeating elements in a Custom Java transform” on page 1498.

3. If you have already defined a Java class, select the class in the **General** tab of the **Properties** page of the transform or, if you have not defined a Java class, complete the following steps to define the required Java class:
   a) In the **General** tab of the **Properties** page of the transform, click **New**.
   b) Select one of the following options, and complete the associated steps:
      - Create a new Java project to store the class:
        i) Select **Create the class in a new Java project to be created** and click **Next**.
        ii) Complete the fields in the dialog (for more information, see Creating a Java project) and click **Next**.
      - Use an existing Java project to store the class:
        i) Select **Create the class in one of the existing Java projects**.
        ii) Select the Java project from the list and click **Next**.

      The **New Java class wizard** is displayed.
   c) Complete the **New Java class wizard**.
      At a minimum, complete the following fields:
      i) In the **Source** field, select the `src` folder of your Java project.
      ii) In the **Package** field, enter the name of a package to contain the new class.
      iii) In the **Name** field, enter a name for the class.
   d) Click **Finish**. If prompted, click **Yes** to create a reference from the application that contains your map to your Java project.
      The Java class is created with a sample method.
   e) In the **General** tab of the **Properties** page of the transform, click **Edit** to complete your Java class.

      The Java class that you provide to the map must have static methods that return the appropriate type for the value of the output element, and take parameters of the appropriate type for the wired inputs.

      You can use the MbElement class in a Java method to pass a complex type, a wildcard **xsd:any**, or a wildcard **xsd:anySimpleType**. For more information, see "Custom Java" on page 1312.

      For example, the following Java method might be used in a Custom Java transform that has three input elements, of types a `xs:string`, `xs:decimal`, and `xs:boolean` and the output element is a `xs:decimal`:

```
public static BigDecimal calSomething(String memType, BigDecimal stdCost, boolean flag) {
 BigDecimal actualCost = stdCost;
 if (flag & memType.startsWith("gold")) {
  BigDecimal discRate = new BigDecimal(0.9);
  actualCost = actualCost.multiply(discRate);
 }
 return actualCost;
}
```

      Note: If the input element that is used to provide a value for a Java method is not of the correct type, you can use a type cast function, for example **xs:int($var)**, to set the required type. For more information, see "Cast type (xs:type)" on page 1299.

4. Configure the method that defines the transformation logic that is applied by the Custom Java transform. In the **General** tab of the **Properties** page of the transform, complete the following steps:
   a) Click **Browse** and complete the following steps:
      i) In the **Select Type** window, enter the name of the Java package in the **Select entries** field. The package must contain the Java class.

         Note: You must start typing the name of your Java package before you can see any classes to choose from in the **Select entries** field.

      ii) Select a Java class and click **OK**.

   Note: If the Java project that contains the Java class does not build in Eclipse, then the Java class is not visible anywhere in the map. You must resolve all the Java errors before you can configure the class and method in the **General** tab of the **Properties** page. You can see the errors in the **Problems** tab.

   b) Configure one Java method. You access the methods that are available through the drop-down.

      If the method has parameters, they are added automatically in the **Parameters** section of the **General** tab.

   c) Set the value of each parameter. Complete the following steps to set the value of a parameter:
      i) Select a parameter.
      ii) Click the **Value** column of a parameter.
      iii) Select an element, or select the option **Edit custom XPath expression parameter**. If you select the edit option, you can define an XPath expression or a call to a static method on an imported Java class that is visible to the map. You can also create a complex expression that includes XPath, Java, and extension functions such as **iib:getUserDefinedProperty("propertyname")**.

   When you define a Java method and a Java class in the **General** tab of the **Properties** page of a **Custom Java** transform, an import is automatically added in the map to refer to the package qualified Java class. A prefix based on the class name is added. All the **public static methods** in this Java class are then available in content-assist when building expressions in other transforms.

   Alternatively, you can use Java class methods that use standard Java types in any expression within your map, for example as part of the condition of an `if` transform. Before you can use Java methods in expressions, import the Java class into the map. The method is then available in content assist (`Ctrl-space`). To import a Java class into a map, configure the **Java imports** tab in the **Properties** page of the map.

What to do next

Deploy and test the message map. For more information, see “Troubleshooting a message map” on page 1587.

Processing complex or repeating elements in a Custom Java transform
You can use the Java MbElement class for mapping inputs and outputs that are not simple types with a **Custom Java** transform.

Using the MbElement class

To use the MbElement class in the Java code that you use in a map, complete the following tasks:

1. Add the MbElement plug-in (**jplugin2.jar**) to the build path of the Java project.

   The plug-in is a JAR file that is provided with the IBM App Connect Enterprise Toolkit. The **jplugin2.jar** is also available in the classes directory of the server installation.

   a. In the Java perspective, right-click the Java project, and select **Properties.**
   b. Select **Java Build Path**.
   c. Select the **Libraries** tab.
   d. Click **Add Variable**.
   e. Select the variable **JCN_HOME** and click **Extend**.
   f. Select **jplugin2.jar**, and click **OK**.
2. Import the MbElement class into your Java source.

   You must add the following code:

```
import com.ibm.broker.plugin.MbElement;
```

Using the Java DOM API

You can use the **Node** class from the standard Java **DOM API** to process complex or repeating elements in a Custom Java transform.

For example, the following code shows a Java method that uses the **Node** class:

```
public static Node nodeMove(Node inEl)
```

Reusing Java code

If your Java code is likely to be used by multiple solutions, store it in a shared library. You can store the Java code in the same shared library as a message map. Alternatively, you can store the Java code separately in a referenced shared library.

When you define transformations in your map that use Java code, you can define a map in a static library project, a shared library project, an application project, or an integration project. You can define the Java code in one or more Java projects. Your map project must reference these Java projects.

Note: When the map uses Java code available in a shared library, you must create the map in the shared library project where the Java code is available.

Mapping a single non-repeating element

When you map a single non-repeating element input to a single non-repeating element output, you can use a Java method with the following signature:

```
public static MbElement mbElMove(MbElement inEl)
```

For example, the following code shows a Java method that copies a sub tree:

```
public static MbElement mbElMove(MbElement inEl)
      {
  MbElement outEl = null;
  try {
   outEl = inEl.copy();
   outEl.copyElementTree(inEl);
  } catch (MbException e) {
   throw (new RuntimeException(e));
  }
  return outEl;
 }
```

Mapping a single repeating element

When you map a single repeating element input to an output repeating element, you can use a Java method with the following signature:

```
public static List<MbElement>; customCompleTypeMove(List<MbElement>; inEls)
```

For example:

```
public static List<MbElement> customCompleTypeMove(List<MbElement> inEls)
      {
  List<MbElement> outEls = new ArrayList<MbElement>();
  try {
   Iterator<MbElement> i = inEls.iterator();
   while (i.hasNext()) {
    MbElement inEl = i.next();
    MbElement outEl = inEl.copy();
    // Do some processing of outEl
    outEls.add(outEl);
   }
  } catch (MbException e) {
   throw (new RuntimeException(e));
  }
  return outEls;
 }
```

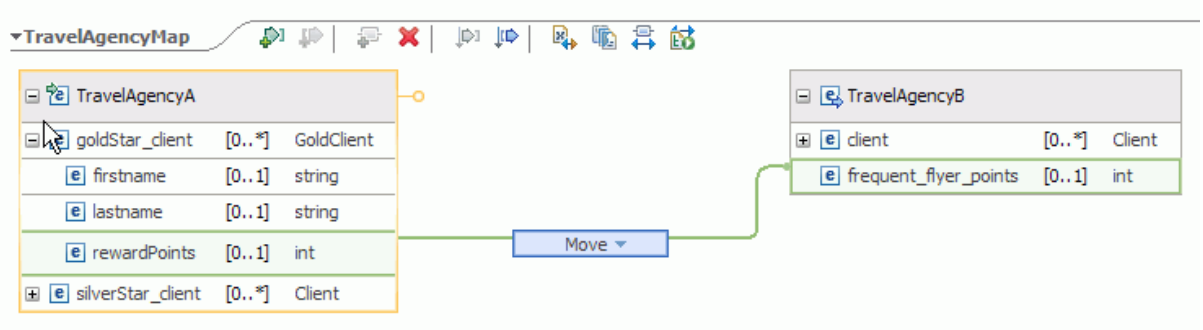
Copying a selected element of a repeating structure to a single output

In the Graphical Data Mapping editor, to copy one element from the input repeating element (array) to an output simple element, use the **Move** transform.

Procedure

1. Define a **Move** transform between the input and the output elements.

   The following figure shows the input and output elements connected by a **Move** transform:



2. Specify the index of the repeating structure that you must copy to the output.
   a) Click the **Move** transform
   b) Switch to the Properties view.
   c) In the **Cardinality** properties page, enter a value in the **Input array indices** field.

      You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see "Selecting the indexes of input array elements" on page 1363.

      For example, enter **3** to copy the third element in the repeating structure (array).

      There is no option to set the cardinality of the output element, because it is a single element.

Copying some values of a repeating element when the input and output structures are the same

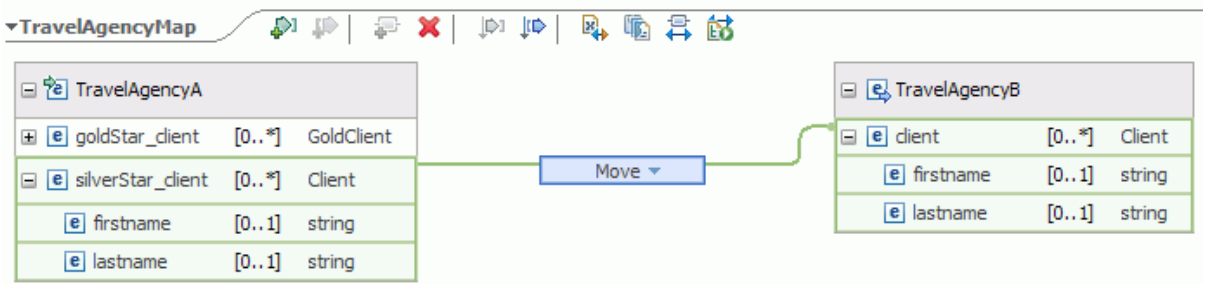
In the Graphical Data Mapping editor, to move selected elements of the input repeating element (array) to an output repeating element of the same type, select a **Move** transform between the elements, and then select the required elements in the **Cardinality** properties page.

Procedure

Complete the following steps to copy some elements of an input array to an output array when both repeating structures are identical:

1. Define a **Move** transform between the input and the output repeating structures.

   The following figure shows the input and output repeating structures of type **Client** connected by a **Move** transform:

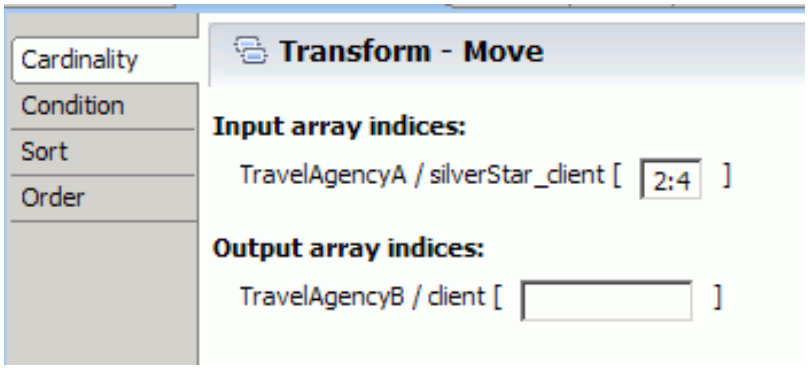


2. Specify the indexes that should be copied to the output repeating structure.
   a) Click the **Move** transform
   b) Switch to the Properties view.
   c) In the **Cardinality** properties page, enter a value in the **Input array indices** field.

      You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see “Selecting the indexes of input array elements” on page 1363.

      For example, to select elements 2, 3, and 4 of the array, set the cardinality to **2:4**.

      The first index element has a cardinality of 1.



Copying some values of a repeating element when the input and output structures are different

In the Graphical Data Mapping editor, use the **For Each** transform to iterate over an input repeating element. Then, to determine the value of the output elements, define transforms in the nested map associated with a **For Each** transform.

About this task

Use the **For Each** transform to move each element of an input array into an output array. The input and output arrays can be of the same type or of different types. For more information, see “For Each” on page 1320.

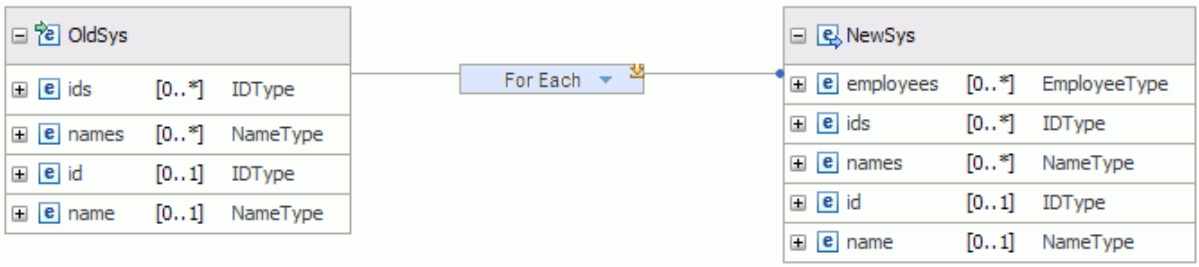
Iteration is performed over the input array.

The nested map associated to a **For Each** transform defines the type of transformations that will be performed for each iteration.

Procedure

Complete the following steps to copy some elements of an input array to an output array when the input and the output repeating elements have different types:

1. Define a **For Each** transform between the input and the output repeating structures.



2. Optional: Specify the indexes of the input repeating structure over which to iterate.
   a) Click the **For Each** transform
   b) Switch to the Properties view.
   c) In the **Cardinality** properties page, enter a value in the **Input array indices** field.

      You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see "Selecting the indexes of input array elements" on page 1363.
3. Edit the nested map by clicking the **For each** transform.
4. Define the transformations required to set the value of the output elements.

   For more information, see "Transforms (Mapping operations)" on page 1280.

Splitting an input message into multiple output messages

You can use a **For Each** transform or a **Join** transform wired to the head of the output message assembly to create a map that takes a single input message and produces multiple instances of an output message model. A typical use of this function is message splitting, in which an input batch message is divided into individual record messages.

About this task

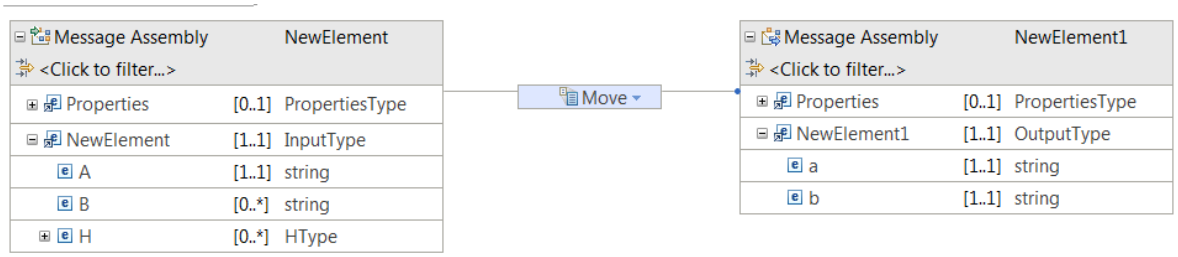
When the map runs, a new message is propagated for each iteration of the **For Each** or **Join** transform.

Procedure

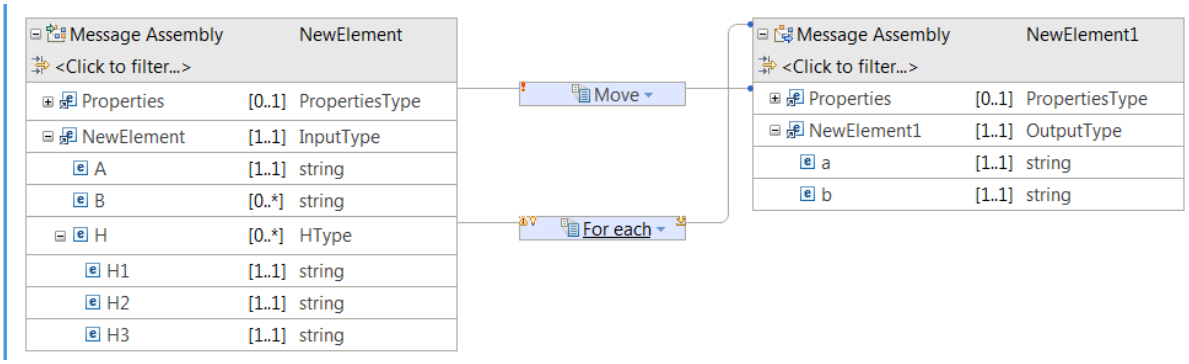
Complete the following steps to split a message into multiple output messages by using the **For Each** transform:

1. Create a map, and add one input element to your input message assembly, and one output element to your output message assembly.

   The input message assembly must contain a repeating element. The values of the elements for each index are used to populate each output message instance.

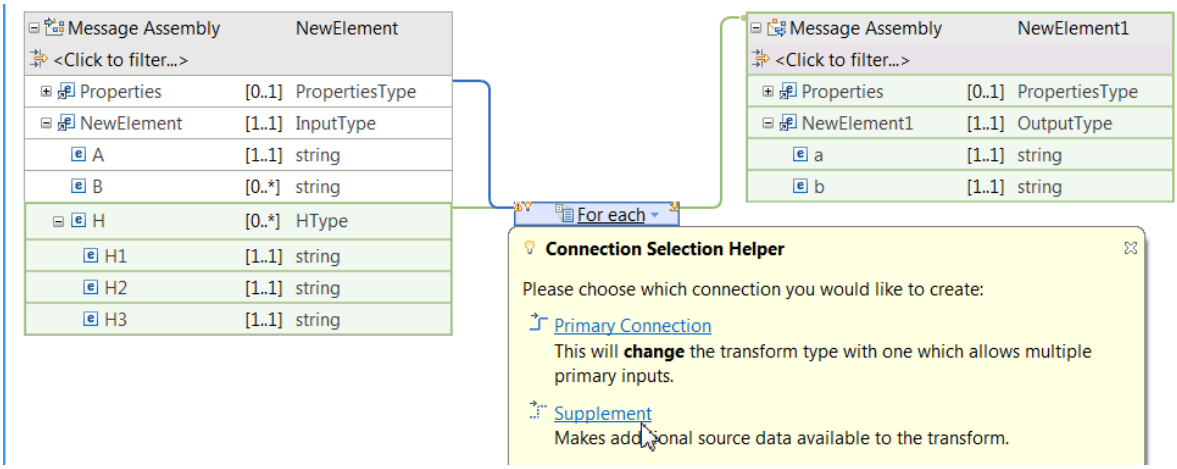


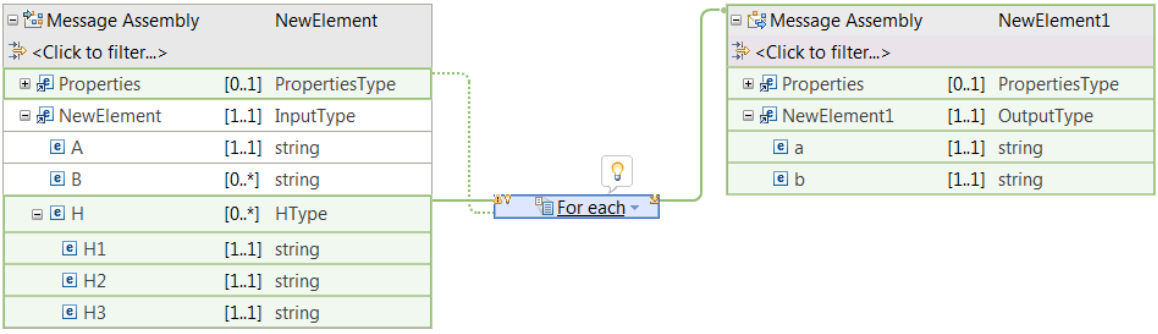
2. Define a **For Each** transform between the input element and the head of the output message assembly.



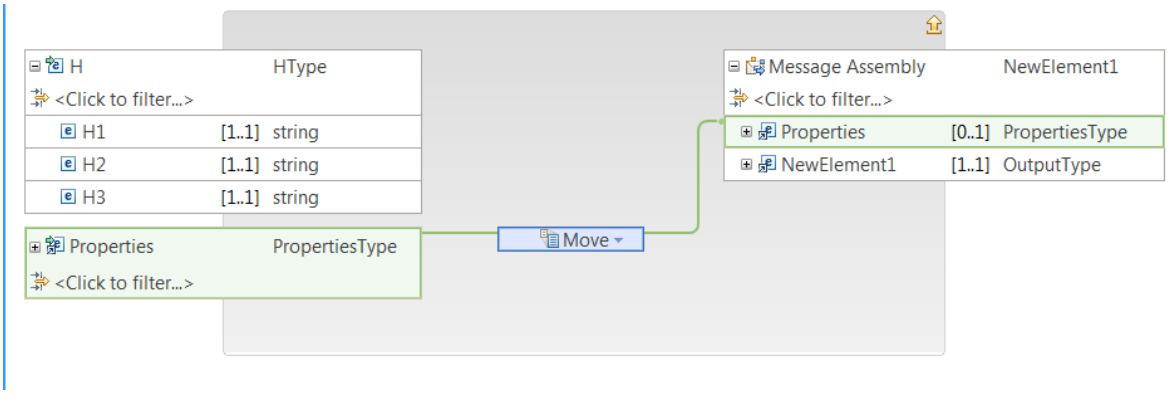
The **Move** transform between the input and the output Properties tree will display an error. Continue with the steps to remove the error.

3. Delete the **Move** transform, and then connect with a supplement connection the input Properties tree to the **For Each** transform.





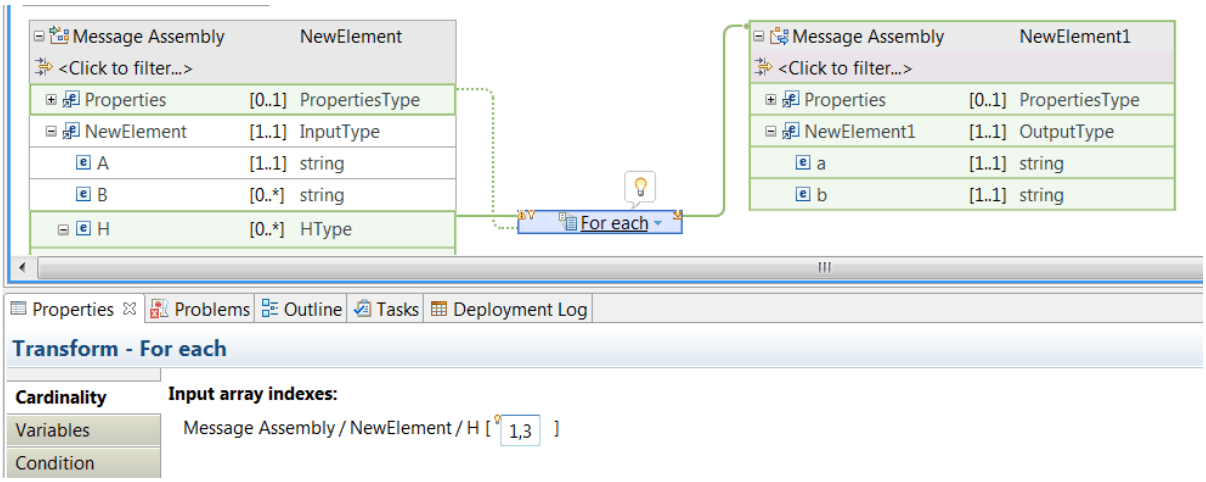
4. Select the **For Each** transform to open the nested map. Then, define a **Move** transform between the input and the output Properties tree.



5. Optional: Return to the **For Each** transform, and configure the indexes of the **For Each** transform for which you want to generate an output message.

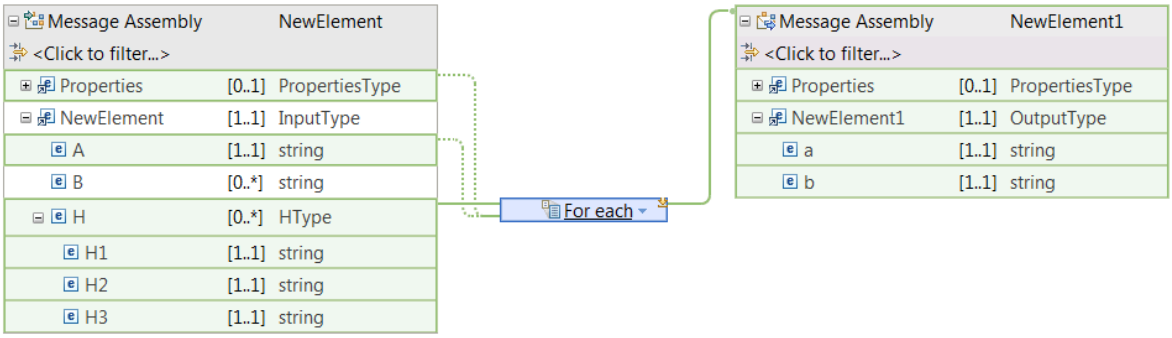
   If you need to create an output message for each index of the repeating structure, then continue with the next step.

   You can configure the **Input array indexes** section to select specific instances of the input array. For more information, see "Selecting the indexes of input array elements" on page 1363.



6. Optional: If you need additional information from the input message to populate output elements, define a supplement connection between each input element to the **For Each** transform.

   When you connect additional input elements with supplement connections to a **For Each** transform, you can use these elements as part of your mapping operations within the nested map.



7. Select the **For Each** transform to open the nested map. Then, define the transformation logic inside the **For Each** nested map.

   For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.

Example

The following example shows how to define the mapping logic in a **For Each** transform after you complete steps 1 to 6:

- Each instance of the **For Each** transform produces an output message.
- The repeating element **H** has three elements that are used to set the values of the output message, which only has two elements.
- An additional input element is needed as part of the transformation. This element is used as part of the conditional expression that determines when a set of transformations is applied.
- An **If** transform is used to model the conditional mapping requirements required to set the value of the output message elements for each index of the **For Each** transform.
- When the value of the input element **A** is equal to the value of the input element **H1**, then the **If** transform is applied. Otherwise, the transformation logic in an **Else** transform is applied.

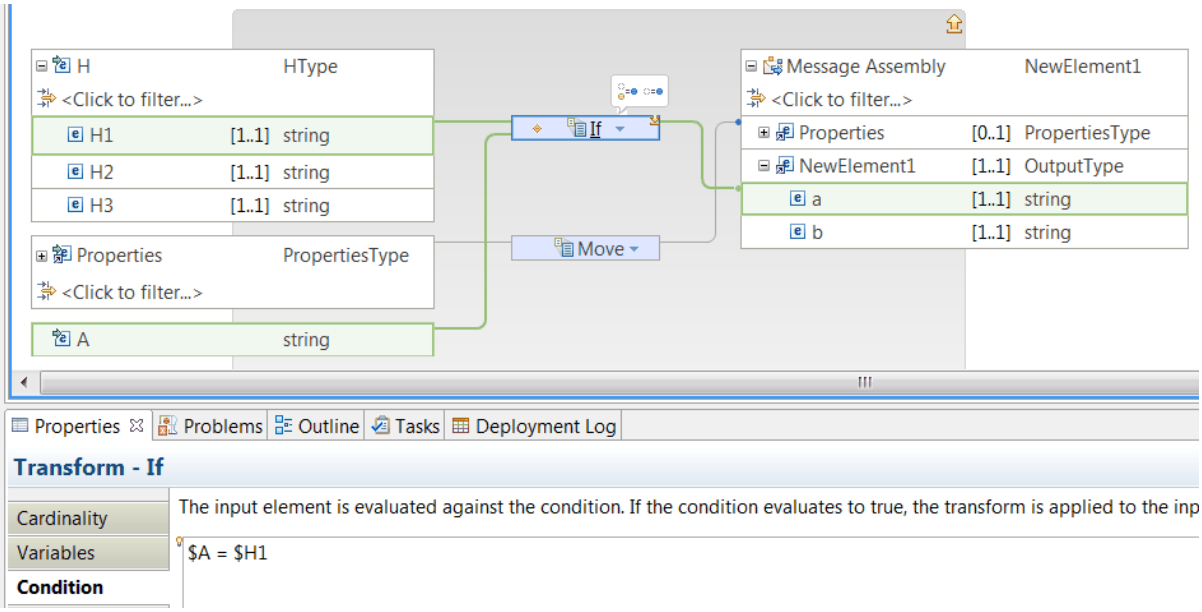
.

Complete the following steps to define the transformation logic:

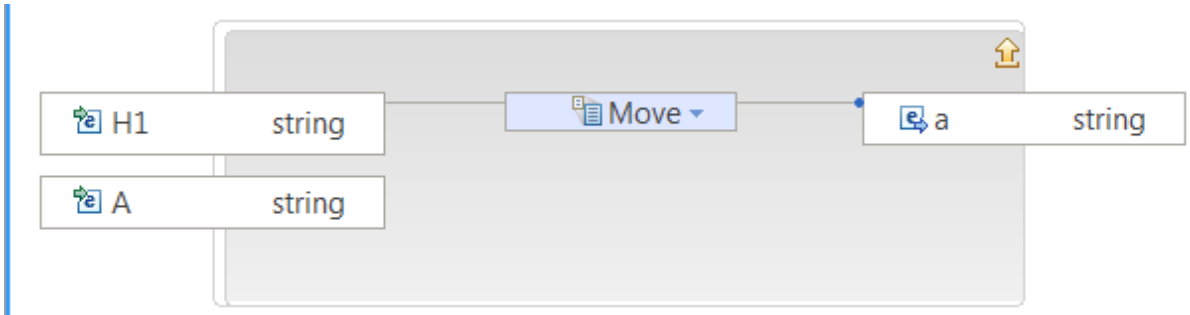
Open the **For Each** transform nested map.

Define an **If** transform between **H** and **a**.

- Define a primary connection between **H** and the **If** transform.
- Define a supplement connection between **A** and the **If** transform.
- Define a connection between the **If** transform and the output element **a**.

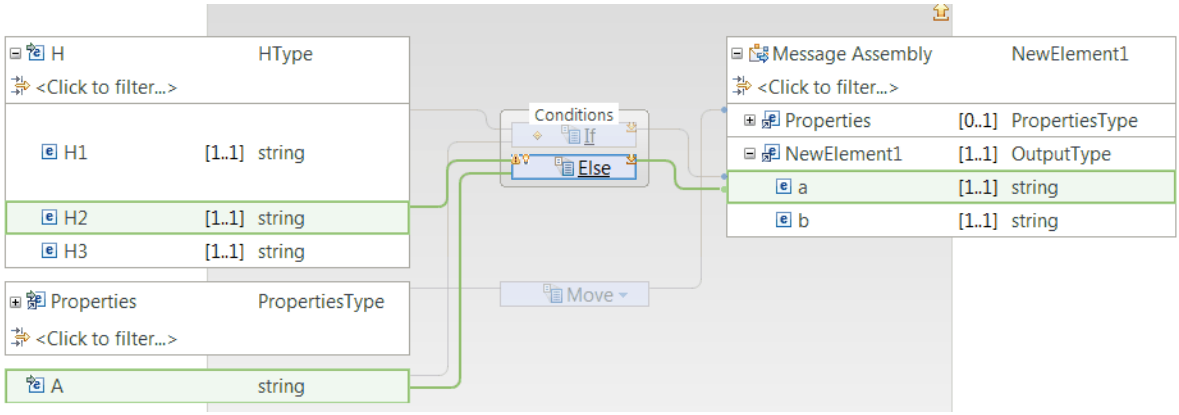


Define a **Move** transform between **H1** and **a**. This operation defines the transformation logic that the **If** transform performs.

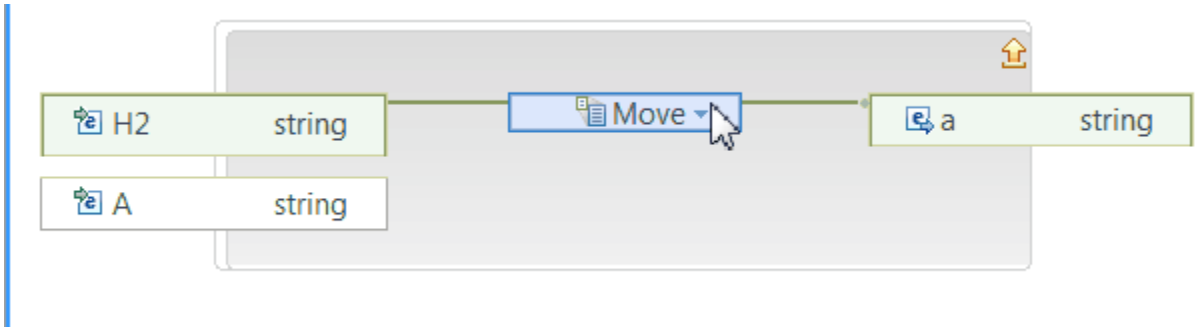


Add the **Else** transform:

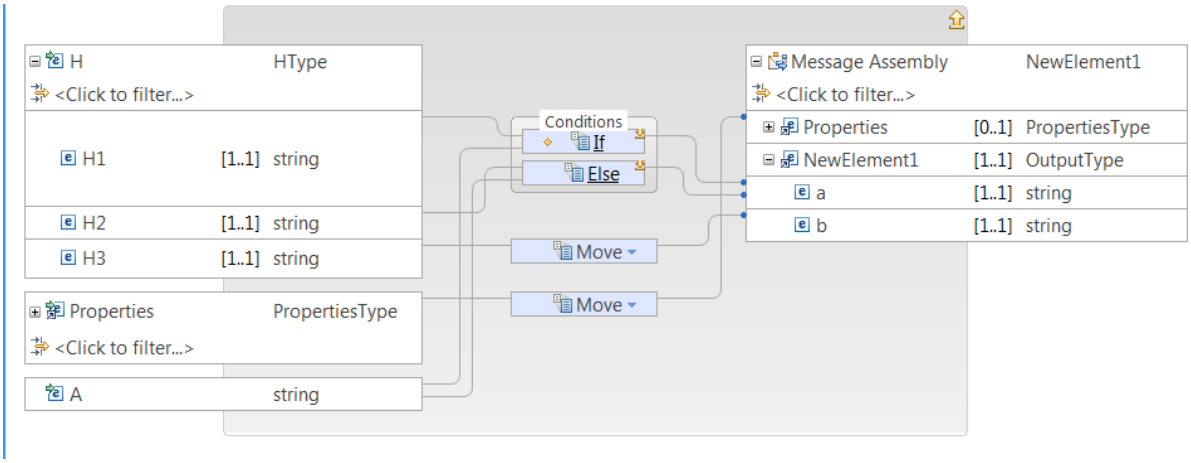
- Define a primary connection between **H** and the **Else** transform.
- Define a supplement connection between **A** and the **Else** transform.
- Define a connection between the **Else** transform and the output element **a**.



Define a **Move** transform between **H2** and **a**. This operation defines the transformation logic that the **Else** transform performs.



The following figure shows the **For Each** transform nested map after all the transformation logic has been implemented:



Mapping an input message into different output messages

You can use the **If** transform to create a map that takes a single input message and produces a different output message based on the conditional expression that you define.

About this task

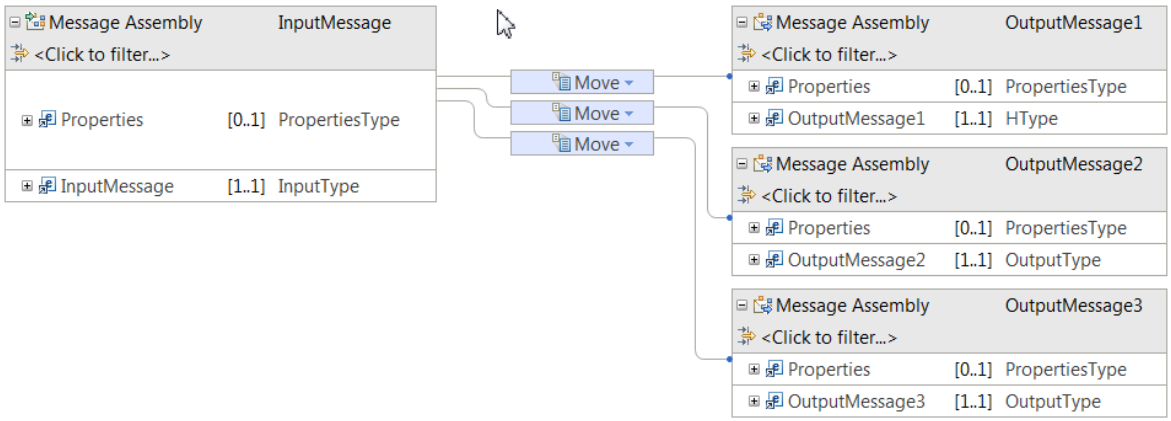
When you configure multiple output message assemblies, each output message assembly has its own properties.

You can configure each output message assembly independently of the others.

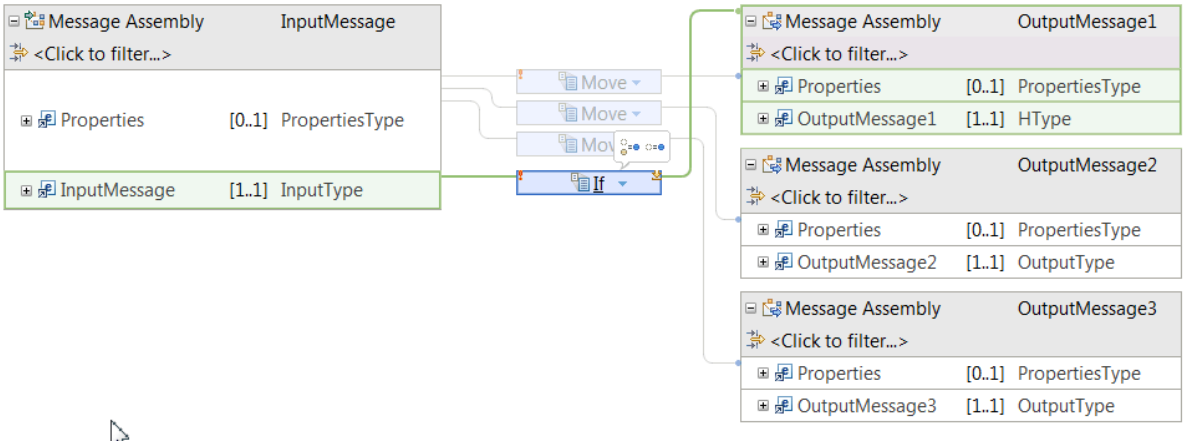
Procedure

Complete the following steps to split a message into different output messages by using the **If** transform:

1. Create a map, and add one input element to your input message assembly, and two or more output message assemblies.

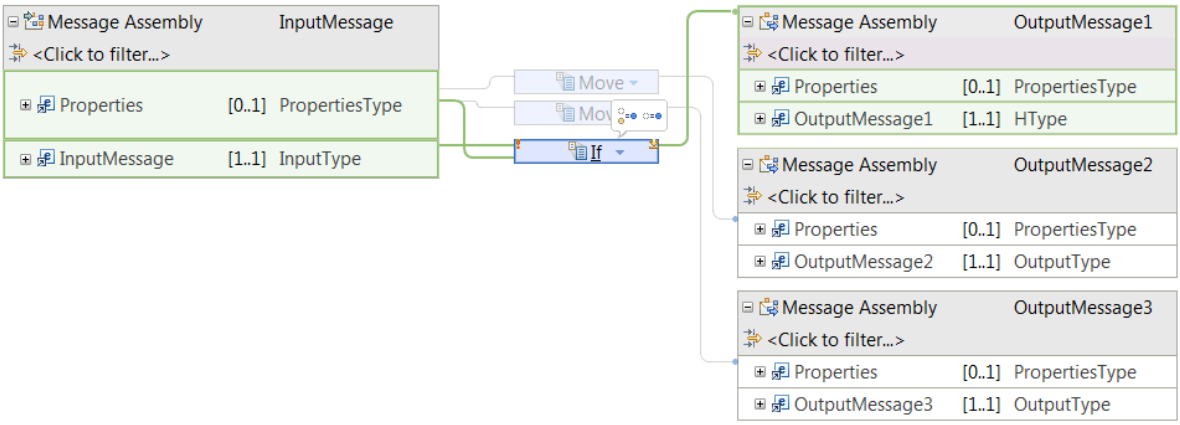


2. Define an **If** transform between the input element and one of the output message assemblies.

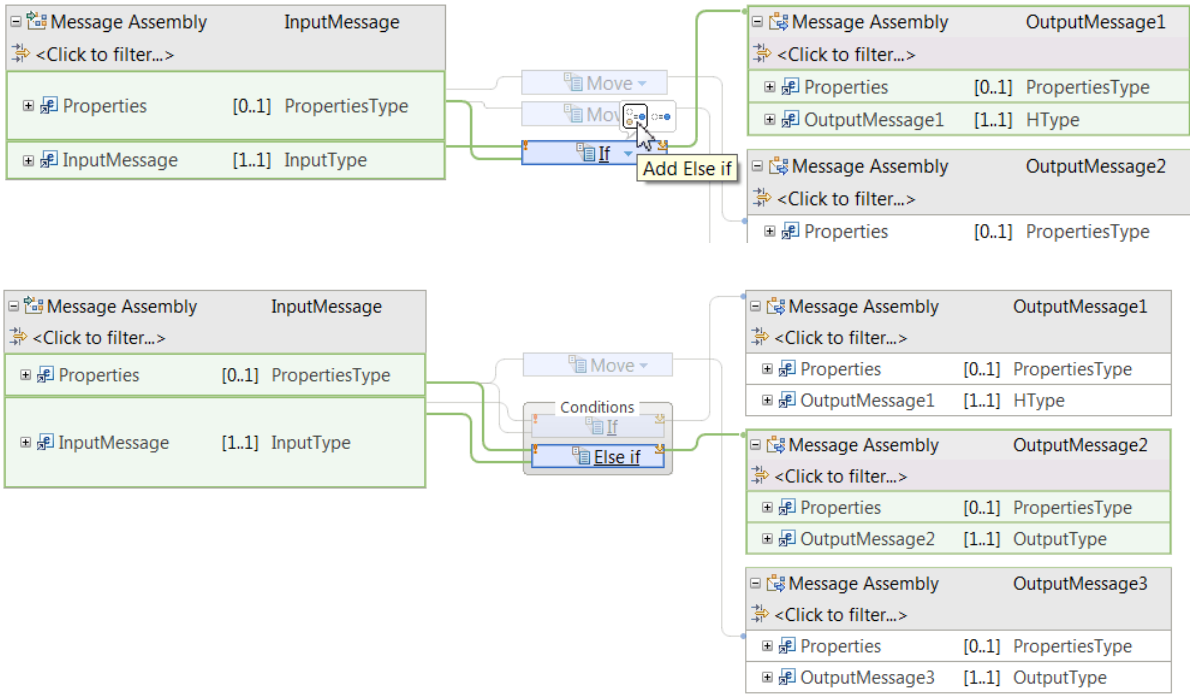


The **Move** transform between the input and the output Properties tree of the first message assembly will display an error. Continue with the steps to remove the error.

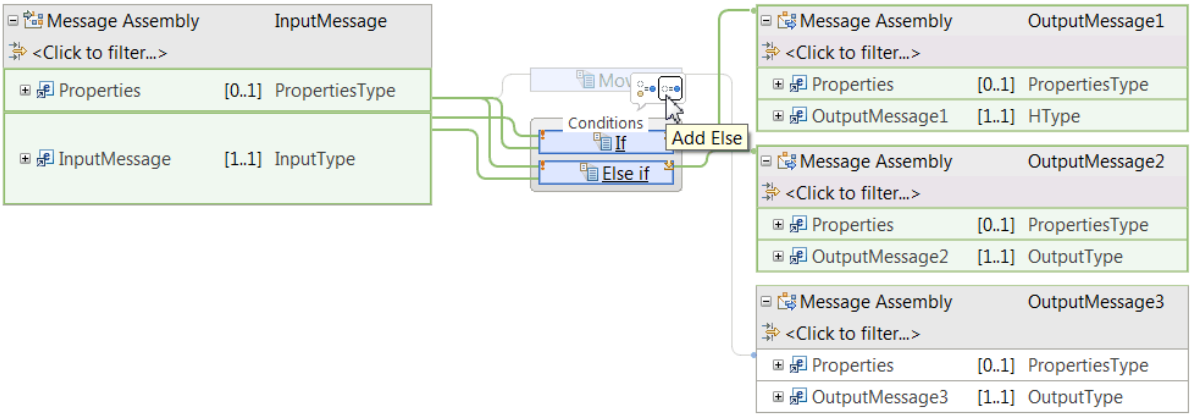
3. Delete the **Move** transform marked with an error, and then connect the input Properties tree to the **If** transform.

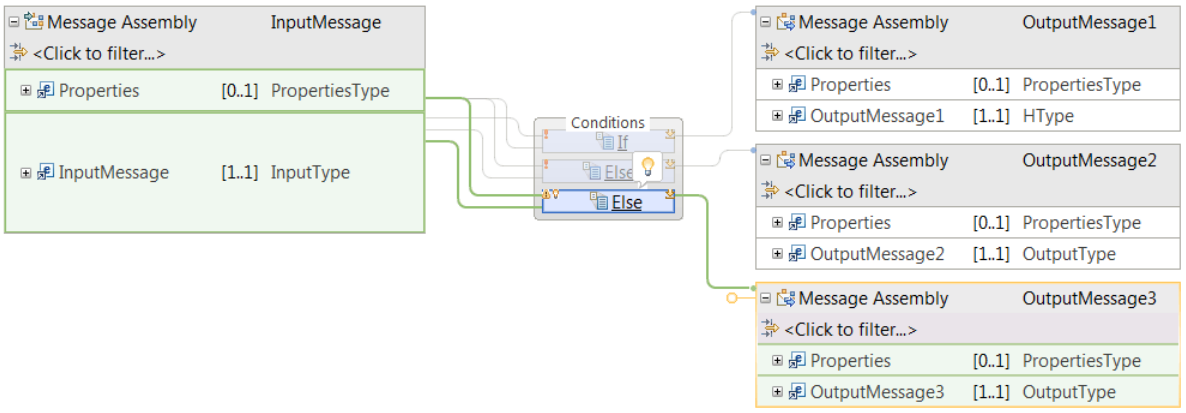


4. Optional: Add the **ElseIf** transform and complete the following steps to connect it to a different output message assembly:
   a) Delete the **Move** transform that connects the Properties tree and the second output message assembly.
   b) Define a connection between the Properties tree and the **ElseIf** transform.
   c) Define a connection between the input message and the **ElseIf** transform.
   d) Define a connection between the **ElseIf** transform and the second output message assembly.

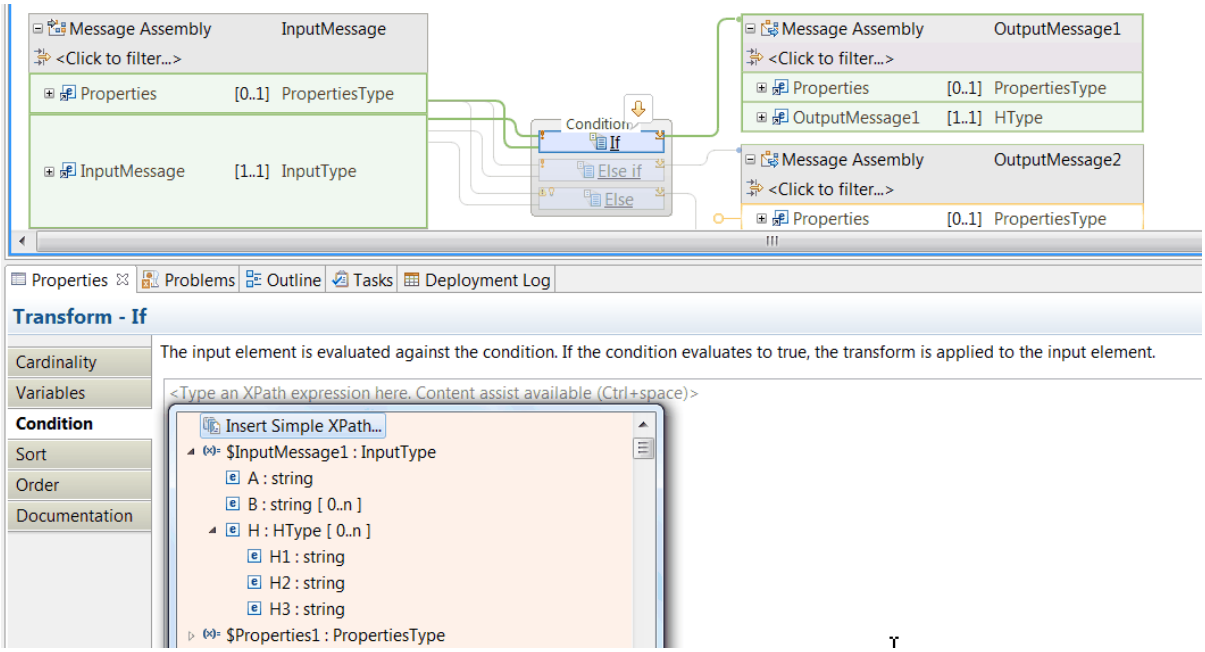


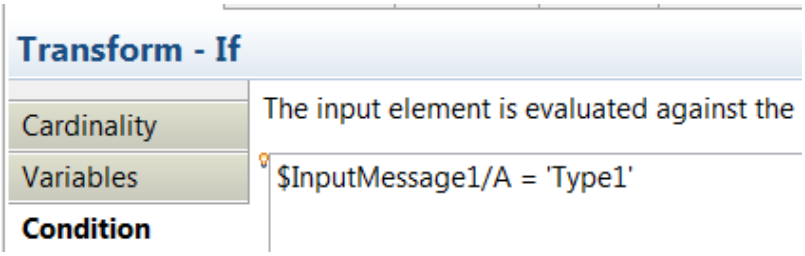
5. Add the **Else** transform and complete the following steps to connect it to a different output message assembly:
   a) Delete the **Move** transform that connects the Properties tree and the third output message assembly.
   b) Define a connection between the Properties tree and the **Else** transform.
   c) Define a connection between the input message and the **Else** transform.
   d) Define a connection between the **Else** transform and the second output message assembly.



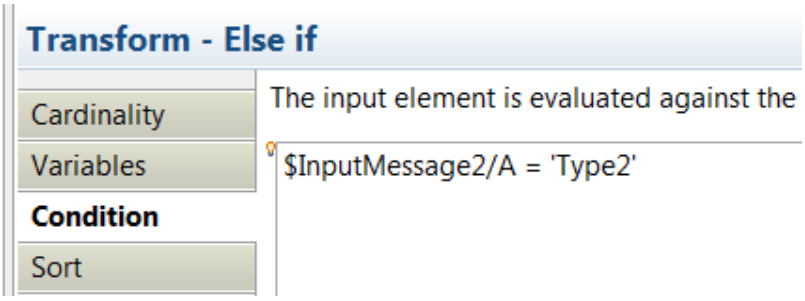


6. Define the conditional expression that determines when the **If** transform is applied and a message based on the first output message assembly is created.
   a) Open the Properties view of the **If** transform.
   b) Define an XPath expression in the **Condition** tab. Use content-assist. For more information, see "Defining an XPath conditional expression for a transform" on page 1433.





7. Define the conditional expression that determines when the **ElseIf** transform is applied and a message based on the second output message assembly is created.
   a) Open the Properties view of the **If** transform.
   b) Define an XPath expression in the **Condition** tab. Use content-assist. For more information, see "Defining an XPath conditional expression for a transform" on page 1433.



Note: When the conditional expression of the **If** transform and the **ElseIf** transform evaluate to **false**, the transformation logic defined for the **Else** transform is applied.

8. Select the **If** transform to open the associated nested map. Then, define transforms between the input and the output elements. Remember to connect the input Properties to the output properties tree with a **Move** transform.

   By default, a **Submap** transform is defined. You can choose to create a submap with your transformation logic, or delete the **Submap** transform and define locally your transformation logic.

   For more information, see "Transform types in the Graphical Data Mapping editor" on page 1282.
9. Select the **ElseIf** transform to open the associated nested map. Then, define transforms between the input and the output elements.
10. Select the **Else** transform to open the associated nested map. Then, define transforms between the input and the output elements.

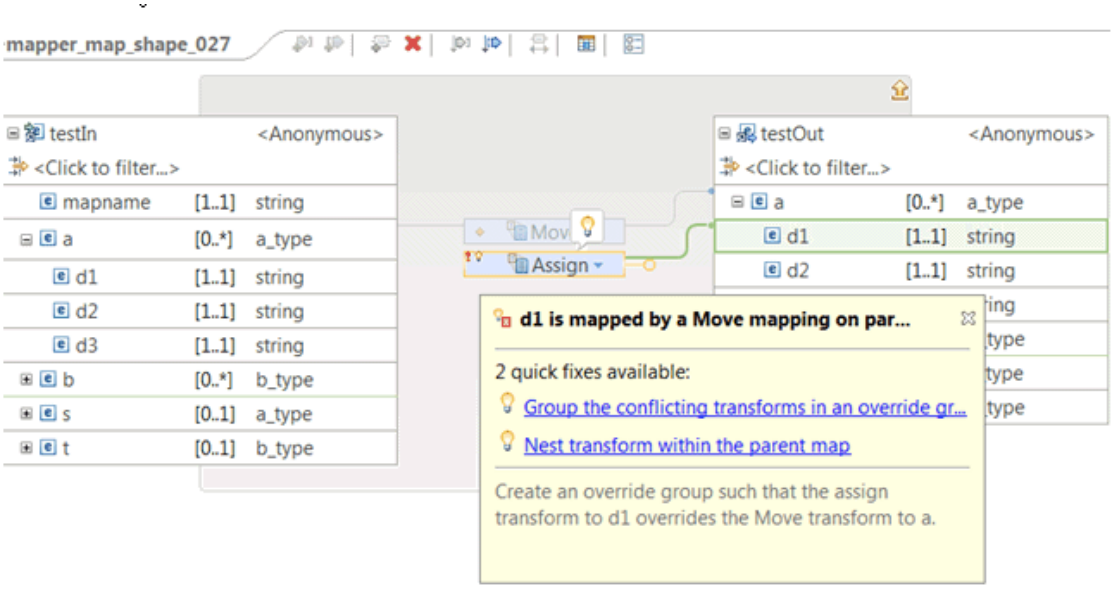
Applying mapping overrides

You can use the **Override** function to copy a complex type from the input to the output object, while updating some of the child elements in the complex type.

About this task

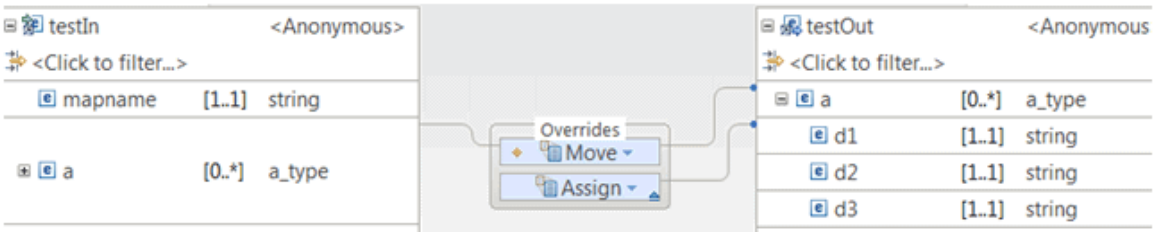
In a message map, you copy a complex type by wiring a **Move** transform from the input object to the output object. You can also add additional transforms to set the value of output elements in the complex object.

As the parent is already mapped, the Graphical Data Mapping editor displays an error marker and offers a Quick Fix.



To resolve the error generated when you copy a complex type while modifying some of the output elements, select the option **Group the conflicting transforms in an overrides group**.

Note: The transforms contained in the overrides group are applied after the parent transform is applied.



Accessing a global cache by using a Mapping node

You can use a Mapping node to interact with a map in an embedded cache or external WebSphere eXtreme Scale grid.

Before you begin

- Read the concept information in Data caching overview.
- Ensure that the embedded cache or external grid is available. The embedded cache is disabled by default. To use the cache, select an integration node level cache policy; see Configuring the embedded global cache.
- If you are connecting to an external grid, create a configurable service to define how the connection is made. For more information, see mqsicreateconfigurableservice command (deprecated).

About this task

You can use a **Cache Put** transform in a Mapping node to store data in the global cache; see “Adding key-value pairs to the global cache by using a Mapping node” on page 1515.

You can use a **Cache Get** transform in a Mapping node to retrieve data from the cache for processing or routing; see “Retrieving a value from the global cache by using a Mapping node” on page 1517.

You can use a **Cache Remove** transform in a Mapping node to remove a key-value pair from the cache; see “Removing a key-value pair from the global cache by using a Mapping node” on page 1519.

If you want to handle any exceptions that are returned by the **Cache** transform, you can add a **Cache Failure** transform to the **Cache** transform group; see "Handling global cache exceptions in a graphical data map" on page 1522.

Adding key-value pairs to the global cache by using a Mapping node
You can use a Mapping node to add key-value pairs to a map in an embedded cache or a WebSphere eXtreme Scale grid.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see "Creating a message map" on page 1382.

About this task

You can use a **Cache Put** transform in a Mapping node to store data in the global cache.

Interactions with the global cache happen outside the message flow transaction, and are committed immediately. If an error occurs downstream of the node that interacts with the global cache, the cache interactions are not rolled back.

To configure a graphical data map to add data to the global cache, complete the following steps:

Procedure

1. Open the graphical data map in the Graphical Data Mapping editor.
2. In the toolbar, click the **Cache Put** icon ( ) to add a **Cache Put** transform to the canvas.
3. Optional: By default, the **Cache Put** transform adds a new key-value pair to the global cache. You can change the action by selecting one of the following options from the General tab of the Properties for the **Cache Put** transform:
   - **Insert entry into cache** (default): Add the key-value pair to the cache.
   - **Update entry in cache**: Update the value that is associated with the key that is already in the cache.
   - **Insert or update entry in cache**: If the key already exists in the cache, update the value that is associated with the key. If the key does not already exist in cache, add the key-value pair to the cache.
4. Provide values for the parameters in the **Cache Put** transform by completing one of the following steps:
   - Map the input elements to the **Cache Put** transform.

     Note: You can also select the elements before you click the **Cache Put** icon. The elements that you select are then automatically mapped to the **Cache Put** transform.
   - Identify fixed values or user-defined properties to assign to the parameters.

   For example, in the following image, the Value element is mapped to the **Cache Put** transform.

5. Double-click the **Cache Put** transform to edit the nested map.

   To edit the nested map, you can also perform any of the following operations:

   - Click the **Cache Put** link in the **Cache Put** transform.
   - Click the arrow in the upper right corner of the **Cache Put** transform.
   - Place the mouse over the **Cache Put** transform, and click **Click here** in the pop-up window.

   The output elements of the nested map are the predefined parameters that are required to perform the **Cache Put** transform. If you mapped elements to the **Cache Put** transform, the elements are displayed as input elements in the nested map.

6. Required: Provide values for the **Value** and **Key** parameters of the **Cache Put** transform by using one of the following options:

   Note: The **Cache Put** transform is marked with an error until a value is provided for the **Value** and **Key** parameters.

   - Map an element from the input tree to a parameter. When you map an input element to the **Value** parameter, you are prompted to apply a mapping cast to redefine the default `xs:anySimpleType` schema type to a specific schema type (see "Casting elements in a message map" on page 1398), so that the global cache entry is created with a specific Java Object type. If you do not use a mapping cast on the **Value** parameter, the Java Object type that is created in the global cache might vary depending on the type of the mapped input element; see "Java Object types that are created for each schema input type" on page 1295. Alternatively, you can use an `xs:type` transform to cast the mapped input element, or assigned value; see "Cast type (xs:type)" on page 1299.

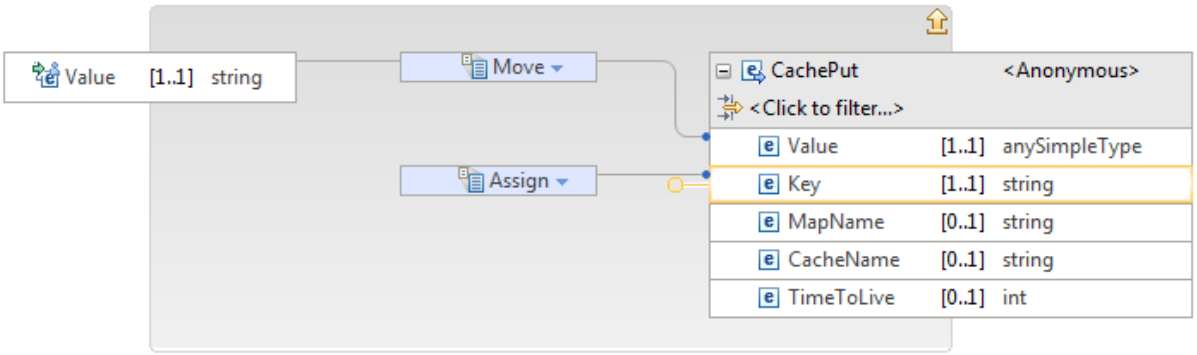
     Note: If the input element is nillable, use one of the following options:

     – Do not cast the target parameter.

     – Make sure that you cast the target parameter to a `String` type, which can have a null value.

   - Set a fixed value for a parameter by right-clicking the parameter in the **Cache Put** transform, clicking **Add Assign**, and adding the required value in the Properties pane. For more information about the **Assign** transform, see "Assign" on page 1289.
   - Set a value for a parameter by using a user-defined property; see "Accessing user-defined properties from a Mapping node" on page 1479.

   For example, in the following image, the content for the **Value** parameter is provided by mapping an element that is named **Value**, and the content for the **Key** parameter is provided by assigning a fixed value.



7. Optional: Map or assign values to the **MapName**, **CacheName**, or **TimeToLive** parameters; for information about valid values for these parameters, see "Cache Put" on page 1293.

8. Optional: Right-click the **Cache Put** transform and select **Cache** > **Return** to implement a nested mapping that is called if the **Cache Put** transform completes successfully. For more information, see "Cache Return" on page 1297.

   Note: You can also add a **Cache Return** transform by placing the mouse over the **Cache Put** transform and selecting the **Cache Return** icon ().
9. Optional: Right-click the **Cache Put** transform and select **Cache** > **Failure** to implement a nested mapping that is called if the **Cache Put** transform fails. For more information, see "Handling global cache exceptions in a graphical data map" on page 1522.

   Note: You can also add a **Cache Failure** transform by placing the mouse over the **Cache Put** transform and selecting the **Cache Failure** icon ().
10. Save the graphical data map.

Results

You added a key-value pair to the global cache.

What to do next

Complete the following tasks:

- Make sure that your global cache is available; see Configuring the embedded global cache or Connecting to a WebSphere eXtreme Scale grid.
- Add the map to a message flow, and deploy the message flow.

For more information about the **Cache Put** transform, see "Cache Put" on page 1293.

Retrieving a value from the global cache by using a Mapping node

You can use a Mapping node to retrieve a value from a map in an embedded cache or a WebSphere eXtreme Scale grid.

Before you begin

You must complete the following task:

- Create a graphical data map by using the Graphical Data Mapping editor. For information, see "Creating a message map" on page 1382.

About this task

You can use a **Cache Get** transform in a Mapping node to retrieve data from the global cache.

To configure a graphical data map to retrieve data from the global cache, complete the following steps:

Procedure

1. Open the graphical data map in the Graphical Data Mapping editor.
2. In the toolbar, click the **Cache Get** icon () to add a **Cache Get** transform to the canvas.
   When you add a **Cache Get** transform, you automatically add a **Cache Return** transform.

3. Provide values for the parameters in the **Cache Put** transform by completing one of the following steps:
   - Map the input elements to the **Cache Get** transform.
   - Identify fixed values or user-defined properties to assign to the parameters.

   Note: You can also map elements from the input tree to the **Cache Return** transform and use these elements to transform the returned cache value.
4. Optional: Map the **Cache Return** transform to the output element that you want to receive the value that is associated with the key in the key-value pair.

   Note: You can also select the elements before you click the **Cache Get** icon. The elements that you select in the input tree are then automatically mapped to the **Cache Get** transform, and the **Cache Return** transform is mapped to the elements that you select in the output tree.

   For example, in the following image, the Key element is mapped to the **Cache Get** transform, and the **Cache Return** transform is mapped to the Value element.
