For SOAPInput nodes the SOAPReply node connected on the HTTP Timeout terminal path must send a SOAP fault response message and the reply status code of 500 cannot be altered. For HTTPInput nodes any response message can be sent from the HTTP Timeout terminal and the reply status code can be changed by updating the `LocalEnvironment.Destination.HTTP.ReplyStatusCode` message tree field.

Using compression with HTTP and SOAP nodes:

You can configure HTTP and SOAP nodes to use HTTP compression and decompression when sending and receiving messages.

The nodes can be configured to compress request messages, accept and decompress responses, and decompress input messages.

Background information

The HTTP transport supports the sending of compressed data. Specific HTTP header fields are used to indicate that the data is compressed, and which compression technique was used for the compression. When an HTTP client makes an HTTP request, it can specify that it accepts a compressed response, and also which types of compressed data it accepts. The three compression techniques supported by the HTTP transport are GZIP, deflate, and compress.

The Accept-Encoding field is used in an HTTP request to indicate which encodings are accepted in a response message to the request. This field is used to specify the values of `gzip`, `deflate`, `compress` and `identity`, which are not case-sensitive. A value of `identity` indicates that the data must not be compressed. A wildcard of `*` indicates that any encoding is accepted. The Accept-Encoding field can also be empty, indicating that no encoding is accepted.

The Content-Encoding header field indicates the encoding that is applied to the data and it can contain the tokens of `gzip`, `deflate`, and `compress`, but not `identity`. When data is compressed for an HTTP message, the Content-Encoding field contains the name of the compression technique that was used, enabling the recipient to identify the compression scheme and correctly decompress the message data.

The TE header field is used in a request header to indicate which extension transfer encodings it will accept in the response. This is similar to the Accept-Encoding field.

The Transfer-Encoding field is similar to the Content-Encoding field, except that it is a property of the message and not of the entity. The Transfer-Encoding field is primarily used to indicate that a response message is chunked. It is possible to receive a Transfer-Encoding header that indicates other transfer encodings such as "chunked, gzip". In this case the gzip applies to the transfer of the data, not the actual data itself.

HTTP compression in WebSphere Message Broker

WebSphere Message Broker supports compression and decompression with the HTTP and SOAP nodes using the Accept-Encoding and Content-Encoding fields as follows:

- In a request node, such as an HTTPRequest or SOAPRequest node, if you select the property to allow compressed responses, the broker sets the Accept-Encoding field on the outbound request.
- When compressing a request, the request nodes set the Content-Encoding header field to indicate that the data is compressed. When receiving a response, the request nodes check the Content-Encoding field to determine if the response is compressed. Multiple values in the header field indicate that the data has been compressed more than once using multiple compression functions.
- When receiving a request, the input nodes check the contents of the Content-Encoding field to determine if the contents of the message are compressed. In response and input nodes, a Content-Encoding value of `x-gzip` is treated as `gzip`.
- WebSphere Message Broker supports only the `gzip` and `deflate` compression encodings; the `compress` encoding is not supported.
- Compression and decompression is handled only through the Accept-Encoding and Content-Encoding header fields; the TE and Transfer-Encoding header fields are not supported.

When compressing a request HTTP message, the node checks the Content-Encoding field to determine if the message data is already compressed. If the data is already compressed in the specified scheme then no further compression is needed. However, if the existing data is already compressed in an encoding that is not specified in the node properties, the node further compresses the compressed bit stream using the encoding specified in the node properties. The value of the Content-Encoding field is updated to indicate the additional encoding applied to the data. For example, a Content-Encoding value of `deflate,gzip` indicates that the message should be first decompressed using deflate and then further decompressed using gzip.

The HTTP and SOAP nodes do not support quality values in the Accept-Encoding field, which allow a user to specify a preferred weighting of compression types for responses. Any quality values in the Accept-Encoding field are ignored.

Using HTTP compression with the HTTP and SOAP nodes

The request nodes can request and process compressed responses. You can configure the request nodes to indicate that compression in responses is allowed, and the node automatically decompresses a compressed response. The Accepts-Encoding header is set to indicate that GZIP and deflate compression techniques are accepted. If the Accept-Encoding header is already set, the node does not override it.

If the request or the AsyncResponse nodes receive a GZIP or deflate compressed response, it is decompressed and any header indication that the message is compressed is removed. If the nodes receive an invalid compressed response or an unrecognized compression function, an exception is raised indicating that the data could not be decompressed.

The request nodes can also send compressed requests. You can configure the node to specify which compression technique is used for the compressed requests that it sends. The value of the Content-Encoding header is set to indicate the compression that is used. You can override this value in the local environment for an individual message. If you override the local environment with a value that is not recognized by the node, the existing node value for Use compression is used.

The input nodes can decompress input data that is compressed using the GZIP and deflate compression scheme. If the input node receives a message that is not compressed validly, a fault message is returned to the client and the input message is not propagated to the message flow. This can occur if:

- The Content-Encoding header is set to an unrecognized compression function
- The message body is not compressed correctly using the named Content-Encoding value.

Web services example messages

Examples of complete HTTP messages show typical content in specific scenarios.

The following examples show complete HTTP messages. The first message is a request sent by an HTTPRequest node to a Web service that provides a lookup service:

```
POST /greenpages/servlet/rpcrouter HTTP/1.0
Host: localhost
Content-Type: text/xml; charset=utf-8
Content-Length: 520
SOAP Action: ""
Cookie: JSESSIONID=0000B5OSLFIUDMQZFAUXKHD5ZDQ:-1

<?xml version='1.0' encoding='UTF-8'?>
<SOAP-ENV:Envelope xmlns:SOAP-ENV="http://schema.xmlsoap.org.soap/envelope/"
                   xmlns:xsi="http://www.w3/2001/XMLSchema-instance"
                   xmlns:xsd="http://www.w3/2001/XMLSchema">
<SOAP-ENV:Body>
<ns1:getUserByName xmlns:ns1="http://tempuri.org/imb.GreenPages"
                   SOAP-ENV:encodingStyle="http:/schemas.xmlsoap.org/soap/encoding/">
<nameField xsl:type="xsd:string">bloggs, joe</nameField>
</ns1:getUserByName>
</SOAP-ENV:Body>
</SOAP-ENV:Envelope>
```

The `Cookie` is an example of a value that can be retrieved from the HTTPRequest tree.

The second message is the corresponding Web service response returned to the HTTPRequest node:

```
HTTP/1.0 200 OK
Server: WebSphere Application Server/4.0
Content-Type: text/xml; charset=utf-8
Content-Length: 1585
Content-Language: en
Connection: close

<?xml version='1.0' encoding='UTF-8'?>
<SOAP-ENV:Envelope xmlns:SOAP-ENV="http://schema.xmlsoap.org.soap/envelope/"
                   xmlns:xsi="http://www.w3/2001/XMLSchema-instance"
                   xmlns:xsd="http://www.w3/2001/XMLSchema">
<SOAP-ENV:Body>
<ns1:getUserByNameResponse xmlns:ns1="http://tempuri.org/imb.GreenPages"
                   SOAP-ENV:encodingStyle="http:/schemas.xmlsoap.org/soap/encoding/">
<return xmlns:ns2="http://www.greenpages.com/schemas/GreenPagesRemoteInterface"
        xsi:type="ns2:imb.UserRecord">
<fullName xsi:type="xsd:string">Joseph Bloggs</fullName>
<empNum xsi:type="xsd:int">65874</empNum>
<deskPhone xsi:type="xsd:string">(718)545-3623</deskPhone>
</return>
</ns1:getUserByNameResponse>
</SOAP-ENV:Body>
</SOAP-ENV:Envelope>
```

Processing Web service messages

Use WebSphere Message Broker nodes and services to connect to other Web services providers and consumers.

About this task

A Web service is a software system designed to support interoperable computer-to-computer interaction over a network. It has an interface described by an XML-based specification; specifically, the Web Service Definition Language, or WSDL.

Web services fulfill a specific task or a set of tasks. A Web service is described using a standard, formal XML notation, called its service description, that provides all the details necessary to interact with the service, including message formats (that detail the operations), transport protocols, and location.

The nature of the interface hides the implementation details of the service, so that it can be used independently of the hardware or software platform on which it is implemented. The interface is also independent of the programming language in which it is written. This interface handles Web service-based applications as loosely coupled, component-oriented, cross-technology implementations. Web services can be used alone, or with other Web services, to carry out a complex aggregation or a business transaction.

The following topics describe how to work with Web services:

- "WebSphere Message Broker and Web services" on page 1602
- "What is SOAP?" on page 1604
- "What is WSDL?" on page 1615
- "What is SOAP MTOM?" on page 1616
- "WS-Addressing" on page 1617
- "WebSphere Service Registry and Repository" on page 1875
- "Message flows for Web services" on page 1619
- "WS-Security" on page 765

WebSphere Message Broker supplies a Java servlet that you can use in an external Web servlet container such as IBM WebSphere Application Server or Apache Tomcat, to receive HTTP requests from Web services client applications. The HTTP

proxy servlet is described in “HTTP proxy servlet overview” on page 856.

WebSphere Message Broker and Web services

A WebSphere Message Broker application can participate in a Web services environment as a service requester, as a service provider, or both.

The SOAP domain supports these formats:

- Common Web services message formats SOAP 1.1, SOAP 1.2, SOAP with Attachments (SwA), and MTOM.
- Consistent SOAP logical tree format, which is independent of the exact message format.
- WS-Addressing and WS-Security standards.

The following nodes are provided for use in the SOAP domain:

- “SOAPInput node” on page 4795
- “SOAPReply node” on page 4819
- “SOAPRequest node” on page 4828
- “SOAPAsyncRequest node” on page 4750
- “SOAPAsyncResponse node” on page 4777
- “SOAPEnvelope node” on page 4786
- “SOAPExtract node” on page 4790

Use the SOAP nodes and SOAP domain where possible; see “Web services: when to use SOAP or HTTP nodes” on page 1582.

Web services support conforms to the following open standards:

- SOAP 1.1 and 1.2
- SOAP Messages with Attachments
- MTOM
- HTTP 1.1

- WSDL 1.1
- WS-Addressing (new SOAP domain only)
- WS-Security (new SOAP domain only)

WSDL is also validated against the WS-I Basic Profile Version 1.1. Conformance to the guidelines in this specification improves interoperability with other applications.

For more information about how a WebSphere Message Broker application can participate in a Web services environment, see the WebSphere Message Broker web page on developerWorks.

Related concepts:

"What is a Web service?"
A Web service is defined by the World Wide Web Consortium (W3C) as a software system designed to support interoperable machine-to-machine interaction over a network.

"WebSphere Message Broker compliance with Web services standards" on page 6704
WebSphere Message Broker complies with the supported Web services standards and specifications, in that you can generate and deploy Web services that are compliant.

"WS-I Basic Profile Version 1.1" on page 6700
WS-I Basic Profile Version 1.1 (WS-I BP 1.1) is a set of non-proprietary Web services specifications, along with clarifications and amendments to those specifications, which together promote interoperability between different implementations of Web services.

What is a Web service?:

A Web service is defined by the World Wide Web Consortium (W3C) as a software system designed to support interoperable machine-to-machine interaction over a network.

A Web service fulfills a specific task or a set of tasks, and is described by a service description in a standard XML notation called Web Services Description Language (WSDL). The service description provides all of the details necessary to interact with the service, including message formats (that detail the operations), transport protocols, and location.

Other systems use SOAP messages to interact with the Web service, typically by using HTTP with an XML serialization in conjunction with other Web-related standards.

The WSDL interface hides the details of how the service is implemented, and the service can be used independently of the hardware or software platform on which it is implemented, and independently of the programming language in which it is written.

Applications that are based on Web services are loosely-coupled, component-oriented, cross-technology implementations. Web services can be used alone, or in conjunction with other Web services to carry out a complex aggregation or a business transaction.

Related concepts:

"WebSphere Message Broker and Web services" on page 1602
A WebSphere Message Broker application can participate in a Web services environment as a service requester, as a service provider, or both.

"Web services external standards" on page 6696
WebSphere Message Broker support for Web services conforms to a number of industry standards and specifications.

What is SOAP?:

SOAP is an XML message format used in Web service interactions. SOAP messages are typically sent over HTTP or JMS, but other transport protocols can be used. The use of SOAP in a specific Web service is described by a WSDL definition.

There are two versions of SOAP in common use: SOAP 1.1 and SOAP 1.2. Both are supported in WebSphere Message Broker. SOAP is defined in the following documents issued by World Wide Web Consortium (W3C):

- Simple Object Access Protocol (SOAP) 1.1 (W3C note).
- SOAP Version 1.2 Part 0: Primer (W3C recommendation).
- SOAP Version 1.2 Part 1: Messaging Framework (W3C recommendation).
- SOAP Version 1.2 Part 2: Adjuncts (W3C recommendation).

Support for SOAP in WebSphere Message Broker includes:

- SOAP parser and domain. See "SOAP parser and domain" on page 1082.
- SOAP nodes to send and receive messages in SOAP format.
- IBM supplied message definitions for SOAP 1.1 and SOAP 1.2. These message definitions support validation, ESQL content assist, and the creation of message maps for use with SOAP messages, in the SOAP and other XML domains. See "IBM supplied messages that you can import" on page 6367.
- HTTP and JMS transport to send SOAP messages. See the W3C SOAP over JMS specification: http://www.w3.org/TR/soapjms/

WSDL validation in WebSphere Message Broker refers to the WS-I Basic Profile. For more information, see the WS-I, and in particular the WS-I Basic Profile document:

- http://www.ws-i.org/
- http://www.ws-i.org/deliverables

This tree format allows you to access the key parts of the SOAP message in a convenient way.

Related reference:

"IBM supplied messages that you can import" on page 6367
You can import IBM supplied messages to create a new message definition file.

The structure of a SOAP message:

A SOAP message is encoded as an XML document, consisting of an <Envelope> element, which contains an optional <Header> element, and a mandatory <Body> element. The <Fault> element, contained in <Body>, is used for reporting errors.

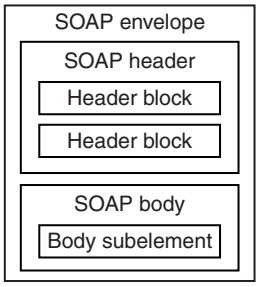
The SOAP envelope
<Envelope> is the root element in every SOAP message, and contains two child elements, an optional <Header> element, and a mandatory <Body> element.

The SOAP header
<Header> is an optional subelement of the SOAP envelope, and is used to pass application-related information that is to be processed by SOAP nodes along the message path; see "The SOAP header" on page 1606.

The SOAP body
<Body> is a mandatory subelement of the SOAP envelope, which contains information intended for the ultimate recipient of the message; see "The SOAP body" on page 1608.

The SOAP fault
<Fault> is a subelement of the SOAP body, which is used for reporting errors; see "The SOAP fault" on page 1608.

XML elements in <Header> and <Body> are defined by the applications that make use of them, although the SOAP specification imposes some constraints on their structure. The following diagram shows the structure of a SOAP message.



The following code is an example of a SOAP message that contains header blocks (the <m:reservation> and <n:passenger> elements) and a body (containing the <p:itinterary> element).

```
<?xml version='1.0' Encoding='UTF-8' ?>
<env:Envelope xmlns:env="http://www.w3.org/2003/05/soap-envelope">
 <env:Header>
  <m:reservation xmlns:m="http://travelcompany.example.org/reservation"
  env:role="http://www.w3.org/2003/05/soap-envelope/role/next">
   <m:reference>uuid:093a2da1-q345-739r-ba5d-pqff98fe8j7d</m:reference>
   <m:dateAndTime>2007-11-29T13:20:00.000-05:00</m:dateAndTime>
  </m:reservation>
  <n:passenger xmlns:n="http://mycompany.example.com/employees"
  env:role="http://www.w3.org/2003/05/soap-envelope/role/next">
   <n:name>Fred Bloggs</n:name>
  </n:passenger>
 </env:Header>
 <env:Body>
  <p:itinerary xmlns:p="http://travelcompany.example.org/reservation/travel">
```

```
   <p:departure>
     <p:departing>New York</p:departing>
     <p:arriving>Los Angeles</p:arriving>
     <p:departureDate>2007-12-14</p:departureDate>
     <p:departureTime>late afternoon</p:departureTime>
     <p:seatPreference>aisle</p:seatPreference>
   </p:departure>
   <p:return>
     <p:departing>Los Angeles</p:departing>
     <p:arriving>New York</p:arriving>
     <p:departureDate>2007-12-20</p:departureDate>
     <p:departureTime>mid-morning</p:departureTime>
     <p:seatPreference></p:seatPreference>
   </p:return>
  </p:itinerary>
 </env:Body>
</env:Envelope>
```

Related concepts:

"The SOAP header"
The SOAP header (the <Header> element) is an optional sub-element of the SOAP envelope, and is used to pass application-related information that is processed by SOAP nodes along the message flow.

The SOAP body (the <Body> element) is a mandatory sub-element of the SOAP envelope, which contains information intended for the ultimate recipient of the message.

"The SOAP fault" on page 1608
The SOAP fault (the <Fault> element) is a sub-element of the SOAP body, which is used for reporting errors.

"SOAP 1.1 and 1.2" on page 6696
SOAP is a lightweight, XML-based, protocol for exchange of information in a decentralized, distributed environment.

The SOAP header:

The SOAP header (the <Header> element) is an optional sub-element of the SOAP envelope, and is used to pass application-related information that is processed by SOAP nodes along the message flow.

The immediate child elements of the header are called *header blocks*. A header block is an application-defined XML element, and represents a logical grouping of data which can be targeted at SOAP nodes that might be encountered in the path of a message from a sender to an ultimate receiver.

SOAP header blocks can be processed by SOAP intermediary nodes, and by the ultimate SOAP receiver node. However, in a real application, not every node processes every header block. Each node is typically designed to process particular header blocks, and each header block is processed by particular nodes.

The SOAP header enables you to add features to a SOAP message in a decentralized manner without prior agreement between the communicating parties. SOAP defines some attributes that can be used to indicate what can deal with a feature and whether it is optional or mandatory. Such control information includes, for example, passing directives or contextual information related to the processing of the message. This control information enables a SOAP message to be extended in an application-specific manner.

Although the header blocks are application-defined, SOAP-defined attributes on the header blocks indicate how the header blocks must be processed by the SOAP nodes. SOAP-defined attributes include:

encodingStyle
Indicates the rules used to encode the parts of a SOAP message. SOAP defines a narrower set of rules for encoding data than the flexible encoding that XML enables.

actor (SOAP 1.1) or role (SOAP 1.2)
In SOAP 1.2, the role attribute specifies whether a particular node will operate on a message. If the role specified for the node matches the role attribute of the header block, the node processes the header. If the roles do not match, the node does not process the header block. In SOAP 1.1, the actor attribute performs the same function.

Roles can be defined by the application, and are designated by a URI. For example, `http://example.com/Log` might designate the role of a node which performs logging. Header blocks that are processed by this node specify `env:role="http://example.com/Log"` (where the namespace prefix `env` is associated with the SOAP namespace name of `http://www.w3.org/2003/05/soap-envelope`).

The SOAP 1.2 specification defines three standard roles in addition to those which are defined by the application:

`http://www.w3.org/2003/05/soap-envelope/none`
None of the SOAP nodes on the message path should process the header block directly. Header blocks with this role can be used to carry data that is required for processing of other SOAP header blocks.

`http://www.w3.org/2003/05/soap-envelope/next`
All SOAP nodes on the message path are expected to examine the header block (provided that the header has not been removed by a node earlier in the message path).

`http://www.w3.org/2003/05/soap-envelope/ultimateReceiver`
Only the ultimate receiver node is expected to examine the header block.

mustUnderstand
This attribute is used to ensure that SOAP nodes do not ignore header blocks which are important to the overall purpose of the application. If a SOAP node determines, by using the **role** or **actor** attribute, that it should process a header block, the action taken depends on the value of the **mustUnderstand** attribute.

- `1` (SOAP 1.1) or `true` (SOAP 1.2): The node must either process the header block in a manner consistent with its specification, or not at all (and throw a fault).
- `0` (SOAP 1.1) or `false` (SOAP 1.2): The node is not obliged to process the header block.

In effect, the **mustUnderstand** attribute indicates whether processing of the header block is mandatory or optional.

relay (SOAP 1.2 only)
When a SOAP intermediary node processes a header block, the SOAP intermediary node removes the header block from the SOAP message. By default, the SOAP intermediary node also removes all header blocks that it

ignored (because the **mustUnderstand** attribute had a value of `false`). However, when the relay attribute is specified with a value of `true`, the SOAP intermediary node retains the unprocessed header block in the message.

Related concepts:

"The SOAP body"
The SOAP body (the <Body> element) is a mandatory sub-element of the SOAP envelope, which contains information intended for the ultimate recipient of the message.

"The SOAP fault"
The SOAP fault (the <Fault> element) is a sub-element of the SOAP body, which is used for reporting errors.

The SOAP body:

The SOAP body (the <Body> element) is a mandatory sub-element of the SOAP envelope, which contains information intended for the ultimate recipient of the message.

The body element and its associated child elements are used to exchange information between the initial SOAP sender and the ultimate SOAP receiver. SOAP defines one child element for the body: the `<Fault>` element, which is used for reporting errors. Other elements in the body are defined by the Web service that uses them.

Related concepts:

"The SOAP header" on page 1606
The SOAP header (the <Header> element) is an optional sub-element of the SOAP envelope, and is used to pass application-related information that is processed by SOAP nodes along the message flow.

"The SOAP fault"
The SOAP fault (the <Fault> element) is a sub-element of the SOAP body, which is used for reporting errors.

The SOAP fault:

The SOAP fault (the <Fault> element) is a sub-element of the SOAP body, which is used for reporting errors.

If present, the SOAP fault element must appear as a body entry and must not appear more than once in a body element. The sub-elements of the SOAP fault element are different in SOAP 1.1 and SOAP 1.2.

SOAP 1.1

In SOAP 1.1, the SOAP fault contains the following sub-elements:

`<faultcode>`
The`<faultcode>` element is a mandatory element in the `<Fault>` element. It provides information about the fault in a form that can be processed by software. SOAP defines a small set of SOAP fault codes covering basic SOAP faults, and this set can be extended by applications.

`<faultstring>`
The `<faultstring>` element is a mandatory element in the `<Fault>` element. It provides information about the fault in a form intended for a human reader.

<faultactor>
The <faultactor> element contains the URI of the SOAP node that generated the fault. A SOAP node that is not the ultimate SOAP receiver must include the <faultactor> element when it creates a fault; an ultimate SOAP receiver is not obliged to include this element, but might do so.

<detail>
The <detail> element carries application-specific error information related to the <Body> element. It must be present if the contents of the <Body> element were not successfully processed. The <detail> element must not be used to carry information about error information belonging to header entries. Detailed error information belonging to header entries must be carried in header entries.

SOAP 1.2

In SOAP 1.2, the SOAP fault contains the following sub-elements:

<Code> The <Code> element is a mandatory element in the <Fault> element. It provides information about the fault in a form that can be processed by software. It contains a <Value> element and an optional <Subcode> element.

<Reason>
The <Reason> element is a mandatory element in the <Fault> element. It provides information about the fault in a form intended for a human reader. The <Reason> element contains one or more <Text> elements, each of which contains information about the fault in a different language.

<Node> The <Node> element contains the URI of the SOAP node that generated the fault. A SOAP node that is not the ultimate SOAP receiver must include the <Node> element when it creates a fault; an ultimate SOAP receiver is not obliged to include this element, but might do so.

<Role> The <Role> element contains a URI that identifies the role in which the node was operating at the point the fault occurred.

<Detail>
The <Detail> element is an optional element, which contains application-specific error information related to the SOAP fault codes describing the fault. The presence of the <Detail> element has no significance as to which parts of the faulty SOAP message were processed.

Related concepts:

"The SOAP header" on page 1606
The SOAP header (the <Header> element) is an optional sub-element of the SOAP envelope, and is used to pass application-related information that is processed by SOAP nodes along the message flow.

"The SOAP body" on page 1608
The SOAP body (the <Body> element) is a mandatory sub-element of the SOAP envelope, which contains information intended for the ultimate recipient of the message.

SOAP nodes:

The SOAP nodes act as points in the flow where Web service processing is configured and applied. Properties on the SOAP nodes control the processing carried out and can be configured by supplying a WSDL definition, or by manually configuring properties, or both.

SOAP nodes

- The SOAPInput and SOAPReply nodes are used in a message flow which implements a Web service. These SOAP nodes are used to construct a message flow that implements a Web service provider. The SOAPInput node listens for incoming Web service requests, and the SOAPReply sends responses back to the client; see “SOAPInput node” on page 4795 and “SOAPReply node” on page 4819.
- A client can send an HTTP GET request to the endpoint exposed by the flow, suffixed with a query string `?wsdl`, and receive a response with the WSDL definition used to configure the flow. For a full description, see “Using WSDL to configure message flows” on page 1664.
- The SOAPRequest node is used in a message flow to call a Web service provider synchronously. Calling a Web service synchronously means that the node sends a Web service request and waits, blocking the message flow, for the associated Web service response to be received before the message flow continues; see “SOAPRequest node” on page 4828.
- The SOAPAsyncRequest and SOAPAsyncResponse nodes are used to construct a message flow (or pair of flows) which calls a Web service asynchronously. Calling a Web service asynchronously means that the SOAPAsyncRequest node sends a Web service request, but the request does not block the message flow by waiting for the associated Web service response to be received because the Web service response is received at the SOAPAsyncResponse node, which is in a separate flow. The Node Correlator identifies the logical pairing of the responses against the original requests. Multiple requests can, therefore, be handled in parallel; see “SOAPAsyncRequest node” on page 4750 and “SOAPAsyncResponse node” on page 4777.
- You can work on the payload of the SOAP body using the SOAPExtract and SOAPEnvelope nodes. The SOAPExtract node can interoperate with the SOAP domain. The SOAP nodes do not require the SOAPEnvelope node, because they can directly handle non-SOAP messages, but the SOAPEnvelope node is still required for the HTTP nodes. See “SOAPExtract node” on page 4790 and “SOAPEnvelope node” on page 4786.
- You can change the Operation mode of the SOAP nodes so that they act in gateway mode. In gateway mode, a WSDL is not required to configure the nodes since they handle generic request/response and one-way SOAP messages that are not tied to a specific WSDL. For more details, see “Gateway operation mode for SOAP nodes” on page 1645.

The W3C SOAP specification refers to "SOAP nodes" meaning a unit of application logic (see Web Services Glossary). Typically, references to "SOAP nodes" in the WebSphere Message Broker Information Center are referring to WebSphere Message Broker SOAP nodes.

If you choose to handle HTTP messages by using the execution group listener, you must carefully check the URL specifications in your HTTPInput and SOAPInput nodes. If both URL specifications match an incoming message, the wrong type of node might get the message, and processing might fail or produce unexpected results. This situation occurs if you specify identical values for the Path suffix for URL properties of the HTTPInput node and the SOAPInput node. It can also occur if you use wildcards in either or both specifications, and an incoming message matches both properties.

Use the SOAPAsyncResponse node in conjunction with the SOAPAsyncRequest node to construct a pair of message flows that call a Web service asynchronously.

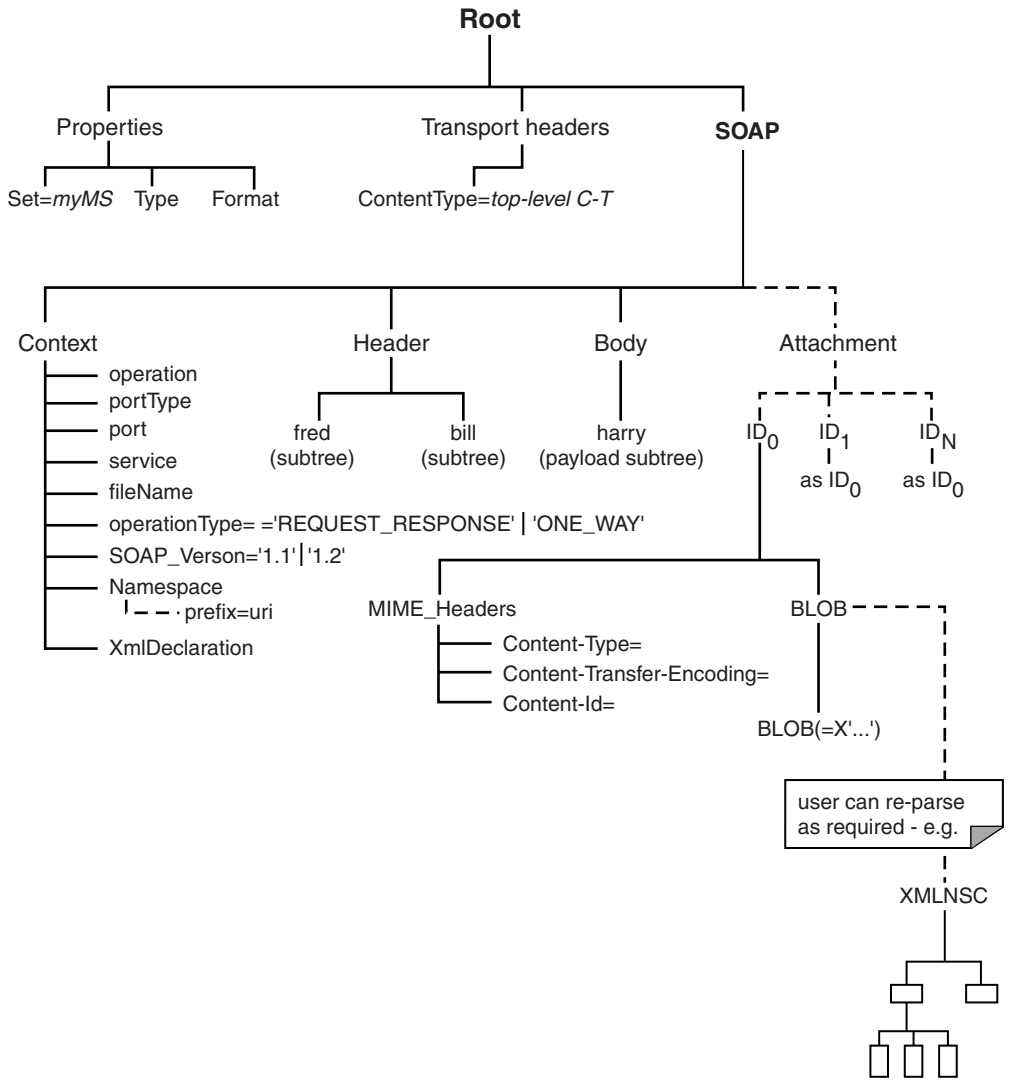
Related information:

"Web services: when to use SOAP or HTTP nodes" on page 1582
HTTP and SOAP nodes can both be used to interact with Web services. Typically you use SOAP nodes when working with SOAP-based Web services.

SOAP tree overview:

This tree format allows you to access the key parts of the SOAP message in a convenient way.

This is a diagrammatic representation of the SOAP domain tree:



The SOAP tree contains the following elements:

SOAP.Header
Contains the SOAP header blocks (children of `Envelope.Header`)

SOAP.Body
Contains the SOAP payload (children of `Envelope.Body`)

The content of the `Body` subtree depends on the WSDL style.

SOAP.Attachment
Contains attachments for an `SwA` message in their non encoded format.

Note that attachments for an `MTOM` message are represented inline as part of the SOAP content in a base 64 representation.

SOAP.Context
Contains the following information:

- Input; populated by the SOAPInput node:
  - `operation` - the WSDL operation name. In Gateway mode, the operation is assumed to be the name of the element that is the first

child of the SOAP Body element, if present, otherwise it is the constant name 'ComIbmBrokerGenericGatewayOperation'.
  - `portType` - the WSDL port type name. In Gateway mode, this item is empty.
  - `port` - the WSDL port name (if known). In Gateway mode, this item is empty.
  - `service` - the WSDL service name (if known). In Gateway mode, the service has the constant name 'ComIbmBrokerGenericGatewayService'.
  - `fileName` - the original WSDL file name. In Gateway mode, this item is empty.
  - `operationType` - one of 'REQUEST_RESPONSE', 'ONE_WAY', 'SOLICIT_RESPONSE', 'NOTIFICATION'. In Gateway mode, without WSDL, this field contains 'GATEWAY'. This means 'REQUEST_RESPONSE' or 'GATEWAY_ONE_WAY', which means that the node has detected the operation type to be one-way.
  - `SOAP_Version` - one of '1.1' or '1.2'.
  - `Namespace` - Contains `nameValue` child elements; the `name` is the Namespace prefix, and the `value` is the Namespace URI as it appears in the bit stream.
  - `XmlDeclaration` - represents the standard XML declaration.
- Output; the following fields can be placed in `SOAP.Context` to provide override information when SOAPRequest or SOAPAsyncRequest nodes serialize a SOAP message:
  - `SOAP_Version` - one of '1.1' or '1.2'
  - `Namespace` - Contains `nameValue` child elements that define the namespace prefix (the `name`) to be used for a specified namespace URI (the `value`).

    An output message uses the namespace prefixes defined here to qualify any elements in the corresponding namespaces.

    If the `SOAP.Context` was originally created at an input node, it might already contain all the namespace prefix definitions that you need.

    If `SOAP.Context` does not exist, or the outgoing message uses additional namespaces, the SOAP parser generates any required namespace prefixes automatically.

    Alternatively, you can specify your own namespace prefix; the specific name of a namespace prefix does not usually affect the meaning of a message, with one important exception. If the message content contains a `qualified name`, the message must contain a matching namespace prefix definition.

    For example, if the output message is a SOAP Fault containing a `<faultcode>` element with the value `soapenv:Server`, a namespace prefix (which is case sensitive) for `soapenv` must be defined in the logical tree:

```
-- Build SOAP Fault message. Note that as well as defining the correct
-- namespace for the Fault element, it is also necessary to bind the
-- namespace prefix used in the faultcode element (this is set up under
-- SOAP.Context.Namespace)

-- Send back a new user defined SOAP 1.2 fault message
DECLARE soapenv NAMESPACE 'http://www.w3.org/2003/05/soap-envelope';
DECLARE xml     NAMESPACE 'http://www.w3.org/XML/1998/namespace';
DECLARE myNS    NAMESPACE 'http://myNS';

SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soapenv = soapenv;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:myNS = myNS;
```

```
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Code.soapenv:Value = 'soapenv:Receiver';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Code.soapenv:Subcode.soapenv:Value = 'my:subcode value';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Reason.soapenv:Text = 'my Reason string';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Reason.soapenv:Text.(SOAP.Attribute)xml:lang = 'en';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Node = 'my Node string';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Role = 'my Role string';
SET OutputRoot.SOAP.Body.soapenv:Fault.soapenv:Detail.my:Text = 'my detail string';
```

```
-- Send back a new user defined SOAP 1.1 fault message
DECLARE soapenv NAMESPACE 'http://schemas.xmlsoap.org/soap/envelope/';
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soapenv = soapenv;

SET OutputRoot.SOAP.Body.soapenv:Fault.faultcode = 'soapenv:Receiver';
SET OutputRoot.SOAP.Body.soapenv:Fault.faultstring = 'my fault string';
SET OutputRoot.SOAP.Body.soapenv:Fault.faultactor = 'my fault actor';
SET OutputRoot.SOAP.Body.soapenv:Fault.detail.Text = 'my detail string';
```

Only `Namespace`, `SOAP_Version`, and `XmlDeclaration` influence the bit stream generated for a SOAP tree; the other fields are for information only.

Web services: when to use SOAP or HTTP nodes:

HTTP and SOAP nodes can both be used to interact with Web services. Typically you use SOAP nodes when working with SOAP-based Web services.

For SOAP-based Web services, several advantages exist if you use the SOAP nodes and the SOAP message domain instead of the HTTP transport nodes and XMLNSC message domain.

- Support for WS-Addressing, WS-Security and SOAP headers.
- A common SOAP logical tree format, independent of the bitstream format.
- Runtime checking against WSDL.
- Automatic processing of SOAP with Attachments (SwA).

- Automatic processing of Message Transmission Optimization Mechanism (MTOM).

Although the HTTP nodes can process SwA messages, you must use the MIME message domain and design your flow to handle the attachments explicitly, and use custom logic to extract and parse the SOAP.

Cases where it might be better to use HTTP nodes include:

- Message flows in which a single request node handles multiple SOAP request and responses from more than one WSDL.
- Message flows that interact with Web services that use different standards, such as REST or XML-RPC.
- Message flow that never use WS-Addressing, WS-Security, SwA, or MTOM.

What is WSDL?:

WSDL is an XML notation for describing a web service. A WSDL definition tells a client how to compose a web service request and describes the interface that is provided by the web service provider.

WebSphere Message Broker supports WSDL 1.1, as defined in the following document issued by the World Wide Web Consortium (W3C): Web Services Description Language (WSDL) 1.1. WebSphere Message Broker support for WSDL also adheres to the Web Services Interoperability Organization (WS-I) Basic profile 1.1; see Web Services Interoperability Organization (WS-I).

A WSDL definition is divided into separate sections that specify the logical interface and the physical details of a web service. The physical details include both endpoint information, such as HTTP port number, and binding information, which specifies how the SOAP payload is represented and which transport is used.

Support for WSDL in WebSphere Message Broker includes:

- Import of WSDL to create message definitions in a message set; see "Importing from WSDL" on page 2946.
- Generation of WSDL from a message set; see "WSDL generation" on page 6340.
- WSDL editor with text and graphical design views.
- Use of WSDL to configure nodes in the SOAP domain; for example, you can drag WSDL onto a node, and a client can request the WSDL that was used to configure a SOAPInput node. For more details, see "Using WSDL to configure message flows" on page 1664
- Use WSDL to create a skeleton message flow by dragging WSDL onto the message flow editor canvas. For more details, see "Using WSDL to configure message flows" on page 1664.

When you import or generate WSDL, the WSDL is validated against the WS-I Basic Profile. You must fix validation errors before the message set can be deployed. Validation warnings do not prevent deployment, but can indicate potential interoperability problems. The validated WSDL becomes an integral part of the message set.

The WSDL editor supports a graphical design view so that you can navigate from the WSDL to its associated message definitions. The message set contains all the message definitions required by message flows that are working with the Web service described by the WSDL. At development time, the message definitions support ESQL Content Assist and the creation of mappings. At run time, the deployed message set supports schema validation in the SOAP, XMLNSC, and MRM domains. In the SOAP domain, runtime checks are also made against the WSDL itself, and WSDL information is included in the SOAP logical tree.

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

"WSDL validation" on page 1661
The WS-I Validator can be used to check your WSDL definitions against the Basic Profile.

"WSDL Version 1.1" on page 6699
Web Services Description Language (WSDL) is an XML format for describing network services as a set of endpoints operating on messages containing either document-oriented or procedure-oriented information.

What is SOAP MTOM?:

SOAP Message Transmission Optimization Mechanism (MTOM) is the use of MIME to optimize the bitstream transmission of SOAP messages that contain significantly large base64Binary elements.

The MTOM message format allows bitstream compression of binary data. Data that would otherwise have to be encoded in the SOAP message is instead transmitted as raw binary data in a separate MIME part. A large chunk of binary data takes up less space than its encoded representation, so MTOM can reduce transmission time, although it can increase processor usage. Candidate elements to be transmitted in this way are defined as base64Binary in the WSDL (XML Schema).

An MTOM message is identified by a Content-Type with a type of `application/xop+xml`.

The SOAP domain handles inbound MTOM messages automatically, and MTOM parts are reincorporated automatically into the SOAP Body.

The use of outbound MTOM messages can be configured on the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes; for details, see "Using SOAP MTOM with the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes" on page 1678.

For details of the external specification published by the World Wide Web Consortium (W3C), see "SOAP MTOM" on page 6697.

WS-Addressing:

Web Services Addressing (WS-Addressing) is a World Wide Web Consortium (W3C) specification that aids interoperability between Web services by defining a standard way to address Web services and provide addressing information in messages.

Start here to find out how WebSphere Message Broker supports WS-Addressing.

The WS-Addressing specification introduces two primary concepts: endpoint references, and message addressing properties. This topic contains an overview of each concept. For further details, select the following links to access the WS-Addressing specifications:

- W3C WS-Addressing specifications
- W3C submission WS-Addressing specification

Endpoint references (EPRs)

EPRs provide a standard mechanism to encapsulate information about specific endpoints. EPRs can be propagated to other parties and then used to target the Web service endpoint that they represent. The following table summarizes the information model for EPRs.

Abstract Property name	Property type	Multiplicity	Description
[address]	xs:anyURI	1..1	The absolute URI that specifies the address of the endpoint.
[reference parameters]*	xs:any	0..unbounded	Namespace qualified element information items that are required to interact with the endpoint.
[metadata]	xs:any	0..unbounded	Description of the behavior, policies and capabilities of the endpoint.

The following prefix and corresponding namespace is used in the previous table.

Prefix	Namespace
xs	http://www.w3.org/2001/XMLSchema

The following XML fragment illustrates an endpoint reference. This element references the endpoint at the URI http://example.com/fabrikam/acct, has metadata specifying the interface to which the endpoint reference refers, and has application-defined reference parameters of the http://example.com/fabrikam namespace.

```
<wsa:EndpointReference xmlns:wsa="http://www.w3.org/2005/08/addressing"
                       xmlns:wsaw="http://www.w3.org/2006/05/addressing/wsdl"
                       xmlns:fabrikam="http://example.com/fabrikam"
                       xmlns:wsdli="http://www.w3.org/2005/08/wsdl-instance"
                       wsdli:wsdlLocation="http://example.com/fabrikam
                       http://example.com/fabrikam/fabrikam.wsdl">
    <wsa:Address>http://example.com/fabrikam/acct</wsa:Address>
    <wsa:Metadata>
        <wsaw:InterfaceName>fabrikam:Inventory</wsaw:InterfaceName>
    </wsa:Metadata>
    <wsa:ReferenceParameters>
        <fabrikam:CustomerKey>123456789</fabrikam:CustomerKey>
        <fabrikam:ShoppingCart>ABCDEFG</fabrikam:ShoppingCart>
    </wsa:ReferenceParameters>
</wsa:EndpointReference>
```

Message addressing properties (MAPs)

MAPs are a set of well defined WS-Addressing properties that can be represented as elements in SOAP headers. MAPs can provide either a standard way of conveying information, such as the endpoint to which message replies should be directed, or information about the relationship that the message has with other messages. The MAPs that are defined by the WS-Addressing specification are summarized in the following table.

Abstract WS-Addressing MAP name	MAP content type	Multiplicity	Description
[action]	xs:anyURI	1..1	An absolute URI that uniquely identifies the semantics of the message. This proprety corresponds to the [address] property of the endpoint reference to which the message is addressed. This value is required.
[destination]	xs:anyURI	1..1	The absolute URI that specifies the address of the intended receiver of this message. This value is optional because, if not present, it defaults to the anonymous URI that is defined in the specification, indicating that the address is defined by the underpinning protocol.
[reference parameters]*	xs:any	0..unbounded	Correspond to the [reference parameters] property of the endpoint reference to which the message is addressed. This value is optional.
[source endpoint]	EndpointReference	0..1	A reference to the endpoint from which the message originated. This value is optional.
[reply endpoint]	EndpointReference	0..1	An endpoint reference for the intended receiver of replies to this message. This value is optional.

Abstract WS-Addressing MAP name	MAP content type	Multiplicity	Description
[fault endpoint]	EndpointReference	0..1	An endpoint reference for the intended receiver of faults relating to this message. This value is optional.
[relationship]*	xs:anyURI plus optional attribute of type xs:anyURI	0..unbounded	A pair of values that indicate how this message relates to another message. The content of this element conveys the [message id] of the related message. An optional attribute conveys the relationship type. This value is optional.
[message id]	xs:anyURI		An absolute URI that uniquely identifies the message. This value is optional.

The abstract names in the previous tables are used to refer to the MAPs throughout this documentation.

The following example of a SOAP message contains WS-Addressing MAPs:

```
<S:Envelope xmlns:S="http://www.w3.org/2003/05/soap-envelope"
            xmlns:wsa="http://www.w3.org/2005/08/addressing"
            xmlns:fabrikam="http://example.com/fabrikam">
    <S:Header>
        ...
     <wsa:To>http://example.com/fabrikam/acct</wsa:To>
              <wsa:ReplyTo>
        <wsa:Address> http://example.com/fabrikam/acct</wsa:address>
              </wsa:ReplyTo>
            <wsa:Action>...</wsa:Action>
              <fabrikam:CustomerKey wsa:IsReferenceParameter='true'>123456789
              </fabrikam:CustomerKey>
             <fabrikam:ShoppingCart wsa:IsReferenceParameter='true'>ABCDEFG
             </fabrikam:ShoppingCart>
              ...
    </S:Header>
        <S:Body>
          ...
        </S:Body>
</S:Envelope>
```

Message flows for Web services

Message flows that need to work with Web services can use either the SOAP domain or one of the XML domains.

The following topic describes fundamental scenarios. Any use of WS-Addressing or WS-Security requires use of the SOAP domain, but otherwise these scenarios apply to both types of message flow.

- "Web services scenarios" on page 1620

The following topics describe both types of flow.

- "SOAP domain message flows" on page 1635
- "XML domain message flows" on page 1643

The following topics describe web services tasks.

- "Working with WS-Addressing" on page 1650
- "Working with WSDL" on page 1661
- "Using timeouts with HTTP and SOAP nodes" on page 1595
- "Using SOAP MTOM with the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes" on page 1678

Related concepts:

"What is SOAP?" on page 1604
SOAP is an XML message format used in Web service interactions. SOAP messages are typically sent over HTTP or JMS, but other transport protocols can be used. The use of SOAP in a specific Web service is described by a WSDL definition.

"WS-Addressing" on page 1617
Web Services Addressing (WS-Addressing) is a World Wide Web Consortium (W3C) specification that aids interoperability between Web services by defining a standard way to address Web services and provide addressing information in messages.

"WS-Security" on page 765
Web Services Security (WS-Security) describes enhancements to SOAP messaging to provide quality of protection through message integrity, message confidentiality, and single message authentication. WS-Security mechanisms can be used to accommodate a wide variety of security models and encryption technologies.

Web services scenarios:

These common Web services scenarios are organized according to the role that is played by the broker.

A key consideration is whether a WSDL description for the Web service already exists.

In scenario A, the WSDL description exists and is imported and used by the message flow.

In scenario B, the WSDL description is generated in an existing message set. The WSDL is used by the message flow and might also be exported for use by an external client.

These scenarios are generic and can be implemented by using the SOAP domain, or an appropriate non-SOAP domain (XMLNSC, MRM, MIME) and basic transport nodes. If you need to use WS-Addressing or WS-Security for a particular implementation, use the SOAP domain.

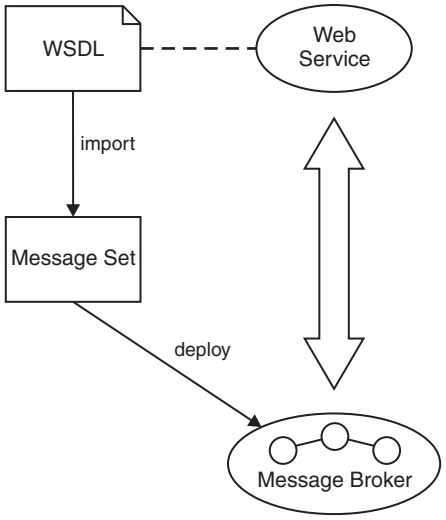
Scenario A: You want the broker to invoke an existing Web service:
See "Broker calls existing Web service" on page 1621

Scenario B: You want the broker to expose a Web service to a non-Web service client: See "Broker implements non-Web-service interface to new Web service" on page 1634

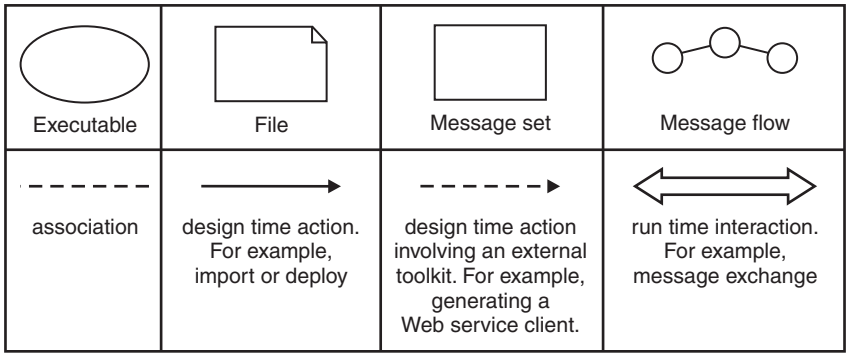
Broker calls existing Web service:

In this scenario, the broker calls an existing Web service implementation. The WSDL for the Web service already exists, and is imported to create a message set.

A message flow based on this message set sends a Web service request and receives the response, for example by using a SOAPRequest node.



Key to symbols:



Possible uses

- You want to call a Web service to do some processing as part of your message flow.
- You have an existing Web service and you want to provide a different interface to it. This could be an alternative Web services interface or a WebSphere MQ interface.
- You have an existing Web service and you want to change its implementation in some way without changing its interface; that is, the broker acts as an intermediary to the Web service. For instance a message flow could be used to enable auditing, or to transparently propagate the Web service response to another application.

Design steps

1. Import WSDL to create a message set containing definitions for the SOAP messages described by the WSDL.
2. Create a message flow to invoke the Web service. If the SOAP domain is used, the message flow uses a SOAPRequest node, SOAPAsyncRequest node, or a SOAPAsyncResponse node. The nodes are configured by using the WSDL imported in Step 1. If required, you can create a skeleton flow from scratch by dropping the WSDL onto a blank message flow editor canvas. If you use the SOAP domain, you must create the message flow by using transport nodes, and an XML or MIME domain. For example, if the WSDL binding specifies HTTP transport, and the request message is SOAP, you can use an HTTPRequest node with the XMLNSC domain. You can then configure the node manually with the endpoint information for the Web service.
3. Build a broker archive file for deployment. The broker archive file contains your message flow and the message set that contains the imported WSDL. The SOAP domain always requires the WSDL to be deployed, because messages are verified against it at run time; also WSDL information is included in the logical tree. The message set includes XML Schema definitions that can be used for message validation in the SOAP, XMLNSC, or MRM domains.

At run time

Your message flow creates an appropriately formatted Web service request, invokes the Web service, and parses the Web service response. If you use the SOAP domain, your message flow uses the SOAP logical tree model. If you do not use the SOAP domain, your message flow uses the logical tree for your selected domain; for example, you use the MIME domain if your Web service messages use SOAP with Attachments.

Example 1

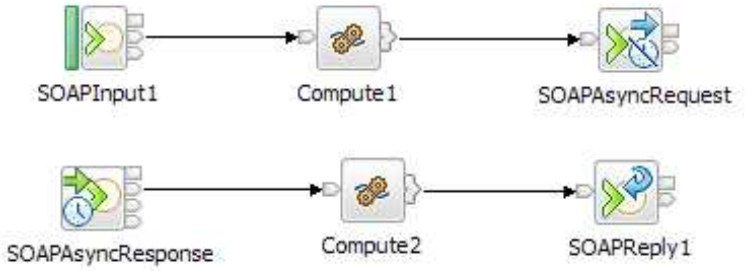
Web service intermediary

In this example a client application uses a Web service called Account, which is made available by another organization. The client is widely distributed in your company. The client uses an operation called getBalance, but the Account service is being modified to change the definition of the getBalance operation. You can construct message flows to provide an interface to the Account service, instead of modifying the client. The message flows can call the Account service to do the work, and the new Web service delegates to the original Web service. The client can now continue to use the Account service, by using the new message flows.

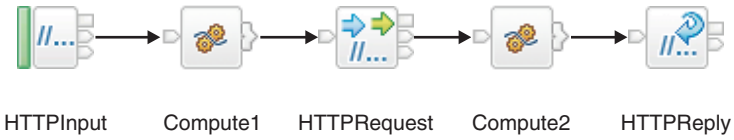
In the examples of typical message flow patterns shown here, the intermediate request node calls the Account service:

- Using SOAPInput, SOAPRequest, and SOAPReply nodes:

- Using SOAPInput, SOAPAsyncRequest, SOAPAsyncResponse, and SOAPReply nodes:



- Using HTTPInput, HTTPRequest, and HTTPReply nodes:



In the message flows in the example, Compute1 modifies the original getBalance message as required by the modified Account service, while Compute2 restores the response message to the original format. If you have imported or generated WSDL, you have a message model for the getBalance operation. If you have a message model defined for the getBalance operation, you can use Mapping nodes instead of Compute nodes.

HTTP details

If you use HTTP transport nodes, as shown in the example, you can configure the HTTPRequest node to generate HTTP headers from the headers that are received by the HTTPInput node. This configuration enables cookies and other application-specific headers to be passed through the message flow. The HTTPReply node can be used task to extract headers from the Web service response, to return to the originating client. To create this configuration, select **Generate default HTTP headers from** on both the HTTPRequest and HTTPReply nodes. Typically, you do not need the original request message to generate the reply to the client, and can select **Replace input message with Web service response** on the HTTPRequest node. If you do want to preserve data from the input request, you can store this in the LocalEnvironment in Compute1, and retrieve it in Compute2 for inclusion in the reply.

Example 2

Using a Web service

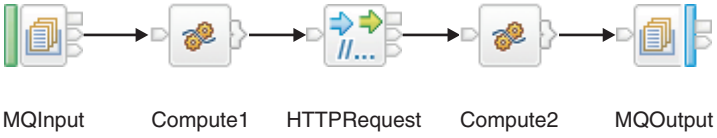
In this example, a WebSphere MQ message flow implements a process for the Human Resource department of your company. As part of this processing, the message flow calls a Web service to retrieve employee ID numbers. Employee ID numbers are maintained in the company's employee directory, which is accessed through a Web service.

In the examples of typical message flow patterns shown here the intermediate request node retrieves the employee ID:

- Using MQInput, SOAPRequest and MQOutput nodes:

- Using MQInput, SOAPAsyncRequest, SOAPAsyncResponse, and MQOutput nodes:

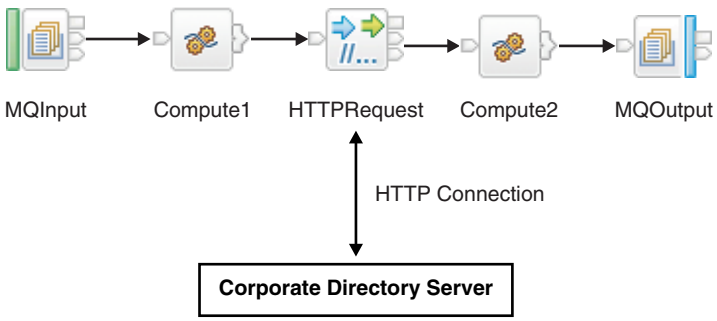
- Using MQInput, HTTPRequest, and MQOutput nodes:



In the message flows in the example, Compute1 prepares the Web service request message and Compute2 processes the response. For example, by incorporating the employee ID in another message. If you have a message model defined, you can use Mapping nodes instead of Compute nodes in these examples.

HTTP details

If you use HTTP transport nodes, as shown in the example, you typically clear the **Replace input message with Web service response** in the HTTPRequest node properties. The response from the corporate directory server is placed in a temporary location in the message tree. The temporary location is specified in the **Response message location** in tree property in the same node. In Compute2, you can code ESQL to retrieve the result, and update the final message.



Using the SOAP domain for these scenarios is preferred. For more information about choosing a domain for Web services, see “WebSphere Message Broker and Web services” on page 1602.

Related concepts:

“XML domain message flows” on page 1643
If you are not using the SOAP domain, your message flow must take account of the bitstream format of the Web service messages with which you are working. A different logical tree format is used by each domain.

“Broker implements new Web service interface”
In this scenario, the broker implements a new Web service interface. The WSDL for the Web service is generated from a message set and made available to clients. A message flow based on this WSDL and message set receives a request and then builds a response message by using data obtained from an existing non-Web-service application.

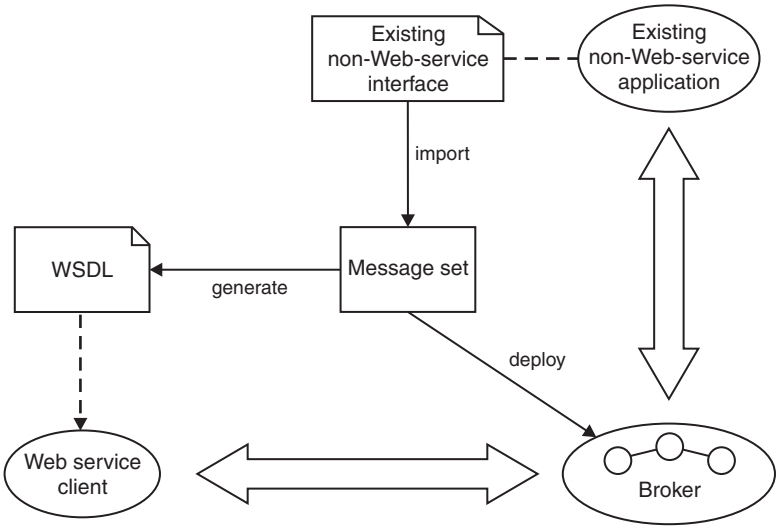
“Broker implements existing Web service interface” on page 1630
In this scenario, the broker implements an existing Web service interface. The WSDL for the Web service already exists, and is imported to create a message set. A message flow based on this message set receives a request, then builds a response message by using data obtained from an existing non-Web-service application.

“Broker implements non-Web-service interface to new Web service” on page 1634
In this Web service scenario, the broker provides compatibility with earlier versions for existing non-Web-service clients to call a new Web services implementation provided by a SOAP toolkit.

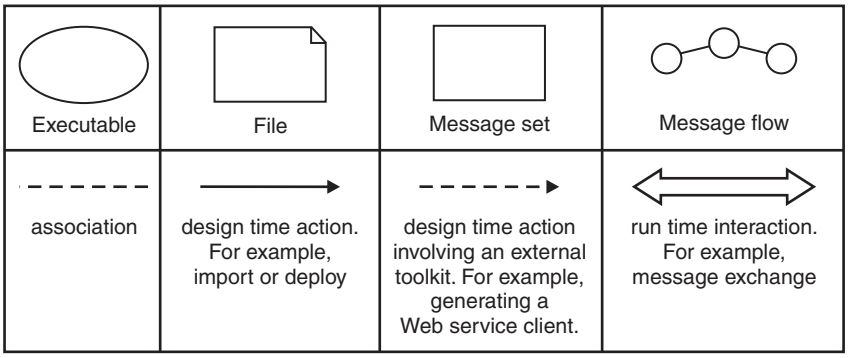
Broker implements new Web service interface:

In this scenario, the broker implements a new Web service interface. The WSDL for the Web service is generated from a message set and made available to clients. A message flow based on this WSDL and message set receives a request and then builds a response message by using data obtained from an existing non-Web-service application.

The following diagram shows a message set being created from an interface definition (for example, a header file) of an existing application that is not currently accessible as a Web service. A WSDL file is generated from the message set and exported for use by a Web service client. A message flow that uses the message set and WSDL is created to call the application. The message flow and message set are deployed to a broker, providing a Web service interface to the original application.



Key to symbols:



This scenario is sometimes referred to as a Web service facade. The design of the Web service interface typically involves some regrouping, restriction, or enhancement of the existing interface, and is not constrained by an existing WSDL definition.

Possible uses

- The broker provides a Web services interface to an existing application, optionally providing other mix-in capabilities such as auditing the requests made.
- Over time the implementation can be changed without affecting the interface presented to the Web services client.

Design steps

1. Create a message set for the business messages, possibly by importing an existing interface definition such as a C header file or COBOL copybook.
2. Generate a WSDL definition from the message set.
3. Use a SOAP toolkit such as Rational Application Developer to create a suitable Web services client based on the WSDL.
4. Develop a message flow to implement the Web service.

At run time

Your message flow receives a Web service request, converts it into a form expected by the existing application and invokes the existing application. The response from the existing application is converted into a valid Web service response.

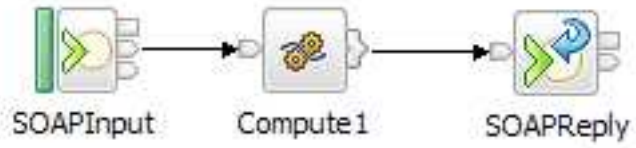
Example 1

In this example, an existing message flow is modified to provide a Web service. If the existing message flow models its data in a message set, a WSDL definition can be generated from that message set and made available to clients.

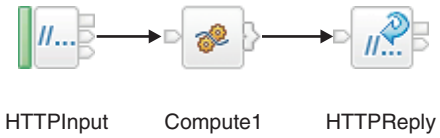
Most message flows that currently use WebSphere MQ for input or output can be adapted to support Web services as a replacement or additional protocol.

The following are typical message flow patterns. In each case the input and reply nodes replace or complement the original MQInput and MQOutput nodes. The main part of the flow is understood to do some useful processing.

- Using SOAPInput and SOAPReply nodes:



- Using HTTPInput and HTTPReply nodes:



If you use the SOAP domain, the logical tree shape will be different from the original domain and you will need to take account of this in the message flow. If you use the HTTP nodes with the original domain, the logical tree shape does not change. For information about choosing the domain, see "WebSphere Message Broker and Web services" on page 1602.

HTTP details

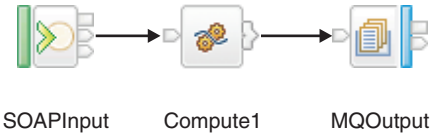
If you use the HTTP nodes, you can configure the HTTPReply node to generate a set of default HTTP headers for the reply message sent to the client. Generating a set of default HTTP headers reduces the modifications that you must make to convert the message flow from one that processes WebSphere MQ messages to a flow that processes HTTP messages.

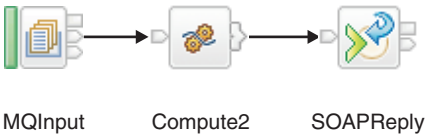
Example 2

In this example, a message flow is created to provide asynchronous access to a WebSphere MQ application.

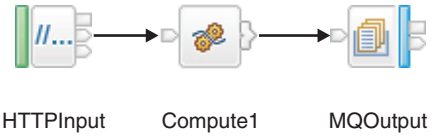
The following are typical message flow patterns. In each case the flow receives the Web service request and build the response by using data returned from the application over WebSphere MQ.

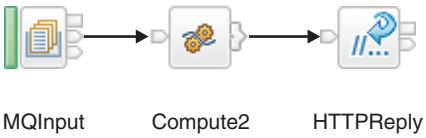
- Using two message flows with SOAPInput and SOAPReply nodes:





- Using two message flows with HTTPInput and HTTPReply nodes:





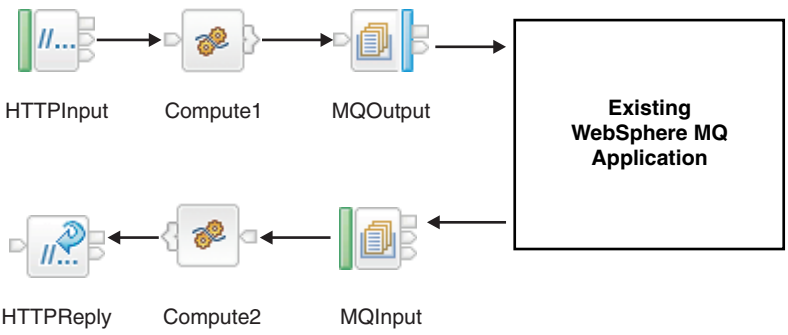
In each case, the first message flow receives inbound requests from a Web service client. The Compute1 node transforms the request and an MQOutput node sends the modified request to the existing application.

In the second message flow, an MQInput node receives the response from the application. The Compute2 node then transforms the message and propagates it to a reply node that responds to the original Web service client.

The Compute1 node must also save some correlation information to be retrieved by the Compute2 node, ensuring that the replies from the WebSphere MQ application are returned to the client that sent the original request.

HTTP details

Using HTTPInput and MQOutput nodes as the outbound message and MQInput and HTTPReply nodes as the response message:



One way to preserve the correlation information is for the Compute1 node to encode the correlation identifier in the outbound message. (Alternatively, the identifier can be stored in a database). The SOAPInput and HTTPInput nodes place the identifier as a field in the local environment tree and the Compute1 node can read and store this value. The location of the identifier differs between the SOAPInput and HTTPInput nodes, as described in the following sections.

SOAP nodes

The Compute2 node reads the SOAP reply identifier from the message and sets LocalEnvironment.Destination.SOAP.Reply.ReplyIdentifier by using this value. The SOAPReply node uses the reply identifier to ensure that the message reaches the correct HTTP client. In the ESQL module for the Compute1 node, include a code statement like the following statement:

```
SET OutputRoot.XMLNS.A.MessageID =
CAST(InputLocalEnvironment.Destination.SOAP.Reply.ReplyIdentifier AS CHARACTER);
```

In the ESQL module for the Compute2 node, include a code statement like the following statement:

```
SET OutputLocalEnvironment.Destination.SOAP.Reply.ReplyIdentifier =
CAST(InputRoot.XMLNS.A.MessageID AS BLOB);
```

HTTP nodes

The Compute2 node reads the HTTP request identifier from the message and sets LocalEnvironment.Destination.HTTP.RequestIdentifier by using this value. The HTTPReply node uses the request identifier to ensure that the message reaches the correct HTTP client. In the ESQL module for the Compute1 node, include a code statement like the following statement:

```
SET OutputRoot.XMLNS.A.MessageID =
CAST(InputLocalEnvironment.Destination.HTTP.RequestIdentifier AS CHARACTER);
```

In the ESQL module for the Compute2 node, include a code statement like the following statement:

```
SET OutputLocalEnvironment.Destination.HTTP.RequestIdentifier =
CAST(InputRoot.XMLNS.A.MessageID AS BLOB);
```

In this scenario, the broker calls an existing Web service implementation. The

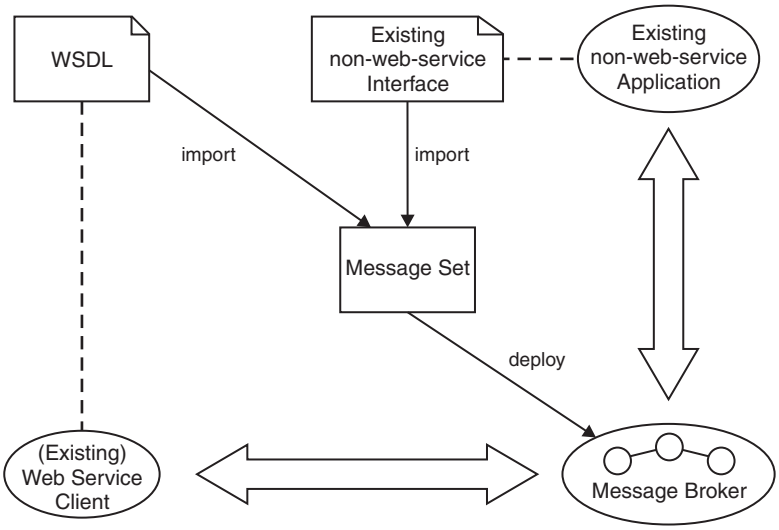
WSDL for the Web service already exists, and is imported to create a message set.

"Broker implements existing Web service interface"
In this scenario, the broker implements an existing Web service interface. The WSDL for the Web service already exists, and is imported to create a message set. A message flow based on this message set receives a request, then builds a response message by using data obtained from an existing non-Web-service application.

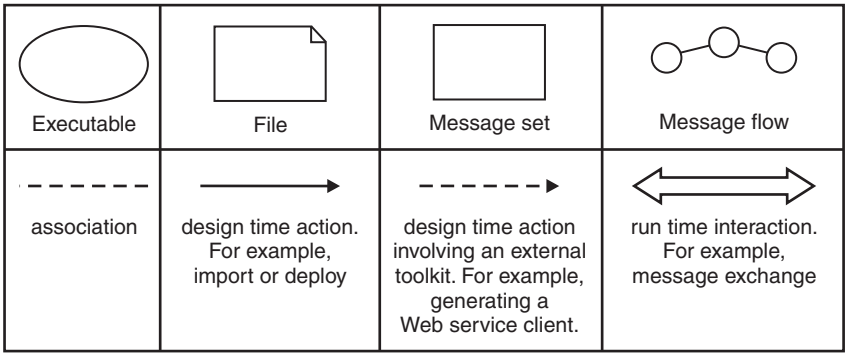
"Broker implements non-Web-service interface to new Web service" on page 1634
In this Web service scenario, the broker provides compatibility with earlier versions for existing non-Web-service clients to call a new Web services implementation provided by a SOAP toolkit.

Broker implements existing Web service interface:

In this scenario, the broker implements an existing Web service interface. The WSDL for the Web service already exists, and is imported to create a message set. A message flow based on this message set receives a request, then builds a response message by using data obtained from an existing non-Web-service application.



Key to symbols:



Possible uses

- The broker provides a Web service implementation with a different quality of service from existing implementations.
- The broker provides a migration strategy for the existing implementation.

Design steps

1. Import WSDL to create a message set containing definitions for the SOAP messages described by the WSDL.
2. Adapt the message set for the required existing interface, possibly by importing an existing interface definition such as a C header file or COBOL copybook.
3. Develop a message flow to implement the Web service.

At run time

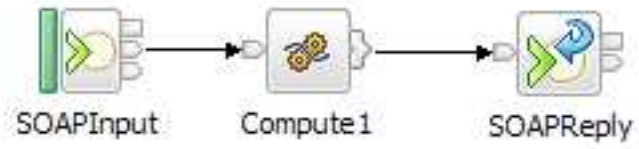
Your message flow receives a Web service request, converts it into a form expected by the existing application and invokes the existing application. The response from the existing application is converted into a valid Web service response.

Example 1

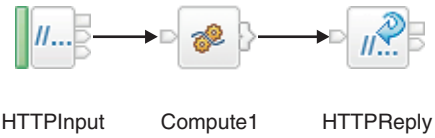
In this example, an existing HTTP Web service client provides information on a particular subject (stock prices or exchange rates, for example). You want to replace this service with an inhouse database lookup solution, but want to make no changes to the clients because these are widely deployed.

Typical message flow patterns are shown in the following examples. In each case the intermediate request node retrieves the information from the database:

1. Using SOAPInput and SOAPReply nodes:



2. Using HTTPInput and HTTPReply nodes:



In the flows above, the input node receives the Web service request. Compute1 then retrieves the required information from the database and generates the required Web service response by using this data. The response is returned to the client by the reply node. In the examples you can use Mapping nodes instead of Compute nodes.

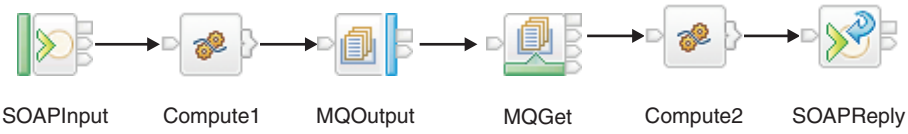
Example 2

In this example, an existing application is exposed as a Web service, but there is a constraint on the interface with the Web service, because a widely distributed

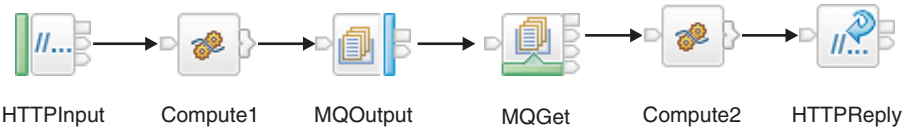
client already uses a similar service that is defined by an existing WSDL definition. The broker offers the same interface to the client, this might be because the original service offers a different quality of service or is to be discontinued.

Typical message flow patterns are shown in the following examples. In each case the message flows receive the Web service request and build the response by using data returned from the application over WebSphere MQ.

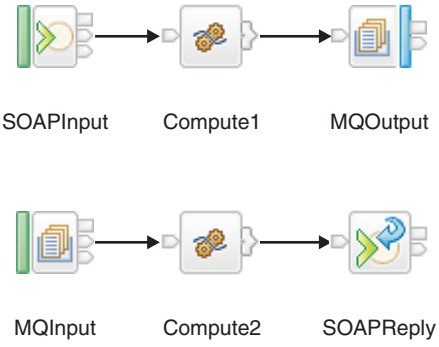
1. Using SOAPInput, SOAPReply and MQGet nodes:



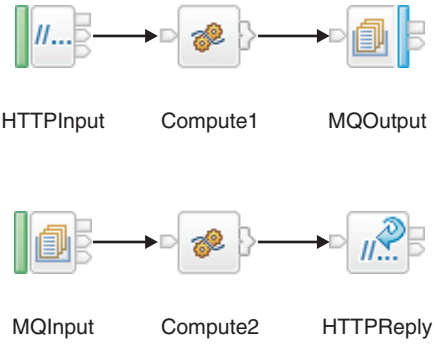
2. Using HTTPInput, HTTPReply and MQGet nodes:



3. Using two message flows with SOAPInput, SOAPReply nodes:



4. Using two message flows with HTTPInput and HTTPReply nodes:



The steps to develop the message flow are:

1. Create a message model for the existing application interface, for example, by importing a C header file for the application.
2. Import an existing WSDL definition for the client.

3. Create a flow by using the message set to implement the Web service interface and mediate with the existing application.

Message flows 1 and 2 show a synchronous call to the application by using MQOutput and MQGet nodes. You can set a timeout in the MQGet node, to allow for failure of the remote application. The request-reply translation is handled in a single transaction enabling simple rollback and recovery. However, each incoming request has to be fully processed and responded to before moving onto the next request. This behavior might affect performance if the application cannot respond quickly. The message flows shown in examples 3 and 4, show an asynchronous equivalent. In each case the first flow stops after sending the message to the application, and becomes available to handle further requests. However, this scenario requires a correlation context to be saved in the request flow, and restored in the reply flow. You can store the correlation context on a queue, then use an MQGet node in the reply flow to retrieve it. This flow design enables the requests to be dispatched to the application promptly, and replies to be returned in the order that they are received. In the examples you can use Mapping nodes instead of Compute nodes.

The use of the SOAP domain for these scenarios is preferred. For more information about choosing a domain for Web services, see "WebSphere Message Broker and Web services" on page 1602.

For more information about the asynchronous request-reply scenario, see "A request-response scenario that uses an MQGet node" on page 1569.

The asynchronous request-reply scenario is also detailed in the following sample which can be adapted for Web service usage:

- Coordinated Request Reply

Another Web services scenario is described in the sample:

- Web services using HTTP nodes

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

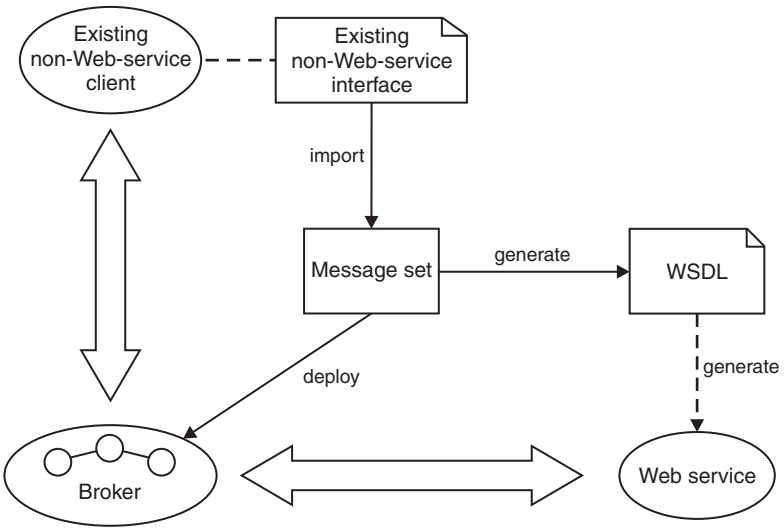
In this Web service scenario, the broker provides compatibility with earlier versions for existing non-Web-service clients to call a new Web services implementation provided by a SOAP toolkit.

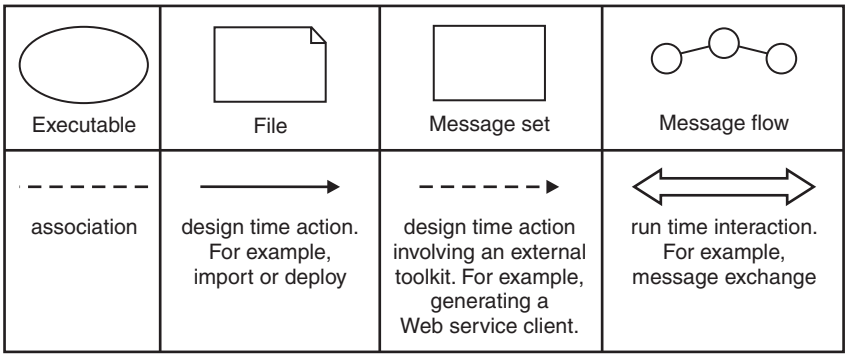
Broker implements non-Web-service interface to new Web service:

In this Web service scenario, the broker provides compatibility with earlier versions for existing non-Web-service clients to call a new Web services implementation provided by a SOAP toolkit.



The diagram shows a message set being created from an interface definition (for example, a header file) that is used by an existing client application. A WSDL file is generated from the message set and is used to create a new Web service implementation. A message flow that uses the message set is created to call the new Web service. The message flow and message set are deployed to a broker, providing the original application interface to the new Web service implementation.

Key to symbols:



Possible uses

You want to migrate an application to a Web service implementation, for example an EJB implementation hosted by an application server to offer better scalability.

However, a significant number of your users have existing clients that cannot be immediately replaced. Existing clients can use the broker to use the new Web service implementation.

Design steps

1. Create a message set for the business messages, for example, by importing an existing interface definition such as a C header file or COBOL copybook.
2. Generate a WSDL definition from the message set.
3. Use a SOAP toolkit or application server to create a suitable Web services implementation based on the WSDL.
4. Develop a message flow to mediate between the original existing client and the new Web service.

At run time

Your message flow receives a request from the existing client, converts it into a Web services request and invokes the Web service. The response from the Web service is converted into a form understood by the existing client.

SOAP domain message flows:

SOAP domain message flows typically use SOAP nodes, WSDL, and a common logical tree format that is independent of the exact format of the Web service message.

The following nodes are provided for use in the SOAP domain:

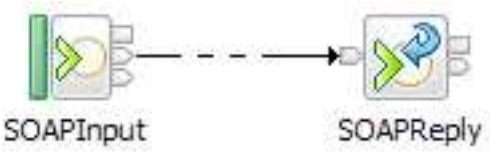
- "SOAPInput node" on page 4795
- "SOAPReply node" on page 4819
- "SOAPRequest node" on page 4828
- "SOAPAsyncRequest node" on page 4750
- "SOAPAsyncResponse node" on page 4777

The following nodes can also be used to simplify SOAP payload processing in a message flow; these nodes are not specific to the SOAP domain.

- "SOAPEnvelope node" on page 4786
- "SOAPExtract node" on page 4790

The SOAP nodes are used together in the following basic patterns:

- As a Web service provider, for example:



- As a Web service consumer, for example:

Or:

- As a Web service facade, for example, by combining the provider and consumer scenarios:

You can use the SOAPExtract node in conjunction with these patterns to extract the SOAP payload. If you are working with the HTTP nodes, you can use the SOAPEnvelope node to rebuild a SOAP envelope.

The main SOAP domain nodes are typically configured by WSDL, and in this mode, a prerequisite for a SOAP domain message flow is a message set containing deployable WSDL. To create a message set containing deployable WSDL, either import existing WSDL or generate WSDL from an existing message set. For more information about creating a new message definition from WSDL, see “Importing from WSDL” on page 2946. For more information about generating WSDL from an existing message set, see “WSDL generation” on page 6340.

Alternatively you can create a new message set and skeleton message flow in one step using the procedure described in “Creating an application based on WSDL or XSD files” on page 1413.

The WSDL then appears in the workbench under **Deployable WSDL** below the message set, although if you have selected `Hide Categories` on the message set, the category heading itself is not shown.

Deployable WSDL can then be used to configure SOAP nodes. You can do this by dragging the WSDL resource onto the node or by selecting the required WSDL resource from the node properties.

Alternatively a new skeleton message flow can be created by dragging and dropping the WSDL on to a blank canvas in the Message Flow editor.

The WSDL is deployed with your completed message flow, enabling the broker to raise exceptions if a Web service message does not correspond to the specified WSDL description.

You can change the operation mode of the SOAP domain nodes so that they act in gateway mode. In gateway mode, a WSDL is not required to configure the nodes because they handle generic request/response and one-way SOAP messages that are not tied to a specific WSDL. For more details, see "Gateway operation mode for SOAP nodes" on page 1645.

A client can send an HTTP GET request to the endpoint exposed by a SOAPInput node, suffixed with a query string `?wsdl`, and receive a response with the WSDL definition used to configure the flow; see "Using WSDL to configure message flows" on page 1664.

The SOAP domain uses a common logical tree format that is independent of the exact format of the Web service message. For details of the SOAP tree format, see "SOAP tree overview" on page 1611. Useful WSDL information is included in the logical tree under `SOAP.Context`.

Related concepts:

"XML domain message flows" on page 1643
If you are not using the SOAP domain, your message flow must take account of the bitstream format of the Web service messages with which you are working. A different logical tree format is used by each domain.

Set up a sample message flow by using WS-Addressing, and test the flow.

Example usage of WS-Addressing:

Set up a sample message flow by using WS-Addressing, and test the flow.

About this task

Complete the steps in the following set of topics.

1. Build the main message flow that includes SOAP nodes, a Filter node, and a Mapping node by following the instructions in "Building the main message flow" on page 1638.
2. Build a logging message flow, so that you can send a reply to an address different from the originating client, by following the instructions in "Building the logger message flow" on page 1640.
3. Deploy the message flows by following the instructions in "Deploying the message flows" on page 1641.
4. Test the message flows, by using a tool that uses HTTP. This task illustrates that the contents of the SOAP message determine where the replies are routed. Follow the instructions in "Testing the message flows" on page 1642.

"Built-in nodes" on page 4293
WebSphere Message Broker supplies built-in nodes that you can use to define your message flows.

Building the main message flow:

You can construct a sample main message flow to use with WS-Addressing.

About this task

These steps are the first in a set of instructions on setting up your system to use WS-Addressing with WebSphere Message Broker; they explain how to set up a message flow to use this feature. This topic describes how to construct a sample main message flow when using WS-Addressing.

Procedure

1. Switch to the Broker Application Development perspective.
2. Create message flow and message set projects using the Start from WSDL and/or XSD files wizard. See "Creating an application based on WSDL or XSD files" on page 1413 for instructions.
3. Select the **Web Services** folder on the message flow palette to display the contents, and drag a SOAPInput node onto the canvas.
4. Add a SOAPExtract node to the message flow to remove the SOAP envelope from the incoming message, followed by a SOAPReply node. Wire the Out terminal of the SOAPInput node to the In terminal of the SOAPExtract node, and wire the Out terminal of the SOAPExtract node to the In terminal of the SOAPReply node.
5. Select the WSDL file that you need under **Deployable WSDL** from the Active Working Set, and drag it onto the SOAPInput node. The SOAPInput node is configured with the WSDL.
6. Select the **Construction** folder on the message flow palette to display the contents.
7. Select a Trace node and move the mouse to the right of the SOAPExtract node.
   a. Click the left mouse button to add the node to the message flow. The name is selected automatically.
   b. Press **Enter** to accept the default name.

c. Wire the submitPORequest terminal of the SOAPExtract node to the In terminal of the Trace node.

8. Select the Trace node to display the properties.
   a. Use the menu to set **Destination** to `File`
   b. Set the **File path** that you require.
   c. Enter the **Pattern** that you require.
9. Expand the **Routing** folder on the palette and select **Filter**.
10. Add the Filter node to the right of the Trace node.
    a. Type the name for the node that you require and press **Enter**.
    b. Wire the Out terminal of the Trace node to the In terminal of the Filter node.
11. Select the Filter node to display the properties.
    a. Enter the **Data source** name that you require.
    b. Change the name of **Filter expression** to the name that you selected for the Filter node.
    c. Clear the **Throw exception on database error** check box.
12. Double-click the Filter node to open the ESQL editor. Create or change the ESQL for the node; for more information, see "Creating ESQL for a node" on page 2394 and "Modifying ESQL for a node" on page 2398.
13. Expand the **Transformation** folder on the palette and select a Mapping node.
14. Add the Mapping node to the right of the Filter node.
    a. Type the name for the node that you require and press **Enter**.
    b. Wire the True terminal of the Filter node to the In terminal of the Mapping node.
    c. Wire the Out terminal of the Mapping node to the In terminal of the Reply node.
15. Select the Mapping node to display the properties, and change the name of Mapping routine to the name that you selected for the Mapping node.
16. Double-click the Mapping node to open the mapping editor.
    a. Select **submitPORequest** as the map source.
    b. Select **SOAP_Domain_msg** as the map target.
    c. Click **OK**
    d. Click **OK** on the tip that is displayed to open the mapping editor.
17. Select **Properties** in both the **source** and **target** pane, right-click, and click **Map by Name**.
    a. Map the source properties to the target properties using drag-and-drop mapping. The Map by Name dialog box appears.
    b. Click **OK** to perform the mapping.
18. Expand **SOAP_Domain_Msg**, then **Body** and **message items** in the target pane.
19. Right-click **Wildcard Message** in the target pane, and click **Create new Submap**.
    a. Expand **Wildcard**.
    b. Scroll down and click **submitPOResponse**.
    c. Click **OK** to create the submap.
20. Use drag-and-drop mapping to select the items that you need in the **Source** pane.

21. Select the first item that you need in the **Target** pane, right-click, and **Enter Expression**. Enter the value that you require in the expression editor and press **Enter** to complete the mapping.

    Repeat the above steps for all the items that you require in the **Target** pane, and save the submap and map by pressing **Ctrl+S**.
22. Expand the **Construction** folder on the message flow editor and select a Throw node.
23. Add the Throw node above the Mapping node
    a. Type the name for the node that you require and press **Enter**.
    b. Wire the False and Unknown terminals of the Filter node to the In terminal of the Throw node.
24. Select the Throw node and, in the Node Properties pane, enter the text that you require in **Message text**.
25. Select the SOAPInput node to display the Node Properties.
    a. Select the **WS Extensions** tab.
    b. Select **Use WS-Addressing** .
26. Save the message flow.

Building the logger message flow:

This is the second of a set of instructions on setting up your system to use WS-Addressing with WebSphere Message Broker, and illustrates the use of a reply being sent to an address other than the originating client.

About this task

This topic describes the construction of a sample logger message flow when using WS-Addressing. This flow echoes back the input while creating a trace entry in a file to indicate that the flow has been invoked.

Procedure

1. Switch to the Broker Application Development perspective.
2. Select the message flow name that you used in "Building the main message flow" on page 1638
3. Press the right mouse button and select **New->MessageFlow**.
   a. Enter the name that you require for this message flow; for example, `Logger`.
   b. Press **Finish** to create the flow.
4. Select the **HTTP** folder on the message flow palette to display the contents.
5. Select an **HTTPInput** node and move the mouse to the left side of the canvas.

a. Click the left mouse button to add the node to the message flow and enter the name `Logger`.
b. Press **Enter** to finish.

6. Select the **HTTPReply** node from the palette and move the mouse to the right of the HTTPInput node, leaving room for a node in between.
   a. Click the left mouse button to add the node to the message flow and enter the name that you require; for example, `Logger`.
   b. Press **Enter** to finish.
7. Select the **Construction** folder on the message flow palette to display the contents.
8. Select a **Trace** node and move the mouse to the right of the HTTPInput node.
   a. Click the left mouse button to add the node to the message flow and enter the name that you require; for example `Trace`.
   b. Press **Enter**.
   c. Wire the `out` terminal of the HTTPInput node to the `In` terminal of the Trace node.
   d. Wire the `out` terminal of the Trace node to the `In` terminal of the HTTPReply node.
9. Select the HTTPInput node to display the properties. In the **Basic** tab:
   a. Enter the **Data source** name that you require.
   b. Change the name of the input node `Logger` as the **Path suffix for URL**.
10. Select the **Input Message Parsing** tab and select `XMLNSC` as the **Message domain**.
11. Select the Trace node to display the properties.
    a. Set **Destination** to `File`
    b. Set the **File path** that you require.
    c. Enter the **Pattern** that you require.
12. Save the message flow.

Deploying the message flows:

This is the third of a set of instructions on setting up your system to use WS-Addressing with WebSphere Message Broker, and illustrates the deployment of the message flows.

About this task

This topic describes the deployment of the message flows that you have already constructed.

Procedure

1. Select the **LocalProject** project under **Broker Archives** in the navigator pane.
   a. Press the right mouse button.
   b. Select **New** > **Message Broker Archive**.
   c. Use the drop-down menu to change the **Project** to `LocalProject`.
   d. Enter the name you selected for the main message flow described in "Building the main message flow" on page 1638 in **Name**.
   e. Press **Finish** to open the Broker Archive Editor.
2. In the Broker Archive Editor, complete the following steps.
   a. In the **Filter working set** list box select the working set name that you used for the main message flow.
   b. In **Message Flows** select the message flow names that you used for the main message flow and logger message flow.
   c. In **Message Sets** select the message set name that you used for the main message set.
   d. Press **Build broker archive** and confirm that the build operation was successful.
   e. Save the updated broker archive file.
3. To deploy the message flows to the default execution groups, right-click the broker archive (BAR) file that you have just built, then click **Deploy File**.
4. Select the default execution group and click **OK** to start the deployment. Ensure that you receive a successful response message, and press **OK** to dismiss the information dialog.
5. Use the **Deployment Log** to confirm that the deploy operation was successful:

Testing the message flows:

This is the fourth of a set of instructions about how to set up your system to use WS-Addressing with WebSphere Message Broker; these instructions illustrate how to test the message flows.

About this task

This topic describes how to test the message flows that you have already constructed. In this scenario, you use a tool that uses HTTP protocol rather than WebSphere MQ protocol. You can use any tool that has the facilities that are described in the following procedure.

Procedure

1. Start the tool and select `http://localhost:nnnn/`, where *nnnn* is the address of the port that you are using.
2. Set the URL to the host, port, and selection for the deployed flow. The SOAPInput nodes listen on a different port from the HTTP nodes, and the listener is built into the execution group rather than using a different process.
3. The SOAPInput node expects a SOAPAction entry in the HTTP headers, therefore you must add one.
   a. Click **Add New Header**.
   b. Enter the **Value** part of the header. The value must match the `SOAPAction` attribute of the `SOAP:operation` element in your code.
   c. Select **New Header** in the **Name** pane.
   d. Change the name from **New Header** to `SOAPAction` and click **Enter**.
4. Select **Load File** and go to the directory that contains the XML file you want to use.
5. Select the file and click **Open**. Note the following conditions:
   - If the message does not include any WS-Addressing entries, the `ReplyTo` and `FaultTo` locations default to `anonymous`. This means that the results are returned on the original client connection.
   - If the message includes a WS-Addressing header (`ReplyTo`) with a value of `anonymous`, the reply is returned to the original client by using the original TCP/IP connection.
   - If the message includes a WS-Addressing header with a value of `FaultTo` explicitly included, the reply is returned to that address rather than the default of using the location that was specified in the `ReplyTo` header.
6. Click **Send** to test the flow. The result appears in the right pane.

XML domain message flows:

If you are not using the SOAP domain, your message flow must take account of the bitstream format of the Web service messages with which you are working. A different logical tree format is used by each domain.

If the messages are SOAP, you can use either the XMLNSC domain or the MRM XML domain. Both domains offer validation. The XMLNSC domain is more efficient, while the MRM XML domain can be useful if you have specific message transformation requirements (for example, if your message flow also uses binary data formats).

If the messages use MIME (for example, SOAP with Attachments or MTOM), you can use the MIME domain. In this case, your message flow typically needs to identify at least the MIME part that corresponds to the SOAP payload, then explicitly parse this part by using the XMLNSC or MRM domain.

In the SOAP domain, WSDL is used to configure your nodes automatically with the appropriate endpoint information. If you are not using the SOAP domain, select and configure the transport nodes manually. Typical WSDL bindings are:

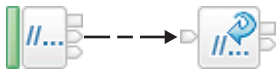
- SOAP/HTTP; in which case, implement a flow by using HTTP nodes. Use the HTTPInput and HTTPReply nodes if a flow implements a Web service, or use the HTTPRequest node if a flow calls a Web service.
- SOAP/JMS; where you implement a flow by using JMS or MQ nodes.

You can configure message flows that receive input messages from clients by using one transport, and interact with a Web service or legacy application by using another.

You can propagate a message to more than one location. For example, the Web service response to be returned to a client by an HTTPReply node might first be sent to an auditing application by using an MQOutput node, after making any required adjustments to the message headers.

Nodes are used together in the following basic patterns, by using HTTP nodes as example transports:

- As a Web service provider, for example:



- As a Web service consumer, for example:

- As a Web service facade, for example:

If required, you can use the SOAPExtract and SOAPEnvelope nodes in conjunction with these patterns to respectively extract the SOAP payload and rebuild a SOAP Envelope.

To enable your message flow to validate messages, deploy an appropriate message set with the flow. An appropriate message set is created either by importing existing WSDL or by generating WSDL from an existing message set. For details

about importing existing WSDL, see “Importing from WSDL” on page 2946. For details about generating WSDL from an existing message set, see “WSDL generation” on page 6340.

You can also create a new message set and flow based on existing WSDL or XSD files; for details, see “Creating an application based on WSDL or XSD files” on page 1413.

The generated message set contains message definitions for the relevant SOAP Envelope version and for the XML payload data defined by the WSDL. In the XMLNSC or MRM XML domains, messages can be validated against the message set; for details, see “Validating messages” on page 1478.

Gateway operation mode for SOAP nodes:

The SOAPInput, SOAPRequest, and SOAPAsyncRequest nodes have two operation modes: WSDL mode, and Gateway mode.

If the node is configured to be in WSDL mode, which is the default, the web service operations performed by the node are specified by a WSDL that configures the node. In Gateway mode, SOAP nodes in a message flow handle generic SOAP request messages in the following scenarios.

Provider scenario
: In a provider scenario, WebSphere Message Broker receives generic SOAP/HTTP or SOAP/JMS requests by using a SOAPInput node, and sends a reply to the originating client by using a SOAPReply node. A single SOAPInput node can receive any SOAP request message, and is not configured with a WSDL.

Consumer scenario
: In a consumer scenario, WebSphere Message Broker can route a SOAP request to any external web service provider by using the SOAPRequest

node or a pair of SOAPAsyncRequest and SOAPAsyncResponse nodes. Endpoint information can be specified in the local environment, which is used dynamically at run time to send the outbound request message.

Façade scenario
In a façade scenario, WebSphere Message Broker can receive SOAP requests from multiple different clients, and route them to any one of multiple back end web service providers, or existing systems. Endpoint information for the back-end web service provider can be specified dynamically at run time by setting values in the local environment.

The SOAP nodes act and are configured differently in the two different operation modes.

- If you configure a node in Gateway mode, some node properties are disabled because they are not applicable in Gateway mode.
  - The WSDL-specific properties are disabled when the node is switched to Gateway mode. The values are not cleared, and can be used if the node is switched back to WSDL mode.
  - The Response Message Parsing properties on the SOAPRequest node are disabled in Gateway mode.
  - Validation of the operation according to the WSDL does not take place because no WSDL exists against which to validate in Gateway mode. If a SOAPAsyncRequest and SOAPAsyncResponse node pair is used in Gateway mode, the validation properties on the SOAPAsyncResponse node are disabled at run time, regardless of the validation settings in the BAR file.
  - No message set is associated with the node, and no schema is used. Therefore, no message validation takes place in Gateway mode. You can configure the flow downstream to enable validation.
  - Outbound MTOM is not supported in Gateway mode because validation cannot take place. However, you can enable validation, and therefore enable MTOM, by setting the Message Set in the local environment. For example:

    ```
    SET OutputRoot.Properties.MessageSet = 'myMessageSet';
    ```

    You might need to also enable validation on the Compute node or the SOAPReply node.
  - In the `User-defined SOAP headers` table on the SOAPInput node, all operations are set to `*`. The `WSDL-defined SOAP headers` table is cleared.
- Transport properties must be configured. The transport-specific properties are mandatory depending on the `Transport` property; for example, the JMS transport properties are mandatory if the selected transport is `JMS`.
- A SOAPInput node can only be configured to receive messages of a single specified transport, for example, HTTP. Use separate input nodes to send or receive messages with different transports.
- A SOAPRequest node can only be configured to send messages of a single specified transport, for example, JMS. However, you can change the transport for any message using the local environment.
- A SOAPAsyncRequest node can only be configured to send and receive messages over a single transport, for example, JMS, and this transport is always used for the paired SOAPAsyncResponse node to receive the response message. However, you can change the outbound request transport for any message by using the local environment. For example, if a SOAPAsyncRequest node is configured to use JMS transport, its paired SOAPAsyncResponse node always expects to receive responses over JMS, and this cannot be changed. At run time, the SOAPAsyncRequest node also then assumes JMS as the default transport.

However, you can instruct it to instead send the request over HTTP by using the local environment. This request includes the WSA:ReplyTo JMS address for the SOAPAsyncResponse node.

- If a SOAPInput node receives a one-way SOAP request, the node attempts to detect that it is a one-way message. However, the node cannot detect all cases, and therefore it is sometimes necessary to instruct the SOAPReply node that it is a one-way message, by using the local environment. For example:

  ```
  SET OutputLocalEnvironment.Destination.SOAP.Reply.Gateway.OneWay = True;
  ```

  For more information, see "One-way messages in Gateway mode" on page 1648.
- If you use the SOAPAsyncRequest node in Gateway mode, you must set the WS-Addressing `Action` property in the local environment in the message flow before the SOAPAsyncRequest node. Set this property by using `OutputLocalEnvironment.Destination.SOAP.Request.WSA.Action`.
- If you use the SOAPRequest node in Gateway mode and the remote service provider expects a SOAPAction, set the SOAPAction in the flow. In Gateway mode the SOAPAction from a WSDL is not available to the node. For example, to set the SOAPAction using ESQL:

  ```
  SET OutputRoot.HTTPRequestHeader.SOAPAction = 'mySoapAction';
  ```

  By default the SOAPRequest node sends an empty SOAPAction of `""`.
- If you use the SOAPRequest node in Gateway mode and are using WS-Addressing, you must set the WS-Addressing `Action` property in the local environment in the message flow before the SOAPRequest node. Set this property by using `OutputLocalEnvironment.Destination.SOAP.Request.WSA.Action`.
- In Gateway mode, you can add inbound "must understand" headers to the SOAPInput node or to the SOAPRequest and SOAPAsyncRequest nodes by specifying the details on the node property. However, if you will be adding services dynamically, where all the "must understand" headers cannot be known in advance, you can add these headers with a wildcard (`*`) for name, namespace, operation, or any combination of the three. This removes the need to redeploy your message flow when new services are added. However, consider that if you add a wildcard for the name, namespace, and also operation, this means that all headers with a "must understand" flag are allowed into the flow.
- If you use the SOAPReply node as part of a façade message flow, with the SOAPInput node set to Gateway mode, and the SOAPRequest node acting in WSDL mode, disable validation on the SOAPReply node or add an explicit Message Set in the Properties folder as documented above. If you do not disable validation or reference a Message Set in the Properties folder, parsing errors occur when the message is serialized.
- In Gateway mode, the SOAP nodes send SOAP 1.1 messages by default, although they also accept inbound SOAP 1.2 messages. To send an outbound SOAP 1.2 message, set the `SOAP.Context` field to indicate that SOAP 1.2 is required. For example, to set this field using ESQL:

  ```
  SET OutputRoot.SOAP.Context.SOAP_Version = '1.2';
  ```

  The outbound message then uses a SOAP 1.2 SOAP Envelope. You can also set the namespace prefix used by the SOAP Envelope. For example, by using ESQL:

  ```
  DECLARE soapenc NAMESPACE 'http://www.w3.org/2003/05/soap-envelope';
  SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soap12 = soapenc;
  SET OutputRoot.SOAP.Context.SOAP_Version = '1.2';
  ```

  In this example, `soap12` is the prefix used in the outbound message.

"Local environment overrides for the SOAPRequest node" on page 4850
You can dynamically override values in the local environment in the same way as setting values in other elements of a message.

One-way messages in Gateway mode:

When you configure a SOAP node using WSDL, the WSDL specifies whether a given node operation is one-way or not. However, configuring a node in Gateway mode without WSDL means that this WSDL information is not available. Therefore, SOAP nodes configured as Gateways automatically attempt to detect one-way Operations based on the message content.

SOAPInput node one-way Operation detection

The SOAPInput node detects one-way messages in different ways depending on the transport used, and whether or not WS-Addressing is configured on the node.

- If the node uses HTTP transport and has WS-Addressing configured, the operation is determined to be one-way if the inbound message uses the special `WSA:None` address for the `WSA:ReplyTo` and `WSA:FaultTo` addresses.
- If the node uses HTTP transport and does not have WS-Addressing configured, no auto detection of one-way messages takes place.
- If the node uses JMS transport and has WS-Addressing configured, the operation is determined to be one-way if either of the following conditions are true:
  - The inbound message uses the special `WSA:None` address (http://www.w3.org/2005/08/addressing/none) for the `WSA:ReplyTo` and `WSA:FaultTo` addresses.
  - There is no JMS ReplyTo destination specified in the inbound message, and the inbound message uses the special `WSA:Anonymous` address (http://www.w3.org/2005/08/addressing/anonymous or http://schemas.xmlsoap.org/ws/2004/08/addressing/role/anonymous) for the `WSA:ReplyTo` and `WSA:FaultTo` addresses.

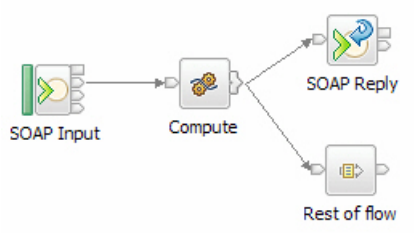
- If the node uses JMS transport and does not have WS-Addressing configured, the operation is determined to be one-way if there is no JMS ReplyTo destination specified in the inbound message.

In Gateway mode, the `SOAP.Context.operationType` field is set to `GATEWAY` if the Operation is determined to be request-response, or `GATEWAY_ONE_WAY` if the Operation is determined to be one-way. If the operation is determined to be one-way, no reply is necessary or allowed. However, if the Operation is not determined to be one-way, the flow is configured with the assumption that the flow sends a reply. Therefore, if the Operation is one-way, you must specify that the Operation is one-way in order to allow the flow to free up resources, and, if HTTP is being used, to send an HTTP 202 acknowledgment back to the originating client. Do this by setting the following field in the local environment before wiring the message to a SOAPReply node:

```
SET OutputLocalEnvironment.Destination.SOAP.Reply.Gateway.OneWay = 'true';
```

This setting instructs the SOAPReply node to complete the Message Exchange Pattern before sending an HTTP 202 acknowledgment, if required, and freeing up its resources.

One approach for using this setting would be in a Gateway flow like this:



In this flow, the Compute node determines if the message is one-way. If the message is one-way, the Compute node sets the local environment one-way setting, and sends a message to the SOAPReply node to complete the Message Exchange Pattern. If the flow is a Gateway flow and the one-way local environment option is set, any message received by the SOAPReply node causes it to ignore the message content and complete the Message Exchange Pattern. The flow can then continue through the other terminal of the Compute node.

It is not an error to send a message to the SOAPReply node with the one-way local environment option set if the message has been automatically determined to be a one-way message.

SOAPRequest node one-way Operation detection

In Gateway mode, the SOAPRequest node automatically detects whether a message is one-way only if WSA is used and the `WSA:ReplyTo` and `WSA:FaultTo` addresses are set to the special `WSA:None` address. To manually instruct the node that the message is one-way, set the following option in the local environment:

```
SET OutputLocalEnvironment.Destination.SOAP.Request.Gateway.OneWay = 'true';
```

For the SOAPRequest node, specifying that a message is one-way indicates to the node that a response is not expected, except for an HTTP 202 acknowledgment if HTTP transport is used. If JMS transport is used, it also allows the message to be

sent under the control of any existing transaction, if the `Transaction mode` is to `Yes` or `Automatic`.

How to use WS-Addressing:

An overview of how you use WS-Addressing with WebSphere Message Broker.

Sending a message to an endpoint reference (EPR)

When sending a message to an endpoint reference, the following processes take place:

- The [`destination`] Message Addressing Property (MAP) is completed from the [`address`] property in the EPR.
- [`reference parameters`] are copied to top level SOAP headers from the [`reference parameters`] property of the EPR.
- The [`action`] property is required, but is not populated from the EPR.

In this context, action is an absolute Internationalized Resource Identifier (IRI) that uniquely identifies the semantics implied by this message, and it must be the same as the HTTP SOAPAction if a non-empty SOAPAction is specified.

- The [message id] property must be specified if this message is part of a request-response Message Exchange Pattern (MEP); the message id is generated by default.

When replying with a non-fault message, the following processes take place:

- The EPR to reply to is selected from the [reply endpoint] MAP.
  - If this property contains the special address none, no reply is sent.
  - If this property contains the special address anonymous, the reply is sent on the return channel of the transport on which the request was received. This is the default value in the absence of any other supplied EPR.
  - Otherwise, the reply is sent to the [address] property in the Reply EPR,
- The [message id] property of the inbound message request is placed into the [relationship] property of the response, along with the predefined relationship of the reply part of the Universal Resource Identifier (URI) - which indicates that this message is a reply.

  For further information on the URI see Web Services Addressing URI Specification.
- A new [message id] property is specified for the reply, and this is generated by default.

SOAP is an XML message format used in Web service interactions. SOAP messages are typically sent over HTTP or JMS, but other transport protocols can be used. The use of SOAP in a specific Web service is described by a WSDL definition.

Related tasks:

"Processing Web service messages" on page 1601
Use WebSphere Message Broker nodes and services to connect to other Web services providers and consumers.

WS-Addressing with the SOAPInput node:

Various options are available when you use WS-Addressing with the SOAPInput node.

The SOAPInput node has a property for processing WS-Addressing information present in the incoming message called Use WS-Addressing.

If you select this property, the WS-Addressing information is processed and the process itself is called engaging WS-Addressing. The default is that WS-Addressing is not engaged.

You can also specify this property in the WSDL, and this property is configurable from the WSDL, automatically by the WebSphere Message Broker Toolkit, when the WSDL is dropped onto the node. The behavior of the node when WS-Addressing is engaged or not engaged is as follows:

Addressing not engaged
: No WS-Addressing processing is performed. If a message is received that contains any WS-Addressing headers they are ignored, and no WS-Addressing processing of any kind is performed, unless they are marked as MustUnderstand.

The inbound WS-Addressing headers in this case are visible in the message when it leaves the SOAPInput node under the Header folder of the SOAP parser in the message tree.

A fault is returned to the client if WS-Addressing headers exist in the incoming message, and they meet both of the following criteria:

- Marked as `MustUnderstand`
- Targeted at the role the SOAPInput node is operating in

Engaging WS-Addressing is how you instruct the node to 'understand' the WS-Addressing headers. In this case the WS-Addressing headers remain in the SOAP Header section of the SOAP parser, and no other SOAP node acts upon them. In all cases, they are treated as a SOAP header with no special meaning assigned to the WS-Addressing headers.

Addressing engaged:

WS-Addressing processing is performed as stated in the WS-Addressing specification. This processing means that messages that contain either submission addressing headers or final addressing headers are accepted.

A fault is returned if both submission addressing headers and final headers are present, and either of the following conditions is met:

- Neither is marked with a role.
- They are both marked with same role and the SOAPInput node is acting in that role.

Assuming that the WS-Addressing headers are valid and the `Place WS-Addressing Headers into LocalEnvironment` check box is selected on the SOAPInput node, all headers (including detectable inbound reference parameters) are removed from the inbound message tree and are placed into the local environment tree under the `SOAP.Input.WSA` folder. Moving the WS-Addressing headers to the local environment indicates that they have been processed by the broker. The headers are removed from the message tree because they have been processed on input; otherwise they would not be valid if the message tree was sent out without further changes. They are stored in the local environment to allow you to inspect them.

Only reference parameters from the final specification are detectable because they have an attribute called `IsReferenceParameter` that allows them to be detected. Submission reference parameter headers do not have this attribute, therefore they are not detectable, and they are not moved into the local environment tree from the message tree.

You can change WS-Addressing reply headers before the SOAPReply node is reached. For more information about changing WS-Addressing information in the local environment, see “WS-Addressing information in the local environment” on page 1656.

Related concepts:

“WS-Addressing” on page 1617
Web Services Addressing (WS-Addressing) is a World Wide Web Consortium (W3C) specification that aids interoperability between Web services by defining a standard way to address Web services and provide addressing information in messages.

"SOAPReply node" on page 4819
Use the SOAPReply node to send SOAP messages from the broker to the originating client in response to a message received by a SOAPInput node.

WS-Addressing with the SOAPReply node:

Various options are available when you use WS-Addressing with the SOAPReply node.

The SOAPReply node uses WS-Addressing if WS-Addressing is engaged on the SOAPInput node that is referenced by the reply identifier of the message entering the reply node.

The SOAPReply node uses addressing information in the `Destination.SOAP.Reply.WSA` folder of the local environment to determine where to send the reply and with what Message Addressing Properties (MAPs).

If the `Destination.SOAP.Reply.WSA` does not exist, or is completely empty when inspected by the SOAPReply node, the node uses the default addressing headers that were part of the incoming message. Therefore, you do not have to propagate the local environment in the default case, and addressing still works as expected.

In the case where folders exist beneath the `Reply.WSA` folder, these folders are used to update the output message. Therefore, you can change, add, or remove parts of the default reply information generated by the input node, because any changes that you made to the tree are reflected in the outgoing message by the SOAPReply node. For details about WS-Addressing information in the local environment, see "WS-Addressing information in the local environment" on page 1656.

If WS-Addressing is not engaged, this node does not perform any WS-Addressing processing.

Use the SOAPReply node to send SOAP messages from the broker to the originating client in response to a message received by a SOAPInput node.

WS-Addressing with the SOAPRequest node:

Various options are available when you use WS-Addressing with the SOAPRequest node.

The SOAPRequest node has a property called `Use WS-Addressing`, for processing WS-Addressing information that is present in the incoming message.

If you select this property, the WS-Addressing information is processed and the process itself is called `engaging WS-Addressing`. The default is that WS-Addressing is not engaged.

You can also specify this property in the WSDL and this is configurable from the WSDL, automatically by the WebSphere Message Broker Toolkit, when the WSDL is dragged onto the node. The behavior of the node when WS-Addressing is engaged or not is as follows:

Addressing not engaged
The node does not add any WS-Addressing headers to the outgoing message, and does not process any WS-Addressing headers that might be present in the response message that is received by the node.

Addressing engaged:
The node first looks at the `Destination.SOAP.Request.WSA` folder in the local environment. If this folder is empty, the node automatically generates all required WS-Addressing Message Addressing Properties (MAPs) in the outgoing message, by using the following default values:

- `Action`, from the WSDL configuration file. If this is not explicitly specified, this defaults to the value that is defined in the WSDL Binding specification.
- `To`, from the `Web Service URL` node property.
- `ReplyTo`, by using the special `Anonymous` address (assuming that the Operation being used is not a one-way message exchange program, in which case a `ReplyTo` by using the special `None` address is specified).
- `MessageID`, a unique UUID is used.

If the `Destination.SOAP.Request.WSA` folder in the LocalEnvironment is not empty, any user supplied MAPs override the default ones that were listed previously, on a property by property basis.

After the response to the request is received and if the `Place WS-Addressing Headers into LocalEnvironment` check box is selected on the SOAPRequest node, the SOAPRequest node removes all WS-Addressing headers from the response message and places them in the `SOAP.Response.WSA` folder. This folder allows you to query the headers in a similar manner to the way the SOAPInput node deals with the Input WS-Addressing headers.

Related reference:

"SOAPRequest node" on page 4828
Use the SOAPRequest node to send a SOAP request to the remote Web service.

WS-Addressing with the SOAPAsyncRequest and SOAPAsyncResponse nodes:

The remote Web service must understand WS-Addressing to be able to work with SOAPAsyncRequest and SOAPAsyncResponse nodes.

The SOAPAsyncRequest and SOAPAsyncResponse nodes require WS-Addressing; therefore, the remote Web service must understand WS-Addressing to process the WS-Addressing headers that are sent from the SOAPAsyncRequest node, and to allow the response to be sent back to the corresponding SOAPAsyncResponse node, which is specified in the `address` property of the `ReplyTo` Message Addressing Property (MAP).

SOAPAsyncRequest node

The SOAPAsyncRequest node has a property called `Use WS-Addressing` that is read-only and has a default value of `true`, indicating that WS-Addressing is mandatory for this node. This property has the effect of permanently engaging WS-Addressing for this node and cannot be changed by the node, or by the WSDL that is used to configure this node.

The node first looks at the `Destination.SOAP.Request.WSA` folder in the local environment. If this folder is empty, the node automatically generates all required WS-Addressing MAPs in the outgoing message, using the following default values:

- `Action`, from the WSDL configuration file. If this value is not specified explicitly, the default value is defined by the WSDL Binding specification.
- `To`, from the `Web Service URL` node property.
- `ReplyTo`, the address of the corresponding SOAPAsyncResponse node.
- `MessageID`, a unique UUID is used.

If the `Destination.SOAP.Request.WSA` folder in the local environment is not empty, any user-supplied MAPs override the default ones listed previously on a property by property basis.

However, because of the nature of the SOAP asynchronous node pair, you cannot specify the `address` property of the `ReplyTo` Message Exchange Program (MEP), and this property is ignored if specified.

When the main MAPs are generated, the node looks in several places to obtain various pieces of context information to send in a `<wmb:context>` element under the `ReferenceParameters` section of the `ReplyTo` endpoint reference. If these locations exist and are not empty, the following additional information is added to the `<wmb:context>`:

- `Destination.SOAP.Request.UserContext`

  This information is added under a subfolder called `UserContext`.
- `Destination.SOAP.Reply.ReplyIdentifier`

  This information is added under a subfolder called `ReplyID`.

Use the user context to specify an arbitrary amount of data that will be sent with the message from the SOAPAsyncRequest node to the SOAPAsyncResponse node.

By using the user context, you can pass state from one node to the other. Ensure that the amount of data that you send is small because this data is placed in the message.

Use the reply identifier to automatically correlate a SOAPInput node in the flow that contains the SOAPAsyncRequest node, with a SOAPReply node in the flow that contains the SOAPAsyncResponse node.

SOAPAsyncResponse node

After the response to the request is received, the SOAPAsyncResponse node can remove all WS-Addressing headers from the response message and places them in the `SOAP.Response.WSA` folder so that you can query the headers, if you select the node property `Place WS-Addressing headers in local environment`.

If the response message contains a user context that was specified by the SOAPAsyncRequest node, the user context is placed in the `SOAP.Response.UserContext` folder in the local environment.

If the response message contains a reply identifier that was specified by the SOAPAsyncRequest node, the reply identifier is placed in the `Destination.SOAP.Reply.ReplyIdentifier` folder in the local environment.

Related concepts:

"WS-Addressing" on page 1617
Web Services Addressing (WS-Addressing) is a World Wide Web Consortium (W3C) specification that aids interoperability between Web services by defining a standard way to address Web services and provide addressing information in messages.

WS-Addressing information in the local environment:

WS-Addressing header information can be placed in the local environment tree where it is visible to a message flow. WS-Addressing header information is only processed by the SOAP nodes.

Inbound messages

Inbound information is placed in the local environment by the SOAP node only if addressing is engaged on the node and you select the `Place WS-Addressing Headers into LocalEnvironment` property on the SOAPInput, SOAPAsyncResponse, or SOAPRequest nodes.

The following table describes the node specific WS-Addressing information in the local environment tree.

Node	Populates local environment property
SOAPInput	`LocalEnvironment.SOAP.Input.WSA.`*`type`*
SOAPAsyncResponse	`LocalEnvironment.SOAP.Response.WSA.`*`type`*
SOAPRequest	`LocalEnvironment.SOAP.Request.WSA.`*`type`*

Where *type* is the structure of the subsection of the local environment WS-Addressing XML schema. For details about how *type* maps to the WS-Addressing properties defined by the WS-Addressing specification, see the "Local environment property type" on page 1658 section of this topic.

The local environment information for inbound messages is for your information only. If you engage addressing on the node, and select the `Place WS-Addressing Headers into LocalEnvironment` property on the node, WS-Addressing information is available for you to look at and use in your flow. The WS-Addressing properties are placed in the local environment after processing by the node. Note that the WS-Addressing folder and all its children are owned by an XMLNSC parser, therefore you can copy elements directly into any other tree that is owned by an XMLNSC parser. However, be aware that if you copy this folder (or any of its children) to a tree that is not owned by an XMLNSC parser, information in the tree is discarded unless you create an XMLNSC parser in the target tree first. This behavior can occur if you, for example, copy from the `InputLocalEnvironment` tree to the `OutputLocalEnvironment` tree.

Outbound messages

You can place outbound WS-Addressing header information in the local environment; however, this practice is necessary only to override the defaults that are generated by the node automatically . Outbound addressing headers are created only if WS-Addressing is enabled on the node.

The following table describes the node specific WS-Addressing information in the local environment tree that can be used to override the defaults for outbound messages.

Node	Populates local environment property
SOAPReply	`LocalEnvironment.Destination.SOAP.Reply.WSA.`*`type`*
SOAPRequest	`LocalEnvironment.Destination.SOAP.Request.WSA.`*`type`*
SOAPAsyncRequest	`LocalEnvironment.Destination.SOAP.Request.WSA.`*`type`*

Where *type* is the structure of the subsection of the local environment WS-Addressing XML schema. For details about how the *type* maps to the WS-Addressing properties defined by the WS-Addressing specification, see the "Local environment property type" on page 1658 section of this topic.

You can modify local environment information for outbound messages. The SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes generate default local environment settings that you can override. One exception to this table is that any attempt to override the WS-Addressing `ReplyTo` address on the SOAPAsyncRequest node is ignored.

For example, the following code shows how to set WS-Addressing information in the local environment for the SOAPRequest node. The WS-Addressing ReplyTo.Address and FaultTo.Address values should be entered as a single string, without line breaks.

```
 SET OutputRoot = InputRoot;
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.To.Address = 'jms:jndi:INPUTQ';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.Address = 'jms:jndi:RESPONSEQ?jndiConnectionFactoryName=QC
jndiInitialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&
jndiURL=file://C:/SOAPJNDIBindings';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.From.Address = 'jms:jndi:INPUTQ';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.Address = 'jms:jndi:RESPONSEQ?jndiConnectionFactoryName=QC
jndiInitialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&
jndiURL=file://C:/SOAPJNDIBindings';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.Action = 'http://WMB_BankImport/NewOperation';
 SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.MessageID = 'test:my:msg:ID:1234578';
```

Local environment property *type*

The local environment property *type* in the preceding tables corresponds to the WS-Addressing part of the local environment XML schema. The following table shows the corresponding message addressing properties (MAPs) of the WS-Addressing local environment schema for all nodes.

Element	Corresponds to abstract WS-Addressing MAP name
To	[destination endpoint]
From	[source endpoint]
ReplyTo	[reply endpoint]
FaultTo	[fault endpoint]
Action	[action]
MessageId	[message id]
RelatesTo	[relationship]
ReferenceParameters	[reference parameters]
Version	This element does not correspond to a MAP, but it is used to identify the version of WS-Addressing. The two main versions of WS-Addressing are Submission and Final. The default version that is used by all nodes is Final. Therefore, for outbound messages, set this element only if you want the version to be Submission. For incoming messages, this element is populated automatically with the version of the WS-Addressing headers that the inbound message used.

For more details about the message addressing properties defined by the WS-Addressing specification, see “WS-Addressing” on page 1617.

For outbound WS-Addressing, you can set an additional local environment property.

Element	Description
AddMustUnderstandAttribute	This element places the SOAP `mustUnderstand` attribute on each WS-Addressing header before the message is sent.

"Example use of WS-Addressing information in the local environment"
This example shows the setting of reference parameters in the local environment along with the corresponding messages as they appear on the wire.

Example use of WS-Addressing information in the local environment:

This example shows the setting of reference parameters in the local environment along with the corresponding messages as they appear on the wire.

In this example the Web service exposes a simple ping operation.

ESQL to add reference parameters

The following ESQL example shows how to specify addressing headers in the local environment.

```
DECLARE Example_ns NAMESPACE 'http://ibm.namespace';

SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.ReferenceParameters.Parameter1 = 'Message Broker';
SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.ReferenceParameters.Example_ns:Parameter2.
 (SOAP.NamespaceDecl)xmlns:Example_ns = 'http://ibm.namespace';
SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.ReplyTo.ReferenceParameters.Example_ns:Parameter2 = 'Ping';

SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.ReferenceParameters.Parameter1 = 'Ping';
SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.ReferenceParameters.Example_ns:Parameter2.
 (SOAP.NamespaceDecl)xmlns:Example_ns = 'http://ibm.namespace';
SET OutputLocalEnvironment.Destination.SOAP.Request.WSA.FaultTo.ReferenceParameters.gns:Parameter2 = 'FAULT';
```

Request message

The following example is of an outgoing SOAP envelope in a message from a SOAPRequest node with `ReplyTo` and `FaultTo` reference parameters generated after using the above ESQL. It also shows the other message addressing properties

(MAPs) that are not set in the local environment, but are generated automatically by the node as a result of engaging WS-Addressing.

```
<NS1:Envelope xmlns:NS1="http://www.w3.org/2003/05/soap-envelope" xmlns:wsa="http://www.w3.org/2005/08/addressing">
  <NS1:Header>
    <wsa:To>http://localhost:7801/Service</wsa:To>
    <wsa:ReplyTo>
      <wsa:Address>http://www.w3.org/2005/08/addressing/anonymous</wsa:Address>
      <wsa:ReferenceParameters>
        <Example_ns:Parameter2 xmlns:Example_ns="http://ibm.namespace">Ping</Example_ns:Parameter2>
        <Parameter1>Message Broker</Parameter1>
      </wsa:ReferenceParameters>
    </wsa:ReplyTo>
    <wsa:FaultTo>
      <wsa:Address>http://www.w3.org/2005/08/addressing/anonymous</wsa:Address>
      <wsa:ReferenceParameters>
        <Example_ns:Parameter2 xmlns:Example_ns="http://ibm.namespace">FAULT</Example_ns:Parameter2>
        <Parameter1>Ping</Parameter1>
      </wsa:ReferenceParameters>
    </wsa:FaultTo>
    <wsa:MessageID>urn:uuid:020C911C16EB130A8F1204119836321</wsa:MessageID>
    <wsa:Action>http://ibm.com/Service/Ping</wsa:Action>
  </NS1:Header>
  <NS1:Body>
    <NS2:Ping xmlns:NS2="http://ibm.com"></NS2:Ping>
  </NS1:Body>
</NS1:Envelope>
```

In the above example, reference parameters are set for the `ReplyTo` and `FaultTo` endpoint references (EPRs). If this message is sent to a SOAPInput node with WS-Addressing engaged, these `ReferenceParameters` are placed in the local environment of the flow that contains the SOAPInput node for use by the flow if the `Place WS-Addressing Headers into LocalEnvironment` property is selected. This option changes only what is placed in the local environment; it does not change the contents of the response message.

Response message

The following SOAP envelope is a response to the outgoing preceding message, as sent by a SOAPReply node. This example shows the MAP processing that happens automatically by the SOAPReply node. In this example, the `FaultTo` reference parameters are not present because the reply is not a SOAP fault. This response also shows where the reference parameters that belonged to the `ReplyTo` EPR appear in the response message.

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/" xmlns:wsa="http://www.w3.org/2005/08/
 addressing">
  <soapenv:Header>
    <wsa:To>http://www.w3.org/2005/08/addressing/anonymous</wsa:To>
    <Example_ns:Parameter2 wsa:IsReferenceParameter="true" xmlns:Example_ns="http://ibm.namespace">Ping</Example_ns:
 Parameter2>
    <Parameter1 wsa:IsReferenceParameter="true">Message Broker</Parameter1>
    <wsa:ReplyTo>
      <wsa:Address>http://www.w3.org/2005/08/addressing/anonymous</wsa:Address>
    </wsa:ReplyTo>
    <wsa:Action>http://ibm.com/Service/PingResponse</wsa:Action>
    <wsa:RelatesTo RelationshipType="http://www.w3.org/2005/08/addressing/reply">urn:uuid:020C911C16EB130A8F1204119836321
 </wsa:RelatesTo>
  </soapenv:Header>
  <soapenv:Body>
    <NS1:PingResponse xmlns:NS1="http://ibm.com">
      <NS1:PingResult>Ping</NS1:PingResult>
    </NS1:PingResponse>
  </soapenv:Body>
</soapenv:Envelope>
```

"WS-Addressing information in the local environment" on page 1656
WS-Addressing header information can be placed in the local environment tree where it is visible to a message flow. WS-Addressing header information is only processed by the SOAP nodes.

Working with WSDL:

Use the following tasks to help you work with WSDL.

- "WSDL validation"
- "Using WSDL to configure message flows" on page 1664
- "WSDL URI formats for JMS" on page 1668
- "WSDL styles" on page 1670
- "Working with rpc-encoded SOAP messages" on page 1671

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

"WSDL validation"
The WS-I Validator can be used to check your WSDL definitions against the Basic Profile.

"WSDL Version 1.1" on page 6699
Web Services Description Language (WSDL) is an XML format for describing network services as a set of endpoints operating on messages containing either document-oriented or procedure-oriented information.

WSDL validation:

The WS-I Validator can be used to check your WSDL definitions against the Basic Profile.

For more information about the WS-I Basic Profile refer to the WS-I, and in particular the WS-I Basic Profile document:

- Web Services Interoperability Organization (WS-I)
- WS-I deliverables index

You can use the WS-I Validator to check your WSDL definitions against the Basic Profile; see "WS-I Basic Profile Version 1.1" on page 6700.

You can run the validator in either of the following ways:

- Manually against a specific `.wsdl` resource in the workbench.

  This option enables you to investigate and fix WS-I compliance problems; all validation issues are displayed as task list errors and warnings.
- Automatically, when WSDL is imported or generated.

  WSDL can be imported using the WSDL Quick Start wizard, the WSDL Importer wizard, or the **mqsicreatemsgdefsfromwsdl** command.

  WSDL can be generated from a message set by using the WSDL Generator wizard.

You can control the behavior of the validator using **Preferences > Web services > Profile Compliance and Validation**. The significant settings are:

- WS-I AP compliance level (WS-I Attachments Profile 1.0)

- WS-I SSBP compliance level (WS-I Simple SOAP Binding Profile 1.0)

You can select one of the following values:

Suggest
Run the validator with errors treated as unrecoverable, but warnings only notified. This is the default setting.

Require
Run the validator with errors and warnings treated as unrecoverable.

Ignore Do no run the validator.

The AP selection applies automatically to the SSBP field, therefore Ignore is not explicitly selectable unless the AP selection is set to Ignore.

The following terms refer to the three broad categories of WSDL definition:

- `document-literal` means the combination `style="document"` and `use="literal"`
- `rpc-literal` means the combination `style="rpc"` and `use="literal"`
- `rpc-encoded` means the combination `style="rpc"` and `use="encoded"`

The following are typical validation problems using the preceding terminology:

Your WSDL is rpc-encoded
WSDL with `use="encoded"` is not WS-I compliant and can lead to operational problems because products of different vendors can make different assumptions about the expected SOAP payload.

WS-I: (BP2406) The use attribute of a `soapbind:body`, `soapbind:fault`, `soapbind:header`, and `soapbind:headerfault` does not have the value of "literal".

Your WSDL is document-literal, but one or more WSDL part definitions refer to XML Schema types.
In `document-literal` WSDL, the SOAP body payload is the XML Schema element that is referred to by the appropriate WSDL part.

If a type is specified instead of an element, the SOAP payload is potentially ambiguous (the payload name is not defined) and interoperability problems are likely.

WS-I: (BP2012) A `document-literal` binding contains `soapbind:body` elements that refer to message part elements that do not have the element attribute.

Your WSDL is rpc-literal or rpc-encoded, but one or more WSDL part definitions refer to XML Schema elements.
In rpc-style WSDL, the SOAP body payload is the WSDL operation name, and its children are the WSDL parts that are specified for that operation.

If an element is specified instead of a type, the SOAP message payload is potentially ambiguous (the payload name might be the WSDL part name or the XML Schema element name), and interoperability problems are likely.

WS-I: (BP2013) An rpc-literal binding contains `soapbind:body` elements that refer to message part elements that do not have the type attribute.

Your WSDL includes SOAP header, headerfault or fault definitions that refer to XML Schema types.

In rpc-style WSDL, the SOAP body is correctly defined through XML Schema types as described above.

SOAP headers and faults, however, do not correspond to an rpc function call in the same way as the body.

In particular, there is no concept of 'parameters' to a header or fault, and a header or fault must always be defined in terms of XML Schema elements to avoid potential ambiguity. Effectively, header and fault definitions in WSDL are always `document-literal`.

WS-I: (BP2113) The `soapbind:header`, `soapbind:headerfault`, or `soapbind:fault` elements refer to `wsd:part` elements that are not defined using only the "element" attribute.

Your WSDL is rpc-literal or rpc-encoded, but no namespace was specified for an operation.

In rpc-style WSDL, the SOAP message payload is the WSDL operation name, qualified by a namespace that is specified as part of the WSDL binding.

If no namespace is specified then the SOAP message payload is potentially ambiguous (the payload name might be in no namespace, or might default to use a different namespace, such as the target namespace of the WSDL definition) and interoperability problems are likely.

WS-I: (BP2020) An rpc-literal binding contains `soapbind:body` elements that either do not have a namespace attribute, or have a namespace attribute value that is not an absolute URI.

Your WSDL includes a SOAP/JMS binding.

If your WSDL uses a SOAP/JMS transport URI it is not WS-I compliant. An error is shown if strict WS-I validation is enabled. To disable strict WS-I validation, click **Window > Preferences > Broker Development > Message Sets > Validation** and select the **WS-I BP 1.1: Allow SOAP/JMS as transport URI**. By default strict WS-I validation is disabled.

Web service interoperability is improved if you implement the following actions:

- Use document-style WSDL whenever possible.
- Use literal encoding, if rpc-style WSDL is necessary.
- Ensure that the WSDL operation definitions are qualified by a valid namespace attribute, if rpc-encoded WSDL must be used.

Use the **mqsicreatemsgdefsfromwsdl** command to import a single WSDL definition.

"Importing from WSDL: generated objects and restrictions" on page 6355
Several objects are generated when you import from WSDL but restrictions might apply.

Using WSDL to configure message flows:

You can use WSDL to configure message flows.

Message flows that work with Web services typically use the SOAP nodes. For details about the SOAP nodes, see "WebSphere Message Broker and Web services" on page 1602.

In WSDL mode, the SOAP nodes are configured by using a WSDL file that was previously imported or generated in a message set, and is displayed under **Deployable WSDL** in the workbench. You can drag the WSDL file onto a SOAP node, or specify it by using the `WSDL file name` property on the node.

You can change the operation mode of the SOAP nodes so that they act in gateway mode. In gateway mode, a WSDL is not required to configure the nodes because they handle generic request/response and one-way SOAP messages that are not tied to a specific WSDL. For more details, see "Gateway operation mode for SOAP nodes" on page 1645.

When you drag a WSDL file onto a SOAP node, the node properties are configured from the properties in the WSDL `address` URI. The transport properties on the SOAP node are populated according to the first binding imported from the WSDL file. Therefore, if the first imported binding describes a JMS transport, the JMS Transport properties are populated; if the first imported binding describes an

HTTP transport, the HTTP Transport properties are populated. If you select another imported binding, the transport properties are populated accordingly. The `portType` appears differently depending on the transport selected.

The WSDL `address` element URI can exist in two different formats, W3C format, or IBM (deprecated) format. The format of the WSDL URI affects the names of the WSDL properties that the parser looks for to populate the SOAP node properties. For example, the `JNDI context parameters` table is not populated when you import an IBM-style WSDL because it does not support these properties in the WSDL address URI. The table is populated only if JNDI context parameters are present in a W3C-style WSDL. For details, see "WSDL URI formats for JMS" on page 1668.

If you supply a service definition, endpoint properties are set automatically, but you can also set or override these properties manually.

Optionally, WSDL definitions can be split into multiple files. The typical arrangement is that a top-level service definition file imports a binding file, the binding file imports an interface file, and this interface file imports or includes schema definition files.

A WSDL `portType` (the logical WSDL interface) is not sufficient on its own to configure a SOAP node; a specific binding is required so that the SOAP payload is well-defined at run time.

A binding defines a use, which can be `document` (the default) or `rpc`. If the use is `document`, the SOAP payload is described by an XML Schema element in the WSDL. If the use is `rpc`, the SOAP payload is the WSDL operation name in a specified namespace.

To create your own message flow, configure the nodes as described. However, you can create a new skeleton message flow by dragging a WSDL definition onto a blank canvas in the Message Flow editor, and selecting a specific WSDL binding. You can also choose the type of flow (service provider or consumer) and the operations to be handled by the flow. The key nodes and properties in the generated message flow are configured, but you must complete the configuration and add any other nodes that you require before deploying the flow. For details about configuring a new Web service by using the wizard, see "Configure New Web Service Usage wizard" on page 6392.

Configuring the SOAP nodes

The following nodes are configured explicitly by WSDL:

- "SOAPInput node" on page 4795
- "SOAPRequest node" on page 4828
- "SOAPAsyncRequest node" on page 4750

The following nodes are configured implicitly by WSDL, because they inherit the WSDL configuration of the node with which they are paired:

- "SOAPReply node" on page 4819
- "SOAPAsyncResponse node" on page 4777

A SOAPReply node is always used with a SOAPInput node. For details of Web service scenarios, see "Web services scenarios" on page 1620.

A SOAPAsyncResponse node is always used with a SOAPAsyncRequest node, associated by the `Unique Identifier` property. For SOAP node usage patterns, see "Web services scenarios" on page 1620.

Querying WSDL with ?wsdl:

You can interrogate web services using ?wsdl.

A web service client can send an HTTP GET request with a `?wsdl` query string to a WebSphere Message Broker web service, and receive a representation of the WSDL that was used to configure the input node that provides the endpoint for the service. You can do this only for input nodes that use HTTP and not JMS transport. The protocol of the HTTP GET request must match the protocol of the flow; therefore if the flow uses SSL, the HTTP GET request must begin `https://`.

The client starts by sending a simple `?wsdl` query and retrieves the complete WSDL definition by following a chain of referenced imports or includes. For example, if the web service endpoint is `http://localhost:7800/test1`, the initial client request is:

```
GET http://localhost:7800/test1?wsdl
```

This request returns the top-level WSDL service definition, which might include imports for further sections of the WSDL definition. For example, if the returned WSDL has a line:

```
<wsdl:import ... location="http://localhost:7800/test1?wsdl=wsdl0"/>
```

then the client sends a corresponding request to retrieve that section of the WSDL:

```
GET http://localhost:7800/test1?wsdl=wsdl0
```

One or more WSDL sections can also have imports for XML Schema data, for example:

```
<xsd:import ... schemaLocation="http://localhost:7800/test1?xsd=xsd0"/>
```

The client again sends a corresponding request to retrieve that data:

```
GET http://localhost:7800/test1?xsd=xsd0
```

Only semantically correct references can be followed:

- `<wsdl:import>` elements that are immediate children of `wsdl:definition` elements
- `<xsd:import>` and `<xsd:include>` elements that are immediate children of `xsd:schema` elements

where `wsdl` is a shorthand (namespace prefix) for `http://schemas.xmlsoap.org/wsdl/`, and `xsd` is a shorthand for `http://www.w3.org/2001/XMLSchema`. A request made to a URI from an element which superficially looks like an `<import>` or `<include>`, for example, an element in a comment, results in a SOAP Fault being returned. Only the simple `?wsdl` query string, and subsequent queries that exactly match those queries specified in semantically valid imports and includes, result in data being returned.

The WSDL definition returned is logically equivalent to the deployable WSDL in the toolkit, with inline schemas externalized. It might not be physically identical to the original imported WSDL definition. Although a SOAPInput is configured with a specific WSDL binding, the WSDL returned also includes other bindings that are not used by the flow if these were part of the original WSDL definition that was imported.

WSDL URI formats for JMS:

You must use WSDL to configure SOAP nodes. When using WSDL with a JMS transport, different URI formats can exist in the `address` element in the WSDL, which affect how properties are parsed and applied to the configured nodes.

Two different URI formats can exist in the WSDL `address` element. Several node properties are initially set from properties in the imported WSDL, which is parsed according to which type of URI is found in the WSDL element. The first type is the W3C SOAP JMS specification format. For example:

```
<soap:address location="jms:jndi:REPLYTOQ2?jndiConnectionFactoryName=QCF&amp;
 jndiInitialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&amp;
 jndiURL=file:/C:/mqsi6/webservices/SOAP/JMS/JNDI&amp;
 targetService=SOAPJMSGenMessageSetSOAP_JMS_Service&amp;
 timeToLive=30000"
/>
```

The second URI format for the `address` element is a proprietary IBM format which is currently deprecated. For example:

```
<soap:address location="jms:/queue?destination=jms/RequestQ&amp;
 connectionFactory=jms/WMBQCF&amp;
 targetService=SOAPJMSGenMessageSetSOAP_JMS_Service&amp;
 initialContextFactory=com.sun.jndi.fscontext.RefFSContextFactory&amp;
 jndiProviderURL=file:/C:/mqsi6/webservices/SOAP/JMS/JNDI"
/>
```

There are several differences between these URI formats. WebSphere Message Broker accepts both URI formats. Different WSDL properties are used to set the SOAP node properties depending on which URI format is used in the WSDL address element.

The following table shows how WSDL properties are parsed into SOAPInput node properties. The columns headed "W3C names in URI" and "W3C allowed values" indicate the property names that the parser looks for when a W3C-style URI is found, and the allowed values for those properties. The columns headed "IBM names in URI" and "IBM allowed values" indicate the property names that the parser looks for when an IBM-style URI is found in the WSDL, and the allowed values for those properties. Where more than one property name is shown in a table cell, the node property is set to the value of the first of those property names found in the WSDL `address` element. Any properties found in the WSDL `address` element that are not parsed into node properties are discarded.

SOAPInput node property name	W3C SOAP/JMS specification names	W3C names in URI	W3C allowed values	IBM names in URI	IBM allowed values
Source	`soapjms:destinationName`	`jms=dest` (in URI)	`<string>`	`destination`	`<string>`
Connection factory name	`soapjms:jndiConnectionFactoryName`	`jndiConnectionFactoryName`	`<string>`	`connectionFactory`	`<string>`
Initial context factory	`soapjms:jndiInitialContextFactory`	`jndiInitialContextFactory`	`<string>`	`initialContextFactory`	`<string>`
JNDI URL bindings location	`soapjms:jndiURL`	`jndiURL`	`<URL>`	`jndiProviderURL`	`<URL>`
JNDI parameters	`soapjms:jndiContextParameter`	`parameter=value`	`<string for name and value>`	N/A	`<string>`
Delivery mode	`soapjms:deliveryMode`	`deliveryMode`	`NON_PERSISTENT` `PERSISTENT`[1]	`deliveryMode` `persistence`	`<int 1 | 2>`
Message priority	`soapjms:priority`	`priority`	`<int 0-9>`	`priority` `Priority`	`<int 0-9>`
Target service	`soapjms:targetService`	`targetService`	`<string>`	`targetService`	`<string>`

Notes:

1. WebSphere Message Broker accepts the values 1 and 2 when parsing a W3C-style URI for compatibility reasons, but the W3C specification allows only the string values `NON_PERSISTENT` and `PERSISTENT` for this property.

The following table shows how WSDL properties are parsed into SOAPRequest andSOAPAsyncRequest node properties. The columns headed "W3C names in URI" and "W3C allowed values" indicate the property names that the parser looks for when a W3C-style URI is found, and the allowed values for those properties. The columns headed "IBM names in URI" and "IBM allowed values" indicate the property names that the parser looks for when an IBM-style URI is found in the WSDL, and the allowed values for those properties. Where more than one property name is shown in a table cell, the node property is set to the value of the first of those property names found in the WSDL address element. Any properties found in the WSDL `address` element that are not parsed into node properties are populated in the `User Parameters` table.

SOAPRequest or SOAPAsyncRequest node property name	W3C SOAP/JMS specification names	W3C names in URI	W3C allowed values	IBM names in URI	IBM allowed values
Destination	`soapjms:destinationName`	`jms=dest` (in URI)	`<string>`	`destination`	`<string>`

SOAPRequest or SOAPAsyncRequest node property name	W3C SOAP/JMS specification names	W3C names in URI	W3C allowed values	IBM names in URI	IBM allowed values
Connection factory name	soapjms:jndiConnectionFactoryName	jndiConnectionFactoryName	<string>	connectionFactory	<string>
Initial context factory	soapjms:jndiInitialContextFactory	jndiInitialContextFactory	<string>	initialContextFactory	<string>
JNDI URL bindings location	soapjms:jndiURL	jndiURL	<URL>	jndiProviderURL	<URL>
JNDI parameters	soapjms:jndiContextParameter	Parameter=value	<string for name and value>	N/A	<string>
Delivery mode	soapjms:deliveryMode	deliveryMode	NON_PERSISTENT PERSISTENT[1]	deliveryMode persistence	<int 1 | 2>
Message expiration	soapjms:timeToLive	timeToLive	<int>	timeToLive	<int>
Message priority	soapjms:priority	priority	<int 0-9>	priority Priority	<int 0-9>
Reply to destination	soapjms:replyToName	replyToName	<string>	replyToName replyTo replyToDestination replyDestination	<string>
Target service	soapjms:targetService	targetService	<string>	targetService	<string>
User parameters	UserProperties	<any other property name>	<string>	<any other property name>	<string>

Notes:

1. WebSphere Message Broker accepts the values 1 and 2 when parsing a W3C-style URI for compatibility reasons, but the W3C specification allows only the string values NON_PERSISTENT and PERSISTENT for this property.

Use the SOAPRequest node to send a SOAP request to the remote Web service.

WSDL styles:

The SOAP nodes are configured using a specific WSDL binding that has a style of either document (the default) or rpc. All operations defined in a specific WSDL binding are usually defined with the same use, which can be either literal (the default) or encoded.

The following terms are used to describe the three general types of WSDL bindings:

1. `document-literal (style="document", use="literal")`
2. `rpc-literal (style="rpc", use="literal")`
3. `rpc-encoded (style="rpc", use="encoded")`

The shape of the runtime SOAP message defined by the WSDL depends on the binding type, as shown in the following table:

WSDL binding type	Description
`document-literal`	The SOAP payload is described by XML schema. The `wrapped document-literal` convention constructs the XML schema so that the first child of the SOAP Body matches the operation name.
`rpc-literal`	The SOAP payload is described by the WSDL (operation and part name) and then by XML schema.
`rpc-encoded`	The SOAP payload has the same general shape as `rpc-literal`, but can carry SOAP encoding annotations designed to give the receiver additional information about the message that is sent. The annotations are slightly different between SOAP 1.1 and SOAP 1.2.

All three WSDL styles are supported by WebSphere Message Broker. The best style for a new service is `document-literal`, and it is also the least likely to cause interoperability problems. You can use the `wrapped document-literal` convention to explicitly associate the SOAP payload with the operation.

Both `document-literal` and `rpc-literal` are WS-I compliant. The `rpc-encoded` style is not WS-I compliant and can cause interoperability problems if the web service client and server use different technologies. Some common issues encountered with WSDL styles are described in "WSDL validation" on page 1661.

It is simple to create and parse SOAP messages described by `document-literal` or `rpc-literal` WSDL, because the payload is standard XML described by the message set created from the WSDL.

For more information, see "Working with rpc-encoded SOAP messages."

Related reference:

"What is WSDL?" on page 1615
WSDL is an XML notation for describing a web service. A WSDL definition tells a client how to compose a web service request and describes the interface that is provided by the web service provider.

Working with rpc-encoded SOAP messages:

The SOAP nodes are configured using a specific WSDL binding that has a style of either `document` (the default) or `rpc`. All the operations defined within a particular WSDL binding are usually defined with the same use, which can be either `literal` (the default) or `encoded`.

SOAP messages that are `rpc-encoded` can carry SOAP encoding annotations that are designed to give the receiver additional information about the message being sent. The following four types of annotations are common:

1. xsi:type

2. encodingStyle
3. Arrays
4. Multi-reference

Arrays and multi-reference elements can cause interoperability problems, and require specific intervention by the message flow developer, as follows:

- If the message flow builds outbound messages incorporating SOAP arrays, use ESQL to add any required attributes, as follows:
  - `arrayType` for SOAP 1.1
  - `arraySize` and `itemType` for SOAP 1.2
- If the message flow receives messages using SOAP arrays, disable validation.
- If the message flow receives messages using multi-reference encoding, disable validation and, if necessary, navigate the resulting logical tree using the `href` (or `ref`) and `id` attributes.

xsi:type

An `xsi:type` attribute can be added to an element to specify its type. For example:

```
<data xsi:type="xsd:string">text</data>
```

where the namespace prefix `xsi` is defined as follows:

```
xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
```

For a web service built from WSDL and XML schema, the type information is already available and the `xsi:type` is redundant.

Generally, when building an outbound message, you do not add `xsi:type` information. The following ESQL example shows how to add `xsi:type` information if it is required:

```
DECLARE xsd NAMESPACE 'http://www.w3.org/2001/XMLSchema';
DECLARE xsi NAMESPACE 'http://www.w3.org/2001/XMLSchema-instance';

SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsd = xsd;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsi = xsi;

SET OutputRoot.SOAP.Body.rpc:op1.part1.data.(SOAP.Attribute)xsi:type = 'xsd:string';
```

When parsing an inbound message, any `xsi:type` information is added to the logical tree in the same way as other attributes, as follows:

```
(0x03000000:PCDataField):data = 'text' (CHARACTER)
(
  (0x03000100:Attribute)http://www.w3.org/2001/XMLSchema-instance:type = 'xsd:string' (CHARACTER)
)
```

encodingStyle

An `encodingStyle` attribute can be added to an element to specify the SOAP encoding style used. For example:

```
<tns:op1 soapenv:encodingStyle="http://schemas.xmlsoap.org/soap/encoding/">
```

where the namespace prefix `soapenv` is defined as the namespace of your SOAP Envelope, as follows:

```
xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/" (SOAP 1.1)
xmlns:soapenv="http://www.w3.org/2003/05/soap-envelope"   (SOAP 1.2)
```

The value itself is a list of URIs, but the values in common use are as follows:

```
"http://schemas.xmlsoap.org/soap/encoding/" (SOAP 1.1)
"http://www.w3.org/2003/05/soap-encoding"   (SOAP 1.2)
```

In SOAP 1.1, the `encodingStyle` attribute can be added to any element. In SOAP 1.2 the `encodingStyle` attribute can be added only to children of Body, Header and Detail.

Generally, you build an outbound message, you do not add the `encodingStyle` attribute. The following ESQL example shows how to add `encodingStyle` information, if it is required:

```
DECLARE soapenv NAMESPACE 'http://schemas.xmlsoap.org/soap/envelope/';
DECLARE soapenc NAMESPACE 'http://schemas.xmlsoap.org/soap/encoding/';

SET OutputRoot.SOAP.Body.tns:op1.(SOAP.Attribute)soapenv:encodingStyle = soapenc;
```

When parsing an inbound message, any `encodingStyle` attributes are added to the logical tree in the same way as other attributes, as follows:

```
(0x03000100:Attribute)http://schemas.xmlsoap.org/soap/envelope/:encodingStyle =
     'http://schemas.xmlsoap.org/soap/encoding/' (CHARACTER)
```

Arrays

A SOAP array is an element containing a sequence of child elements of the same type. In the following XML schema example, there is a type called *data* with two elements: a simple string and an array. In the schema, the field called *array* has an unspecified number of children of type string. The name of those child elements is not specified.

```
<xsd:complexType name="ArrayOfString">
  <xsd:complexContent mixed="false">
    <xsd:restriction base="soapenc:Array">
 <xsd:attribute wsdl:arrayType="xsd:string[]" ref="soapenc:arrayType"/>
    </xsd:restriction>
  </xsd:complexContent>
</xsd:complexType>

<xsd:complexType name="data">
  <xsd:sequence>
     <xsd:element name="simple" type="xsd:string"/>
     <xsd:element name="array"  type="tns:ArrayOfString"/>
  </xsd:sequence>
</xsd:complexType>
```

The namespaces used in the example are from WSDL 1.1 and SOAP 1.1, as follows:

```
xmlns:xsd="http://www.w3.org/2001/XMLSchema"
xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/"
xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
```

The following example is part of a valid instance document matching the schema:

```
<array soapenc:arrayType="xsd:string[]">
  <item>item1</item>
  <item>item2</item>
</array>
```

When you build an outbound message, you must add the appropriate attributes. For example, the following ESQL shows how to add the `arrayType` attribute:

```
DECLARE xsd     NAMESPACE 'http://www.w3.org/2001/XMLSchema';
DECLARE soapenc NAMESPACE 'http://schemas.xmlsoap.org/soap/encoding/';
```

```
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsd = xsd;

SET OutputRoot.SOAP.Body.rpc:op1.p1.array.(SOAP.Attribute)soapenc:arrayType = 'xsd:string[]';
```

The attributes used by SOAP 1.1 and SOAP 1.2 are different. SOAP 1.1 uses the `arrayType` attribute. The size of the array can be specified, but is not required. SOAP 1.2 uses two separate attributes. The equivalent SOAP 1.2 attributes for the previous example are `soapenc:itemType="xsd:string"` and `soapenc:arraySize="2"`, where the namespace prefixes are defined as follows:

```
xmlns:xsd="http://www.w3.org/2001/XMLSchema"
xmlns:soapenc=" http://www.w3.org/2003/05/soap-encoding"
```

You must disable validation if your message flow receives SOAP encoded messages containing SOAP arrays. The instance document cannot be validated against the schema when parsing an inbound message, because the name of the array items is not defined by the schema.

Multi-reference

The following example shows a SOAP 1.1 request message for a WSDL `rpc-encoded` operation called `op1`:

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/"
                  xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/">
  <soapenv:Body   xmlns:xsd="http://www.w3.org/2001/XMLSchema"
                  xmlns:rpc="http://example/rpc">
    <rpc:op1>
       <p1>
         <simple>text</simple>
         <array soapenc:arrayType="xsd:string[]">
           <Item>item1</Item>
           <Item>item2</Item>
         </array>
       </p1>
    </rpc:op1>
  </soapenv:Body>
</soapenv:Envelope>
```

A SOAP implementation can reorganize this logical message to use multi-reference elements, as follows:

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/"
                  xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/">
  <soapenv:Body   xmlns:xsd="http://www.w3.org/2001/XMLSchema"
                  xmlns:rpc="http://example/rpc">
    <rpc:op1>
      <p1 href="#id1"/>
    </rpc:op1>
    <rpc:data id="id1">
      <simple>text</simple>
      <array href="#id2"/>
    </rpc:data>
    <soapenc:Array id="id2" soapenc:arrayType="xsd:string[]">
      <Item>Array Element 0</Item>
      <Item>Array Element 1</Item>
    </soapenc:Array>
  </soapenv:Body>
</soapenv:Envelope>
```

The message is logically equivalent to the first example, but the children of elements `p1` and `array` have been split out into separate sibling elements and then referenced using the `href` attribute.

The introduced elements, such as <data>:

- Can be referenced from more than one location, which allows the message to state that such elements are identical, as opposed to separate items which have the same value. The message size could be reduced if a shared element is large and referenced many times.
- Can directly or indirectly reference themselves, which allows the message to represent a graph that contains circular references.

Neither of these considerations applies to the previous example.

Generally, when you build an outbound message, you do not encode multi-reference elements unless the message represents a graph. Otherwise, the multi-reference encoding is optional. The following ESQL example shows how to encode multi-reference elements:

```
-- ESQL namespace prefixes
DECLARE soapenc NAMESPACE 'http://schemas.xmlsoap.org/soap/encoding/';
DECLARE xsd     NAMESPACE 'http://www.w3.org/2001/XMLSchema';
DECLARE rpc NAMESPACE 'http://example/rpc';

-- define XML namespace prefixes
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:soapenc = soapenc;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:xsd = xsd;
SET OutputRoot.SOAP.Context.Namespace.(SOAP.NamespaceDecl)xmlns:rpc = rpc;

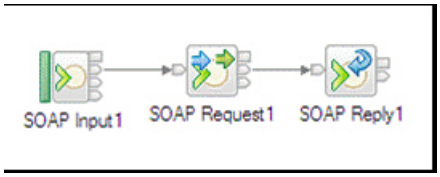
-- build request message
SET OutputRoot.SOAP.Body.rpc:op1.p1.(SOAP.Attribute)href = '#id1';

SET OutputRoot.SOAP.Body.rpc:data.(SOAP.Attribute)id = 'id1';
SET OutputRoot.SOAP.Body.rpc:data.simple = 'text';
SET OutputRoot.SOAP.Body.rpc:data.array.(SOAP.Attribute)href = '#id2';

SET OutputRoot.SOAP.Body.soapenc:Array.(SOAP.Attribute)id = 'id2';
SET OutputRoot.SOAP.Body.soapenc:Array.(SOAP.Attribute)soapenc:arrayType = 'xsd:string[]';
SET OutputRoot.SOAP.Body.soapenc:Array.Item[1] = 'item1';
SET OutputRoot.SOAP.Body.soapenc:Array.Item[2] = 'item2';
```

When parsing an inbound message, multi-reference elements do not match the XML schema from the web service WSDL. If validation is enabled on a SOAP node, then an exception is thrown. If you use multi-reference encoding, then you must disable validation.

When you have a logical tree built from the message, you can propagate this tree to another SOAP node for output. For example, with a façade flow as shown in the following diagram, if the SOAPRequest node receives a response using multi-reference encoding, you can propagate the logical tree for the response to the SOAPReply node, and a SOAP message with multi-reference encoding is returned to the original client.



The original client must also understand the multi-reference encoding.

To manipulate the logical tree for a multi-reference encoded message, navigate the `href` and `id` attributes in ESQL. These attributes are slightly different in SOAP 1.1 and SOAP 1.2, as follows:

- In SOAP 1.1, the referencing element has an attribute `href="#id"` and the item referenced `id="id"`.
- In SOAP 1.2, the referencing element has an attribute `ref="id"` and the item referenced `id="id"`.

"WSDL styles" on page 1670
The SOAP nodes are configured using a specific WSDL binding that has a style of either `document` (the default) or `rpc`. All operations defined in a specific WSDL binding are usually defined with the same use, which can be either `literal` (the default) or `encoded`.

Using timeouts with HTTP and SOAP nodes:

Connect the HTTP Timeout terminal of the HTTPInput or SOAPInput nodes to further nodes to process timeouts.

Before you begin

Before you start:

- Read the message flows overview.
- Read about the options that you have for processing Web service messages, and learn more about SOAP and HTTP.

About this task

You can configure message flows that start with an HTTPInput or SOAPInput node by connecting the HTTP Timeout terminal to further nodes for processing timeouts:

- On SOAPInput nodes, messages are propagated through this terminal only when you are using an HTTP binding.
- On HTTPInput nodes, messages are propagated through this terminal only when you have configured your execution groups such that the HTTP nodes are using the embedded execution group listener.

If these conditions are not met when you deploy the BAR file for the message flow that includes one of these nodes, a warning is generated, and the path of the message flow that you have connected to the HTTP Timeout terminal is ignored. No further warnings are generated until the next restart.

To set a static timeout value in an input node:

1. Create a message flow, or open an existing flow.
2. In the Message Flow editor, select the input node for this message flow. The node properties are displayed in the Properties view (below the editor pane).
3. Set an appropriate time for the timeout interval in the property `Maximum client wait time`. The default interval is 180 seconds.

   If this time expires, and you have not connected one or more nodes to the HTTP Timeout terminal, the listener that received the client request message responds with a SOAP Fault message indicating that a timeout has occurred.
4. If you want to provide customized timeout processing, connect one or more nodes to the HTTP Timeout terminal. You must include in this sequence the

reply node that matches the input node. Therefore, if your message flow starts with an HTTPInput node, you must include an HTTPReply; if your message flow starts with a SOAPInput node, you must include a SOAPReply node.

To set a dynamic timeout value in an input node:

- Override the timeout value set on the input node by using the Java plug-in API to update it in a JavaCompute node using the `MbUtilities.changeIdentifierTimeout()` method. The following code shows an example of the `changeIdentifierTimeout` method:

```
MbMessage localEnv = assembly.getLocalEnvironment();
MbElement rootElem = localEnv.getRootElement();
MbElement repIdElement = rootElem.getFirstElementByPath(
   "/Destination/SOAP/Reply/ReplyIdentifier");
Object repId = repIdElement.getValue();
boolean success = changeIdentifierTimeout((byte[])repId, timeout);
```

- Override the timeout value set on the input node by using the "CHANGEIDENTIFIERTIMEOUT function" on page 5292.

You can derive the value that you use to replace the existing value by several means; for example:

- Create a configurable service of type UserDefined to define a timeout value, and retrieve the appropriate property.
- Read a record from a database.
- Use a value from a field within the message body.

By propagating from the HTTP Timeout terminal you can then change the contents of the responses that your message flow sends to the client. The processing on the sequence of nodes that you connect to the HTTP Timeout terminal is also subject to a further timeout, so that the client always gets a response within a known timeout interval.

When a message is propagated from the HTTP Timeout terminal the message tree contains the input headers of the original input message and a message body that is the fault timeout message. The original message body along with other information relating to the timeout can be accessed in the LocalEnvironment message tree. For example, the following record can be found in the LocalEnvironment:

```
(0x01000000:Name):HTTP = (
  (0x01000000:Name):Input = (
    (0x01000000:Name):Timeout = (
      (0x03000000:NameValue):OriginalClientLastWaitTime = 10 (INTEGER)
      (0x03000000:NameValue):OriginalClientWaitTime     = 15 (INTEGER)
      (0x03000000:NameValue):OriginalMessageMadeTheFlow = TRUE (BOOLEAN)
      (0x03000000:NameValue):OriginalRequestIdentifier  =
         X'485454500000000000000000000000c00c000000000000' (BLOB)
      (0x03000000:NameValue):OriginalInboundMessage     = X'3c3e' (BLOB)
    )
  )
)
```

For SOAPInput nodes the SOAPReply node connected on the HTTP Timeout terminal path must send a SOAP fault response message and the reply status code of 500 cannot be altered. For HTTPInput nodes any response message can be sent from the HTTP Timeout terminal and the reply status code can be changed by updating the `LocalEnvironment.Destination.HTTP.ReplyStatusCode` message tree field.

Using SOAP MTOM with the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes:

The use of outbound MTOM messages can be configured on the SOAPReply, SOAPRequest, and SOAPAsyncRequest nodes.

The nodes have a property called `Allow MTOM`, which defines whether MTOM can be used.

An MTOM output message is written if all of the following criteria are met:

- The `Allow MTOM` property is selected on the **WS Extensions** tab.
- Validation is enabled. The `Validate` property on the SOAPRequest and SOAPAsyncRequest nodes controls validation of the anticipated response

message and not validation of the outgoing request. MTOM output is therefore suppressed unless you set `Validate` to `Content and value` on a preceding input node or transformation node.

- No child elements exist below `SOAP.Attachment` in the logical tree. If child elements are present, SOAP with Attachments (SwA) is used.
- Elements exist in the output message that are identified as base64Binary in the associated XML Schema and whose length does not fall below a default threshold size of 1000 bytes.

You can use the local environment setting `MTOMThreshold` to override the MTOM element size threshold. The MTOM element size threshold is set to a default value of 1000 bytes.

The `Allow MTOM` node property and the `MTOMThreshold` setting can both be overridden in the local environment.

The overrides that apply at a SOAPReply node are:

- `LocalEnvironment.Destination.SOAP.Reply.AllowMTOM`, which can have a value of true or false
- `LocalEnvironment.Destination.SOAP.Reply.MTOMThreshold`, which is an integer value in bytes

The equivalent overrides for a SOAPRequest or SOAPAsyncRequest node are:

- `LocalEnvironment.Destination.SOAP.Request.AllowMTOM`, which can have a value of true or false
- `LocalEnvironment.Destination.SOAP.Request.MTOMThreshold`, which is an integer value in bytes

Related concepts:

"SOAP nodes" on page 1609
The SOAP nodes act as points in the flow where Web service processing is configured and applied. Properties on the SOAP nodes control the processing carried out and can be configured by supplying a WSDL definition, or by manually configuring properties, or both.

Processing JMS messages

JMS is the standard J2EE messaging API for building enterprise messaging applications. WebSphere Message Broker provides built-in input and output nodes for its supported protocols.

The JMS specification offers an abstract, provider-independent messaging interface, so that you can write messaging applications to this common API regardless of the underlying messaging implementation.

JMS offers two common ways of messaging on which to build messaging applications: point-to-point and publish/subscribe (pub/sub). JMS applications send messages to JMS destinations, which can be queues (in the point-to-point domain) or topics (in the pub/sub domain).

JMS is defined in the following documents from Sun Microsystems:

- JMS specifications from Sun Microsystems

JMS can be used as a transport for SOAP as described in the following document issued by the World Wide Web Consortium (W3C):

- SOAP over Java Message Service 1.0 (W3C recommendation)

Java Message Service (JMS) API

WebSphere Message Broker supports the Java Message Service (JMS) application programming interface (API).

The JMS is an application programming interface that provides Java language functions for handling messages. Developed by messaging vendors, including IBM, in partnership with Sun Microsystems, Inc., the JMS API provides a common interface to access different enterprise messaging systems, including WebSphere MQ. This interface is appropriate for point-to-point and publish/subscribe applications.

Messaging clients in JMS are called *JMS clients*, and the messaging system is called the *JMS provider*. A *JMS application* is a business system that comprises JMS clients and at least one JMS provider. Client applications that use the JMS interface are written in the Java programming language, and are therefore restricted to the levels of JVM that are supported on the operating system in the business environment.

If you have existing end-user applications that are written to these interfaces, they can typically run unchanged in a broker environment. You must create the message flows to interact with these applications from the supported protocols by using the appropriate input and output nodes. WebSphere Message Broker provides built-in input and output nodes for its supported protocols, and other nodes that support transformation to and from JMS message formats. You can also create your own user-defined nodes to support additional protocols.

You can also create end-user applications to interact with the broker.

WebSphere Broker JMS Transport

The WebSphere Broker JMS Transport is a service that connects applications that send and receive messages that conform to the Java Message Service (JMS) standard.

You can use the WebSphere Broker JMS Transport to support the following operations:

- Receive a JMS message as input.
- Create a JMS message for output.
- Work with message flows that do not expect JMS messages.

All JMS messages must conform to the Java Message Service Specification, version 1.1.

To use the WebSphere Broker JMS Transport, you must deploy a message flow that contains at least one of the built-in JMS nodes, which support the exchange of JMS messages. You can create message flows to receive messages from JMS destinations, and send messages to JMS destinations. These destinations are accessible through a connection to a JMS provider. In sending and receiving messages, the JMS nodes behave like JMS clients.

You can also use two transformation nodes, the JMSMQTransform node and the MQJMSTransform node, with the JMSInput and JMSOutput nodes so that they can interact with nodes that expect a propagated message to contain an MQMD (and MQRFH2) header.

- The JMSMQTransform node takes the output of the JMSInput node, and produces a message that can be handled by an MQOutput node.
- The MQJMSTransform node transforms a message with an MQMD (and optional MQRFH2) header into a message that is expected by the JMSOutput node.

If you want to change or add content to the headers in JMS messages, you can include a JMSHeader node in the message flow to modify fields without programming.

You can configure the JMS nodes to work with the WebSphere MQ JMS provider, WebSphere Application Server Version 6.0, the IBM Service Integration Bus, and all JMS providers that conform to the Java Message Service Specification, version 1.1. WebSphere Message Broker supports Java 6 (also known as Java 1.6).

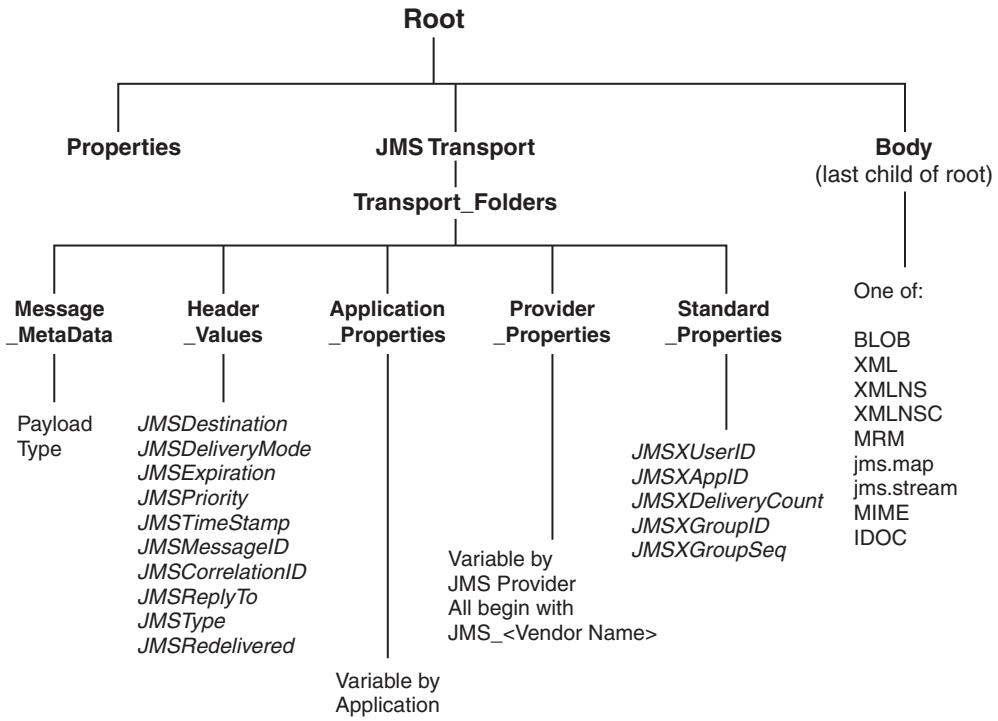
"JMSHeader node" on page 4529
Use the JMSHeader node to modify contents of the JMS Header_Values and Application properties so that you can control the node's output without programming.

Simplified JMS message representation:

The JMSInput node receives an input message as a Java object, and not as a bit stream wire format (as is the case with an MQInput node). The message does not populate an MQMD and RFH2 header, but instead populates a new message tree that represents a JMS message in a more native way.

To represent a JMS message in a message tree, a new canonical form has been created. This message tree allows for representation of JMS message header data, and message properties. The JMS message tree is in a format that is recognizable to Java programmers.



For details about the structure and content of the JMS message tree, see "Representation of messages in the JMS Transport" on page 1691.

Related concepts:

"JMS message transformation"
The JMSInput and JMSOutput nodes expect JMS messages, and therefore expect a native JMS message tree representation.

"JMS message for output" on page 1700
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

"JMSInput node" on page 4532
Use the JMSInput node to receive messages from JMS destinations. JMS destinations are accessed through a connection to a JMS provider.

JMS message transformation:

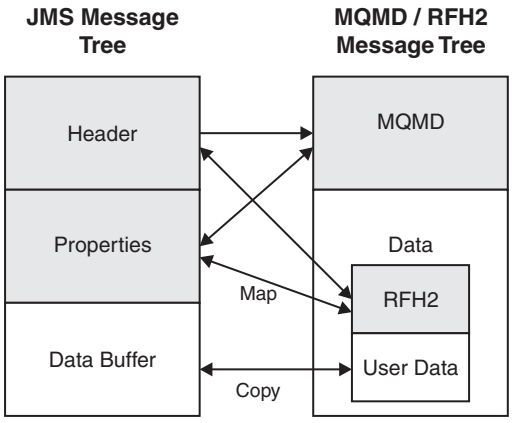
The JMSInput and JMSOutput nodes expect JMS messages, and therefore expect a native JMS message tree representation.

You can use the following nodes to transform messages between a WebSphere MQ JMS message tree and a JMS message tree:

- JMSMQTransform node
- MQJMSTransform node

These nodes do not have any configurable properties. The JMSMQTransform node transforms a native JMS message tree to a WebSphere MQ JMS message tree, and the MQJMSTransform node performs the transformation in the opposite direction.

The following diagram provides an overview of the mapping scheme that is used:



This mapping diagram uses the same scheme as the WebSphere MQ JMS provider to convert between a JMS message and an MQMD or MQRFH2 message.

When transforming between a WebSphere MQ message tree and a native JMS message tree, the transformation nodes copy elements from different parts of a message tree:

- The following fields are copied from the JMS message to the MQMD, if they exist in the incoming JMS message:

JMS field	**MQMD field**
JMSMessageID	MsgId
JMSCorrelationID	CorrelId
JMSPriority	Priority
JMSDeliveryMode	Persistence
JMSQApplid	PutApplName
JMSUser	UserIdentifier
JMSXDeliveryCount	BackoutCount - 1
JMSTimeStamp	PutDate, PutTime

- The following fields are copied from the JMS message to the MQRFH2 JMS folder:

JMS field	**MQRFH2 JMS field**
JMSDestination	Dst

JMS field	MQRFH2 JMS field
JMSDeliveryMode	Dlv
JMSExpiration	Exp
JMSPriority	Pri
JMSTimestamp	Tms
JMSCorrelationID	Cid
JMSReplyTo	Rto

- The following fields are copied from the MQMD to the JMS message:

MQMD field	JMS field
Expiry	JMSExpiration
Persistence	JMSDeliveryMode
Priority	JMSPriority
MsgId	JMSMessageID
CorrelId	JMSCorrelationID
BackoutCount = 0	JMSRedelivered = false
BackoutCount > 0	JMSRedelivered = true
GroupId	JMSGroupid
MsgSeqNumber	JMSGroupseq
UserIdentifier	JMSUser
PutApplName	JMSApplid
PutDate, PutTime	JMSTimeStamp

- The following fields are copied from the MQRFH2 JMS folder to the JMS message:

MQRFH2 JMS field	JMS field
Dst	JMSDestination
Dlv	JMSDeliveryMode
Pri	JMSPriority
Cid	JMSCorrelationID
Rto	JMSReplyTo

Example message flow scenario: JMSInput node to MQOutput node

1. A JMSInput node is configured to subscribe to topic ABC.
2. An application that is connected to the JMS server publishes on topic ABC.
3. A publication is received at the JMSInput node.
4. The node extracts data from the JMS message.

5. The JMS message is passed to the JMSMQTransform node where the message is converted to a WebSphere MQ message.
6. The MQOutput node receives the WebSphere MQ message, and publishes the message on a WebSphere MQ queue.

The final destination is a WebSphere MQ queue, therefore the message must pass through a JMSMQTransform node to convert the message tree to a WebSphere MQ JMS format before it reaches the MQOutput node.

Example message flow scenario: MQInput node to JMSOutput node

1. An MQInput node receives a message from a WebSphere MQ queue.
2. The MQInput node creates a WebSphere MQ message.
3. The MQ message is passed to the MQJMSTransform node where the message tree is converted to a JMS format.
4. The JMSOutput node receives the JMS message and publishes the JMS message on topic XYZ.

Additional examples

These examples show some of the solutions that you can achieve when you use the JMS Transport. Other solutions are possible; for example, the message can be passed to a Compute node or a JavaCompute node and the contents can be modified as required.

Look at the following sample for examples of the JMS nodes being used in message flows:

- JMS Nodes

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

"JMS message for output" on page 1700
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

JMS message structure:

JMS messages have a defined structure that includes headers and payloads.

The following figure depicts the JMS message structure:

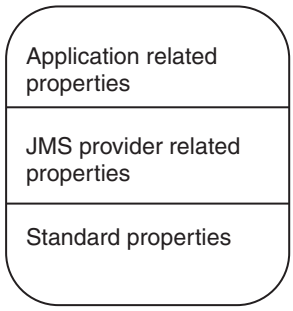
Header

A header must be present in every JMS message, and it is assigned automatically. Most of the values in the header are set by the JMS provider when the message is put to a JMS destination. Some values can be declared by the JMS client when it creates a JMS session, or when it creates the message consumer or producer; for example, *JMSDeliveryMode*, *JMSExpiration*, *JMSReplyTo*, and *JMSCorrelationID* are created when the JMS client creates a JMS session or creates the message consumer or producer.

The data elements of each header comprise name-value pairs and they can be any of the Java following types: Boolean, byte, short, char, long, int, float, double, string, or byte[].

Properties

The properties are optional, and can be divided into the following subsections:



- *Application-related properties*

  A Java application can assign application-related properties, which are set before the message is delivered. The property names of the application are meaningful only to the sending and receiving applications.
- *Provider-related properties*

  Every JMS provider can define proprietary properties that can be set either by the client or automatically by the provider. Provider-related properties are prefixed with *JMS_* followed by the vendor name and the specific property name. For example, the WebSphere MQ JMS client sets the provider property to be *JMS_IBM_MsgType*.
- *Standard properties*

  These properties are set by the JMS provider when a message is sent. The JMS provider vendor can choose to not support any standard properties, to support some standard properties, or to support all standard properties. Standard property names start with *JMSX*; for example: *JMSXUserid* or *JMSXDeliveryCount*.

The properties are handled as name-value pairs, and they can be any of the following Java types: Boolean, byte, short, char, long, int, float, double, string, or byte[].

Payload

The payload type defines the JMS message. It can be one of the six JMS message types that are described in "JMS message types" on page 1690.

JMS does not define a wire format. The Java Message Service Specification, version 1.1 describes the physical representation of how a message is structured.

Related reference:

"JMS message types" on page 1690
JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where the payload is the body of a message that holds the content.

When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

"JNDI administered objects" on page 1702
JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

JMS message types:

JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where the payload is the body of a message that holds the content.

JMS specifies only the interface and does not specify the implementation. This approach allows for vendor-specific implementation and transportation of messages while using a common interface.

The following table describes the six message types:

Message type	Description
Message	The base class. This message type is used for event notification, and does not have a payload.
BytesMessage	The payload is stored as an array of bytes. This message type is useful for exchanging data in a format that is native to the application, and when JMS is used as a transport between two systems, where the JMS client does not know the message payload type. Use this message type to transmit XML messages to ensure that the message is transmitted efficiently, and is not subject to unnecessary data conversion.
TextMessage	Data is stored as a string. This message type is useful for exchanging simple text messages.
StreamMessage	A Stream message is a sequence of primitive Java types. The message object tracks the order and the types of these primitives within the stream. Formal conversion rules apply; for example, an exception is thrown if a JMS application tries to read a double value as a short value. Refer to the Java Message Service Specification, version 1.1 for a full list of the conversion rules. `21ABCDEFGH32.345` is an example of a StreamMessage payload. It consists of the following three fields: • An Integer, `21` • A String, `ABCDEFGH` • A Float, `32.345` If the data structure is unknown, the generic method `readObject()` can be used to return the next object in the stream. If the structure of the data is known, the JMS client can be specific about the type of object being accessed.

Message type	Description
MapMessage	The payload of a MapMessage is stored as a set of name-value pairs. The name is defined as a string and the value is typed. The MapMessage is useful for delivering keyed data that can change from one message to the next. `NumberOfCopies:5` is an example of a MapMessage payload, where `NumberOfCopies` is the key and `5` is the value. Data can be accessed by using `getMapNames()`, which returns a Java Enumeration object. It is possible to iterate through the MapMessage by using `hasMoreElements()` to retrieve the mapped name-value pairs.
ObjectMessage	The Object message carries a serializable Java Object as its payload. It is useful for exchanging Java objects.

Related reference:

"JMS message structure" on page 1688
JMS messages have a defined structure that includes headers and payloads.

"Representation of messages in the JMS Transport"
Messages that are sent in the JMS Transport are represented by the JMS Transport message tree.

"JMS message as input" on page 1693
The JMS message is a Java object, and therefore you cannot parse the message as a bit stream. When the message is received, the header data, property data, and payload data are extracted by using the JMS API.

"JMS message for output" on page 1700
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

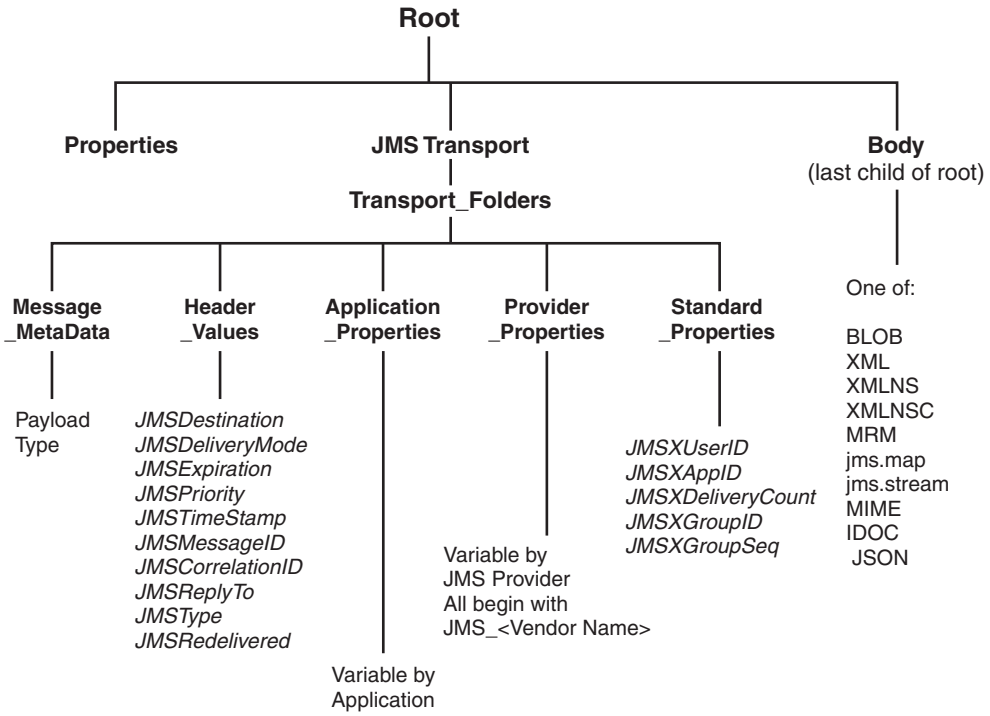
JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

Representation of messages in the JMS Transport:

Messages that are sent in the JMS Transport are represented by the JMS Transport message tree.

The following figure depicts the JMS message tree that is propagated from the JMSInput node and can be propagated to the JMSOutput and JMSReply nodes. The JMSOutput and JMSReply nodes populate details of the JMS message that is sent to the LocalEnvironment WrittenDestination folder, as described in "JMSOutput node" on page 4549.



JMSTransport

- *Header_Values* subfolder:

  This subfolder is mandatory and is always created.

- Properties subfolders:

  JMS message properties are optional; if they are present in the message, they are stored in the appropriate properties subfolder.

- *Message_MetaData* subfolder:

  This subfolder is included to preserve the payload type of the JMS message. The folder is used by the JMSOutput node when it creates a JMS message. The payload type can be one of the values shown in the following table.

Message type	**Payload values**
Base JMS message with no payload	jms_none
TextMessage	jms_text
BytesMessage	jms_bytes
MapMessage	jms_map
StreamMessage	jms_stream
ObjectMessage	jms_object

Body

The message payload is stored in the body folder, which is the last child of Root. The payload is transferred by using one of the following message domain parsers:

- XML
- XMLNS
- XMLNSC

- BLOB
- JMSMap
- JMSStream
- MRM
- MIME
- IDOC
- JSON

Related concepts:

"Simplified JMS message representation" on page 1683
The JMSInput node receives an input message as a Java object, and not as a bit stream wire format (as is the case with an MQInput node). The message does not populate an MQMD and RFH2 header, but instead populates a new message tree that represents a JMS message in a more native way.

When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

"JMSInput node" on page 4532
Use the JMSInput node to receive messages from JMS destinations. JMS destinations are accessed through a connection to a JMS provider.

JMS input message header and property data:

The JMSInput node obtains header and property data from JMS messages.

Header data

The JMSInput node extracts header data from messages by using JMS API methods. Header data is stored as name-value pairs in the *Header_Values* folder. The API methods return the value; for example, to get the value for the header field *JMSTimestamp*, the JMSInput node uses the `getJMSTimestamp( )` method. A similar method is provided for each of the following fixed header fields:

- JMSDestination
- JMSDeliveryMode
- JMSExpiration
- JMSPriority
- JMSTimeStamp
- JMSMessageID
- JMSCorrelationID
- JMSReplyTo
- JMSType
- JMSRedelivered

Property data

In a similar way to how the header data is obtained, the JMSInput node extracts property data from messages by using JMS API methods. Property data is stored as name-value pairs in the properties folders. The API method returns a value for every property name with which it is supplied.

XML representation of header and property data

The JMSInput node uses the header and property data to create an XML representation of the JMSTransport folders. The node passes the XML data to the JMSTransport parser as a byte array. The byte array is then used to populate or to refresh the elements in the message tree.

Preservation of Java type

A scheme is not required to preserve knowledge of the Java type because the header value Java types are fixed and known. The JMS message properties are optional, therefore a scheme is required to preserve the Java type of the property values. The scheme used is that which is implemented by the WebSphere MQ JMS client and the Real-timeInput node.

Java type information is represented as a metadata in the form of a keyword `dt='DataType'` where *Datatype* is a string. The Java type is passed in the XML as part of the element name `<ElementName dt='DataType'>Value</ElementName>`. *Datatype* can be any of the following values:

Datatype value	Definition
String	Any sequence of characters, excluding `<` and `&`
Boolean	The character `0` or `1`, where 1 is equal to "true"
bin.hex	Hexadecimal digits representing octets
I1	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -128 to 127 inclusive.
I2	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -32768 to 32767 inclusive.
I4	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -2147483648 to 2147483647 inclusive.
I8	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the range -9223372036854775808 to 9223372036854775807 inclusive.
int	A number, expressed by using the digits 0..9, with optional sign (no fractions or exponent). The value must lie in the same range as the datatype value`I8`. This number can be used in place of one of the `I*` types if the sender does not want to associate a particular precision with the property.
R4	A floating point number, expressed by using the digits 0..9, optional sign, optional fractional digits, optional exponent. Magnitude <= 3.40282347E+38, and>= 1.175E-37
R8	A floating point number, expressed by using the digits 0..9, optional sign, optional fractional digits, optional exponent. Magnitude <= 1.7976931348623E+308, and>= 2.225E-307

"JMS message for output" on page 1700
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

"Real-timeInput node" on page 4646
The Real-timeInput node, available in earlier versions of WebSphere Message Broker, is not supported in WebSphere Message Broker Version 7.0. See for information about migrating your message flows from WebSphere Message Broker to WebSphere Message Broker Version 7.0.

JMS Message payload:

How payload is extracted from the JMS message for each of the JMS Message types.

The payload for some of the JMS message types can be extracted as a whole from the message object by using the JMS API. The payload is passed as a bit stream to a broker parser. This is true for the following message types:

- BytesMessage
- TextMessage
- ObjectMessage

  Additional processing is required to deal with the ObjectMessage payload because the JMS ObjectMessage payload is a serialized Java Object.

  The JMSInput node obtains the payload by calling `getObject( )` on the message. `getObject( )` returns a de-serialized object of the original class. This class definition must be made available to the JMSInput node, and you should ensure that it is accessible through the broker's Java class path. (The class path is defined in the mqsiprofile batch file, which is in the broker's executable directory; for example, on Windows, this is `mqsiprofile.cmd` in the *`install_dir`*`/bin` directory.) The JMSInput node invokes the BLOB parser, which creates the message body by using a bit stream that is created from the object.

  The Java Object can be subsequently re-serialized in a JavaCompute node or a user-defined extension, and is updated by using its method calls.

The payload for MapMessage and StreamMessage can be extracted only as individual elements and must be reformatted by the JMSInput node before it can be used to create the message body.

- **MapMessage payload**

  The JMSMap domain is a synonym for the broker XML parser, which expects a stream of XML data. MapMessage payload data however, is extracted as sets of name-value pairs from the message object. The JMS API is used to obtain the name-value pairs.

The JMSInput node appends each name-value pair to a bit stream as an XML element and value, and preserves the type of the value by using the `dt=` attribute.

The following example shows the XML that is generated by the JMSInput node for the MapMessage payload:

```
<map>
    <Item_8_of_10_Char dt='char'>A</Item_8_of_10_Char>
     <Item_5_of_10_Double dt='r8'>999999.0</Item_5_of_10_Double>
     <Item_10_of_10_String>Last Map Item</Item_10_of_10_String>
     <Item_9_of_10_Boolean dt='boolean'>0</Item_9_of_10_Boolean>
     <Item_2_of_10_Integrer dt='i4'>999</Item_2_of_10_Integrer>
     <Item_3_of_10_Short dt='i2'>9999</Item_3_of_10_Short>
     <Item_7_of_10_Byte dt='i1'>9</Item_7_of_10_Byte>
     <Item_6_of_10_Float dt='r4'>2.24</Item_6_of_10_Float>
     <Item_1_of_10_String>P2P Map Msg Number:1</Item_1_of_10_String>
     <Item_4_of_10_Long dt='i8'>99999</Item_4_of_10_Long>
          </map>
```

In this example, the message contains 10 fields. The field names have been generated by a JMS Client application, and take the form `item_n_of_x_t`, where:

- `n` is the sequence number in which the item was added to the message,
- `x` is the total number of items in the map,
- `t` is the type of the value.

The map data is not returned from the JMS API the order in which it was received.

- **StreamMessage payload**

  The StreamMessage payload data is a sequence of fields, where each field has a specific type. The fields do not have associated names and so a default element name `elt` is used to generate the XML elements. Similar to the MapMessage, the JMS API allows for fields only to be retrieved individually. The JMSInput node extracts fields from the JMS message and appends each to a bit stream in XML format.

  The following is an example of the XML that is generated by the JMSInput node for the StreamMessage payload:

```
<stream>
     <elt>P2P Stream Message  Number :7</elt>
     <elt dt='i4'>999</elt>
     <elt dt='i2'>9999</elt>
     <elt dt='i8'>99999</elt>
     <elt dt='r8'>999999.0</elt>
     <elt dt='r4'>2.24</elt>
     <elt dt='i1'>9</elt>
     <elt dt='char'>A</elt>
     <elt dt='boolean'>0</elt>
     <elt>Last Stream Item</elt>
</stream>
```

  In this example, 10 typed values are added to the StreamMessage by a JMS client application.

Related concepts:

"JMS parsers and domains" on page 1116
The JMSMap and JMSStream domains can be used for modeling messages that are produced by the implementations of the Java Messaging Service standard.

Related reference:

"JMS message structure" on page 1688
JMS messages have a defined structure that includes headers and payloads.

"JMS message types" on page 1690
JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where the payload is the body of a message that holds the content.

"Representation of messages in the JMS Transport" on page 1691
Messages that are sent in the JMS Transport are represented by the JMS Transport message tree.

"JMS input message header and property data" on page 1694
The JMSInput node obtains header and property data from JMS messages.

"JMS message payload and appropriate parser"
Configure the JMSInput node properties to specify the message domain that will be used to parse the JMS message payload.

"JMS message for output" on page 1700
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

JMS message payload and appropriate parser:

Configure the JMSInput node properties to specify the message domain that will be used to parse the JMS message payload.

When the JMSInput node creates a message tree from the JMS message payload, the appropriate message domain for that payload must be used. Therefore, the JMSInput node must know the type of JMS message that it expects to receive. The JMSInput node extracts the payload from the JMS message using the appropriate JMS API, then passes the payload data to the parser for the domain. The parser creates the body portion of the message tree.

The message domain is derived according to the following criteria and in the following order of precedence:

1. "The Message domain property is set to a specific domain"
2. "The Message domain property is left blank (default) and the JMSType header field from the JMS input message is used to indicate the domain" on page 1699
3. " The Message Domain property is left blank (default) and the JMSType header field from the JMS input message is also left blank" on page 1699

The Message domain property is set to a specific domain

In this case, the node expects to receive only the allowed JMS message types for that domain, as shown by the following table:

	Valid JMS message types				
Message domain	**BytesMessage**	**TextMessage**	**MapMessage**	**StreamMessage**	**ObjectMessage**
BLOB	•	•			•
XMLNS		•			
XMLNSC		•			
MRM	•	•			
JMSMap			•		
JMSStream				•	
MIME	•	•			

Message domain	Valid JMS message types				
	BytesMessage	**TextMessage**	**MapMessage**	**StreamMessage**	**ObjectMessage**
IDOC	•	•			
XML		•			

- If the JMSInput node receives a JMS message type that is not valid for the message domain that is configured in the JMSInput node, the node issues a warning and backs out the message either to the source JMS provider destination, or to the backout destination.
- If you specify the MRM domain, you must also specify the `Message set`, `Message type` and `Message format` node properties.
- If you specify the IDOC domain, you must also specify the `Message set` and `Message format` node properties.
- If you specify the XMLNSC domain, and you want to validate input messages, you must also specify the `Message set` node property.

The Message domain property is left blank (default) and the JMSType header field from the JMS input message is used to indicate the domain

The JMSType header field must be set according to the URI format shown in the following table. The domain in the `mcd:` string can be uppercase or lowercase.

JMSType	Message domain
`mcd://BLOB`	BLOB
`mcd://MRM/[set]/[type]/[?format=fmt]`	MRM
`mcd://XMLNS`	XMLNS
`mcd://XMLNSC/[set]`	XMLNSC
`mcd://IDOC/[set]/[?format=fmt]`	IDOC
`mcd://MIME`	MIME
`mcd://XML`	XML

- If the JMSInput node receives a JMS message type that is not valid for the message domain configured in the JMSType header, the node issues a warning and backs out the message either to the source JMS provider destination, or to the backout destination.
- If the JMSType field does not conform to this URI format, the message is handled in the BLOB domain.
- For details of the `[type]` syntax, refer to “Specifying namespaces in the Message Type property” on page 1208.
- If the XMLNSC domain is specified, use `[set]` only if you want to validate input messages.

The Message Domain property is left blank (default) and the JMSType header field from the JMS input message is also left blank

The message domain is set according to the JMS message Java class as follows:

JMS message type	Message domain
TextMessage	XML
BytesMessage	BLOB

JMS message type	Message domain
MapMessage	JMSMap
StreamMessage	JMSStream
ObjectMessage	BLOB

Related concepts:

"JMS Message payload" on page 1696
How payload is extracted from the JMS message for each of the JMS Message types.

"JMS message for output"
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

JMS message for output:

When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

The node extracts the *Message_MetaData* and obtains the payload type information to identify which JMS message type to create for output. If the *Message_MetaData* folder is not present, the output node creates a BytesMessage by default.

Header data

The JMSOutput node extracts the JMS header data from the XML string, and uses this data to populate the values for the JMS header fields in the message.

Property data

The JMSOutput node extracts the property values from the XML string. The XML elements contain type information that identifies which Java Object type to create for each property value.

Message payload

The message payload is obtained from the JMS message as a bit stream. For TextMessage and BytesMessage payloads, the bit stream can be passed to the JMS API directly to create the appropriate payload.

For MapMessage and StreamMessage payloads, the individual elements must be extracted from the XML bit stream. The output node calls the appropriate JMS API method to create the map or stream fields in the message.

For an ObjectMessage payload, the JMSOutput node reserializes the bit stream payload by using the object class. The object class must be available in the Java class path for the broker. The class path is defined in the **mqsiprofile** batch file, which is in the directory that contains the executable files for the broker; for example, on Windows, the file is `mqsiprofile.cmd` in the *install_dir*`/bin` directory.

Sending JMS messages

The JMSOutput node generates and supports:

Sending a datagram message
A message with sufficient information to reach its destination, but without an expectation of there being a response as defined in the node attributes.

Sending a Reply message
The message is treated as a reply as defined by the JMSReplyTo property value.

Sending a Request message
The JMSOutput node sends a message to a defined JMS destination with the expectation of a response from the recipient.

See "Using the Message Destination Mode" on page 4551 for more information about how you perform these tasks.

Message publication

The message is published to the JMS destination that has been specified as a property of the JMSOutput node. However, if the JMSReplyTo header field is set in the JMS message, the JMSOutput node treats the message as a reply to a previous request, and publishes the message to the JMS destination of the previous request.

Related reference:

"JMS message structure" on page 1688

The JMS message is a Java object, and therefore you cannot parse the message as a bit stream. When the message is received, the header data, property data, and payload data are extracted by using the JMS API.

"JNDI administered objects"
JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

JNDI administered objects:

JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

JMS clients use JNDI to browse a naming service to obtain references to administered objects. *Administered objects* are JMS connection factory and JMS destination objects, where JMS destination objects are topics and queues. Administered objects are created and configured by a system administrator.

To create and configure JNDI administered objects, refer to the JMS provider documentation. If you are using the WebSphere MQ JMS provider, see the sample JMSAdmin definitions file that is included with WebSphere MQ and refer to the *Using Java* section in the WebSphere MQ Version 7 Information Center online.

Location of JNDI administered objects

JNDI administered objects are stored in the bindings. This storage can be either file system based or based on LDAP (Lightweight Directory Access Protocol). LDAP is a software protocol that enables everyone to locate organizations, individuals, and other resources; for example, locating files and devices in a network, either on the public Internet or on a corporate intranet.

LDAP is part of X.500, which is a standard for directory services in a network.

Naming service

A naming service associates names with distributed objects so that the administered objects are located by using names and not complex network addresses. JNDI provides an abstraction that hides the specifics of the naming service, which makes client applications more portable.

A JMS client specifies a *JNDI InitialContext* to obtain a JNDI connection to the JMS messaging server. The InitialContext is the starting point in any JNDI lookup and acts like the root of a file system. The JMS directory service that is being used determines the properties that are used to create an InitialContext.

WebSphere MQ Version 7 Information Center online

JMS message selector:

A message selector allows a JMS consumer to be more selective about the messages that it receives from a particular topic or queue.

A message selector uses message properties and headers as criteria in conditional expressions. These expressions use Boolean logic to declare which messages are delivered to a client, such as the JMSInput node.

The following table demonstrates the construction of a message selector. It comprises an identifier, such as the *JMSPriority* header, or an application controlled property *myProperty1*. The selector string must specify an operator followed by a literal.

Element	Valid values
Identifiers	• Property or header field reference (such as *JMSPriority*, *myProperty1*) • The following values are not possible: NULL, TRUE, FALSE, NOT, AND, OR, BETWEEN, LIKE, IN, IS
Operators	AND, OR, LIKE, BETWEEN, =, <>, <,>, <=, >=, IS NULL, IS NOT NULL
Literals	• The two Boolean literals, TRUE and FALSE • Exact number literals that have no decimal point; for example, +25, -399, 40 • Approximate number literals. These literals can use scientific notation or decimal; for example, -21.4E4, 5E2, +34.4928

The JMSInput node provides a free format string *PropertySelector*, to specify selectors that filter or include application properties. The node also has properties for specific header properties, where the identifier is implicit and is generated by the node. For the header selectors, the operator and literal part of the string must be specified.

If more than one selector is specified the node generates a composite selector string, where the individual selector strings are concatenated with the `AND` operator, and each selector string part is wrapped with parentheses.

The following are examples for each of the selector properties:

Selector property	Description
PropertySelector	`OrderValue> 100.00` This string is used directly as shown.
TimeStamp	`BETWEEN 1057576423231 AND 10575788993265` Messages that are put between these two Java times only (where Java time is milliseconds since 01 Jan 1970) is delivered to the JMSInput node. In this case, the string generated is prefixed with the identifier *JMSTimestamp*.
Delivery Mode	`PERSISTENT` This setting means that only messages marked by the sender as being `PERSISTENT` should be delivered to the JMSInput node. In this case, the string that is generated is prefixed with the identifier *JMSDeliveryMode*.
Priority	`>= 5 AND <= 8` This setting means that only messages marked by the sender as having a priority `5`, `6`, `7`, or `8` are delivered to the JMSInput node. In this case, the string generated is prefixed with the identifier *JMSPriority*.
Message ID	`> WMBRK123456` This setting returns messages with a Message ID that is greater than the value specified. In this case, the string generated is prefixed with the identifier *JMSMessageID*.
Redelivered	`FALSE` This setting means that messages that have not been redelivered are received by the node. In this case, the string generated is prefixed with the identifier *JMSRedelivered*.
Correlation ID	`= WMBRKABCDEFG` This setting returns messages whose Correlation ID is equal to the value `WMBRKBABCDEFG`. In this case, the string generated is prefixed with the identifier *JMSCorrelationID*.

Related concepts:

"JMS Transactionality" on page 1705
JMS destinations that supply messages to an input node, or receive messages from an output node, can be sync-point coordinated as part of a message flow global transaction.

Related reference:

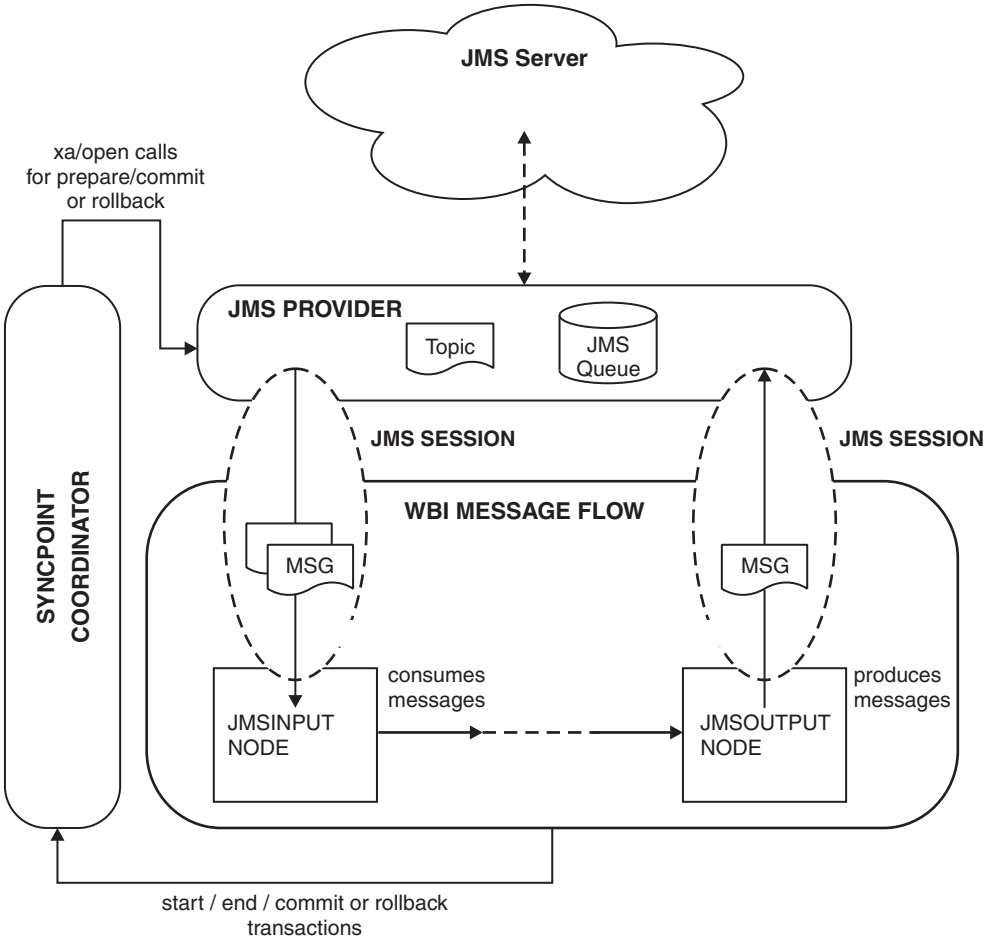
"JMS properties for application communication models" on page 1708
JMS clients can operate with both publish/subscribe and point-to-point messages. The publish/subscribe and point-to-point application communication models use virtual channels called *destinations*. In the publish/subscribe model, the destinations are *topics*. For the point-to-point model, the destinations are known as *queues*.

"JMS message domain properties" on page 1707
The JMSInput node can receive message payloads that correspond to all of the JMS message types that are specified in the JMS Specification, version 1.1.

JMS Transactionality:

JMS destinations that supply messages to an input node, or receive messages from an output node, can be sync-point coordinated as part of a message flow global transaction.

Transactions involving the sync-point coordinator



In this diagram, messages are consumed from a queue by a JMSInput node, and are produced to a JMS queue by a JMSOutput node. The nodes are connected to, and are in session with, a JMS provider. Any message flow input node can inform the external sync-point coordinator when a message flow transaction starts and ends, and whether any resources that have been affected by the flow should be committed or rolled back.

The sync-point coordinator sends XA/Open compliant requests to all participating resource managers to inform them to prepare. Any changes are either committed or rolled back. Resource managers, for example, WebSphere MQ, DB2 and any XA compliant JMS provider can participate in a global transaction.

The external sync-point coordinator is WebSphere MQ on operating systems other than z/OS, and RRS (Resource Recovery Services) on z/OS.

On z/OS, the only JMS provider that is supported is the IBM WebSphere MQ Java Client, and the only transport mode supported for that client is BIND mode.

Nodes that use JMS transport, such as the JMS and SOAP nodes, can participate in a global transaction only if the JMS provider to which they connect supports the XA/Open interface through the JMS `XAResource` Class. An example JMS provider is the WebSphere MQ Java Client.

You can specify a generic connection factory (`recoverXAQCF`) for recovery of XA coordinated transactions.

In-doubt transactions

In-doubt transactions can occur when a resource manager does not reply to a call from the sync-point manager, where the call is to commit or to rollback resources. During start up of the broker's WebSphere MQ queue manager, an initial recovery step is taken to ensure that any in-doubt transactions are resolved before the broker message flows start to process new input. A JMS provider that participates in broker global transactions is included in this recovery step.

On operating systems other than z/OS, WebSphere MQ requires an administration task to be carried out before deployment. This task registers a broker component, which is a shared library, with the queue manager by referring the shared library to a switch file.

When the broker's WebSphere MQ queue manager starts up, it loads the switch file. The switch file forwards XA/Open transaction calls from the sync-point coordinator to the JMS Provider. This ensures that the JMS resources that participate in the transaction can be coordinated in synchronization with other resource managers that are involved in the same transaction.

Additional configuration is required to enable global transaction support for the nodes using JMS transport; see "Configuring JMS and SOAP nodes to support global transactions" on page 1716.

Related tasks:

"Configuring JMS and SOAP nodes to support global transactions" on page 1716
To include nodes that use JMS transport, such as the JMS and SOAP nodes, in globally coordinated transactions, you must complete additional configuration.

Related reference:

"JMS message types" on page 1690
JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where the payload is the body of a message that holds the content.

"JMS message structure" on page 1688
JMS messages have a defined structure that includes headers and payloads.

"JNDI administered objects" on page 1702
JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

"JMSInput node" on page 4532
Use the JMSInput node to receive messages from JMS destinations. JMS destinations are accessed through a connection to a JMS provider.

"JMSOutput node" on page 4549
Use the JMSOutput node to send messages to JMS destinations.

"SOAPInput node" on page 4795
Use the SOAPInput node to process client SOAP messages, so that the broker operates as a SOAP Web Services provider.

"SOAPRequest node" on page 4828
Use the SOAPRequest node to send a SOAP request to the remote Web service.

"SOAPAsyncRequest node" on page 4750
Use the SOAPAsyncRequest node with the SOAPAsyncResponse node to construct a pair of message flows that call a Web service asynchronously.

JMS message domain properties:

The JMSInput node can receive message payloads that correspond to all of the JMS message types that are specified in the JMS Specification, version 1.1.

The JMS Specification is defined in Java Message Service Specification, version 1.1. For more information, see "JMS message types" on page 1690.

Set the JMSInput node properties to specify how the message payload is to be parsed. For more information, see "JMSInput node" on page 4532 and "JMS message payload and appropriate parser" on page 1698.

The JMSOutput node has no message domain properties.

Related concepts:

"JMS Transactionality" on page 1705
JMS destinations that supply messages to an input node, or receive messages from an output node, can be sync-point coordinated as part of a message flow global transaction.

"Specifying namespaces in the Message Type property" on page 1208
When using the MRM domain, the *Message Type* property is used to specify the name of the message.

"Multipart messages" on page 1191
A *multipart message* contains one or more other messages within its structure. The contained message is sometimes referred to as an *embedded message*.

"JMS properties for application communication models" on page 1708
JMS clients can operate with both publish/subscribe and point-to-point messages. The publish/subscribe and point-to-point application communication models use virtual channels called *destinations*. In the publish/subscribe model, the destinations are *topics*. For the point-to-point model, the destinations are known as *queues*.

"JMS message types" on page 1690
JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where the payload is the body of a message that holds the content.

"JMSInput node" on page 4532
Use the JMSInput node to receive messages from JMS destinations. JMS destinations are accessed through a connection to a JMS provider.

"JMS message selector" on page 1703
A message selector allows a JMS consumer to be more selective about the messages that it receives from a particular topic or queue.

"JMS message payload and appropriate parser" on page 1698
Configure the JMSInput node properties to specify the message domain that will be used to parse the JMS message payload.

JMS properties for application communication models:

JMS clients can operate with both publish/subscribe and point-to-point messages. The publish/subscribe and point-to-point application communication models use virtual channels called *destinations*. In the publish/subscribe model, the destinations are *topics*. For the point-to-point model, the destinations are known as *queues*.

The following application communication model properties can be configured for JMSInput and JMSOutput nodes:

Property	Description
Connection Factory Name	A string name that is passed to JNDI to look up the administered connection factory object. The connection factory object is used to create a connection to the JMS destination. • For a client operating as a publish/subscribe client, the connection factory name is for a TopicConnectionFactory. • For a client operating as a point-to-point client, the connection factory name is for a QueueConnectionFactory.
Subscription Topic	The string name that is passed to JNDI to look up the JMS topic destination. The topic is used to create a JMS session when the node is being used to process publish/subscribe messages.
Durable Subscription ID	This is a JMSInput node property only. It is a string identifier that is specified if the node is to subscribe to a durable subscription topic. A durable subscription is one that outlasts the client's connection to a message server. When a durable subscriber is disconnected from the server, the server stores messages that are published. Therefore, when the durable subscriber reconnects, the message server sends all the unexpired messages. Durable subscriptions cannot be unsubscribed from a message flow. A separate administration task unsubscribes a previously registered durable subscription. Some JMS providers supply an administration tool to perform this action.
Source Queue	The string name that is passed to JNDI to look up the JMS queue destination. The queue is used to create a JMS session when the node is being used to process point-to-point messages.

The `Subscription Topic` and `Source Queue` properties are mutually exclusive because they configure the node to work with either the publish/subscribe message model or the point-to-point message model.

A `Durable subscription ID` is not valid without a `Subscriber Topic` property.

A message selector allows a JMS consumer to be more selective about the messages that it receives from a particular topic or queue.

Working with JMS

Learn about the concepts and tasks involved in configuring message flows to support JMS messages.

Before you begin

Before you start: Read the following topics for an overview of the concepts related to processing JMS messages

- "WebSphere Broker JMS Transport" on page 1681
- "Java Message Service (JMS) API" on page 1680
- "JMS Transactionality" on page 1705
- "JMS message selector" on page 1703
- "JMS properties for application communication models" on page 1708
- "JMS message domain properties" on page 1707

About this task

The following areas are included:

- "Configuring resources for processing JMS messages" on page 1714
- "Troubleshooting JMS nodes" on page 1730

Connection to different JMS providers:

The JMSInput and JMSOutput nodes are compatible with all JMS providers that conform to the Java Message Service Specification, version 1.1.

If you want these nodes to participate in coordinated transactions, the JMS provider must support the XAResource interface, as defined in the Java Message Service Specification, version 1.1.

JBoss exception handling

If you use JBoss from a JMSInput node, set the `jmsAsyncExceptionHandling` property to true on the JMSProviders configurable service so that the broker can detect a failure in the JMS connection. This property is set to true by default on the provided JBoss configurable service definition.

Related concepts:

"JMS message transformation" on page 1684
The JMSInput and JMSOutput nodes expect JMS messages, and therefore expect a native JMS message tree representation.

Related tasks:

"Configuring JMS nodes to communicate with WebSphere Application Server service integration bus" on page 1710
You can configure a stand-alone JMS client and JMS nodes to communicate with service integration bus (SIBus) in WebSphere Application Server Version 6 and Version 7.

"Configuring JMS nodes to communicate with Oracle AQ" on page 1712
You can configure the JMS nodes to communicate with Oracle AQ (Oracle 11g and above). This communication requires an LDAP 3 compliant server to hold definitions for JNDI lookup by the JMS nodes.

Related reference:

"JMS message types" on page 1690
JMS defines six message interface types; a base message type and five subtypes. The message types are defined according to the type of the message *payload*, where

the payload is the body of a message that holds the content.

"JMS message structure" on page 1688
JMS messages have a defined structure that includes headers and payloads.

"JNDI administered objects" on page 1702
JNDI (Java Naming and Directory Interface) is a standard Java extension that provides a uniform API for accessing various directory and naming services.

"JMS message for output" on page 1700
When the JMSOutput node receives a JMS message, it calls the JMSTransport parser to return an XML bit stream containing the JMSTransport section of the message, so that it can be examined and processed.

"JMSInput node" on page 4532
Use the JMSInput node to receive messages from JMS destinations. JMS destinations are accessed through a connection to a JMS provider.

Configuring JMS nodes to communicate with WebSphere Application Server service integration bus:

You can configure a stand-alone JMS client and JMS nodes to communicate with service integration bus (SIBus) in WebSphere Application Server Version 6 and Version 7.

About this task

Procedure

1. Complete the following steps in WebSphere Application Server. For more information, see the WebSphere Application Server documentation.
   a. Create a messaging bus.
   b. Add a bus member.
   c. Restart the WebSphere Application Server server.
   d. Create a queue destination on the bus.
   e. Create a JMS queue on the default messaging provider.
   f. Create a Queue Connection Factory (QCF) on the default messaging provider.

      Ensure that the messaging provider URL is specified in the QCF definition, particularly if the JMS client and messaging bus are on different computers. The provider endpoint URL must have the following format:

      ```
      bus_member_host_name:7276:BootstrapBasicMessaging
      ```

      where 7276 is the default SIB endpoint address. Do not use 127.0.0.1 or localhost for the bus member host name.
2. Test the WebSphere Application Server configuration by using a stand-alone JMS client and completing the following steps.
   a. Put the following two JAR files in your class path: `com.ibm.ws.sib.client.thin.jms_7.0.0.jar` and `com.ibm.ws.ejb.thinclient_7.0.0.jar`.

      Copy these JAR files from the WebSphere Application Server Version 7 installation directory under the runtimes subdirectory. If you are using a non-IBM JRE, you also need the `com.ibm.ws.orb_7.0.0.jar` file.
   b. Ensure that the provider URL is set to `iiop://WAS_server_host_name:boot_strap_port`.
   c. Ensure that you specify the correct boot strap port.

d. Ensure that the Queue Connection Factory and JMS Queue properties are set to the values defined in the WebSphere Application Server configuration.
e. Compile the JMS client code.
f. Run the JMS client with the following IBM ORB debug parameters turned on.

```
java -Dcom.ibm.CORBA.Debug=true -Dcom.ibm.CORBA.CommTrace=true -Dcom.ibm.CORBA.D ebug.Outpu
```

This command produces CORBA debug output in the `client.log` file in the same directory.

3. Complete the following steps in WebSphere Message Broker.
   a. Stop the broker.
   b. Create a directory (for example, `c:\WebSphere_WAS_Client`) and copy the following two JAR files from WebSphere Application Server Version 7 Thin Client for JMS.
      - `com.ibm.ws.sib.client.thin.jms_7.0.0.jar`
      - `com.ibm.ws.ejb.thinclient_7.0.0.jar`

      Alternatively, you can copy these files from the WebSphere Application Server installation directory *WAS home*`/runtimes`.
   c. Configure the JMS service in WebSphere Message Broker by using the **mqsichangeproperties** command. The JMS provider WebSphere_WAS_Client exists; therefore you can change the client JAR file path for that provider.

```
mqsichangeproperties broker_name -c JMSProviders -o WebSphere_WAS_Client -n jarsURL -v WAS_
```

   d. Configure the JMSInput node as shown in the following example. For more information about these properties, see "JMSInput node" on page 4532.
      - Specify the name of the JMS provider; for example, Client for WebSphere Application Server.
      - Specify the initial context factory; for example, `com.ibm.websphere.naming.WsnInitialContextFactory`.
      - Specify the location of the JNDI bindings in the format `iiop://`*WAS_server_host_name*`:`*WAS_server_boot_strap_port*.
      - Set the connection factory name to QCF.
   e. Ensure that the JMS connection has been established before the message flow starts by using the Windows Event Viewer.

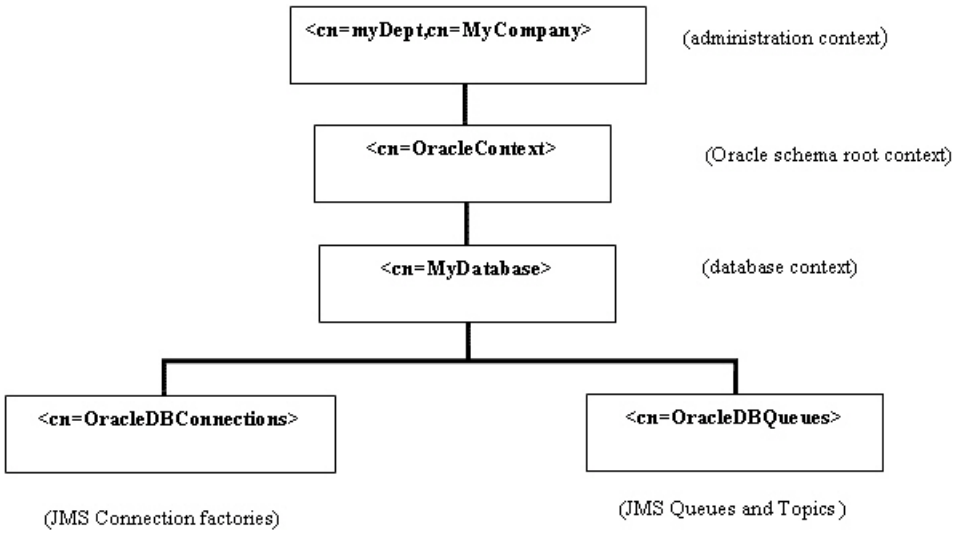
Configuring JMS nodes to communicate with Oracle AQ:

You can configure the JMS nodes to communicate with Oracle AQ (Oracle 11g and above). This communication requires an LDAP 3 compliant server to hold definitions for JNDI lookup by the JMS nodes.

About this task

Procedure

1. Complete the following steps in Oracle AQ, referring to Oracle documentation for the specific details of each step.
   a. You must install the Oracle Internet Directory Server (OID) to host the JNDI administered objects for Oracle AQ.
      - You can configure Oracle AQ to register JMS connection factories and destinations (queues and topics) automatically with the OID server when these JMS connection factories and destinations are created in the Oracle database.
   b. Create the database tables to hold the JMS queues and topics.
   c. Create the JMS queues and topics and associate them with the tables created in step 1b.
2. Add definitions for the JMS connections to the LDAP server to permit the broker JMS nodes to complete JND lookup and connect to the Oracle AQ server.
   a. Register JMS connection factories with the OID LDAP server by using the administrative tools provided by Oracle.
   b. The following diagram describes the shape of the directory tree for JNDI administered objects for Oracle AQ.



3. Copy the Oracle AQ JMS client JAR files to a local directory that is accessible by the broker.
   - The `aqapi.jar` file is found on the Oracle AQ server in directory *oracle_install_path*`/rdbms/jlib`.
   - The `ojdbc5.jar` file is found on the Oracle AQ server in directory *oracle_install_path*`/jdbc/lib`.
   - The orai18n.jar found on the Oracle AQ server in directory *oracle_install_path*`/jlib`.
4. Modify the JMSProviders configurable service for Oracle AQ; for example:

```
mqsichangeproperties MyBroker –c JMSProviders –o Oracle_AQ
   -n jarsURL,
      InitialContextFactory,
      jndiBindingsLocation
   -v location of the Oracle Jars,
      com.sun.jndi.ldap.LdapCtxFactory,
      ldap://LDAP_server_address:LDAP_listener_port
```

5. Configure the properties on the JMS Connection tab of the JMS node (input, output, or reply node) as shown in the following example. For more information about these properties, see "JMSInput node" on page 4532.
   - Set the `JMS provider name` property to `Oracle_AQ`.
   - Set the `Initial context factory` property; for example:

     ```
     com.sun.jndi.ldap.LdapCtxFactory
     ```

     For all nodes that refer to the JMSProviders configurable service, if this property is set on the configurable service, it overrides the property that is set on the node.
   - Set the `Location JNDI bindings` property; for example:

     ```
     ldap://LDAP_server_address:LDAP_listener_port
     ```

     For all nodes that refer to the JMSProviders configurable service, if this property is set on the configurable service, it overrides the property that is set on the node.
   - Set the `Connection factory name` property. This name must be the fully qualified path in the LDAP directory; for example:

     ```
     cn=QCF,cn=oracledbconnections,cn=ORCL,cn=OracleContext,
     ou=MyDept,o=MyCompany
     ```

     Where
     - cn=QCF is the JMS connection factory name.
     - cn=oracledbconnections is the branch for JMS connection factory definitions.
     - cn=ORCL is the Oracle AQ database name.
     - cn=OracleContext is the root of the Oracle RDBMS schema.
     - ou=MyDept, o=MyCompany is the installation-specific LDAP administrative context.
6. On the Basic tab, configure the JMS destinations (queue or topic) properties.
   - Set the `Source queue` property on the JMSInput node. This queue must be the fully qualified path in the LDAP directory; for example:

     ```
     cn=JMS.Queue,cn=oracleDBQueues,cn=ORCL,cn=OracleContext,
     ou=MyDept,o=MyCompany
     ```

     Where
     - cn=JMS.Queue is the JMS queue.
     - cn=oracleDBQueues is the branch for JMS queues and topic definitions.
     - cn=ORCL is the Oracle AQ database name.

- cn=OracleContext, is the root of the Oracle RDBMS schema.
- ou=MyDept, o=MyCompany is the installation-specific LDAP administrative context.

7. Before the message flow starts, ensure that the JMS connection has been established by using the Windows Event Viewer.

Configuring resources for processing JMS messages:

A number of nodes are provided in WebSphere Message Broker for processing and routing JMS messages. Follow the links in this topic to find out how to configure the JMS nodes and broker resources for processing JMS messages.

About this task

WebSphere Message Broker provides the following nodes for working with JMS messages:

JMSInput node
Use a JMSInput node if the messages are received from a JMS application.

JMSOutput node
Use a JMSOutput node if the messages are sent to a JMS destination.

JMSReply node
The JMSReply node has a similar function to the JMSOutput node, but the JMSReply node sends JMS messages only to the reply destination that is supplied in the JMSReplyTo header field of the JMS message tree. Use the JMSReply node to treat a JMS message that is produced from a message flow as a reply to a JMS input message, and when you have no other routing requirements.

JMSMQTransform node
Use the JMSMQTransform node to transform a message with a JMS

message tree into a message that has a tree structure that is compatible with the format of messages that are produced by the WebSphere MQ JMS provider.

The JMSMQTransform node can be used to send messages to existing message flows and to interoperate with WebSphere MQ JMS and WebSphere MQ Publish/Subscribe.

MQJMSTransform node
Use the MQJMSTransform node to receive messages that have a WebSphere MQ JMS provider message tree format, and transform them into a format that is compatible with messages that are to be sent to JMS destinations.

You can use the MQJMSTransform node to send messages to existing message flows and to interoperate with WebSphere MQ JMS and WebSphere MQ Publish/Subscribe.

JMSHeader node
Use a JMSHeader node to change JMS Header_Values properties, or add, modify, or delete JMS Application properties without programming.

SOAPInput node
Use a SOAPInput node for SOAP messages received from a JMS application.

SOAPReply node
The SOAPReply node sends SOAP messages using JMS transport only to the reply destination specified in the received message. Use the SOAPReply node to treat a JMS message that is produced from a message flow as a reply to a JMS input message.

SOAPRequest node
Use a SOAPRequest node to send a SOAP request to a remote Web service. This node is a synchronous request and response node, and blocks after sending the request until the response is received.

SOAPAsyncRequest and SOAPAsyncResponse nodes
Use a SOAPAsyncRequest node with a SOAPAsyncResponse node to construct a pair of message flows that call a Web service asynchronously.

To use JMS nodes in your message flows, there are additional configuration steps in the broker environment that you might need to complete. See the following topics for information about additional configuration tasks that you might need to complete:

- "Configuring JMS and SOAP nodes to support global transactions" on page 1716
- "Windows systems: modifying the queue manager authorization" on page 1723
- "Securing JMS connections and JNDI lookups" on page 1725

Configuring JMS and SOAP nodes to support global transactions:

To include nodes that use JMS transport, such as the JMS and SOAP nodes, in globally coordinated transactions, you must complete additional configuration.

About this task

If you require transaction coordination, choose a JMS provider that conforms to the Java Message Service Specification, version 1.1 and that supports the JMS XAResource API through the JMS session.

If the message designer has specified a non-XA-compliant provider, the non-transactional mode only is supported. In this case, you must set the Transaction mode property to None for all JMS and SOAP nodes that use JMS transport.

To configure the nodes:

Procedure

1. Switch to the Broker Application Development perspective.
2. Set the message flow property Coordinated Transaction to yes in the BAR file properties.
3. For each node that uses JMS transport that is required in the global transaction, set the Transaction mode property to Global in the message flow editor.
4. Create a Queue Connection Factory and use either the default name, *recoverXAQCF*, or supply your own name. See the JMSInput or JMSOutput node for further details about creating JNDI administered objects.
5. On distributed systems, you must set up a stanza for each JMS provider that you want to use, before deployment.

   The following table shows the JMS provider switch files that are provided on each operating system.

Platform	32-bit file	64-bit file
AIX		`libJMSSwitch.so`
HP-Itanium		`libJMSSwitch.so`
Linux on POWER		`libJMSSwitch.so`
Linux on IBM z Systems		`libJMSSwitch.so`
Linux on x86	`libJMSSwitch.so`	
Linux on x86-64		`libJMSSwitch.so`
Solaris on SPARC		`libJMSSwitch.so`
Solaris on x86-64		`libJMSSwitch.so`
Windows on x86	`JMSSwitch.dll`	
Windows on x86-64	`JMSSwitch32.dll`	`JMSSwitch.dll`

   Select the appropriate link for details of this task on the operating system, or systems, that your enterprise uses:

   - Linux UNIX Linux and UNIX systems
   - Windows Windows systems

     On Windows only, you must also modify the queue manager authorization, as described in "Windows systems: modifying the queue manager authorization" on page 1723.

   For further information, see the following topics:

   - "Configuring for coordinated transactions" on page 4535 in the JMSInput node topic
   - "Configuring for coordinated transactions" on page 4553 in the JMSOutput node topic

   z/OS On z/OS, the only JMS provider that is supported is the IBM WebSphere MQ Java Client, and the only transport mode supported for that client is BIND mode; no further configuration steps are required.

What to do next

The JMS provider might supply additional JAR files that are required for transactional support; for more informaiton, see the documentation that is supplied with the JMS provider. For example, on distributed systems, the WebSphere MQ JMS provider supplies an extra JAR file, `com.ibm.mqetclient.jar`.

You must add any additional JAR files to the broker `shared_classes` directory:

- Linux UNIX On Linux and UNIX: `var/mqsi/shared-classes`.
- Windows On Windows, `%ALLUSERSPROFILE%\Application Data\IBM\MQSI\shared-classes`, where `%ALLUSERSPROFILE%` is the environment variable that defines the system working directory. The default directory depends on the operating system:
  - On Windows XP and Windows Server 2003: `C:\Documents and Settings\All Users\Application Data\IBM\MQSI\shared-classes`
  - On Windows Vista and Windows Server 2008: `C:\ProgramData\IBM\MQSI\shared-classes`

  The value can vary for different computers.

For more information, see the section about making the JMS provider client available to the JMS nodes in "JMSInput node" on page 4532.

Optional: To secure the JMS connection factory, the JNDI bindings, or both, see "Securing JMS connections and JNDI lookups" on page 1725.

Use the SOAPAsyncRequest node with the SOAPAsyncResponse node to construct a pair of message flows that call a Web service asynchronously.

Linux and UNIX systems: configuring the queue manager to coordinate JMS resources:

Define a stanza in the broker's queue manager `qm.ini` file for each new JMS provider, where the JMS provider can be specified by a JMS node included in a message flow that is running on the broker.

About this task

The parameters that are defined in `XAOpenString` are comma delimited and positional. Represent missing optional parameters by a comma if you include other parameters later in the string.

The following stanza entry is an example that you can add when using WebSphere MQ Java as the JMS provider:

```
XAResourceManager:
    Name=WBIWMQJMS
    SwitchFile=/install_dir/lib/JMSSwitch.so
    XAOpenString=<Initial Context Factory>,
              <location of JNDI bindings>'
              <LDAP Principal>,
              <LDAP Credentials>,
              <Recovery Connection Factory Name>,
              <JMS Principal>,
              <JMS Credentials>
              ThreadOfControl=THREAD
```

where:

install_dir
Is the location of the WebSphere Message Broker installation. This value is mandatory where the LDAP parameters are omitted, but a user-defined Queue Connection Factory is specified for recovery.

<Initial Context Factory>
Is the Initial Context Factory identifier for the JMS provider; this value is required.

<Location of JNDI bindings>
Is either the file path to the bindings file, or the LDAP directory location of the JNDI administered objects that can be used to create an initial context factory for the JMS connection. When supplying the file path to the bindings file, do not include the file name. See the JMSInput or JMSOutput node for further details on creating the JNDI administered objects; this value is required.

<LDAP Principal>
Is an optional parameter used to specify the principal (user ID) that might be required when an LDAP database is used to hold the JNDI administered objects.

<LDAP Credentials>
Is an optional parameter used to specify the Credentials (password) that might be required if a password protected LDAP database is used to hold the JNDI administered objects.

<Recovery Connection Factory Name>
Is an optional parameter used to specify the name of a Queue Connection Factory object in the JNDI administered objects for recovery purposes, when the non default name is required.

<JMS Principal>
Is an optional parameter for the user ID required to connect to a JMS provider, using a secure JMS Connection Factory.

<JMS Credentials>
Is an optional parameter for the password required to connect to the same JMS provider in conjunction with the JMS principal.

Switch files are installed in the *install_dir* `/lib` directory. To simplify the contents of the `qm.ini` file, create a symbolic link to the switch file for the queue manager to retrieve from `/var/mqm/exits` (for 32-bit brokers) or `/var/mqm/exits64` (for 64-bit brokers). For example:

```
ln -s install_dir/lib/libJMSSwitch.so /var/mqm/exits/JMSSwitch

ln -s install_dir/lib/libJMSSwitch.so /var/mqm/exits64/JMSSwitch
```

If you create a link for both 32-bit and 64-bit switch files on a single computer, ensure that you specify the same name in `/exits` and in `/exits64`, as shown in the example.

The values for the Initial Context factory and Location of JNDI bindings in the stanza must match the values that you specified in the JMS or SOAP nodes in the message flows.

All LDAP parameters must match the values that you specified on the **mqsicreatebroker** or **mqsichangebroker** command.

The Recovery Factory Name must match a Queue Connection Factory name that is created in the JNDI administered objects. If you do not specify a name, a default factory called `recoverXAQCF` is used. In either case, this value must refer to a JNDI administered object that has already been created.

The JMS Principal and JMS Credentials must be configured together.

The following example shows the format of a stanza in the `qm.ini` file that describes a JMS provider for global transactions:

```
XAResourceManager:
    Name=XAJMS_PROVIDER1
    SwitchFile=/opt/var/mqsi/lib/JMSSwitch.so
    XAOpenString= com.sun.jndi.fscontext.RefFSContextFactory,
              /Bindings/JMSProvider1_Bindings_Directory,
              ,
              ,
              ,
              myJMSuser1,
              passwd
              ThreadOfControl=THREAD
```

where:

XAJMS_PROVIDER1
Is the user-defined name for the resource manager

/opt/var/mqsi
Is the <Installation Path>

com.sun.jndi.fscontext.RefFSContextFactory
Is the <Initial Context Factory>

/Bindings/JMSProvider1_Bindings_Directory
Is the location of the bindings

myJMSuser1
Is the <JMS Principal>

passwd
Is the password used in <JMS Credentials>

In this example, the optional fields `<LDAP Principal>`, `<LDAP Credentials>`, and `<Recovery Connection Factory Name>` are not required, therefore the positional comma delimiters only are configured in the `XAOpenString` stanza.

Windows systems: configuring the queue manager to coordinate JMS resources:

Use WebSphere MQ Explorer to configure the XA resource managers for the queue manager.

About this task

Complete the following steps:

Procedure

1. Open WebSphere MQ Explorer.
2. Select the queue manager for your broker and click **Properties**.
3. Select **XA resource managers** in the left pane and click **Add**.
4. Complete the fields to define a new resource manager:
   - **Name**: Enter the name of the resource manager; for example, WBIWMQJMS.
   - **SwitchFile**: On Windows on x86, enter the full path of the switch file; for example, *install_dir*\bin\JMSSwitch.dll. On Windows on x86-64, enter **JMSSwitch**.
   - **XAOpenString**: Enter the following values, which are comma delimited and positional. Represent missing optional parameters by a comma if you include other parameters later in the string.

     Initial Context Factory
     The Initial Context Factory identifier for the JMS provider; this value is required.

     Location of JNDI bindings
     Either the file path to the bindings file, or the LDAP directory location of the JNDI administered objects that can be used to create an initial context factory for the JMS connection. If you supply the file path to the bindings file, do not include the file name. See the JMSInput or JMSOutput node for further details about creating the JNDI administered objects; this value is required.

     LDAP Principal
     Optional: The principal (user ID) that might be required when an LDAP database is used to hold the JNDI administered objects.

     LDAP Credentials
     Optional: The credentials (password) that might be required if a password protected LDAP database is used to hold the JNDI administered objects.

     Recovery Connection Factory Name
     Optional: The name of a Queue Connection Factory object in the JNDI administered objects for recovery purposes, when the non default name is required.

     JMS Principal
     The user ID that is required to connect to a JMS provider, using a secure JMS Connection Factory.

     JMS Credentials
     The password that is required to connect to the same JMS provider in conjunction with the JMS principal.

     The values for the Initial Context factory and Location of JNDI bindings in the stanza must match the values that you specified in the JMS or SOAP nodes in the message flows.

     All LDAP parameters must match the values that you specified on the **mqsicreatebroker** or **mqsichangebroker** command.

     The Recovery Factory Name must match a Queue Connection Factory name that is created in the JNDI administered objects. If you do not specify a name, a default factory called `recoverXAQCF` is used. In either case, this value must refer to a JNDI administered object that has already been created.

     The JMS Principal and JMS Credentials must be configured together.

- **XACloseString**: Leave this field blank.
- **ThreadOfControl**: Set the value `Thread`.

5. Click **OK** to complete the XA resource manager definition.
6. Click **OK** to close the queue manager properties dialog.
7. Click **File** > **Exit** to close WebSphere MQ Explorer.
8. On Windows on x86, copy the switch file (for example, `JMSSwitch.dll`) to the `\exits` subdirectory in the WebSphere MQ installation directory. On Windows on x86-64, copy the switch file `JMSSwitch32.dll` to the `\exits` subdirectory in the WebSphere MQ installation directory, and rename it to `JMSSwitch.dll`. Copy the switch file `JMSSwitch.dll` to the `\exits64` subdirectory in the WebSphere MQ installation directory.

What to do next

Next: modify the queue manager authorization.

Use the SOAPAsyncRequest node with the SOAPAsyncResponse node to construct a pair of message flows that call a Web service asynchronously.

Windows systems: modifying the queue manager authorization:

Authorize the broker and queue manager to access shared resources that are associated with the JMS provider.

Before you begin

Before you start:

Set up the JMSProviders configurable service; for more information, see “Making the JMS provider client available to the JMS nodes” on page 4534 (in the JMSInput node topic) or “Making the JMS provider client available to the JMS nodes” on page 4550 (in the JMSOutput node topic).

About this task

Complete the following steps on the Windows system on which the broker is running:

Procedure

1. If you defined the broker queue manager when you created the broker by running the **mqsicreatebroker** command, the two components share the same administrative ID, defined as the broker service ID, and you do not have to take any further action.
2. If you specified an existing queue manager when you created the broker, check that its administrative ID is the same ID as that used for the service ID of the broker. If the ID is not the same, change the queue manager ID to be the same as the broker service ID:
   a. Click **Start** > **Run** and enter dcomcnfg. The Component Services window opens.
   b. In the left pane, under Console Root, expand **Component Services** > **Computers** > **My Computer** and click **DCOM Config**.
   c. In the right pane, under DCOM Config, right-click the WebSphere MQ service labelled **IBM MQSeries Services**, and click **Properties**.
   d. Click the **Identity** tab.
   e. Select **This user** and enter the user ID and password for the broker service ID to associate that ID with the queue manager.
   f. Click **OK** to confirm the change.

Securing JMS connections and JNDI lookups:

If you want additional security for JMS connectivity and the JMS nodes or SOAP nodes using JMS transport, two configuration options are supported.

About this task

When you include JMS nodes in your message flow, you can optionally secure JMS connection resources. You can secure one, both, or neither of these options, depending on the level of security and access that you want to enforce.

Procedure

1. To secure a JMS connection:
   a. Specify the Connection Factory Name property on the node. You must set this property for every node using JMS transport.
   b. Use the **mqsisetdbparms** command to authorize the user ID and password for the specified connection factory. For example:

      ```
      mqsisetdbparms MyBroker1 -n jms::tcf1 -u myuserid -p secret
      ```

      where `tcf1` is the name of the connection factory that matches the node property that you set.
2. To secure JNDI bindings lookups:
   a. Specify the Initial Context Factory property on the node. You must set this property for every node using JMS transport.
   b. Use the **mqsisetdbparms** command to authorize the user ID and password for the specified context factory. For example:

      ```
      mqsisetdbparms MyBroker1 -n jndi::com.sun.jndi.fscontext.RefFSContextFactory
           -u myuserid -p secret
      ```

      where `com.sun.jndi.fscontext.RefFSContextFactory` is the name of the initial context factory that you set.

Configuring the broker to enable a JMS provider's proprietary API:

Some JMS providers provide an alternative interface to the standard JMS specification for particular JMS API calls. In these cases, IBM supplies a Java class to interface with that proprietary API.

About this task

For example, BEA WebLogic uses a component called a *Client Interposed Transaction Manager* to allow a JMS client to obtain a reference to the XAResource that is associated with a user transaction.

If the WebSphere Message Broker JMS nodes use BEA WebLogic as the JMS provider, and the nodes must participate in a globally coordinated message flow, you must modify the configurable services properties that are associated with that vendor. The following table shows the properties that have been added to the configurable service for BEA WebLogic.

JMS provider	Property	Purpose	Default value
BEA_WebLogic	`proprietaryAPIHandler`	The name of the IBM supplied Java class to interface with a JMS provider's proprietary API.	`com.ibm.broker.apihandler.BEAWebLogicAPIHandler`
	`proprietaryAPIAttr1`	The Initial Context Factory class name for the vendor	`weblogic.jndi.WLInitialContextFactory`
	`proprietaryAPIAttr2`	The URL of the WebLogic bindings	*URL JNDI bindings*
	`proprietaryAPIAttr3`	The DNS name of the JMS server	*Server name*

In the list of JMS provider configurable services, the name of the IBM supplied Java class is set to the default value for the `proprietaryAPIHandler` property. Typically, you do not need to change this value, unless you are instructed to do so by an IBM Service team representative.

Procedure

- Use the **mqsichangeproperties** command to modify values of the properties for this JMS provider.

  The following example shows how to change the values of the properties `proprietaryAPIAttr2` and `proprietaryAPIAttr3` for the JMS provider

configurable service definition called BEA_Weblogic, where these properties represent the URL of the WebLogic bindings and the DNS Server name of the BEA WebLogic JMS Server:

```
mqsichangeproperties MB7BROKER -c JMSProviders -o BEA_Weblogic
-n proprietaryAPIAttr2,proprietaryAPIAttr3 -v t3://9.20.94.16:7001,BEAServerName
```

- Use the **mqsireportproperties** command to display the properties for a JMS provider.

  The following example shows how to display the properties for all the broker's JMS provider resources (the default JMS provider resources and those configurable services that are defined with the **mqsicreateconfigurableservice** command):

  ```
  mqsireportproperties MB7BROKER -c JMSProviders -o BEA_WebLogic –r
  ```

  The result of this command has the following format:

  ```
  ReportableEntityName=''
  JMSProviders
    BEA_Weblogic=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
      proprietaryAPIAttr1='weblogic.jndi.WLInitialContextFactory'
      proprietaryAPIAttr2='t3://9.20.94.16:7001'
      proprietaryAPIAttr3='BEAServerName'
      proprietaryAPIAttr4='default_none'
      proprietaryAPIAttr5='default_none'
      proprietaryAPIHandler='com.ibm.broker.apihandler.BEAWebLogicAPIHandler'
  ```

  The default location for the JMS provider JAR files is the broker's shared-classes directory. You can specify an alternative location for the JAR files by using the **mqsichangeproperties** command, as shown in the following example:

  ```
  mqsichangeproperties MB7BROKER -c JMSProviders -o BEA_WebLogic -n jarsURL
  -v /var/mqsi/WebLogic
  ```

  On Windows, the file location cannot be a mapped network drive on a remote Windows computer; the directory must be local or on a Storage Area Network (SAN) disk.

- Use the **mqsicreateconfigurableservice** command to add a JMS provider.

  The following example shows how to add a JMS provider called BEAV91 for broker MB7BROKER, specifying the name of an IBM supplied Java class called `com.ibm.broker.apihandler.BEAWebLogicAPIHandler` to handle vendor-specific API calls:

  ```
  mqsicreateconfigurableservice MB7BROKER -c JMSProviders -o BEAV91
  -n proprietaryAPIHandler,proprietaryAPIAttr1,proprietaryAPIAttr2,proprietaryAPIAttr3
  –v com.ibm.broker.apihandler.BEAWebLogicAPIHandler,weblogic.jndi.WLInitialContextFactory,
  t3://9.20.94.16:7001,BEAServerName
  ```

- If you have defined a user-defined JMS provider configurable service, set the value for the `proprietaryAPIHandler` property manually.

Enabling batch acknowledgment for JMS messages:

Configure JMS message flows to send a batch acknowledgment for receipt of non-transactional JMS messages.

About this task

You can configure message flows that use the JMS transport to send an acknowledgment to the JMS server of all non-transactional JMS messages that have not previously been acknowledged. You might want to enable batch acknowledgment if there is high network latency and want to send an acknowledgment of received messages only after a threshold has been reached.

JMS flows send acknowledgment responses in accordance with the acknowledge setting on the JMS Session created by the broker. The default setting is `AUTO_ACKNOWLEDGE`, which causes JMS flows to send an acknowledgment response after receiving each non-transactional message. You can change this setting to use `CLIENT_ACKNOWLEDGE` instead by setting the properties `clientAckBatchSize` and `clientAckBatchTime` on the JMSProviders configurable service. If `CLIENT_ACKNOWLEDGE` is used, the broker calls the acknowledge() method only after a set time interval has passed, or a set number of messages are received.

Related tasks:

Processing bytes messages with JMS nodes:

The default behavior of WebSphere Message Broker when processing bytes messages can affect clients that are designed to use the readUTF() and writeUTF() methods. Construct an equivalent UTF bit stream by using a Compute node.

About this task

By default, WebSphere Message Broker processes bytes messages by using the readBytes() and writeBytes() JMS methods. By using these methods, the payload is written or read as a raw byte array. For the input message, the behavior is based on the serialization of the message tree; for the output message, the resulting bit stream is passed to the user-specified parser to construct a logical tree.

This behavior can affect clients that are designed to use the readUTF() and writeUTF() methods. A UTF string contains encoded length information as well as the raw bit stream. To construct an equivalent UTF bit stream that can be read by the readUTF() method, complete the following steps.

Procedure

1. Add a Compute node immediately before a JMSOutput node.
2. Double-click the Compute node to open the corresponding ESQL file.
3. Use the ESQL shown in the following example to construct an equivalent UTF bit stream from an XMLNSC input message. This bit stream can be understood by a client that uses the readUTF() message.

```
CALL CopyMessageHeaders();

DECLARE byteData BLOB ASBITSTREAM (InputRoot.XMLNSC ccsid
InputProperties.CodedCharSetId);
DECLARE stringData CHARACTER CAST(byteData AS CHARACTER ccsid
InputProperties.CodedCharSetId );
DECLARE dataLen INTEGER LENGTH (byteData);

DECLARE blobLen BLOB CAST(dataLen AS BLOB ENCODING
InputProperties.Encoding);
DECLARE str2byteBlobLen CHARACTER SUBSTRING (CAST(blobLen AS
CHARACTER) FROM 15 FOR 4);

SET OutputRoot.BLOB.BLOB = CAST(str2byteBlobLen as BLOB) ||
byteData ;
```

SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

Troubleshooting JMS nodes:

Review possible problems with nodes using JMS transport.

The following errors might occur:

- "Managing badly formed messages"
- "Diagnosing problems when using globally coordinated transactions"
- "Problems with JNDI Administered Objects" on page 1731

In all cases of error, if the underlying cause is a JMS exception that has been thrown by the JMS provider, the broker BIP event message includes the text message from the JMS exception to help diagnosis.

Managing badly formed messages:
If a message cannot be processed by the JMS input node, or has been rolled back as part of a global transaction, the message is backed out to the source destination. The message is then delivered again to the input node.

To prevent badly formed messages from interrupting the processing of valid messages, the node properties can be configured as described in the following table.

Property	Description
`Backout destination`	This property specifies a JMS destination to which backed out messages are routed if the JMS message property *JMSX_DeliveryCount*, which is set by the JMS provider, exceeds the backout threshold. The JMS destination must be applicable to the message model being used by the node; for example, if a subscription topic has been configured on the node, the JMS destination must also be a topic.
`Backout threshold`	This property specifies the integer value that controls a message that is sent to the backout destination. A threshold value of 3 indicates that if the input node receives a message where the value of the *JMSX_DeliveryCount* property exceeds 3, the message is sent to the backout destination and is removed from the source destination. See "Configuring the backout threshold property" on page 4544.

Diagnosing problems when using globally coordinated transactions:
This problem is not applicable to z/OS.

In addition to the broker service trace, another trace log is provided to diagnose problems that could occur when a node using JMS transport participates in a global message flow transaction. That is, at least one JMS node in the message flow has the `Transaction Mode` property set to `Global`.

To capture the trace log, complete the following steps:

1. Define an environment variable called *XAJMS_TRACEFILE* that is available to the broker queue manager.
2. Set the value of the environment variable. This value must be a character string that represents the location and file name of the trace log. For example, on Windows, the variable can be configured as shown in the following example:

   ```
   XAJMS_TRACEFILE = c:\JMSSwitchLog
   ```
3. When the broker queue manager starts, it performs a recovery step to resolve any previous broker transactions that the JMS provider considers to be in doubt. This queue manager process writes to two trace logs during this stage. The two trace logs are:
   - *XAJMS_TRACEFILE valuePID*.txt, where *PID* is the process ID of the queue manager start process. This file is produced from the broker JMSSwitch library; for more information, see "JMS Transactionality" on page 1705.

     The previous example produces a file called JMSSwitchLog2596.txt, where the queue manager start up process ID is 2596.
   - *XAJMS_TRACEFILEXARecoveryTrace*.txt, which is produced by the recovery component of the broker that connects to the JMS provider.
4. After the broker queue manager has completed recovery, the broker starts and creates a file called *XAJMS_TRACEFILE valuePID*.txt, where *PID* is the process ID of the queue manager start process. This file is produced from the broker JMSSwitch library; for more information, see "JMS Transactionality" on page 1705.

Neither of these trace files require extra formatting.

Problems with JNDI Administered Objects:
Description of problem: The JMS node is unable to obtain the Initial Context Factory or a JNDI administered object, such as the Connection Factory or JMS destination, and message BIP4640 is issued.

Corrective action
1. Verify that the JNDI bindings have been built correctly, and can be reached at the location specified in the node.
2. Check that the values specified in the node for the Connection Factory Name and Source Queue or Destination Queue properties exist in the JNDI bindings.
3. Ensure that the correct keyword is used to match the location of the bindings:
   - file:// when the administered objects have been created in a .bindings file
   - ldap:// when the administered objects exist in an LDAP directory
   - iiop:// when CORBA is used to access the administered objects
4. When the bindings are file based, do not specify the .bindings file name in the node property.
5. Ensure that the Initial Context Factory Class name is set correctly, as specified in the documentation for the JMS provider.
6. Ensure that the Initial Context Factory Class name does not include a file path.
7. Ensure that a JMS destination (Topic or Source Queue or Destination Queue) specified in the node property exists in the JNDI administered objects.
8. Ensure that the JMS Provider jarsURL property has been set correctly by using the **mqsichangeproperties** command. To verify the value, use the following command:

   ```
   mqsireportproperties MB7BROKER -c JMSProviders -o JMSProvider –r
   ```

The JMS nodes continue to attempt to obtain the JNDI administered objects. Correct any problems and rebuild the bindings. The JMS node should automatically detect the changes and attempt to start.

- If the problem is resolved by rebuilding the bindings, the JMS node detects the changes automatically and attempts to start.
- If the problem is resolved by updating the node properties, you must redeploy the flow before it can connect successfully.
- If the problem is resolved by updating the properties of the JMSProviders configurable service, you must restart the execution group for the changes to take effect.

Description of problem: A JMS node is unable to connect for a JMS provider and issues message BIP4648.

Corrective action:

1. Verify that the JMS provider server is running. If it is offline, start the server.
2. Verify that the JMS provider server is available from the broker environment.
3. Ensure that the JMS provider Java `.jar` files have been placed into the broker shared-classes directory on distributed systems, or that on z/OS, that these `.jar` files have been defined to the broker CLASSPATH and any native libraries defined in the broker LIBPATH.

The JMS nodes continue to attempt to connect to the JMS provider. Correct any problems and the JMS node should automatically detect the changes and attempt to connect to the provider.

Description of problem: A JMS node is unable to obtain a JMS destination and issues message BIP4642.

Corrective action

1. Investigate the cause of the problem described by the JMS exception message that might be included in the BIP event message.
2. Check that the name of the JMS destination that is defined in the relevant node property (Topic, Source Queue or Destination Queue) has been defined correctly in the JNDI administered objects.
3. Verify that the underlying system resource that is used by the JMS provider for the JMS destination has been configured correctly

Description of problem: A JMS input node does not attempt to reconnect to a JMS provider following a connection failure, or a restart of the JMS provider.

Corrective action: If the JMS provider is implemented by using a model that pushes on the JMS client, rather than a traditional polling model, the JMS provider might not throw an exception when calling receive() on a broker connection. To resolve this problem, set the jmsAsyncExceptionHandling property of the JMSProviders configurable service to true for this JMS provider.

Service trace is one of two types of optional trace that are available in WebSphere Message Broker and provides more information than that provided by the entries that are written to the Event Log or to user trace. Service trace is inactive by default; you must activate it explicitly by using a command.

Processing TCP/IP messages

You can use WebSphere Message Broker to connect to applications that use raw TCP/IP sockets for transferring data.

About this task

If you have existing applications that use raw TCP/IP sockets for transferring data, you can use the WebSphere Message Broker TCP/IP nodes to connect to the applications, without needing to enable them for WebSphere MQ.

WebSphere Message Broker implements access to the TCP/IP input and output streams through the following nodes:

- "TCPIPClientInput node" on page 4854
- "TCPIPClientOutput node" on page 4867
- "TCPIPClientReceive node" on page 4877
- "TCPIPServerInput node" on page 4890
- "TCPIPServerOutput node" on page 4903
- "TCPIPServerReceive node" on page 4913

For information about how to use the TCP/IP support, see "Working with TCP/IP" on page 1750.

The following topics contain information that you need to understand before you can use TCP/IP in a WebSphere Message Broker application:

WebSphere Broker TCP/IP Transport

The WebSphere Broker TCP/IP Transport is a service that connects applications that use raw TCP/IP sockets for transferring data.

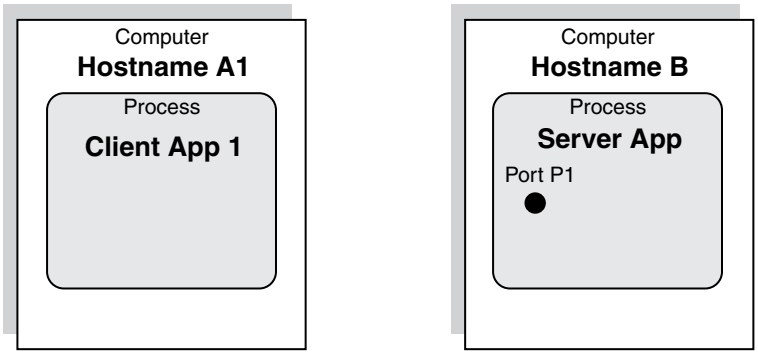
TCP/IP sockets provide a simple way of connecting computer programs together, and this type of interface is commonly added to existing stand-alone applications. TCP/IP provides a mechanism for transferring data between two applications, which can be running on different computers. The transfer of data is bidirectional; provided that the TCP/IP connection is maintained and no data is lost, the sequence of the data is kept. A significant advantage of using TCP/IP directly is that it is quick and simple to configure, which makes it a useful mechanism for processes that do not require message persistence (for example, monitoring).

However, the use of TCP/IP sockets for transferring information between programs does have some limitations:

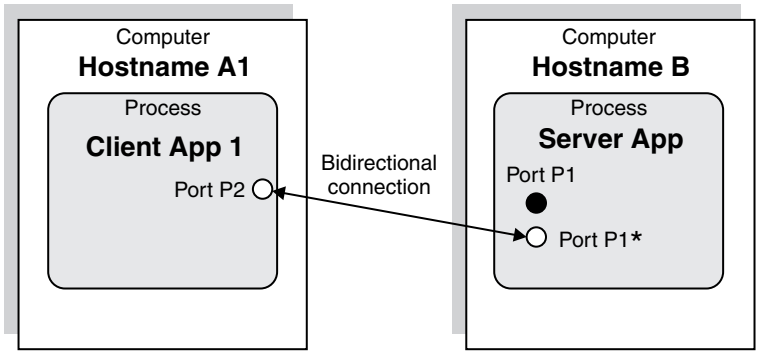
- It is non-transactional
- It is not persistent (the data is written to an in-memory buffer between the sender and receiver)
- It has no built-in security
- It provides no standard way of signaling the start and end of a message

For these reasons, it can be preferable to use a transport mechanism like WebSphere MQ, which has none of these limitations. However, if you have existing applications that use raw TCP/IP sockets for transferring data, you can use the WebSphere Message Broker TCPIP nodes to connect to the applications without needing to enable them for WebSphere MQ, so that you can develop a WebSphere Message Broker solution quickly.

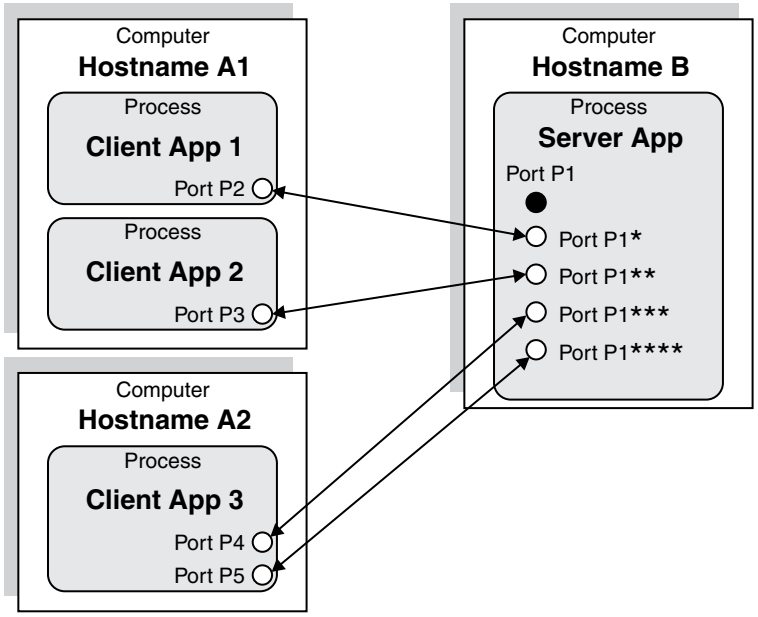
A TCP/IP connection between two applications has a client end and a server end, which means that one application acts as a server and the other as a client. The terms client and server refer only to the mechanism used to establish a connection; they do not refer to the pattern of data exchange. When the connection has been established, both client and server can perform the same operations and can both send and receive data. The following diagram illustrates the locations of client and server applications:



1. The server application listens on a local port (on the computer that is running the application) for requests for connections to be made by a client application.
2. The client application requests a connection from the server port, which the server then accepts.
3. When the server accepts the request, a port is created on the client computer and is connected to the server port.
4. A socket is created on both ends of the connection, and the details of the connection are encapsulated by the socket.
5. The server port remains available to listen for further connection requests:

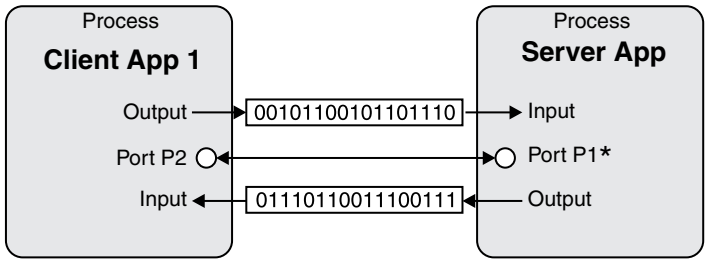


The server can accept more connections from other client applications. These connections can be in the same process, in a different process on the same computer, or on a different computer:



Only one server application can exist, but any number of different client processes can connect to the server application. Any of these applications (client or server) can be multithreaded, which enables them to use multiple connections.

When the connection has been established, two data streams exist: one for inbound data and another for outbound data:



The client and server ends of the connection are identical and both can perform the same operations. The only difference between them is that the output stream of the client is the input stream of the server, and the input stream of the client is the output stream of the server.

The two streams of data are independent and can be accessed simultaneously from both ends. The client does not need to send data before the server.

The example illustrated in the previous diagram can be simplified in the following way, showing that the client and server have access to a socket that has an input stream and an output stream:

TCP/IP nodes

WebSphere Message Broker implements access to the TCP/IP input and output streams through a series of nodes.

Two sets of TCP/IP nodes exist: TCPIPServer nodes and TCPIPClient nodes. Both sets have identical function in terms of accessing the data streams; however, one set uses client connections and the other set uses server connections. As a result,

the nodes establish the connections in different ways but they use the streams in the same way when the connections have been established.

The main difference between the properties of the nodes is that the TCPIPServer nodes do not allow the host name to be changed (because it must always be `localhost`). All TCPIPServer nodes that use the same port must be in the same execution group because the port is tied to the running process. TCPIPClient nodes on the same port can be used in different execution groups, but client connections cannot be shared because the client connections are tied to a particular execution group, which maps to a process. Within the two sets of nodes (TCPIPClient and TCPIPServer), are three types of node:

- TCPIPServerInput and TCPIPClientInput
- TCPIPServerReceive and TCPIPClientReceive
- TCPIPServerOutput and TCPIPClientOutput

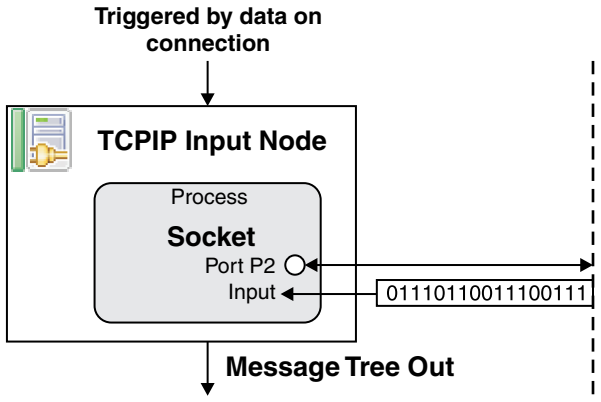
The input and receive nodes access the input stream to retrieve data, and the output nodes access the output stream to send data. No single node can access both streams at the same time. To access both streams simultaneously, you must connect multiple nodes in a message flow.

Input nodes

The input node allows access to a connection's input stream. The node is triggered by the arrival of data in the stream and starts processing the message flow. The input node controls thread and transaction management. The TCP/IP nodes are not transactional in the way that they interact with TCP/IP, but other nodes in the same flow can be transactional (for example, WebSphere MQ nodes). The input node does not create a thread for every connection being used, but waits for two requirements to be met:

- A connection is available that still has an open input stream
- Data is available on the input stream (at least 1 byte)

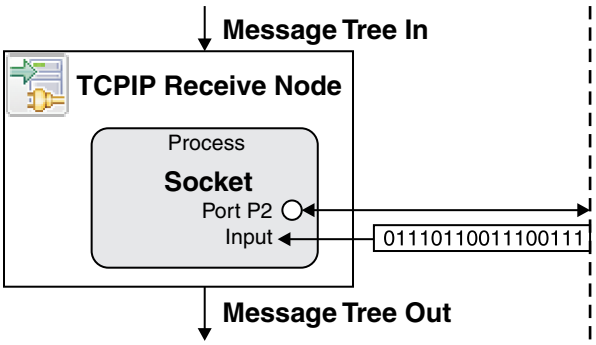
For example, 1,000 TCP/IP connections can be handled by one input node that has only one additional instance. This situation is possible because the node does not poll the connections, but is triggered when the specified conditions are met.



Receive nodes

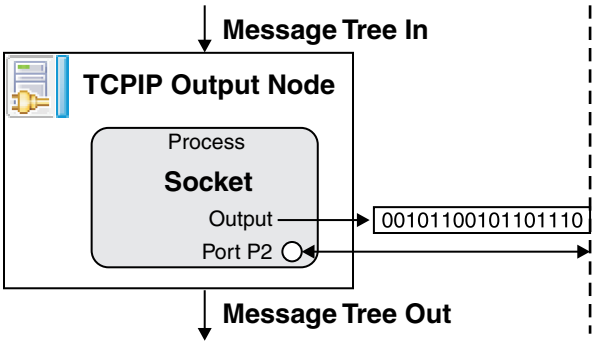
The receive node is triggered to read data from a connection when a message arrives on its In terminal. It waits for data to arrive, then sends it to the Out

terminal. You can configure the receive node to use a particular connection (by specifying a connection's ID) or to use any available connection. If the node is configured to use any available connection, it receives data from the first connection that has data available.



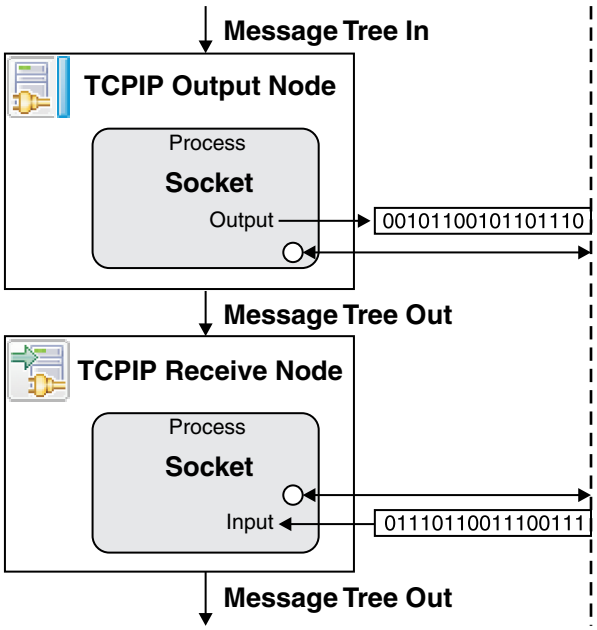
Output nodes

The output node sends data to a connection. It is triggered by a message arriving on its In terminal, then it sends the data contained in the message to the stream. The same message that is received in the node is sent to the Out terminal.



Combining nodes

The six client and server nodes can be combined to provide more complex operations. For example, an output node followed by a receive node enables a synchronous request of data:



If the message flows used are single threaded and only one connection ever exists, the sequence of nodes requires no further configuration. Two additional mechanisms are included to enable multithreading and multiple connections:

- A connection ID to ensure that the same connection is used by multiple nodes
- The ability to reserve connections so that they can be accessed only when the ID is specified

One connection in multiple nodes

Every connection has a unique identifier assigned to it when it is created. Whenever a node uses a connection, the ID that is used is written to the local environment. Any nodes that use it later in the flow can access the same connection by specifying the ID; the receive and output nodes find the ID by searching in a specified location in the local environment. By default, the location in which a node writes its connection details is different from the location in which the next node looks to see if there is an ID to use. The nodes can be configured to use the ID that was sent by a previous node. For example, the combination of the output and receive nodes shown in “Combining nodes” on page 1740 can be configured so that the receive node uses the WrittenDestination data from the preceding output node.

The use of the ID enables a series of nodes to access the same connection, but does not prevent two message flow threads accessing the same connection. When a connection is used for the first time, it can be reserved so that no other nodes can access it unless they know the ID. For example, the combination of the output and receive nodes shown in “Combining nodes” on page 1740 reserves the connection so that no other threads can access it before the receive node uses it. By default, the receive node then releases the connection when it has finished.

The ability to reserve connections (and access them by specifying the correct ID) enables you to build up complex interactions with TCP/IP connections that span whole flows and even multiple message flows. As a result, the TCP/IP interactions can be used with other asynchronous transport mechanisms like WebSphere MQ.

Reserved connections must be released at some time, otherwise they remain unavailable indefinitely. For more information about reserved and available connections, see "Connection management."

Correlating replies across flows

You can use the TCP/IP nodes in asynchronous patterns, in which data is sent out through a TCP/IP output node and received back through a TCP/IP input node. The spanning of two message flows causes any state in the first flow to be lost and therefore inaccessible from the second flow. The TCP/IP nodes enable you to store some reply details on a connection, and these details are then available for the input node to use when a new event arrives on the same connection. By default, this data is taken from the local environment, but you can configure the nodes to take the data from any location, including the Correlid field and message IDs in WebSphere MQ headers.

Connection management

TCP/IP connections are requested by the client connection manager and accepted by the server connection manager.

The execution group process contains the connection manager, which makes the connections. Only one execution group can have server nodes using a specific port at any one time; deployment to a second execution group causes a deployment error. Client nodes can be deployed to different execution groups, but each execution group has its own pool of connections, and therefore its own minimum and maximum number of connections.

TCPIP nodes do not directly create or manage any TCP/IP connections, but acquire them from the connection manager's internal pool. For example, two output nodes using the same connection details share the same connection manager. The TCPIP nodes can define the connection details to be used by specifying one of the following values:

- Host name and port
- Name of a configurable service.

If a host name and port are specified, the node uses these values when requesting connections. If a configurable service is specified, the node obtains the values for the port and host name from the values defined in the configurable service. The connection manager supports other configurable parameters in addition to the host name and port, and you can define all of these values when you are using a configurable service. When the host name and port are specified on the node, the connection manager obtains the rest of the required values from the default configurable service. However, if a configurable service is defined that is using the host name and port number, the values from that configurable service are used.

The connection manager is created when the first node that requires connections from it is deployed. The connection manager is deleted when the last remaining node using it has been removed from the execution group (which means that the connection manager is no longer being used by any deployed nodes). For example, this process can occur when existing flows are redeployed, because redeployment involves deleting all existing nodes before creating them again.

Server connections

The server connection manager starts listening for server connections when it starts, and it keeps accepting connections until the maximum number of connections (as specified in the configurable service) is reached. Any attempts to make connections after this point are refused. TCP/IP servers do not create connections; they accept connection requests only from other applications. As a result, you cannot force the creation of connections within a message flow.

Client connections

The client connection manager starts and keeps making client connections until the minimum number of connections (as defined in the configurable service) is reached. By default, the minimum number of connections is zero, which means that no connections are made. Whenever the number of connections drops below the minimum value, the connection manager starts creating more client connections. The client output and receive nodes initiate the creation of new client connections whenever none are available for them to use, unless the maximum number (as defined in the configurable service) has been reached.

Reserving and releasing connections

Each connection has an input stream and an output stream, both of which have two main states within the connection manager: available and reserved.

When a node requests a connection for input or output, without specifying the ID of a particular connection, it is given any available connection on the required stream. If no connections are available, and if the node is a client node, a new connection is made, but only if the maximum number of connections has not yet been reached. Any connection in the available state can be used by only one node at a time, but when a node has finished using it, any other node (from any flow or thread) can access it.

You can restrict access to a stream on a connection by reserving the connection. When a connection is in the reserved state, no other node can access the stream without specifying the ID of the connection. For example, an input node can request an available connection, and, when it has finished reading the data, put the stream into the reserved state. While the stream is in the reserved state, no input node (including the node that put the stream into the reserved state) can access it because input nodes can access only available streams. The only nodes that can access the stream must have the connection ID, which is written to the outgoing local environment when the data is passed down the message flow. As a result, receive nodes can read more data on the same connection, but only if the receive node is configured to use the ID from the local environment of the input node.

When a connection is reserved, ownership of the connection is given to a current thread of processing. This processing can span separate message flows, if required.

The reserve mechanism provides the following options:

- Leave unchanged
- Reserve
- Release
- Reserve and release at the end of the flow

For all nodes, the stream is left available (not reserved) by default. For many types of processing you can leave this default unchanged; for example, when you are moving data from an input stream to a file. The main purpose of reserving a stream is to connect a series of nodes to give complex processing on a stream in an ordered, controlled, synchronous sequence.

You can use the `Reserve and release at end of flow` option to reserve a connection and to ensure that the connection's stream is released when one iteration of the message flow has finished processing (including any error conditions that might occur).

If you require the processing to span multiple message flows (for example, for asynchronous request and reply), you must reserve a stream without releasing it at the end of the message flow. See the following sample for an example:

- TCPIP Client Nodes

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

A disadvantage of reserving a stream between message flows is the potential for a stream never to be released. To avoid this problem, set an expiry time on the connection so that it is closed after a specified period of inactivity.

Another benefit of reserving an input stream is that the connection cannot be closed until it is either released or expired (even if an end application closes its end of the connection), which is useful when the end of the stream is being used to delimit messages in the stream.

File descriptors

If your WebSphere Message Broker application is running on Sun Solaris 10 on SPARC, you might need to increase the number of file descriptors. The following error in the `syslog` indicates that additional file descriptors are required:

```
Failed to create a client connection using hostname: '', port: ''. Reason: 'Invalid argument'
```

You can also try the following two methods to resolve the error:

- Change the *MQSIJVERBOSE* environment variable, for example:

  ```
  export MQSIJVERBOSE=-Djava.nio.channels.spi.SelectorProvider=sun.nio.ch.PollSelectorProvider
  ```

- Change the limit of maximum file handles to *value* instead of *RLIM64_INFINITY*

Scenarios: TCP/IP:

Two scenarios illustrate how TCP/IP might be used as part of a business solution.

- "Expense submission"
- "Price-change notification" on page 1747.

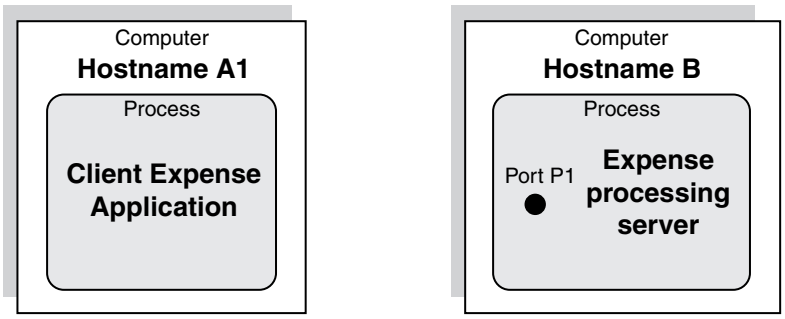
Expense submission: **Scenario:**

A company has an expense-submission system based on a central expense-processing application, which receives completed expense forms from end users. The users complete the forms by using a local application, which stores the form until it is completed. When it has been completed, the form is transferred to the central system where it is processed. Any further notifications are sent to the user by email.

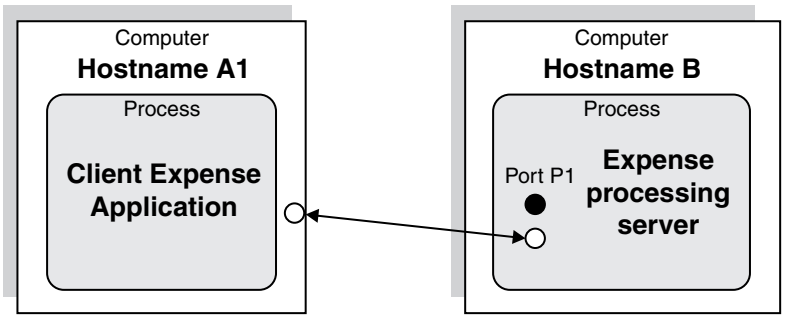
How TCP/IP is used:

One client application exists for each end user, and one central application processes all the expense forms. Each client application connects to a TCP/IP server port on the server application and sends the expense form in a fixed-field-size structure similar to a COBOL structure. The flow of processing is:

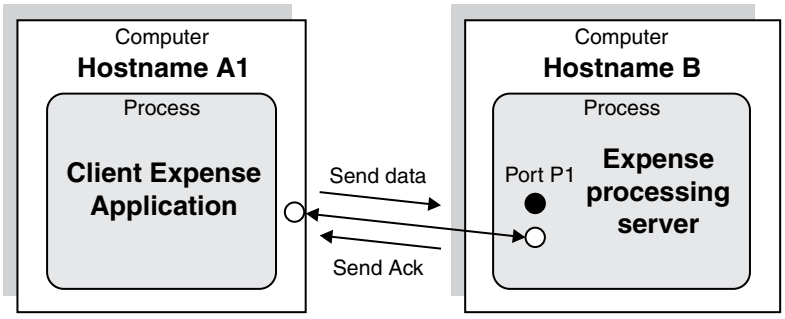
1. The user enters information into the form in the client expense application.



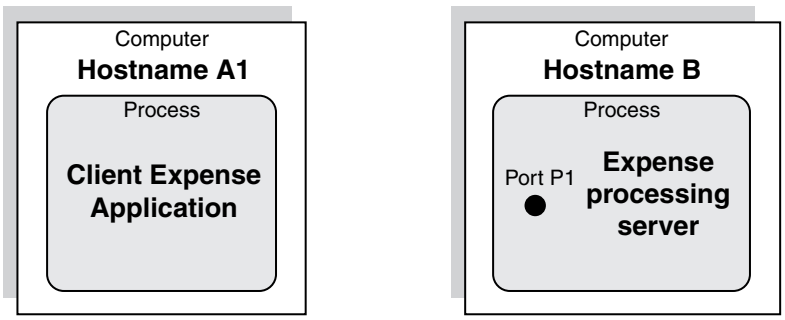
2. The user submits the completed form and the client application connects to the server.



3. The client application sends the data to the server and receives an acknowledgment.



4. The connection is closed by the client.

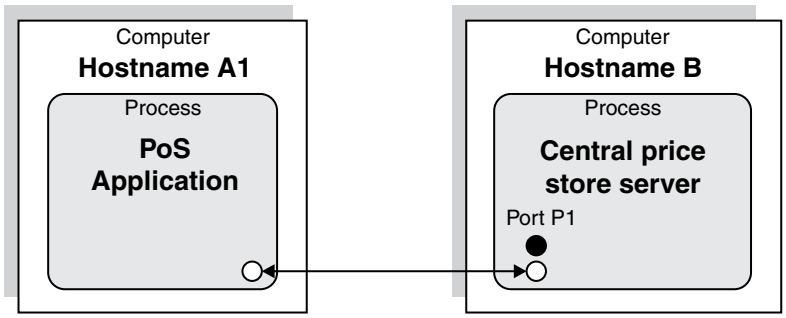


Price-change notification: **Scenario:**

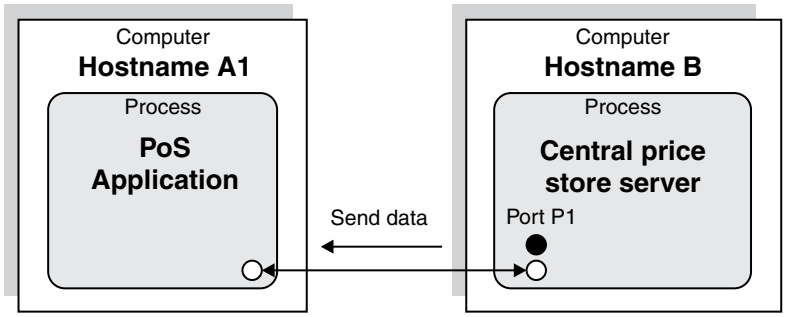
A company has a central server, which stores the catalog price of everything that the company sells. This information is required by all Point of Sale (PoS) terminals in all the stores, and each PoS terminal must be notified when any price changes. The PoS terminals connect to the central server and wait for any process changes. The server sends any process changes to all connected client applications.

How TCP/IP is used:

1. When the PoS application starts, it connects to the central server.



2. Whenever the server has a new price, it publishes it to all the connected clients.



3. The PoS stays connected until it shuts down.

See "Scenarios: Message Broker using TCP/IP" on page 1749 for an example of how these scenarios can be modified to use WebSphere Message Broker.

Use the TCPIPServerReceive node to receive data over a server TCP/IP connection.

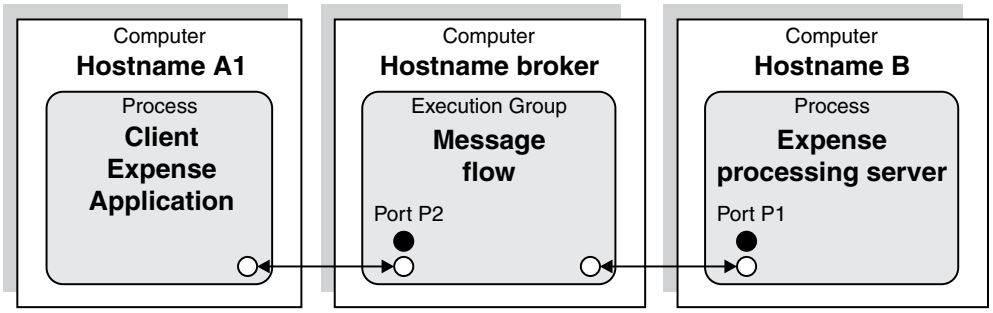
Scenarios: Message Broker using TCP/IP:

WebSphere Message Broker can be added to systems that use TCP/IP for transport, to generate a more flexible architecture for communication between components.

The scenarios in the "Scenarios: TCP/IP" on page 1746 topic show how systems can be created to use TCP/IP as a transport mechanism. The following sections show how WebSphere Message Broker can be added to those systems to generate a more flexible architecture for communication between components:

- "Expense submission" illustrates TCP/IP to TCP/IP routing
- "Price-change notification" on page 1750 illustrates routing and transformation to other formats

Expense submission: The expense submission scenario shown in the "Scenarios: TCP/IP" on page 1746 topic requires a direct connection from the client applications to the end server. With that model it is difficult to add new consumers of the expense submission information, and it is also difficult to change the end application that processes them. However, by adding WebSphere Message Broker as an intermediary router, the two systems can be separated without any changes to their interfaces, as shown in the following diagram:



Price-change notification: The price-change notification scenario shown in the "Scenarios: TCP/IP" on page 1746 topic can be modified to use a message broker for routing and transformation. It could also allow support for other protocols like WebSphere MQ, which would allow new applications to be written to different interfaces without the need for changing the current client or server applications:

Transferring XML data from a TCP/IP server socket to a WebSphere MQ queue:

Transfer XML data from a TCP/IP server socket to a WebSphere MQ queue, by creating a message flow with TCPIPServerInput and MQOutput nodes.

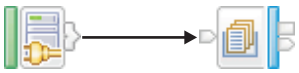
About this task

Scenario: A client application opens a TCP/IP socket and sends an XML document. The end of the document is signalled by the closure of the client connection.

Instructions: The following steps describe how to write a message flow that can receive the XML document and write it to a WebSphere MQ queue:

Procedure

1. Create a message flow called TCPIP_Task1 with a TCPIPServerInput node and an MQOutput node. For more information about how to do this, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the MQOutput node.



3. Set the following properties of the TCPIPServerInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14141`.
   b. On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
4. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK1.OUT1`.
5. Save the message flow.

Use the MQOutput node to send messages to clients that connect to the broker using the WebSphere MQ Enterprise Transport and that use the MQI and AMI application programming interfaces.

Transferring binary (CWF) data from a TCP/IP server socket to a flat file:

Transfer binary Custom Wire Format (CWF) data from a TCP/IP server socket to a flat file, by the use of a message set and a message flow with TCPIPServerInput and FileOutput nodes.

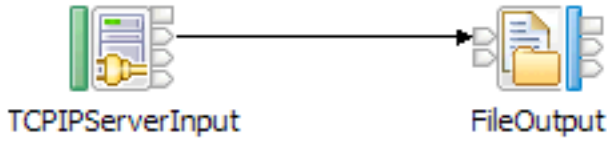
About this task

Scenario: A client application opens a TCP/IP socket and sends a binary (CWF) document. The end of the document is signaled by the closure of the client connection.

Instructions: The following steps describe how to write a message flow that can receive the binary document and write it to a flat file. Each message is written to a separate file, the name of which is based on the ID of the connection.

Procedure

1. Create a message set called Task2_MsgSet. For more information, see "Creating a message set" on page 2842.
2. Create a message flow called TCPIP_Task2 with a TCPIPServerInput node and a FileOutput node. For more information, see "Creating a message flow" on page 1431.
3. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the FileOutput node.



4. Set the following properties of the TCPIPServerInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14142`.
   b. On the **Input Message Parsing** tab, set the following properties:
      - Set the `Message domain` property to `MRM`.
      - Set the `Message set` property to `Task2_MsgSet`.
      - Set the `Message type` property to `Task2_MsgType`.
      - Set the `Message format` property to `Binary1`.
5. Set the following properties of the FileOutput node:
   a. On the **Basic** tab, set the following properties:
      - Set the `Directory` property to `c:\temp\task2`.
      - Set the `File name or pattern` property to `Task2.out`.
   b. On the **Request** tab, set the `Request file name property location` property to `$LocalEnvironment/TCPIP/Input/ConnectionDetails/Id`.
6. Save the message flow.

7. Create a project reference between the message flow project and the message set project:
   a. Right-click the message flow project, and click **Properties**.
   b. Click **Project References**.
   c. Select the message set project that contains your message set (Task2_MsgSet).
   d. Click **OK**.

Receiving data on a TCP/IP server socket and sending data back to the same connection:

Receive data on a TCP/IP server socket, then send the data to the same connection, by the use of a message flow with TCPIPServerInput and TCPIPServerOutput nodes.

About this task

Scenario: A client application opens a TCP/IP socket and sends an undefined document (of any format or size). The end of the document is signalled by the client closing the output stream (but not the connection), and waiting for the same data to be sent back.

Instructions: The following steps describe how to write a message flow that can receive the data and echo it back to the same connection:

Procedure

1. Create a message flow called TCPIP_Task3 with a TCPIPServerInput node and a TCPIPServerOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the TCPIPServerOutput node.

3. Set the following properties of the TCPIPServerInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14143`.
   b. On the **Advanced** tab, set the `Input stream modification` property to `Reserve input stream and release at end of flow`.
4. Set the following properties of the TCPIPServerOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14143`.
   b. On the **Request** tab, set the `ID location` property to `LocalEnvironment/TCPIP/Input/ConnectionDetails/Id`.
   c. On the **Advanced** tab, set the `Close connection` property to `After data has been sent`.
5. Save the message flow.

Sending XML data from a WebSphere MQ queue to a TCP/IP client socket:

Send XML data from a WebSphere MQ queue to a TCP/IP client socket, by the use of a message flow with MQInput and TCPIPClientOutput nodes.

About this task

Scenario: A server application listens on a TCP/IP socket and waits for a TCP/IP client to connect and send data. The end of the document is signalled by the client closing the connection.

Instructions: The following steps describe how to write a message flow that can take a message from a WebSphere MQ queue, make the client connection, and send the data to the server application:

Procedure

1. Create a message flow called TCPIP_Task4 with an MQInput node and a TCPIPClientOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.

3. Set the following properties of the MQInput node:
   a. On the **Basic** tab, set the `Queue name` property to `TCPIP.TASK4.IN1`.
   b. On the **Input message parsing** tab, set the `Message domain` property to `XMLNSC`.
4. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14144`.
   b. On the **Advanced** tab, set the `Close connection` property to `After data has been sent`.
5. Save the message flow.

Sending CWF data from a flat file to a TCP/IP client socket:

Send Custom Wire Format (CWF) data from a flat file to a TCP/IP client socket, by the use of a message flow with FileInput and TCPIPClientOutput nodes.

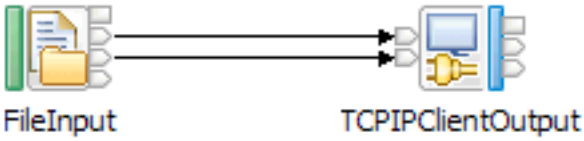
About this task

Scenario: An application writes 100–byte binary records into a flat file.

Instructions: The following steps describe how to open a new client TCP/IP connection and send the binary data with a binary termination character x'00FF'. When the whole file is finished, the client connection is closed:

Procedure

1. Create a message flow called TCPIP_Task5 with a FileInput node and a TCPIPClientOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the FileInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the End of Data terminal of the FileInput node to the Close terminal of the TCPIPClientOutput node.



4. Set the following properties of the FileInput node:
   a. On the **Basic** tab, set the `Input directory` property to `c:\temp\task5`.
   b. On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
5. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14145`.
   b. On the **Advanced** tab, set the `Close connection` property to `After data has been sent`.
   c. On the **Records and elements** tab, set the following properties:
      - Set the `Record definition` property to `Record is delimited data`.
      - Set the `Delimiter` property to `Custom delimiter (Hexadecimal)`.
      - Set the `Custom delimiter` property to `00FF`.
6. Save the message flow.

Sending data to a TCP/IP client connection and receiving data back on the same connection (synchronous):

Send fixed-size data to a TCP/IP client connection and receive fixed-size data back on the same connection (synchronously), by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientReceive, and MQOutput nodes.

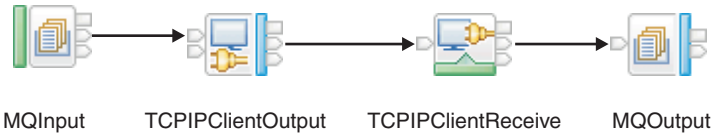
About this task

Scenario: An application sends synchronous data between TCP/IP client connections.

Instructions: The following steps describe how to create a message flow that sends data out from a client connection and waits on the same connection for a reply to be returned. The request is synchronous in the same flow, because the TCPIPClientReceive node waits for data to be returned.

Procedure

1. Create a message flow called TCPIP_Task6 with an MQInput node, a TCPIPClientOutput node, a TCPIPClientReceive node, and an MQOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientOutput node to the In terminal of the TCPIPClientReceive node.
4. Connect the Out terminal of the TCPIPClientReceive node to the In terminal of the MQOutput node.



5. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK6.IN1`.
6. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14146`.
   b. On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
7. Set the following properties of the TCPIPClientReceive node:
   a. On the **Basic** tab, set the `Connection details` property to `14146`.
   b. On the **Advanced** tab, set the following properties:
      - Set the `Output stream modification` property to `Reserve output stream and release at end of flow`.
      - Set the `Input stream modification` property to `Reserve input stream and release at end of flow`.
   c. On the **Request** tab, set the `ID location` property to `$LocalEnvironment/WrittenDestination/TCPIP/Output/ConnectionDetails[1]/Id`.
   d. On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
8. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK6.OUT1`.
9. Save the message flow.

What to do next

Sending data to a TCP/IP client connection and receiving data back on the same connection (asynchronous):

Send fixed-size data to a TCP/IP client connection and receive fixed-size data back on the same connection (asynchronously), by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientInput, and MQOutput nodes.

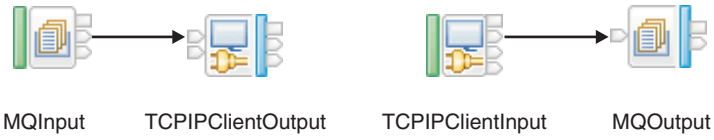
About this task

Scenario: An application sends asynchronous data between TCP/IP client connections.

Instructions: The following steps describe how to create a message flow to send data through a client connection and wait on the same connection for a reply to be returned. The request is performed asynchronously in two different flows (the TCPIPClientInput does not wait for data to be returned on this connection, but instead monitors all available connections).

Procedure

1. Create a message flow called TCPIP_Task7 with an MQInput node, a TCPIPClientOutput node, a TCPIPClientInput node, and an MQOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientInput node to the In terminal of the MQOutput node.



4. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK7.IN1`.
5. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14147`.
   b. On the **Advanced** tab, set the `Output stream modification` property to `Reserve output stream`.
   c. On the **Records and elements** tab, set the following properties:
      - Set the `Record definition` property to `Fixed length`.
      - Set the `Length` property to `100`.
6. Set the following properties of the TCPIPClientInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14147`.
   b. On the **Advanced** tab, set the `Output stream modification` property to `Release output stream and reset Reply ID`.
   c. On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Fixed length`.
      - Set the `Length` property to `100`.
7. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK7.OUT1`.
8. Save the message flow.

Establishing a client session over a TCP/IP connection:

Configure a TCPIPClientInput node to open a session over an existing TCP/IP connection, before any data is sent or received.

About this task

You can use the Open terminal of the TCPIPClientInput node to enable processing to start when a connection is opened, rather than when data first arrives. If the Open terminal is connected, an empty message is sent to the Open terminal when a connection is created. This message has the local environment set to the connection details.

The connection associated with the message is reserved from the general connection pool until propagation to the Open terminal has finished. However, the connection can be accessed using the connectionId specified in the local environment. Each connection that is created is sent to the Open terminal, including any connections that are created mid-flow by a TCPIPClientReceive node or TCPIPClientOutput node.

If the Open terminal is not attached, open events are automatically made available in the connection pool.

The following steps show how to configure a message flow that contains a TCPIPClientInput node, with the Open terminal configured to start processing when a TCP/IP connection is created.

Procedure

1. Create a message flow containing a TCPIPClientInput node, a Compute node, and a TCPIPClientOutput node. For information about how to do this, see "Creating a message flow" on page 1431.
2. Connect the Open terminal of the TCPIPClientInput node to the In terminal of the Compute node.
3. Connect the Out terminal of the TCPIPClientInput node to the In terminal of the TCPIPClientOutput node.
4. On the TCPIPClientInput node, set the `Connection details` property (on the **Basic** tab) to `14143`.
5. On the Compute node, set the `ESQL` property (on the **Basic** tab) to:

```
CREATE COMPUTE MODULE test_Compute1
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  -- CALL CopyMessageHeaders();
  CALL CopyEntireMessage();
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
```

```
    SET I = I + 1;
   END WHILE;
  END;

  CREATE PROCEDURE CopyEntireMessage() BEGIN
   SET OutputRoot = InputRoot;
  END;
 END MODULE;
```

6. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14143`.
   b. On the **Request** tab, set the `ID location` property to `LocalEnvironment/TCPIP/Input/ConnectionDetails/Id`.
7. Save the message flow.

Broadcasting data to all currently available connections:

Broadcast data to all current connections, by the use of a message flow with MQInput and TCPIPServerOutput nodes.

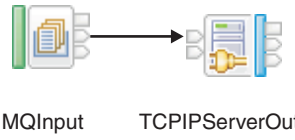
About this task

Scenario: Several applications connect into the message flow and wait to be sent data.

Instructions: The following steps describe how to send data to all the connected client applications:

Procedure

1. Create a message flow called TCPIP_Task8 with an MQInput node and a TCPIPServerOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPServerOutput node.



3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK8.IN1`.
4. Set the following properties of the TCPIPServerOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14148`.
   b. On the **Advanced** tab, set the `Send to:` property (in the **Broadcast options** group) to `All available connections`.
5. Save the message flow.

Configuring a server socket so that connections expire after a specified time:

Configure a TCP/IP server socket so that connections expire after a specified time, by the use of the **mqsicreateconfigurableservice** command.

About this task

Scenario: The TCPIPServer configurable service called `Task9` is configured to run on port `14149`. The connections expire when they have not been used for 5 seconds.

Instructions: Use the **mqsicreateconfigurableservice** command to set up connections that expire when they have not been used for a specified length of time. The TCP/IP node can specify either the port to be used or the name of the configurable service. For example:

```
mqsicreateconfigurableservice BRK6 -c TCPIPServer -o Task9
-n Port,ExpireConnectionSec -v 14149,5
```

Configuring a client socket to make 100 connections at deployment or startup time:

Configure a TCP/IP client socket to make 100 connections at deployment or startup time, by using the **mqsicreateconfigurableservice** command.

About this task

Use the **mqsicreateconfigurableservice** command to set up the client broker to establish 100 connections when it is created. By default, the client connections are not made until they are required by one of the TCP/IP nodes. For example:

```
mqsicreateconfigurableservice MB7BROKER -c TCPIPClient -o Task10
-n Port,MinimumConnections -v 14150,100
```

In this example, the TCPIPClient configurable service called `Task10` is configured to run on port `14150`, and 100 connections are created.

Configuring a server socket to receive XML data ending in a null character:

Configure a server TCP/IP socket to receive XML data ending in a null character, by the use of a message flow with TCPIPServerInput and MQOutput nodes.

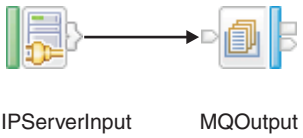
About this task

Scenario: A client application sends XML data that is delimited by a null character (hex code '00').

Instructions: The following steps describe how to break up the record based on the null character, then parse the data.

Procedure

1. Create a message flow called TCPIP_Task11 with a TCPIPServerInput node and an MQOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the MQOutput node.



3. Set the following properties of the TCPIPServerInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14151`.
   b. On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
   c. On the **Records and elements** tab, set the following properties:
      - Set the `Record detection` property to `Delimited`.
      - Set the `Delimiter` property to `Custom delimiter`.
      - Set the `Custom delimiter` property to `00`.
4. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK11.IN1`.
5. Save the message flow.

Configuring a server socket to receive XML data and discover the end of a record (by using the message model):

Configure a server socket to receive XML data and use the message model to determine the end of a record, by the use of a message flow with TCPIPServerInput and MQOutput nodes.

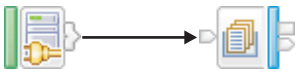
About this task

Scenario: A client application sends an XML document with no clear indication of the end of the record.

Instructions: The following steps show how to break up the record by the use of the XML parser to signal when the whole XML document as been received. The parser uses the end XML tag to signal the end of the message.

Procedure

1. Create a message flow called TCPIP_Task12 with a TCPIPServerInput node and an MQOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the TCPIPServerInput node to the In terminal of the MQOutput node.



3. Set the following properties of the TCPIPServerInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14151`.
   b. On the **Input Message Parsing** tab, set the `Message domain` property to `XMLNSC`.
   c. On the **Records and elements** tab, set the `Record detection` property to `Parsed record sequence`.
4. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK12.IN1`.
5. Save the message flow.

Use the MQOutput node to send messages to clients that connect to the broker using the WebSphere MQ Enterprise Transport and that use the MQI and AMI application programming interfaces.

Configuring a server output node to close all connections:

Configure a server output node to close all connections on a specified port.

About this task

Scenario: A server output node is configured to close all connections on a specified port.

Instructions: The following steps show how to create a message flow that closes all TCP/IP connections on port 14153:

Procedure

1. Create a message flow called TCPIP_Task13 with an MQInput node and a TCPIPServerOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the Close terminal of the TCPIPServerOutput node.

3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK13.IN1`.
4. Set the following properties of the TCPIPServerOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14153`.
   b. On the **Advanced** tab, set the `Send to:` property (in the **Broadcast options** group) to `All available connections`.
5. Save the message flow.

Configuring a client socket to store reply correlation details:

Configure a client TCP/IP socket to store reply correlation details, by the use of a message flow with MQInput and TCPIPClientOutput nodes.

About this task

Scenario: A client TCP/IP socket is configured to store response returned on the input stream.

Instructions: The following steps show how to set the Reply ID on a connection, which can be used when a response is returned on the input stream:

Procedure

1. Create a message flow called TCPIP_Task14 with an MQInput node and a TCPIPClientOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.

3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK14.IN1`.
4. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14154`.
   b. On the **Request** tab, set the `Reply ID location` property to `$Root/MQMD/MsgId`.
5. Save the message flow.

Writing close connection details to a file:

Configure a message flow to write details of a connection closure to a file, by the use of TCPIPServerInput, Compute, and FileOutput or FTEOutput nodes.

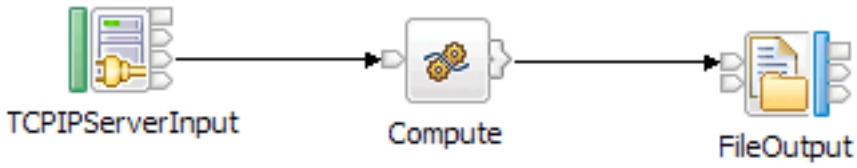
About this task

Scenario: A message flow writes close connection details to a file. The scenario uses the FileOutput node; the steps shown also apply to the FTEOutput node.

Instructions The following steps show how to configure a message flow to write details of the closure of any connection to a file:

Procedure

1. Create a message flow called TCPIP_Task15 with a TCPIPServerInput node, a Compute node, and a FileOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Close terminal of the TCPIPServerInput node to the In terminal of the Compute node.
3. Connect the Out terminal of the Compute node to the In terminal of the FileOutput node.



4. On the TCPIPServerInput node, set the `Connection details` property (on the **Basic** tab) to `14155`.
5. On the Compute node, set the `ESQL` property (on the **Basic** tab) to:

```
BROKER SCHEMA Tasks

CREATE COMPUTE MODULE TCPIP_Task15_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  -- CALL CopyMessageHeaders();
  -- CALL CopyEntireMessage();
  Set OutputRoot.XMLNSC.CloseEvent = InputLocalEnvironment.TCPIP;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;
```

```
 CREATE PROCEDURE CopyEntireMessage() BEGIN
  SET OutputRoot = InputRoot;
 END;
END MODULE;
```

6. Set the following properties of the FileOutput node.
   a. On the **Basic** tab, set the following properties:
      - Set the `Directory` property to `c:\temp\Task15`.
      - Set the `File name or pattern` property to `CloseEvents.txt`.
   b. On the **Records and elements** tab, set the `Record definition` property to `Record is unmodified data`.
7. Save the message flow.

Configuring a client node to dynamically call a port:

Configure a client node to dynamically use a port and hostname that are set in the local environment, by the use of a message flow with MQInput, Compute, and TCPIPClientOutput nodes.

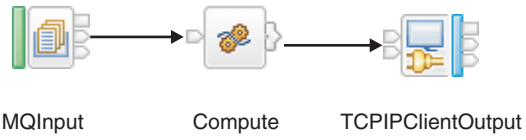
About this task

Scenario: A client node dynamically calls a port.

Instructions: The following steps show how to override the connection details specified on a client output node to dynamically use a port and hostname that are set in the local environment:

Procedure

1. Create a message flow called TCPIP_Task16 with an MQInput node, a Compute node, and a TCPIPClientOutput node. For more information, see “Creating a message flow” on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the Compute node.
3. Connect the Out terminal of the Compute node to the In terminal of the TCPIPClientOutput node.



4. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK16.IN1` .
5. On the Compute node, set the `ESQL` property (on the **Basic** tab) to:

```
BROKER SCHEMA Tasks
CREATE COMPUTE MODULE TCPIP_Task16_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  -- CALL CopyMessageHeaders();
  CALL CopyEntireMessage();
  set InputLocalEnvironment.Destination.TCPIP.Output.Hostname = 'localhost';
  set InputLocalEnvironment.Destination.TCPIP.Output.Port = 14156;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
```

```
 END WHILE;
END;

CREATE PROCEDURE CopyEntireMessage() BEGIN
 SET OutputRoot = InputRoot;
END;
END MODULE;
```

6. On the TCPIPClientOutput node, set the `Connection details` property (on the **Basic** tab) to `9999`.
7. Save the message flow.

Configuring a server receive node to wait for data on a specified port:

Configure a TCPIPServerReceive node to block the message flow and wait for data to arrive on any connection.

About this task

Scenario: A server receive node is configured to wait for data on a specified port.

Instructions: The following steps show how to configure a TCPIPServerReceive node to wait for data on port 14157:

Procedure

1. Create a message flow called TCPIP_Task17 with an MQInput node and a TCPIPServerReceive node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPServerReceive node.

3. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK17.IN1`.
4. On the TCPIPServerReceive node, set the `Connection details` property (on the **Basic** tab) to `14157`.
5. Save the message flow.

Sending and receiving data through a TCP/IP client connection, delimiting the record by closing the output stream (asynchronous):

Send data through a TCP/IP client connection and receive data back on the same connection (asynchronously), by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientInput, and MQOutput nodes.

About this task

Scenario: An application sends asynchronous data between TCP/IP client connections.

Instructions: The following steps describe how to create a message flow to send data through a client connection and wait on the same connection for a reply to be returned. The request is performed asynchronously in two different flows; the TCPIPClientInput node does not wait for data to be returned on this connection, but monitors all available connections. The outgoing record is delimited by closing the output stream, and the reply message is delimited by the remote server closing the input stream. The connection is then completely closed by the node.

Procedure

1. Create a message flow called TCPIP_Task18 with an MQInput node, a TCPIPClientOutput, a TCPIPClientInput node, and an MQOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientInput node to the In terminal of the MQOutput node.

4. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK18.IN1`.
5. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14158`.
   b. On the **Advanced** tab, select `Close output stream after a record has been sent`.
   c. On the **Records and elements** tab, set the `Record definition` property to `Record is unmodified data`.
6. Set the following properties of the TCPIPClientInput node:
   a. On the **Basic** tab, set the `Connection details` property to `14158`.
   b. On the **Advanced** tab, set the `Close connection` property to `After data has been received`.
   c. On the **Records and elements** tab, set the `Record detection` property to `End of stream`.
7. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK18.OUT1`.
8. Save the message flow.

Sending and receiving data on the same TCP/IP client connection, closing input and output streams (synchronous):

Send data through a TCP/IP client connection and wait on the same connection for a reply to be returned, by the use of a message flow with MQInput, TCPIPClientOutput, TCPIPClientReceive, and MQOutput nodes.

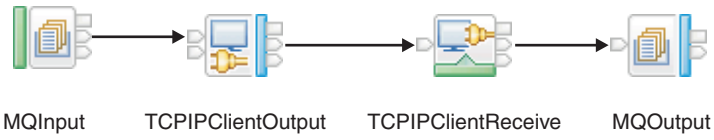
About this task

Scenario: An application sends synchronous data on the same TCP/IP client connection.

Instructions: The following steps describe how to create a message flow that sends out data through a client connection and waits on the same connection for a reply to be returned. The request is synchronous within the same flow, as a result of the TCPIPClientReceive node waiting for data to be returned. The outgoing message is delimited by closing the output stream, and the reply data is delimited by the remote application closing the input stream.

Procedure

1. Create a message flow called TCPIP_Task19 with an MQInput node, a TCPIPClientOutput node, a TCPIPClientReceive node, and an MQOutput node. For more information, see "Creating a message flow" on page 1431.
2. Connect the Out terminal of the MQInput node to the In terminal of the TCPIPClientOutput node.
3. Connect the Out terminal of the TCPIPClientOutput node to the In terminal of the TCPIPClientReceive node.
4. Connect the Out terminal of the TCPIPClientReceive node to the In terminal of the MQOutput node.



5. On the MQInput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK19.IN1`.
6. Set the following properties of the TCPIPClientOutput node:
   a. On the **Basic** tab, set the `Connection details` property to `14159`.
   b. On the **Advanced** tab, set the following properties:
      - Select `Close output stream after a record has been sent`.
      - Set the `Input stream modification` property to `Reserve input stream and release at end of flow`. It is important to reserve the input stream so that it is not closed before the receive node processes the return data.
   c. On the **Records and elements** tab, set the `Record definition` property to `Record is Unmodified Data`.
7. Set the following properties of the TCPIPClientReceive node:
   a. On the **Basic** tab, set the `Connection details` property to `14159`.
   b. On the **Advanced** tab, set the `Close connection` property to `After data has been received`.
   c. On the **Request** tab, set the `ID location` property to `$LocalEnvironment/WrittenDestination/TCPIP/Output/ConnectionDetails[1]/Id`.
   d. On the **Records and elements** tab, set the `Record detection` property to `Connection closed`.
8. On the MQOutput node, set the `Queue name` property (on the **Basic** tab) to `TCPIP.TASK19.OUT1`.
9. Save the message flow.

Processing email messages

You can configure the EmailOutput node to deliver an email from a message flow to an email server that supports Simple Mail Transfer Protocol (SMTP). You can also configure the EmailInput node to retrieve an email from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

About this task

The topics in the following sections describe how the EmailOutput and the EmailInput nodes work, and how to use them to send and receive email messages.

- "Sending emails" on page 1787
- "Receiving emails" on page 1799

Sending emails

You can use the EmailOutput node to send email messages, with or without attachments, to one or more recipients. The EmailOutput node delivers an email message from your message flow to an email server that supports Simple Mail Transfer Protocol (SMTP), which you specify.

The following topics describe how the EmailOutput node works and how to use it to send email messages.

Use the EmailInput node to retrieve an email, with or without attachments, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

Sending emails

You can configure WebSphere Message Broker to send an email, with or without attachments, to a static or dynamic list of recipients.

About this task

You can configure the EmailOutput node to send an email, with or without a single attachment, with a static subject and static text, to a static list of recipients. You can also construct a message flow that can produce an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time.

You can use the `SMTP Server and Port` property of the EmailOutput node to specify the host name of the SMTP server that the broker uses to send emails, or to specify an alias that refers to a configurable service that is defined on the broker. To enable the configurable service, use the **mqsicreateconfigurableservice** and **mqsichangeproperties** commands, as shown in the following example:

```
mqsicreateconfigurableservice BROKER -c SMTP -o MYSERVER
mqsichangeproperties BROKER -c SMTP -o MYSERVER -n serverName -v smtp.hursley.ibm.com:25
```

If the value of the `SMTP Server and Port` property is set to the defined alias (in this case, MYSERVER), any values that are overridden by the administrator

(smtp.hursley.ibm.com:25 set on the command line as the server name) are used in preference to any statically defined value or override value in the local environment.

The order of preference for value selection is:

1. The value that is specified in the configurable service if an alias exists with the name that was supplied in the `SMTP Server and Port` property.
2. The server name that is specified in the local environment.
3. The value of the `SMTP Server and Port` property that is specified on the node.

Any alias can be removed by using the **mqsideleteconfigurableservice** command, so that the node reverts to resolving the host name from the value that is set in the local environment or on the node. While most configurable service properties are set by the **mqsichangeproperties** command, security identities (user IDs and passwords) are typically set by using the **mqsisetdbparms** command and are referenced in a separate SecurityIdentity property, for example:

```
mqsisetdbparms BROKER -n smtp::MyIdentity -u userName -p password
mqsichangeproperties BROKER -c SMTP -o MYSERVER -n securityIdentity -v MyIdentity
```

The topics in this section describe the different ways in which you can use the EmailOutput node to send email messages.

Procedure

- To send an email with a static subject and static text to a static list of recipients, see "Sending an email" on page 1789.
- To send an email with an attachment, see "Sending an email with an attachment" on page 1790.
- To send an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time, see "Producing dynamic email messages" on page 1791.
- To send an email that is constructed from a MIME message, see "Sending a MIME message" on page 1795.
- To configure the SMTP server, port number, and security identity for the EmailOutput node as a broker external resource, see "Changing connection information for the EmailOutput node" on page 1798.

Sending an email:

You can send an email with a static subject and static text to a static list of recipients.

About this task

Use the WebSphere Message Broker Toolkit to configure the properties on the EmailOutput node so that you can send an email with a statically defined subject and text, and no attachments, to a statically defined list of recipients. The same email is sent to the same recipients. This method is useful when you want to test the EmailOutput node, or when notification alone is sufficient.

Procedure

1. Switch to the Broker Application Development perspective.
2. Add an EmailOutput node to your message flow.
3. Edit the following properties of the EmailOutput node.
   a. On the **Basic** tab, add the SMTP Server and Port information (for example, *smtp.server.com:25*).
   b. On the **Email** tab, add the email addresses of recipients by using the `To Addresses`, `Cc Addresses`, and `Bcc Addresses` properties.
   c. On the **Email** tab, add the email address of the sender by using the `From Address` and `Reply-To Address` properties.
   d. On the **Email** tab, provide a subject for the email by using the `Subject of email` property.
   e. On the **Email** tab, provide the text of the email by using `Email message text` property.
4. Save the changes.
5. Add the message flow to the BAR file and deploy.

Results

When a message is passed into the deployed EmailOutput node, an email is sent to the defined set of recipients, containing the subject and text specified on the node.

Related tasks:

"Sending an email with an attachment" on page 1790
You can send an email with a fixed subject and fixed text, and an attachment, to a static list of recipients.

You can produce an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time.

"Sending a MIME message" on page 1795
You can send an email that is constructed from a MIME message.

"Changing connection information for the EmailOutput node" on page 1798
You can configure the SMTP server, port number, and security identity for the EmailOutput node as a broker external resource.

Sending an email with an attachment:

You can send an email with a fixed subject and fixed text, and an attachment, to a static list of recipients.

About this task

You can configure an EmailOutput node to send an email with a single attachment. To send an email with multiple attachments, see "Producing dynamic email messages" on page 1791.

Use the WebSphere Message Broker Toolkit to configure the properties on the EmailOutput node so that you can send an email with a statically defined subject and text, and an attachment, to a statically defined list of recipients. This method causes the email message to be constructed as a MIME message. The subject, text, and list of recipients remains static, but the content of the attachment is sought dynamically from the message that is passed to the EmailOutput node at run time. The location of the attachment in the message is defined statically.

Procedure

1. Switch to the Broker Application Development perspective.
2. Add an EmailOutput node to your message flow.
3. Edit the following properties of the EmailOutput node.
   a. On the **Basic** tab, add the SMTP Server and Port information (for example, *smtp.server.com:25*).
   b. On the **Email** tab, add the email addresses of recipients by using the `To Addresses`, `Cc Addresses`, and `Bcc Addresses` properties.
   c. On the **Email** tab, add the email address of the sender by using the `From Address` and `Reply-To Address` properties.
   d. On the **Email** tab, provide a subject for the email by using the `Subject of email` property.
   e. On the **Email** tab, provide the text of the email by using `Email message text` property.
   f. On the **Attachment** tab, set the `Attachment Content` property by using either an ESQL or XPath expression, referring to an element in the message tree; for example, *Body.BLOB*.
   g. On the **Attachment** tab, set the `Attachment Content Name` property with the name of the attachment as it appears in the email.
   h. On the **Attachment** tab, set the `Attachment Content Type`, `Attachment Content Encoding`, and `Multipart Content Type` properties to determine the type of attachment that is sent in the MIME message.
4. Save the changes.
5. Add the message flow to the BAR file and deploy.

Results

When a message is passed into the deployed EmailOutput node, an email is sent to the defined set of recipients, containing the subject, text, and attachment specified on the node.

Related tasks:

"Sending an email" on page 1789
You can send an email with a static subject and static text to a static list of recipients.

You can produce an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time.

"Sending a MIME message" on page 1795
You can send an email that is constructed from a MIME message.

"Changing connection information for the EmailOutput node" on page 1798
You can configure the SMTP server, port number, and security identity for the EmailOutput node as a broker external resource.

Producing dynamic email messages:

You can produce an email where the SMTP server, list of recipients, subject, text, and multiple attachments are all determined at run time.

About this task

You can create a message flow that produces an email with multiple attachments. To configure an EmailOutput node to send an email with a single attachment, static subject, and static text to a static list of recipients, see "Sending an email with an attachment" on page 1790.

The node properties that you set when sending an email can be optional, and can be overridden at run time by values that you specify in the local environment, email output header (EmailOutputHeader), or the body of the message. To use this method, previous nodes in the message flow must construct these overrides. Where a text value is not specified in the node properties for the main body of the email, the body of the message that is passed to the EmailOutput node is used.

The following examples show how to set up the recipient, sender, subject, SMTP server, and message body information in ESQL (with a Compute node) and Java (with a JavaCompute node).

Using a Compute node:
About this task

```
CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  CALL CopyMessageHeaders();

  -- Add recipient information to the EmailOutputHeader
```

```
  SET OutputRoot.EmailOutputHeader.To = '<recipient email address>';
  SET OutputRoot.EmailOutputHeader.Cc = '<recipient email address>';
  SET OutputRoot.EmailOutputHeader.Bcc = '<recipient email address>';

  -- Add sender information to EmailOutputHeader
  SET OutputRoot.EmailOutputHeader.From = '<sender email address>';
  SET OutputRoot.EmailOutputHeader."Reply-To" = '<reply email address>';

  -- Add subject to EmailOutputHeader
  SET OutputRoot.EmailOutputHeader.Subject = 'Replaced by ESQL compute node.';

  -- Add SMTP server information to the LocalEnvironment
  SET OutputLocalEnvironment.Destination.Email.SMTPServer ='<smtp.server:port>';

  -- Create a new message body, which will be sent as the main text of the email.
  SET OutputRoot.BLOB.BLOB = CAST('This is the new text for the body of the email.' AS BLOB CCSID 1208);

  RETURN TRUE;
 END;
```

To write white space characters (such as newline (NL), carriage return (CR), and line feed (LF) characters) in the text string that is produced as the email body, you can add the following lines of code.

```
DECLARE crlf CHAR CAST(X'0D0A' AS CHAR CCSID 1208);
DECLARE myEmailBodyTxt CHAR;
SET myEmailBodyTxt [equals char] 'this is the first line' || crlf ||
    'this is the second line' || crlf ||
    'this is the third line';
SET OutputRoot.BLOB.BLOB = CAST(myEmailBodyTxt AS BLOB CCSID 1208);
```

Using a JavaCompute node:

About this task

```
public void evaluate(MbMessageAssembly assembly) throws MbException {
  MbOutputTerminal out = getOutputTerminal("out");

  // Create a new assembly to propagate out of this node, as we want to update it
  MbMessage outMessage = new MbMessage();
  copyMessageHeaders(assembly.getMessage(), outMessage);
  MbMessage outLocalEnv = new MbMessage(assembly.getLocalEnvironment());
  MbMessage outExceptionList = new MbMessage(assembly.getExceptionList());
  MbMessageAssembly outAssembly = new MbMessageAssembly(assembly, outLocalEnv, outExceptionList, outMessage);
  MbElement localEnv = outAssembly.getLocalEnvironment().getRootElement();

  // Create the EmailOutputHeader parser. This is where we add recipient, sender and subject information.
  MbElement root = outMessage.getRootElement();
  MbElement SMTPOutput = root.createElementAsLastChild("EmailOutputHeader");

  // Add recipient information to EmailOutputHeader
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "To", "<recipient email address");
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Cc", "<recipient email address");
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Bcc", "<recipient email address");

  // Add sender information to EmailOutputHeader
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "From", "<sender email address>");
  SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Reply-To", "<reply email address>");
```

```
// Add subject information to EmailOutputHeader
SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Subject", "Replaced by Java compute node.");

// Create Destination.Email. This is where we add SMTP server information
MbElement Destination = localEnv.createElementAsLastChild(MbElement.TYPE_NAME, "Destination", null);
MbElement destinationEmail = Destination.createElementAsLastChild(MbElement.TYPE_NAME, "Email", null);
destinationEmail.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "SMTPServer", "<smtp.server:port>");

// Set last child of root (message body)
MbElement BLOB = root.createElementAsLastChild(MbBLOB.PARSER_NAME);
String text = "This is the new text for the body of the email";
BLOB.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB", text.getBytes());

outMessage.finalizeMessage(MbMessage.FINALIZE_VALIDATE);

out.propagate(outAssembly);  }
```

Using the local environment:
About this task

Use the local environment to specify overrides to the SMTP server connection information and attachments.

Local environment	Description
Destination.Email.SMTPServer	The Server:Port of the SMTP server. Port is optional; if you do not specify it, the default value is 25.
Destination.Email.SecurityIdentity	The security identity for authentication with the SMTP server, which can be the name of the userid and password pair that is defined using the **mqsisetdbparms** command, or it can reference an external resource that has a securityIdentity attribute that references a userid and password that are defined using the **mqsisetdbparms** command. In both cases, the value is appended after the string "smtp::". For example, if you use the **mqsisetdbparms** command to create a userid and password of *smtp::myUseridPassword*, the securityIdentity that is specified on the node, or indirectly in an external resource, is *myUseridPassword*.
Destination.Email.BodyContentType	Identifies that the body of the email message contains HTML rather than plain text. You can set this property to text/plain, text/html, or text/xml; text/plain is the default value.
Destination.Email.MultiPartContentType	The type of multipart, including related, mixed, and alternative. You can set any value here.
Destination.Email.Attachment.Content	Either the actual attachment (BLOB/text), or an XPath or ESQL expression that references an element; for example, an element in the message tree or LocalEnvironment. The value of the referenced element is taken as the content of the attachment. • If the element is a BLOB, it is an attachment. • If the element is text, check to see if it can be resolved to another element in the message tree or LocalEnvironment. If it can be resolved, use that element. If it cannot be resolved, add this element as the attachment.
Destination.Email.Attachment.ContentType	The type of attachment (also known as Internet Media Type), including text/plain, text/html, and text/xml. You can set any value here.
Destination.Email.Attachment.ContentName	The name of the attachment.

Local environment	Description
Destination.Email.Attachment.ContentEncoding	The encoding of the attachment: 7bit, base64, or quoted-printable. • 7bit is the default value that is used for ASCII text. • Base64 is used for non ASCII, whether non English or binary data. This format can be difficult to read. • Quoted-printable is an alternative to Base64, and is appropriate when most of the data is ASCII with some non-ASCII parts. This format is more readable; it provides a more compact encoding because the ASCII parts are not encoded.

Using the email output header:
About this task

Use the email output header to specify overrides to the SMTP server connection information and attachments. The EmailOutputHeader is a child of Root. Values that you specify in this header override equivalent properties that you set on the EmailOutput node. Use the SMTP output header to specify any of the email attributes, such as its recipients.

Location	Description
Root.EmailOutputHeader.To	A comma-separated list of email addresses.
Root.EmailOutputHeader.Cc	A comma-separated list of email addresses.
Root.EmailOutputHeader.Bcc	A comma-separated list of email addresses.
Root.EmailOutputHeader.From	A comma-separated list of email addresses.
Root.EmailOutputHeader.Reply-To	A comma-separated list of email addresses.
Root.EmailOutputHeader.Subject	The subject of the email.

Use the JavaCompute node to work with messages by using the Java language.

Sending a MIME message:

You can send an email that is constructed from a MIME message.

About this task

You can pass a MIME message to the EmailOutput node, which uses the MIME parser to write the MIME message to a bit stream. This message is then sent to the list of recipients in the EmailOutputHeader. Local environment overrides are not considered when a MIME message is passed. You do not need to configure the EmailOutput node in the following examples.

The following examples show how to set up the recipient, sender, subject, SMTP server, and message body information in ESQL (with a Compute node) and Java (with a JavaCompute node).

Using a Compute node:
About this task

```
CREATE FUNCTION Main() RETURNS BOOLEAN
BEGIN

   CALL CopyMessageHeaders();

   -- Add recipient information to the EmailOutputHeader
   SET OutputRoot.EmailOutputHeader.To = '<recipient email address>';
   SET OutputRoot.EmailOutputHeader.Cc = '<recipient email address>';
   SET OutputRoot.EmailOutputHeader.Bcc = '<recipient email address>';

   -- Add sender information to EmailOutputHeader
   SET OutputRoot.EmailOutputHeader.From = '<sender email address>';
   SET OutputRoot.EmailOutputHeader."Reply-To" = '<reply email address>';

   -- Add subject to EmailOutputHeader
   SET OutputRoot.EmailOutputHeader.Subject = 'Dynamic MIME message in ESQL.';

   -- Add SMTP server information to the LocalEnvironment
   SET OutputLocalEnvironment.Destination.Email.SMTPServer ='<smtp.server:port>';

   -- Create a new MIME message body, which will be sent as the main text of the email,
   -- including an attachment.
   CREATE FIELD OutputRoot.MIME TYPE Name;
   DECLARE M REFERENCE TO OutputRoot.MIME;

   -- Create the Content-Type child of MIME explicitly to ensure the correct order. If we set
   -- the ContentType property instead, the field could appear as the last child of MIME.
   CREATE FIELD M."Content-Type" TYPE NameValue VALUE 'multipart/related; boundary=myBoundary';
   CREATE FIELD M."Content-ID"   TYPE NameValue VALUE 'new MIME document';

   CREATE LASTCHILD OF M TYPE Name NAME 'Parts';
   CREATE LASTCHILD OF M.Parts TYPE Name NAME 'Part';
   DECLARE P1 REFERENCE TO M.Parts.Part;
```

```
   -- First part:
   --   Create the body of the email.
   --   The body of the email has the text 'This is the main body of the email.'.
   CREATE FIELD P1."Content-Type" TYPE NameValue VALUE 'text/plain; charset=us-ascii';
   CREATE FIELD P1."Content-Transfer-Encoding" TYPE NameValue VALUE '8bit';
   CREATE LASTCHILD OF P1 TYPE Name NAME 'Data';
   CREATE LASTCHILD OF P1.Data DOMAIN('BLOB') PARSE(CAST('This is the main body of the email.'
AS BLOB CCSID 1208));

   CREATE LASTCHILD OF M.Parts TYPE Name NAME 'Part';
   DECLARE P2 REFERENCE TO M.Parts.Part[2];

   -- Second part:
   --   Create the attachment of an email.
   --   The attachment is called 'attachment.txt' and contains the text 'This is an attachment.'.
   CREATE FIELD P2."Content-Type" TYPE NameValue VALUE 'text/plain; charset=us-ascii; name=attachment.txt';
   CREATE FIELD P2."Content-Transfer-Encoding" TYPE NameValue VALUE '8bit';
   CREATE LASTCHILD OF P2 TYPE Name NAME 'Data';
   CREATE LASTCHILD OF P2.Data DOMAIN('BLOB') PARSE(CAST('This is an attachment.' AS BLOB CCSID 1208));

   RETURN TRUE;
END;
```

Using a JavaCompute node:

About this task

```
public void evaluate(MbMessageAssembly assembly) throws MbException {
   MbOutputTerminal out = getOutputTerminal("out");
   MbOutputTerminal fail = getOutputTerminal("fail");

   // Create a new assembly to propagate out of this node, as we want to
   // update it
   MbMessage outMessage = new MbMessage();
   copyMessageHeaders(assembly.getMessage(), outMessage);
   MbMessage outLocalEnv = new MbMessage(assembly.getLocalEnvironment());
   MbMessage outExceptionList = new MbMessage(assembly.getExceptionList());
   MbMessageAssembly outAssembly = new MbMessageAssembly(assembly, outLocalEnv, outExceptionList, outMessage);
   MbElement localEnv = outAssembly.getLocalEnvironment().getRootElement();

   // Create the EmailOutputHeader parser. This is where we add recipient,
   // sender and subject information.
   MbElement root = outMessage.getRootElement();
   MbElement SMTPOutput = root.createElementAsLastChild("EmailOutputHeader");

   // Add recipient information to EmailOutputHeader
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "To", "<recipient email address>");
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Cc", "<recipient email address>");
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Bcc", "<recipient email address>");

   // Add sender information to EmailOutputHeader
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "From", "<sender email address>");
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Reply-To", "<reply email address>");

   // Add subject information to EmailOutputHeader
   SMTPOutput.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Subject", "Dynamic MIME message in Java.");

   // Create Destination.Email. This is where we add SMTP server information.
```

```
   MbElement Destination = localEnv.createElementAsLastChild(MbElement.TYPE_NAME, "Destination", null);
   MbElement destinationEmail = Destination.createElementAsLastChild(MbElement.TYPE_NAME, "Email", null);
   destinationEmail.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "SMTPServer", "<smtp.server:port>");

   // Set last child of root (message body) as MIME.
   MbElement MIME = root.createElementAsLastChild("MIME");

   // Create the Content-Type child of MIME explicitly to ensure the correct order.
   MIME.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Type", "multipart/related;
boundary=myBoundary");
   MIME.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-ID", "new MIME document");
   MbElement parts = MIME.createElementAsLastChild(MbElement.TYPE_NAME, "Parts", null);
   MbElement part, data, blob;
   String text;

   // First part:
   //   Create the body of the email.
   //   The body of the email has the text 'This is the main body of the email.'.
   part = parts.createElementAsLastChild(MbElement.TYPE_NAME, "Part", null);
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Type", "text/plain; charset=us-ascii");
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Transfer-Encoding", "8bit");
   data = part.createElementAsLastChild(MbElement.TYPE_NAME, "Data", null);
   blob = data.createElementAsLastChild("BLOB");
   text = "This is the main body of the email.";
   try {
  blob.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB", text.getBytes("UTF8"));
   } catch (UnsupportedEncodingException e) {
  fail.propagate(outAssembly);
   }

   // Second part:
   //   Create the attachment of an email.
   //   The attachment is called 'attachment.txt' and contains the text 'This is an attachment.'.
   part = parts.createElementAsLastChild(MbElement.TYPE_NAME, "Part", null);
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Type", "text/plain; charset=us-ascii;
name=attachment.txt");
   part.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "Content-Transfer-Encoding", "8bit");
   data = part.createElementAsLastChild(MbElement.TYPE_NAME, "Data", null);
   blob = data.createElementAsLastChild("BLOB");
   text = "This is an attachment.";
   try {
  blob.createElementAsLastChild(MbElement.TYPE_NAME_VALUE, "BLOB", text.getBytes("UTF8"));
   } catch (UnsupportedEncodingException e) {
  fail.propagate(outAssembly);
   }

   outMessage.finalizeMessage(MbMessage.FINALIZE_VALIDATE);
   out.propagate(outAssembly);
}
```

You can configure the SMTP server, port number, and security identity for the EmailOutput node as a broker external resource.

Changing connection information for the EmailOutput node:

You can configure the SMTP server, port number, and security identity for the EmailOutput node as a broker external resource.

About this task

Use an alias that is specified in the `SMTP Server and Port` property on the EmailOutput node. The security identity references a user ID and password pair that is defined on the broker by using the **mqsisetdbparms** command.

Procedure

1. Use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command to create an SMTP broker external resource for the alias that is specified on the node.
2. Then use the **mqsichangeproperties** command to create an SMTPServer property with the value in the form of *server:port*. The port value is optional; if you do not specify it, the default value is 25. You can also use the **mqsichangeproperties** command to create an SMTPSecurityIdentity property with a value that is the name of a security identity that can be resolved at run time to a user ID and password for authentication with the SMTP server.

   For example:

```
mqsicreateconfigurableservice MY_BROKER –c SMTP –o SMTP_MyAlias
```

   followed by:

```
 mqsichangeproperties MY_BROKER –c SMTP –o SMTP_MyAlias –n serverName –v smtp.hursley.ibm.com:25
```

   These commands override the SMTP server and port values that are specified on any nodes that also specify an alias of SMTP_MyAlias. If the local environment contains any overrides, they take preference over the broker external resource properties. See the following example:

```
mqsichangeproperties MY_BROKER –c SMTP –o SMTP_MyAlias –n securityIdentity –v mySecurityIdentity
```

   You must also use the **mqsisetdbparms** command to define the security identity at the broker run time.

Related concepts:

"Using the WebSphere Message Broker Explorer to work with configurable services" on page 644

Use the **mqsisetdbparms** command to associate a specific user ID and password (or SSH identity file) with one or more resources that are accessed by the broker.

Receiving emails

You can configure the EmailInput node to receive an email, with or without an attachment, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

About this task

You can use the `Email server` property on the EmailInput node to specify the protocol, host name, and port of the email server that the broker uses to receive emails. Alternatively, you can specify a configurable service name that refers to an EmailServer configurable service that is defined on the broker. To enable the configurable service, use the **mqsicreateconfigurableservice** and **mqsichangeproperties** commands, as shown in the following examples:

```
mqsicreateconfigurableservice MB7BROKER -c EmailServer -o
myEmailConfigurableServiceName
```

```
mqsichangeproperties MB7BROKER -c EmailServer -o myEmailConfigurableServiceName
  -n serverName -v pop3://myemailserver.com:12345
```

If the value of the `Email server` EmailInput node property is set to the defined configurable service name, any values set by the administrator on the command line are used in preference to any statically defined value.

The following list details the order of preference for value selection:

1. The email server URL value that is specified in the EmailServer configurable service `serverName` property, if a configurable service exists that matches the name that is supplied in the `Email server` EmailInput node property.
2. The email server URL value of the `Email server` property that is specified directly on the EmailInput node.

A configurable service can be removed by using the **mqsideleteconfigurableservice** command, so that the EmailInput node reverts to resolving the email server URL from the value that is set on the node. For more information about creating, changing, reporting, and deleting configurable services, see "Changing connection information for the EmailInput node" on page 1805.

While most configurable service properties are set by using the **mqsichangeproperties** command, security identity support, such as an email server user ID and password pair, is typically set by using the **mqsisetdbparms** command. Security identity support can be configured by setting the `Security identity` EmailInput node property or EmailServer configurable service `securityIdentity`

property to reference a security identity object. However, the security identity object must first be created by using the **mqsisetdbparms** command, for example:

```
mqsisetdbparms MB7BROKER -n email::mySecurityIdentity -u myUserID -p myPassword
mqsichangeproperties MB7BROKER -c EmailServer -o myEmailConfigurableServiceName -n
securityIdentity -v mySecurityIdentity
```

For more information about email server security identity support, see "**mqsisetdbparms** command" on page 3954.

The topics in this section describe the different ways in which you can use the EmailInput node to receive email messages.

Procedure

- To receive an email, see "Receiving an email" on page 1801.
- To configure the email server URL and security identity for the EmailInput node as a broker external resource, see "Changing connection information for the EmailInput node" on page 1805.

Receiving an email:

You can receive an email, with or without attachments, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

Before you begin

Before you start:

This topic assumes that you have already created a message flow. For more information, see "Creating a message flow" on page 1431.

About this task

Use the WebSphere Message Broker Toolkit to configure the properties on the EmailInput node so that you can receive an email, with or without attachments.

Procedure

1. Add an EmailInput node to your message flow.
2. Edit the following EmailInput node properties:
   a. On the **Basic** tab, add the email server URL, or the EmailServer configurable service name as the `Email server` property value, as described in "EmailInput node" on page 4394. For example, `pop3://myemailserver.com:12345` or `imap://myemailserver.com:56789`.
   b. On the **Security** tab, add the security identity object name of the email server user ID and password pair as the `Security identity` property value. For more information about email server security identity support, see "**mqsisetdbparms** command" on page 3954.
   c. Configure the following properties on the **Retry** tab:
      - `Retry mechanism`: The Retry mechanism property defines how the EmailInput node handles a message flow failure. Valid values are `Failure`, `Short Retry`, or `Short and Long Retry`. The default value for this property is `Short and long retry`, which indicates that the email is retried until the short retry threshold is met, then long retry takes place, meaning that the email is never deleted from the email server, but also that the email is infinitely retried. Emails are deleted from the email server if the email message fails and this property value is not set to `Short and Long Retry`.
      - `Retry threshold`: The Retry threshold property is the number of times to try the message flow transaction again when the `Retry mechanism` property value is set to `Short Retry`. The default value for this property is `0`.
      - `Short retry interval (in seconds)`: The Short retry interval is the interval, in seconds, between each retry if the `Retry threshold` property value is not set to zero. The default value for this property is `0`. If the email is retried until the short retry threshold is met and the email fails, the email is routed to the failure terminal, and the email is deleted from the email server.
      - `Long retry interval (in seconds)`: The Long retry interval is the interval, in seconds, between each retry, if the `Retry mechanism` property value is `Short and Long Retry`, and the short retry threshold has been exhausted. The default value for this property is `300` seconds.

- `Action on failing email`: The Action on failing email property determines the action that the EmailInput node takes with the input data source after all attempts to process the email contents fail. The Action on failing email property is a read only property that is set to a default value of `Delete Email`, which is used with the Retry mechanism property. If the Retry mechanism property is set to `Short and Long Retry`, the message flow continues to try to retrieve the email from the email server, meaning that the email is never deleted. If the Retry mechanism property is not set to `Short and Long Retry`, the Action on failing email property value `Delete Email` is used, and the email is deleted from the email server.

3. Save the changes.
4. Add the message flow to the BAR file and deploy.

   When a message is passed into the deployed EmailInput node, an email is received from the email server and the body of the email message, and any attachments, are propagated in the Multipurpose Internet Mail Extensions (MIME) domain. All other information relating to the email is stored in the `Root.EmailInputHeader` MIME logical tree. For a complete list of the email elements that are propagated in the MIME logical tree when you use an EmailInput node, see "EmailInput node" on page 4394.

   When an email containing an attachment is received, the EmailInput node places different parts of the email body in the MIME domain, so that they are associated with the MIME parser. The MIME tree location that the EmailInput node builds to house the information is the same location that the EmailOutput node expects email data to be in when sending an email. The attachment is stored in the MIME logical tree in directory `Root.MIME.Parts.Part.Data`. Where Content-Type describes the type of data that is in the attachment.

   Viewing the `Root.Properties.ContentType` value in the MIME domain allows you to write logic to parse the attachment. For more information about the MIME logical tree, see "MIME parser and domain" on page 1117.

Results

Received emails are deleted from an email server that supports POP3 or IMAP only when the emails have been successfully propagated after being processed by the EmailInput node Failure, Out, or Catch terminals, and the message flow has successfully executed. This does not form part of a globally coordinated transaction.

Emails are deleted from the email server under the following circumstances:

- The Failure terminal is not connected.
- An exception occurs in the Failure terminal.
- The email message fails and the `Retry mechanism` property value is not set to `Short and Long Retry`.
- The `Retry threshold` is not set to `0` and the `Short retry interval` property value has been exhausted.

For more information about processing responses from an EmailInput node, and for information about rollback handling, see "Processing responses from an EmailInput node" on page 1804.

Related concepts:

"MIME parser and domain" on page 1117
Use the MIME domain if your messages use the MIME standard for multipart messages.

"Manipulating messages in the MIME domain" on page 2612
A MIME message does not need to be received over a particular transport. For example, a message can be received over HTTP by using an HTTPInput node, or over WebSphere MQ by using an MQInput node. The MIME parser is used to process a message if the message domain is set to MIME in the input node properties, or if you are using WebSphere MQ, and the MQRFH2 header has a message domain of MIME.

Use the EmailInput node to retrieve an email, with or without attachments, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

Processing responses from an EmailInput node:

The EmailInput node can return different response messages that indicate the success or failure of receiving an email, with or without attachments, from an email server that supports Post Office Protocol 3 (POP3) or Internet Message Access Protocol (IMAP).

Before you begin

Before you start:

Ensure that you have developed a message flow with an EmailInput node, as described in "Receiving an email" on page 1801.

About this task

The EmailInput node has three output terminals:

- Failure: The output terminal to which the message is routed if an EmailInput node failure is detected when a message is propagated, or an EmailInput node fails to access the email server. Connect the Failure terminal of this node to another node in the message flow to process errors.
- Out: The output terminal to which the message is routed if it has been propagated successfully. Connect the Out terminal of this node to another node in the message flow to process the message further, or send the message to an additional destination.
- Catch: The output terminal to which a message is routed if an exception is thrown downstream and caught by this node. Exceptions are caught only if this terminal is attached.

Procedure

- **Processing successful returns**

  When an EmailInput node successfully receives an email, the resulting message is propagated to the Out terminal.
- **Processing downstream message flow exceptions**

  If a message flow exception occurs downstream of the Failure terminal in the message flow, a message is routed to the Catch terminal. If you do not have the `Retry mechanism` property value set to `Short and Long Retry` on the EmailInput node Retry tab, the current transaction is rolled back.
- **Handling failures in the node**

  Any other failures are propagated to the Failure terminal. Possible failures include:
  - A problem retrieving an email message. For example, an inability to communicate with the target email server because of a connection or authentication error. If this occurs, the connection is re attempted when the polling interval expires. Each connection failure occurrence causes an appropriate message in user trace.
  - A problem parsing an email.
  - An internal EmailInput node exception or error is detected before the message is propagated to the Out terminal. For example, a malformed email is received, causing the EmailInput to propagate the message and an exception list to the Failure terminal.
  - The `Retry mechanism` property value is set to `Failure`, causing an immediate message to be sent to the Failure terminal.

– The `Retry threshold` is not set to `0` and the `Short retry interval` property value has been exhausted, causing a message to be routed to the failure terminal, and the email being deleted from the email server.

If the failure terminal is not connected, or an exception occurs down the Failure terminal, or the email message fails and you have not set the `Retry mechanism` property value to `Short and Long Retry`, the email is deleted from the email server.

Results

You can use the EmailServer configurable service to change connection details for the EmailInput node. See "Changing connection information for the EmailInput node" for details about creating, changing, reporting, and deleting an EmailServer configurable service.

Before you begin

Before you start:

- Read "Configurable services" on page 1296 to find out more about configurable services.
- Read "Receiving emails" on page 1799 for background information.

About this task

Use the EmailServer configurable service to change the email server connection information for the EmailInput node. The properties of the EmailServer configurable service are described in "Configurable services properties" on page 3766.

Creating, changing, reporting, and deleting configurable services

Procedure

1. To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates an EmailServer configurable service for the email server that is running at `pop3://test.email.server.ibm.com` port 12345. The security identity is identified by *mySecurityIdentityObjectName* in this example:

   ```
   mqsicreateconfigurableservice MB7BROKER -c EmailServer -o
   myEmailConfigurableServiceName -n serverName,securityIdentity -v
   pop3://test.email.server.ibm.com:12345,mySecurityIdentityObjectName
   ```

2. To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. You must stop and start the execution group for the change of property value to take effect. This example changes the EmailInput node that is configured to use the *myEmailConfigurableServiceName* configurable service. After you run this command, the EmailInput node connects to the production system (`pop3://production.email.server.ibm.com:12345`) instead of the test system (`pop3://test.email.server.ibm.com:12345`).

   ```
   mqsichangeproperties MB7BROKER -c EmailServer -o myEmailConfigurableServiceName
     -n serverName -v pop3://production.email.server.ibm.com:12345
   ```

3. To display all EmailServer configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

   ```
   mqsireportproperties MB7BROKER -c EmailServer -o AllReportableEntityNames -r
   ```

4. You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

   ```
   mqsideleteconfigurableservice MB7BROKER -c EmailServer -o
   myEmailConfigurableServiceName
   ```

   You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

Related concepts:

"Using the WebSphere Message Broker Explorer to work with configurable services" on page 644
Configurable services are used to define properties that are related to external services on which the broker relies. Use the WebSphere Message Broker Explorer to view, add, modify and delete configurable services.

Working with files

You can use the FileInput, FileRead, and FTEInput nodes in your message flows to process data from files. You can use the FileOutput node and FTEOutput node to send data from a message flow into a file.

About this task

Using files is one of the most common methods of storing data. You can create message flows to process data in files, accepting data in files as input message data, and producing output message data for file-based destinations. The following file nodes are provided:

- FileInput node. Use this node to receive messages from files in the file system of the broker or, by using FTP or SFTP, in a remote file system. The node generates output message data that any of the output nodes can use, which means that messages can be generated for clients using any of the supported transport protocols to connect to the broker. For more information, see "Using a local file as input for your message flow" on page 1834.
- FTEInput node. Use this node to start a message flow when files are received over a WebSphere MQ File Transfer Edition network. For more information, see "Receiving a file by WebSphere MQ File Transfer Edition" on page 1845.
- CDInput node. Use this node to start a message flow when files are received over a IBM Sterling Connect:Direct network. For more information, see "Receiving a file using IBM Sterling Connect:Direct" on page 1847.
- FileRead node. Use this node to read data from a file in the middle of a message flow. For more information, see "Routing or enriching a message based on the contents of a file" on page 1837.
- FileOutput node. Use this node to write messages to a file in the file system of the broker or, by using FTP or SFTP, in a remote file system. The node can create new files and replace existing files. For more information, see "Writing a file to your local file system" on page 1853.
- FTEOutput node. Use this node to send a file to a remote destination by using a WebSphere MQ File Transfer Edition network. For more information, see "Sending a file by WebSphere MQ File Transfer Edition" on page 1859.

The FileInput and FTEInput nodes start the message flow when a new file arrives, whereas the FileRead node must be connected to another node to start the message flow transaction. The FileRead node also provides keyed access to identify a record, unlike the FileInput node, which processes all records in order.

By using these five nodes, you can also process large files without the complete message being held in memory, and you can simplify the processing of files that have large numbers of repeating entries.

If you want to work with files, read these topics:

- "WebSphere Broker File Transport" on page 1808

WebSphere Broker File Transport

WebSphere Broker File Transport is a service that connects applications to data maintained in files.

You can use the WebSphere Broker File Transport to support the following operations.

- Read messages from files in the broker file system.
- Read messages from files in a remote file system.
- Write messages to a file in the broker file system.
- Write messages to a file in a remote file system.
- Process large files without having to hold the complete message in memory.
- Simplify the processing of files that have large numbers of repeating entries.

These operations are implemented by the following built-in nodes:

- FileInput
- FileOutput
- FileRead
- FTEInput
- FTEOutput
- CDInput
- CDOutput

To use the WebSphere Broker File Transport, you must deploy a message flow that contains one of these nodes.

The FileInput node can read one or more messages from a file in a specified input directory or on a remote FTP or SFTP server, and propagate each message as a separate flow transaction. The part of a file that generates one message flow transaction is called a record. A file can be a single record, or a series of records. The node can handle messages in the following message domains:

- MRM
- XMLNSC
- DataObject
- XMLNS
- JMSMap
- JMSStream

- MIME
- BLOB
- XML
- IDOC

The FileOutput node writes one or more messages from message flow transactions to a file in the broker file system. Each message, as it is written to a file, is converted to a sequence of bytes called a record. Records are accumulated until a process is triggered that completes the file and places it either in the specified output directory or a remote FTP or SFTP server directory.

The FTEOutput node processes messages in the same way as the FileOutput node. When the file is complete, the node sends it to the remote agent.

The CDOutput node processes messages in the same way as the FileOutput node. When the file is complete, the node sends it to the IBM Sterling Connect:Direct network.

The following topics contain more information about processing files:

IBM Sterling Connect:Direct overview and concepts

An overview of IBM Sterling Connect:Direct and its terminology when used with WebSphere Message Broker.

IBM Sterling Connect:Direct is a managed file transfer product that transfers files between, and within, enterprises.

IBM Sterling Connect:Direct, in conjunction with WebSphere Message Broker uses the following terminology:

Connect:Direct server

An application that runs on a machine requiring IBM Sterling Connect:Direct functionality. Files are transferred between two Connect:Direct servers.

- The primary Connect:Direct server, also referred to as the PNODE.
- The secondary Connect:Direct server, also referred to as the SNODE, that receives the transferred file and places the file on the local file system.

Connect:Direct-S

Connect:Direct server which transfers files to other Connect:Direct servers.

Connect:Direct-R

Connect:Direct application that connects to a Connect:Direct server and requests that server does some form of processing. WebSphere Message Broker acts as a Connect:Direct-R to request transfers or receive information about transfers.

WebSphere Message Broker CDInput node

Use the WebSphere Message Broker CDInput node to receive messages that have been transferred to a given Connect:Direct server.

If two or more input nodes are deployed to listen on the same Connect:Direct server, only one receives the file and which one that is cannot be determined. There is some distribution between the nodes, and this is equivalent to having two or more MQInput nodes listening on the same queue.

CDInput nodes can be used in different flows, and in different execution groups, against the same Connect:Direct server.

You can configure the CDInput node to process only a subset of files transferred to the server, based on the directory name and the file name. This allows for multiple CDInput nodes within the same execution group to receive specific files, depending on the filters used.

See "IBM Sterling Connect:Direct concepts" on page 1811 for further information on the CDInput node, CDOutput node, and Connect:Direct server.

WebSphere Message Broker CDOutput node

Use the WebSphere Message Broker CDOutput node to serialize the message tree to a file and then transfer it to a secondary Connect:Direct server using a primary Connect:Direct server. A directory under the work path within the execution group is used as the staging area, until the file is ready to be transferred. Once the file is transferred, it is deleted from the staging area.

Initparm

The definition of the startup parameters for the primary Connect:Direct server (PNODE) and secondary Connect:Direct server (SNODE).

Netmap

The definition of a connection between the primary and secondary Connect:Direct servers.

Processname

The name given to a process that is run in IBM Sterling Connect:Direct. More than one process can be given the same name, and each process is identified uniquely using the process number.

Note that WebSphere Message Broker nodes work purely as clients connecting to the external Connect:Direct server, using the IBM Sterling Connect:Direct Java Application Interface.

By default, WebSphere Message Broker attempts to connect to a local Connect:Direct server, on the default port:

- When sending a file using CDOutput nodes, or
- To be notified of files to process using CDInput nodes.

To enable the CDOutput and CDInput nodes to connect to the local Connect:Direct server, you must set up a username and password using the "**mqsisetdbparms** command" on page 3954.

IBM Sterling Connect:Direct concepts

The CDInput node receives messages that have been transferred to a given Connect:Direct server.

The node receives both the contents of the file and meta data provided by IBM Sterling Connect:Direct on the transfer. One or more CDInput nodes can be used to receive transfers, either in the same flow, different flows, or different execution groups; for any given transfer only one CDInput node receives a message.

You can also specify which transfer a CDInput node can receive, using filters based on directory and file name of the transfer. Once the transfer has been processed there are a set of options of what to do with the transferred file; for further details see "CDInput node" on page 4305.

A simple flow that takes all transferred files from a Connect:Direct server and writes them to a WebSphere MQ queue could contain a CDInput node and an MQOutput node.

Once the CDInput node has been notified of a file to be processed, it processes the file in the same way that a normal FileInput node does. The CDInput node is

notified by the Connect:Direct server manager when a transfer occurs. The notification message is persistently stored on WebSphere MQ and survives broker and queue manager restarts.

The Connect:Direct server manager is defined and runs using a configurable service called *CDServer*. This configurable service is used for administering the access, and processing files using IBM Sterling Connect:Direct.

For more details on the *CDServer* configurable service, see "*CDServer* configurable service properties" on page 3798

Two WebSphere MQ queues are used to store transfer details from the Connect:Direct server:

- SYSTEM.BROKER.CD.STATS
- SYSTEM.BROKER.CD.TRANSFERS

For each successful transfer to the Connect:Direct server, a message is placed on the TRANSFERS queue, which is used to trigger the CDInput node to process the file.

The STATS queue contains internal data used by WebSphere Message Broker to record which transfers have been processed by WebSphere Message Broker.

Clearing both sets of these queues causes all transfers that have occurred up to the current time to be ignored; there is no need, for example, for a restart.

The input node does not poll for transfers, but is triggered instead when they arrive. However, the Connect:Direct server manager does need to poll for events to notify the CDInput node about a transfer. The Connect:Direct server manager has a polling interval of one second.

The CDInput and CDOutput nodes go through the Connect:Direct server manager to both send and receive transfers from a given server, the name of which is set on the node. The Connect:Direct server manager properties are defined using a *CDServer* configurable service.

The Connect:Direct server manager organizes:

- Monitoring the Connect:Direct server for transfers which need to be processed by the CDInput nodes.
- Sending commands created by the CDOutput node to the Connect:Direct server to perform transfers.

In both cases, the Connect:Direct server manager can be used to configure the directory structure to a shared file system, used to both send and receive files from the Connect:Direct server.

The high-level structure of the directory might be different on the two different machines and you can define properties on the Connect:Direct server manager to give the correct mapping.

See "Advanced configuration properties when using IBM Sterling Connect:Direct nodes" on page 727 for further information.

The *Default* configurable service connects to the Connect:Direct server on the local host using the default port. You can modify the default configurable service to a more complex configuration with the CD server on different ports, or a different

machine, or change the node to use a completely different configurable service which is set up to use a different port and hostname.

As well as defining connections details, you can also configure other key properties, such as the location of staging directories and mapping between directories on different machines.

See “Advanced configuration properties when using IBM Sterling Connect:Direct nodes” on page 727 for further information.

The Connect:Direct server manager is started and stopped by the CDInput and CDOutput nodes as required and is not an artifact that is deployed or seen in the deployment view; all of its function is defined by the properties in the configurable service. If transfers happen while WebSphere Message Broker is stopped (or IBM Sterling Connect:Direct flows are stopped) they are not missed and are processed as soon as the flows restart. All transfers are persistent and survive both broker and queue manager restarts.

The configurable service security identity must have adequate permission for the Connect:Direct server manager within the execution group to detect all transfers that are sent to the Connect:Direct server. For example: On UNIX systems, the user's stanza within the `userfile.cfg` in Connect:Direct must have `:cmd.selstats=A:\`. This property can either be set explicitly, or inherited from the higher-level property `:admin.auth=y:\`. If this permission is not present, then the CDInput nodes do not detect or process files that were transferred by other users. For more information about the security identifier, see "**`securityIdentifier`**" in “*CDServer* configurable service properties” on page 3798.

The broker makes a number of API connections to the local Connect:Direct server to process inbound transfers, and to request outbound transfers.

The broker creates one API connection per configurable service per execution group. This creation enables CDOutput nodes to process files sent to the local Connect:Direct server. If there are multiple configurable services that relate to the same Connect:Direct server, then multiple API connections are established.

In addition to these connections, each message flow instance that uses a CDOutput node also creates an API connection to submit transfer requests to the Connect:Direct server. Where there are multiple flows that contain CDOutput nodes, or where these flows have extra defined instances, the broker creates multiple API connections. If the number of API connections that are required exceeds the maximum that is configured in the Connect:Direct server, then the connection fails causing a BIP7951E exception, containing the following information: "`Error: Logon failed! Attempted to exceed maximum API connections`". Avoid this error by increasing the maximum client connections for the Connect:Direct server. The maximum number of connections that are accepted by a Connect:Direct server on UNIX is controlled by the **`api.max.connects`** parameter. For more information about this parameter, and the equivalent settings on other operating systems, see the IBM Sterling Connect:Direct product documentation: http://www.ibm.com/support/knowledgecenter/SS4PJT_5.2.0/cd_52_welcome.html.

How the broker processes files

The broker reads files with the FileInput, FTEInput, and FileRead nodes, and writes files with the FileOutput and FTEOutput nodes.

WebSphere Message Broker can read messages from files and write messages to files in the local file system, or on a network file system that is local to the broker. The following lists the nodes that provide this capability, and the required access permissions for the directories and files they operate on:

- FileInput node: read and write permissions on the input directory and input files.
- FileOutput node: read and write permissions on the output directory.
- FileRead node: read permissions on the input directory and input files. Note: if a Finish File action is used (to move, rename or delete the file), write permissions on the input directory and input files is also required.

The FileInput, FileOutput, and FileRead nodes inherit the permissions assigned to the broker's user ID and group. See your operating system documentation for details on how to set permissions and the impact on file access.

You can use the FTEInput and FTEOutput nodes to receive or send files to a destination on a WebSphere MQ File Transfer Edition network.

You can use the CDInput and CDOutput nodes to receive or send files to a destination on an IBM Sterling Connect:Direct network.

A file, or a record within a file, is analogous to a message in a queue. The directory that contains the file is analogous to a message queue.

How the broker reads a file at the start of a flow

The FileInput node processes messages that are read from files. The FileInput node searches a specified input directory (in the file system attached to the broker) for files that match specified criteria. Optionally, files from a remote FTP or SFTP

server can be moved to the local directory whenever the directory is to be scanned. You can find the file that you require by specifying an explicit file name or a file name pattern that includes wildcard characters. If the file is locked, it is ignored during the directory scan.

The FileInput node creates an `mqsitransitin` subdirectory in the input directory. The `mqsitransitin` subdirectory holds and locks the input files while they are being processed. The broker reads the file and propagates a message, or messages, by using the contents of the file.

If an execution group that processes files in this input directory is removed, check the `mqsitransitin` subdirectory for partially processed or unprocessed files. Move any such files back into the input directory and remove the execution group UUID prefix from the file names, so that they can be processed by a different execution group. For more information about the `mqsitransitin` subdirectory, see "How multiple file nodes share access to files in the same directory" on page 1818.

In the FileInput node, you can specify how the records are derived from the file. The contents of a file can be interpreted as:

- A single record (whole file)
- Separate records, each of a fixed length (fixed-length records)
- Separate records each delimited by a specified delimiter (delimited records)
- Separate records that are recognized by a parser that you specify (parser record sequence)

After the file has been successfully processed, it is either deleted from the file system or moved to an archive subdirectory of the specified (local) directory.

When the last record of the file has been processed successfully, if the End of Data terminal of the FileInput node is connected in the message flow, an End of Data message is propagated to the End of Data terminal. The End of Data message consists of an empty BLOB message and a `LocalEnvironment.File` structure, and it allows explicit end-of-flow processing to be performed in another part of the message flow.

The message (or messages) propagated from the file can be used as input to any message flow and output node. You can create a message flow that receives messages from files and generates messages for clients that use any of the supported transports to connect to the broker.

Whenever a message is propagated from a file, the FileInput node stores information about the file in the LocalEnvironment.File message tree. This information includes the offset of the record of the message in the file that is being processed, and the record number in that file. In addition, when a wildcard is used in a file name pattern, the characters matched in the file name are placed in the WildcardMatch element of the local environment tree.

If a file is backed out, or a file is left in the `mqsitransitin` subdirectory because processing failed, remove the execution group UUID prefix from the file name and move it back into the input directory. Processing is automatically retried, beginning at the first record in the file.

The FTEInput node receives files from the WebSphere MQ File Transfer Edition network. The broker reads the file and propagates a message, or messages, by using the contents of the file. After an FTEInput node has processed a file, the file

is deleted. For details of information that the FTEInput node provides in the local environment, see “Using local environment variables with file nodes” on page 1820.

The CDInput node receives files from the IBM Sterling Connect:Direct network. The broker reads the file and propagates a message, or messages, by using the contents of the file. After a CDInput node has processed a file, the file is deleted. For details of information that the CDInput node provides in the local environment, see “Using local environment variables with file nodes” on page 1820.

The FileRead node can read a whole file, or a single, nominated record. A common use of the FileRead node is to route or enrich messages based on the contents of the file. When developing the message flow you can specify the name and location of the file to be read. You can override these values at run time based on the contents of a message. TheFileRead node reads a file in the middle of a message flow.

The FileRead node complements the existing FileInput and FileOutput nodes.

How the broker reads a file from the middle of a flow

The FileRead node locks files when they are being read and does not move files to a subdirectory to read them. Files can be read completely or separated into records, in the same way as the FileInput node. After the file has been processed by the FileRead node, it can be deleted, archived, or left unchanged.

How the broker writes a file

The FileOutput, CDOutput, and FTEOutput nodes write messages to files in the file system of the broker. When a message is received on the In terminal of the node, it creates and writes a file as a series of one or more records. One record is written to a file for every message received. The name of the file is specified either by a file name pattern in the node or an explicit file name that is either specified in the node or derived from the message.

You can specify how the records are accumulated in files:

- A single record (whole file). The file that is created consists of one record.
- Concatenated records (unmodified records). The records are not padded to any required length, and they are not separated by a delimiter.
- Uniform length records (fixed-length records). Records that are shorter than the specified length are padded to the required length.
- Separate records (delimited records). Records are either terminated or separated by a specified delimiter.

The message flow informs the output node that there are no more records to write by sending a message to its Finish File terminal. The file is then delivered to the appropriate destination:

- FileOutput node: The file is then moved to the specified output directory.

  Optionally, the file can be moved to a directory on a remote FTP or SFTP server. The server is identified by the `Remote server and port` property on the node. Alternatively, you can override the node property by setting a value in the local environment (see “Local environment overrides for the FileOutput node” on page 4443).

- FTEOutput node: The file is sent to the destination agent on the WebSphere MQ File Transfer Edition network.
- CDOutput node: The file is sent to the IBM Sterling Connect:Direct network.

If the output node produces a single record from the file (whole file), the file is moved immediately to the output directory without requiring a message to be propagated to the Finish File terminal. In this case, any message sent to the Finish File terminal of the node has no effect on any file, but the message is still propagated to a message flow attached to the End of Data terminal.

Recognizing file records as messages to be parsed:

Use the FileInput, FTEInput and FileRead nodes to segment your input file into messages that are to be parsed.

The node segments your input file into messages that are to be parsed by one of the following parsers:

- MRM Custom Wire Format (CWF)
- MRM Tagged Delimited String Format (TDS)
- XMLNSC

The `Message domain` property of the node specifies the parser to use; MRM or XMLNSC. Specify `Parsed Record Sequence` for the `Record detection` property so that the node splits the file into messages to be parsed by either the MRM parser or XMLNSC parser.

The MRM parser

If you select an MRM parser, ensure that the message model has a defined message boundary and does not rely on the parse being stopped when it reaches the end of the bit stream. If the final element has a *maxOccurs* value of -1, the parser continues to read bytes until the end of the bit stream or until it encounters bytes that cause a parsing exception. In either case, the parser is unable to identify the end of one message and the start of the next. If you use *Data Element Separation*

= `Use Data Pattern`, ensure that the pattern recognizes a specified number of bytes. Be aware, therefore, that a pattern of `*` identifies all available characters and so would read an entire input file.

If you use delimited separations with message group indicators and terminators, ensure that the combination of group indicator and terminator does not match a record delimiter. For example, a message might start with a left brace ({) and end with a right brace (}). If there is a delimiter of }{ within the message, the delimiter matches the boundary between multiple messages; as a result, a delimiter within the current message might be identified as a message boundary. This might cause bytes in a subsequent message to be included in the current message causing parser exceptions or unexpected content in the parse tree.

The XMLNSC parser

If you select the XMLNSC parser, the end of the root tag marks the end of the message. XML comments, XML processing instructions, and white space that appear after the end of the XML message are discarded. The start of the next XML message is marked either by the next XML root tag or the next XML prolog.

How multiple file nodes share access to files in the same directory

WebSphere Message Broker controls access to files so that only one file node at a time can read or write to a file.

When a message flow uses the FileInput or FileOutput node, additional instances (threads) might be associated with the message flow, or file nodes in other message flows in the same or different execution groups might refer to files in the same directory. WebSphere Message Broker controls the way in which multiple processes

read from and write to files by moving the files to the mqsitransitin directory during processing, and locking them while they are being processed. The mqsitransitin directory is a subdirectory of the input directory specified in the FileInput node.

The broker locks the files that are being read by the FileInput node or written by the FileOutput node, to prevent other execution groups from reading or changing the files while they are being processed. The broker unlocks the file:

- When a FileInput node finishes processing the input file.
- When a FileOutput node finishes writing the file and moves it from the transit directory to the output directory.

Note: The FTEInput node does not use a transit directory. Each execution group has its own WebSphere MQ File Transfer Edition agent, and a node processes only files sent to the agent for which the node is deployed. The execution group ensures that only one node in the execution group processes each file.

Reading a file

When the FileInput node reads a file, it first moves the file into the mqsitransitin directory, where it is held during processing. A prefix (containing the UUID of the execution group) is added to the file name to indicate which execution group is processing the file. While the file is in this directory, no other execution groups can access the file. The broker maintains a lock subdirectory in the mqsitransitin directory, to ensure that files in the input directory are accessed by only one execution group at a time.

If multiple message flows or instances within an execution group are reading from the same input directory, only one instance of one message flow is allocated to reading it. Each record in the file is serially processed by this instance. Other instances of the message flow, or other message flows, can simultaneously process other files, the names of which match the pattern specified in the File name or pattern property of the node.

While a file is being processed, the file system is used to lock the file. As a result, other programs (including other execution groups) are prevented from reading, writing, or deleting the file while it is being processed by the file nodes.

While a FileInput node is reading a file, the file remains in the mqsitransitin directory until it has been fully processed (or until an unrecoverable error occurs). If the file is to be retained, it is held in a subdirectory of the mqsitransitin directory.

When the file has been processed, it is moved from the mqsitransitin directory back to the input directory. However, if the execution group stops unexpectedly while the file is in the mqsitransitin directory, you can manually restore the input file to the input directory by removing the execution group UUID prefix from the file name, and then moving it to the input directory. The input file is then processed by the next FileInput node that scans the directory.

If you use an NFS server, and have File nodes in different execution groups that access the same directory on the NFS server, ensure that you are using NFS version 4 to correctly support file locking.

Writing a file

Files that are created and written by a FileOutput node are put in the output directory when they are finished. While records are being added to a file, it is kept in the `mqsitransit` subdirectory.

Each record is written by a single message flow instance. All message flow instances that are configured to write records to a specific file can append records to that file. Because instances can run in any order, records that they write might be interleaved, which means that the sequence of records might be altered. If you require the sequence of records in the output file to be maintained, ensure that only one FileOutput node instance uses the file. To ensure that only one FileOutput node instance uses the file, configure the message flow that contains the node to use the additional instances pool with zero instances, and ensure that other message flows do not write to the same file.

While a file is being processed, the file system is used to lock the file. As a result, other programs (including other execution groups) are prevented from reading, writing, or deleting the file while it is being processed by the file nodes. This lock is retained for a short period after a FileOutput node writes to the file without finishing it, leaving it in the transit directory. If message flows that are in the same execution group use the same output file and run sufficiently quickly, the broker does not relinquish the lock before the file is finished. However, if the message flows have longer intervals between them, the broker relinquishes the lock and another process or execution group can acquire a lock on the file. To prevent this situation, ensure that output directories are not shared between execution groups.

Using local environment variables with file nodes

You can use fields in the local environment to dynamically alter the behavior of the FileInput, FileOutput, FTEInput, and FTEOutput nodes. You can also find what values the output nodes used to process the file.

These fields are available in the following message tree structures:

- LocalEnvironment.File
- LocalEnvironment.File.Read
- LocalEnvironment.WrittenDestination.File
- LocalEnvironment.Destination.File
- LocalEnvironment.Destination.File.Remote
- LocalEnvironment.Wildcard.WildcardMatch
- LocalEnvironment.FTE
- LocalEnvironment.WrittenDestination.FTE

- LocalEnvironment.Destination.FTE
- LocalEnvironment.CD
- LocalEnvironment.CD.Transfer
- LocalEnvironment.Destination.CD
- LocalEnvironment.WrittenDestination.CD

LocalEnvironment.File fields

When you use the FileInput node, it stores information that you can access in the LocalEnvironment.File message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the input directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name and extension.
LastModified	TIMESTAMP	Date and time the file was last modified.
TimeStamp	CHARACTER	Date and time the input node started processing the file in the Coordinated Universal Time (UTC) zone, as a character string. This data is the string used to create archive and backout file names if a timestamp is included.
The following elements contain data about the current record:		
Offset	INTEGER	Start of the record within the file. The first record starts at offset 0. If this element is part of the End of Data message tree, this value is the length of the input file.
Record	INTEGER	Number of the record within the file. The first record is record number 1. If this element is part of the End of Data message tree, this value is the number of records.
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. If this element is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. It is set to TRUE if the current record is empty. If this element is part of the End of Data message tree, this value is always set to TRUE.

This structure is propagated with each message written to the Out terminal of the FileInput node and with the empty message written to the End of data terminal.

LocalEnvironment.File.Read fields

When the FileRead node propagates a message, it stores valid information about it in the LocalEnvironment.File.Read message tree. If the input file is empty, an empty message is propagated. The following table lists the LocalEnvironment.File.Read message tree structure.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the input directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`). Alternatively this path relates to the file nodes root directory, which can be overridden with the same environment variable as used for the FileInput and FileOutput nodes.
Name	CHARACTER	File name and extension.
LastModified	TIMESTAMP	Date and time the file was last modified.
TimeStamp	CHARACTER	Date and time the FileRead node started processing the file as a character string, in the Coordinated Universal Time (UTC) zone.
The following elements contain data about the current record:		
Offset	INTEGER	The offset in the file the record starts at. The first byte in the file is offset 0.
NextRecordOffset	INTEGER	The offset in the file that the next record starts at, relative to the start of the file, and is 1 byte after the end of the current record. If the end of the file is reached, then the value is not given in the local environment.
EndOfFile	BOOLEAN	The FileRead node sets this element to TRUE when it has read the last record of the input file. It is therefore always TRUE when the detection property is `Record is Whole File`.
RecordNumber	INTEGER	The number of the record in the file relative to the offset the read node starts reading from. The value is always 1 unless the filter expression is being used, in which case it reflects the number of the record that was selected.
NoMatchReason	STRING	The reason why a message is sent to the "No match" terminal. Null if the message is sent to the Out terminal. Possible reasons: • NoFile – the file does not exist. • NoData – the file exists but has no records. • NoRecord – the file exists and contains records but none match the filter expression.
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. If this element is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. It is set to TRUE if the current record is empty.
Archive/Directory	STRING	The name of the directory where the file was archived.
Archive/Name	STRING	The name of the file where the file was archived.

This structure is propagated with each message written to the Out terminal of the FileRead node and with the empty message written to the End of data terminal.

LocalEnvironment.WrittenDestination.File fields

When you use the FileOutput node, it stores information that you can access in the LocalEnvironment.WrittenDestination.File message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Action	CHARACTER	Possible values are: • `Replace` if an output file of the same name is replaced. • `Create` if a new output file is created. • `Append` if this value is associated with a record that is appended to an output file. • `Finish` if a Finish File message is received and no file is found to finish (for example, if `Record is Whole File` is specified and a message is sent to the Finish File terminal). • `Transmit` if the file was transferred by FTP or SFTP and the file was not retained.
Timestamp	CHARACTER	The date and time, in character string form, when the node started to process this file. This value prefixes the names of files that are archived if you specify `Time Stamp`, `Archive and Replace Existing File` in the `Output file action` property on the **Basic** tab.

LocalEnvironment.Destination.File fields

When you use the FileOutput and FileRead nodes, you can override the directory and name properties with elements in the message tree. The default location for these overrides is LocalEnvironment.Destination.File, although you can change this location by using the properties on the `Request directory property location` and `Request file name property location` on the FileOutput node. When you use the FileRead node, you can also override the length and offset properties. The fields of this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	This property specifies the absolute or relative directory path of the output directory in the form that is used by the file system of the broker. For example, on Windows systems, this path starts with the drive letter prefix (such as C:) and use a backslash (\) as the directory delimiter. On UNIX systems, the path includes a slash (/) as the directory delimiter.
Name	CHARACTER	This property specifies the file name of the output file. The FileOutput node does not perform wildcard replacement on the value of the element. For example, if its value is `Input*.txt`, the FileOutput node tries to write to a file with an asterisk (*) in its name. It might or might not succeed, depending on whether an asterisk is a valid character for files in the file system to which it is writing.
Length	INTEGER	This property specifies the length of the record to read from the file. The value is only used if the record detection option fixed length is being used.
Offset	INTEGER	This property specifies the offset in the file to start searching for a record. Offset 0 means start from the beginning and is the default value if no override is given.

Element Name	Element Data Type	Description
Archive/Directory	STRING	The directory where the file is archived to when using one of the file disposition archive options. By default the file is archived to 'mqsiarchive' under the file input directory. Any path is not relative to the input directory but relative to the `MQSI_FILENODES_ROOT_DIRECTORY`.
Archive/Name	STRING	The pattern to use to create an archive file name. Only one star is allowed in the file name and the star is replaced with the first star replace in the file pattern name. If `Archive with Time Stamp` is specified, then a time stamp is appended to the archive name.

LocalEnvironment.Destination.File.Remote fields

When you use the FileOutput node with the `Remote Transfer` property selected, you can override the directory name with an element in the local environment tree. The fields of this structure are described in the following table.

Element Name	Element Data Type	Description
Remote.ServerDirectory	CHARACTER	This property specifies the absolute or relative directory path of the output directory on the remote server. The property has no effect if SFTP or FTP is not enabled on the FileOutput node. Format the path according to the path syntax that is accepted by the FTP server, typically by using UNIX-style slash (/) directory delimiters.
Remote.Server	CHARACTER	This property specifies the name of an FtpServer configurable service, a server name, or a server name and port (using the syntax `serverName:port`) to use to connect to when connecting to an FTP or SFTP server from the FileOutput node. The property has no effect if SFTP or FTP is not enabled on the FileOutput node.

LocalEnvironment.Wildcard.WildcardMatch field

On the FileInput, CDInput, and FTEInput nodes, you can specify a file name pattern that contains wildcard characters. The input nodes copy the characters in the file name matched by wildcards, together with any intermediate characters, to LocalEnvironment.Wildcard.WildcardMatch.

Element Name	Element Data Type	Description
WildcardMatch	CHARACTER	The character string in the file name matched by wildcards in the file name pattern.

On the FileOutput, CDOutput, and FTEOutput nodes, you can use a wildcard character in the file name pattern. If you include the single wildcard character, '*', in the file name pattern, the node uses the value that is stored in LocalEnvironment.Wildcard.WildcardMatch. This is useful if you have a message flow where the input and output nodes are working with the same file; you can preserve the name of the input file on the output nodes. You can also use standard methods for manipulating the value of the WildcardMatch element to whatever you want; you must not use a FileInput or FTEInput node.

See “File name patterns” on page 1830 for more information.

LocalEnvironment.FTE fields

When you use the FTEInput node, it stores information that you can access in the LocalEnvironment.FTE and LocalEnvironment.FTE.Transfer message trees. The LocalEnvironment.FTE message tree stores information relating to the current record and is populated by the broker. The fields in this structure are described in the following table:

Element Name	Element Data Type	Description
TimeStamp	CHARACTER	Date and time the input node started processing the file in the Coordinated Universal Time (UTC) zone, as a character string. This data is the string used to create archive and backout file names if a timestamp is included.
Offset	INTEGER	Start of the record within the file. The first record starts at offset 0 bytes. When Offset is part of the End of Data message tree, this value is the length of the input file.
Record	INTEGER	Number of the record within the file. The first record is record number 1. When Record is part of the End of Data message tree, this value is the number of records.
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. When Delimiter is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. IsEmpty is set to TRUE if the current record is empty. When IsEmpty is part of the End of Data message tree, this value is always set to TRUE.

The LocalEnvironment.FTE.Transfer message tree contains information received from WebSphere MQ File Transfer Edition regarding the transfer or file; see WebSphere File Transfer Edition Information Center for more details. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the input directory.
JobName	CHARACTER	The name for the transfer.
Name	CHARACTER	File name and extension (per file).
LastModified	TIMESTAMP	Date and time the file was last modified (per file).
SourceAgent	CHARACTER	The name of the agent sending the file.
DestinationAgent	CHARACTER	The name of the agent to send the file to.
OriginatingHost	CHARACTER	The name of the host from which the transfer was submitted.
TransferId	CHARACTER	The unique name of the transfer.
MQMDUser	CHARACTER	The WebSphere MQ user ID in the MQMD of the transfer request message.
OriginatingUser	CHARACTER	The user ID of the user that submitted the transfer request.
TransferMode	CHARACTER	The mode of the transfer. Valid values are `Binary` or `Text`.
TransferStatus	CHARACTER	The status of the transfer of the file.
FileSize	INTEGER	The size of the file being transferred.
ChecksumMethod	CHARACTER	The only allowed value is `MD5`.

Element Name	Element Data Type	Description
Checksum	CHARACTER	If the ChecksumMethod element is set to MD5, this element is the actual checksum in hex string format.
DestinationAgentQmgr	CHARACTER	The name of the queue manager of the destination agent to send the file to.
SourceAgentQmgr	CHARACTER	The name of the queue manager of the source agent that sent the file.
OverallTransferStatus	CHARACTER	The overall status of the transfer.
TotalTransfers	INTEGER	The total number of files successfully transferred.
TransferNumber	INTEGER	The number of the current file in the transfer.

These structures are propagated with each message written to the Out terminal of the FTEInput node and with the empty message written to the End of data terminal.

LocalEnvironment.WrittenDestination.FTE fields

When you use the FTEOutput node, it stores information that you can access in the LocalEnvironment.WrittenDestination.FTE message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
DestinationAgent	CHARACTER	The name of the agent to send the file to.
DestinationQmgr	CHARACTER	The name of the destination queue manager.
JobName	CHARACTER	The name for the transfer.
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as C:).
Name	CHARACTER	File name of the output file.
Overwrite	BOOLEAN	Specifies whether files on the destination system can be overwritten when the destination agent moves files of the same name there. If the destination agent fails to overwrite the file, the transfer fails and the transfer logs report the failure. The FTEOutput node does not throw or log any errors.
TransferId	CHARACTER	The unique name of the transfer initiated by the FTEOutput node.

LocalEnvironment.Destination.FTE fields

When you use the FTEOutput node, you can override its Destination agent, Destination queue manager, Job name, Destination file directory, Destination file name, and Overwrite files on destination system properties with elements in the message tree. You can also call a program on the destination agent before starting the transfer, or when the transfer is finished. The default location for these overrides is LocalEnvironment.Destination.FTE. The fields of this structure are described in the following table.

Element Name	Element Data Type	Description
DestinationAgent	CHARACTER	The name of the agent to send the file to.
DestinationQmgr	CHARACTER	The name of the destination queue manager.
JobName	CHARACTER	The name for the transfer.

Element Name	Element Data Type	Description
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Overwrite	BOOLEAN	Specifies whether files on the destination system can be overwritten when the destination agent moves files of the same name there. If the destination agent fails to overwrite the file, the transfer fails and the transfer logs report the failure. The FTEOutput node does not throw or log any errors.
PreDestinationCall.Name	CHARACTER	Call a program on the destination agent before starting the transfer. This element supplies the name of an Ant script to run. You cannot call other programs that are not Ant scripts, or pass parameters to the calls. The Ant script can access all the metadata defined for the transfer, including user metadata added using the local environment override LocalEnvironment.Destination.FTE.UserDefined. See WebSphere File Transfer Edition Information Center for more details of how to use the PreDestinationCall function.
PostDestinationCall.Name	CHARACTER	Call a program on the destination agent after completing the transfer. This element supplies the name of an Ant script to run. You cannot call other programs that are not Ant scripts, or pass parameters to the calls. The Ant script can access all the metadata defined for the transfer, including user metadata added using the local environment override LocalEnvironment.Destination.FTE.UserDefined. See WebSphere File Transfer Edition Information Center for more details of how to use the PostDestinationCall function.

LocalEnvironment.CD fields

When you use the CDInput node, it stores information that you can access in the LocalEnvironment.CD and LocalEnvironment.CD.Transfer message trees. The LocalEnvironment.CD message tree stores information relating to the current record and is populated by the broker. The fields in this structure are described in the following table:

Element Name	Element Data Type	Description
Transfer	Folder	Contains meta data from the IBM Sterling Connect:Direct transfer.
Timestamp	CHAR	Timestamp of the file.
Offset	INTEGER	Start of the record within the file. The first record starts at offset 0 bytes. When Offset is part of the End of Data message tree, this value is the length of the input file.
Record	INTEGER	Number of the record within the file. The first record is record number 1. When Record is part of the End of Data message tree, this value is the number of records.
Delimiter	CHARACTER	The characters used to separate this record from the preceding record, if `Delimited` is specified in `Record detection`. The first record has a null delimiter. When Delimiter is part of the End of Data message tree, this value is the delimiter that follows the last record, if any.
IsEmpty	BOOLEAN	Whether the record propagated by the message flow is empty. IsEmpty is set to TRUE if the current record is empty. When IsEmpty is part of the End of Data message tree, this value is always set to TRUE.

These structures are propagated with each message written to the Out terminal of the CDInput node and with the empty message written to the End of data terminal.

LocalEnvironment.CD.Transfer

The LocalEnvironment.CD.Transfer message tree contains information received from IBM Sterling Connect:Direct regarding the transfer or file. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
ProcessName	CHARACTER	The process name of the script transferring the file.
StepName	CHARACTER	The step name causing the transfer to take place.
ProcessNumber	INTEGER	The number of the process running the process script.
Submitter	CHAR	The user ID submitting the process script.
Accounting	CHAR	The secondary node (SNODE) accounting details for the process script.
SourcePath	CHAR	The source path of the file on the primary node (PNODE) machine.
DestinationPath	CHAR	The destination path of the file on the secondary node (SNODE) machine
Directory	CHARACTER	The directory which the file is copied to.
Name	CHARACTER	The name of the file copied to.
PrimaryNodeName	CHARACTER	The name of the primary node from which the file was copied.
SecondaryNodeName	CHARACTER	The name of the secondary node.

LocalEnvironment.Destination.CD fields

When you use the CDOutput node, you can override various destination system properties with elements in the message tree. The default location for these overrides is LocalEnvironment.Destination.CD. The fields of this structure are described in the following table

Element Name	Element Data Type	Description
SNODE	CHARACTER	The name of the secondary Connect:Direct server (SNODE) to send the file to.
ProcessName	CHARACTER	The process name that the script uses to run.
Accounting	CHARACTER	Accounting data shown when the script is running on both the primary Connect:Direct server (PNODE) and secondary Connect:Direct server (SNODE).
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as `C:`).
Name	CHARACTER	File name of the output file.
Copy.From	CHARACTER	The final part of the path name is the IBM Sterling Connect:Direct process script property you want to change. This is either a direct `<option name>` on the FROM clause, or a value in the `<SYSOPTS>` option. You must take care to ensure that the created script is valid, because any existing value created by the node is overridden.

Element Name	Element Data Type	Description
Copy.To	CHARACTER	The final part of the path name is the IBM Sterling Connect:Direct process script property you want to change. This is either a direct <option name> on the TO clause, or a value in the <SYSOPTS> option. You must take care to ensure that the created script is valid, because any existing value created by the node is overridden.

LocalEnvironment.WrittenDestination.CD fields

When you use the CDOutput node, it stores information that you can access in the LocalEnvironment.WrittenDestination.CD message tree. The fields in this structure are described in the following table.

Element Name	Element Data Type	Description
ProcessName	CHARACTER	The name of the process sending the file.
ProcessNumber	CHARACTER	The number of the process sending the file.
Directory	CHARACTER	Absolute directory path of the output directory in the form used by the file system of the broker. For example, on Windows systems, this starts with the drive letter prefix (such as C:).
Name	CHARACTER	File name of the output file.
PrimaryNodeName	CHARACTER	The name of the primary Connect:Direct server (PNODE)
PrimaryNodeOS	CHARACTER	The operating system of the primary Connect:Direct server
SecondaryNodeName	CHARACTER	The name of the secondary Connect:Direct server (SNODE)
SecondaryNodeOS	CHARACTER	The operating system of the secondary Connect:Direct server (this might not be the same as the WebSphere Message Broker operating system)

File name patterns

You can specify a file name pattern, using wildcard characters, to identify a file to be read by the FileInput and FTEInput nodes. You can also specify a file name pattern, using a single wildcard character, to name the file to be created by the FileOutput and FTEOutput nodes.

Using file name patterns with the FileInput and FTEInput nodes

The input nodes read files from a specified directory and propagate messages based on the contents of these files. Only files with names that match a pattern (the input pattern), as specified in the FileInput node's `File name or pattern` property or the FTEInput node's `File name filter` property, are read.

The match might be with a file name or a character sequence (a pattern). A pattern is a sequence containing at least one of the following wildcard characters:

Wildcard character	Description	Example
*	Any sequence of zero or more characters	`*.xml` matches all file names with an `xml` extension
?	Any single character	`f??????.csv` matches all file names consisting of the letter `f` followed by six characters, then the sequence `.csv`.

The default pattern is `*`, which matches all file names.

You cannot specify file names that contain the following characters: the asterisk ('*'), the question mark ('?'), or file name separator characters ('/' and' \').

For example:

- If you want the FileInput node to process all files that have a certain extension, such as `xml`, set its `File name or pattern` property to `*.xml` and the node will process all files in the directory that have this extension.

If you deploy the flow to a Windows server, file names match the pattern irrespective of case. However, if you deploy the flow to a Linux, UNIX, or z/OS server, file names must match the pattern character string and its case.

Pattern matching

The FileInput and FTEInput nodes set the LocalEnvironment.Wildcard.WildcardMatch element to the string matched by wildcards in the file name. The following are some examples of pattern matching with the value in this element, where the value in the FileInput node's `File name or pattern` property is `File????.from*.xml`:

- If the FileInput node finds a file with the file name `File1234.fromHQ.xml`, there is a match. The value in the LocalEnvironment.Wildcard.WildcardMatch element is set to `1234.fromHQ` and the node processes the file.
- If the file name is `File123.fromHQ.xml`, there is no match because there are insufficient characters between the `File` and `.from` elements of the file name. The FileInput node ignores this file.
- If the file name is `File2345.from.xml`, there is a match. The value in the LocalEnvironment.Wildcard.WildcardMatch element is set to `2345.from` and the node processes the file. In this example, the `*` in the character string in the `File name or pattern` property matches a string of zero characters. If you require the character string between the `from` and `.xml` elements of the file name to always have at least one character, you specify the `File name or pattern` property with a value of `File????.from?*.xml`.

Using file name patterns with the FileOutput and FTEOutput nodes

The node writes messages to files that it creates or replaces in the broker's file system. Only patterns containing a single wildcard character (the asterisk, '*') are allowed in this property. The file name to be used is determined in the following way:

- If the file name property contains no wildcard, the value of this property is the name of the file created. This value must be a valid file name on the file system that hosts the broker to which the message flow is deployed.
- If the file name property contains a single wildcard, the value of the element LocalEnvironment.Wildcard.WildcardMatch in the current message replaces the wildcard character, and the resulting value is the name of the file created. This value must be a valid file name on the file system that hosts the broker to which the message flow is deployed. If the WildcardMatch value is not found, the wildcard character is replaced by the empty string.

You cannot specify file names that contain the following characters: the asterisk ('*'), the question mark ('?'), file name separator characters ('/' and' \'). The name of the file can be overridden by values in the current message.

If the `File name or pattern` property on the FileOutput node is empty, the name must be overridden by the current message. Wildcard substitution occurs only if this property is not overridden in this way.

File names are passed to the file system to which the broker has access, and have to respect the conventions of these file systems. For example, file names on Windows systems are not case-sensitive; on UNIX systems, file names that differ by case are considered distinct.

Example: If the FileInput node has `*.out` in the `File name or pattern` property, and the incoming file is `myfile`, the name of the outgoing file is `myfile.out`.

FTP and SFTP considerations

You can use the FileInput node to transfer files from a remote FTP or SFTP server and process them. Only files with names that match the file name pattern specified in the node are read. If your broker is on an operating system that respects case sensitivity (such as UNIX), you might specify a pattern that includes a combination of uppercase and lowercase characters. If you then use this pattern to process files that are in a directory on a remote FTP or SFTP server, and this server is running on an operating system that does not respect case sensitivity (such as Windows), file name matching might fail with the result that no files are processed. This failure occurs because the file names on the remote server are not in mixed case. If your broker is on an operating system that does not respect case sensitivity, any pattern that you specify might be matched by more than one file on a remote FTP or SFTP server that is running on an operating system on which case sensitivity is significant. Each of these files is then processed sequentially.

You can use the FileOutput node to write files to a remote FTP or SFTP server. Only files with names that match the pattern specified in the node are written. If your broker is running on an operating system that respects case sensitivity (such as UNIX), you might specify a pattern that includes a combination of uppercase and lowercase characters. However, if you then use this pattern to write files to a directory on a remote FTP or SFTP server running on an operating system that does not respect case sensitivity (such as Windows), the file name is written in uppercase rather than in the way that it was specified in your pattern.

If the name of a file on a remote FTP server contains one or more characters that are not valid on the operating system on which the broker where you specified the file name pattern is running, the file is not transferred from the FTP server for processing by the FileInput node.

Archiving

Files that are successfully processed by the FileInput node or FileOutput node can optionally be moved to the `mqsiarchive` subdirectory of the input or output directory.

The input directory of the FileInput node has a subdirectory called `mqsiarchive`. The output directory of the FileOutput node also has a subdirectory called `mqsiarchive`. Archiving is not enabled for the FTEOutput and FTEInput nodes.

FileInput node

Files that are processed successfully by the FileInput node are moved to the `mqsiarchive` subdirectory if the FileInput node's `Action on successful processing` property is set to `Move to Archive Subdirectory` or `Add Timestamp and Move to Archive Subdirectory`.

Select the `Replace duplicate archive files` check box to overwrite existing files in the `mqsiarchive` subdirectory. If you do not set this option, and a file with the same name already exists in the archive subdirectory, the node stops processing files. Every time that the node returns from its polling wait period, it issues a pair of messages, BIP3331 and a more specific one describing the problem. To avoid writing too many messages, duplicate messages are suppressed for increasing periods of time, until eventually they are issued only about once every hour. In this circumstance, the system administrator must stop the flow, correct the problem, then restart the flow.

Clear the `Replace duplicate archive files` check box only if you are sure either that the input files have unique names, or that some other process will remove a file from the archive directory before the FileInput node processes another of the same name. If you cannot ensure this, either specify `Add Timestamp and Move to Archive Subdirectory` in the `Action on successful processing` property so that archived files have unique names, or select the `Replace duplicate archive files` check box

FileOutput node

Files that are processed successfully by the FileOutput node are moved to the `mqsiarchive` subdirectory if the `Output file action` property of the FileOutput node is set to `Archive and Replace Existing File` or `Time Stamp, Archive and Replace Existing File`.

Select the `Replace duplicate archive files` check box to overwrite existing files in the `mqsiarchive` subdirectory. If you do not set this option, and a file with the same name already exists in the archive subdirectory, the node generates an exception when it tries to move the successfully processed file and the file remains in the transit subdirectory.

Using a local file as input for your message flow:

Learn how to use the FileInput node to read a file on your local file system and then propagate messages that are based on the contents of that file.

Before you begin

This example shows how one combination of values in the `Record detection`, `Delimiter`, and `Delimiter type` properties can be used to extract messages from a file. The example describes the FileInput node of a message flow and assumes that

the rest of the flow has already been developed. It is also assumed that a Windows system is being used. To complete this example task, you must first have added a FileInput node to a message flow. You also need the following resources:

- An input file. To follow this example scenario, create an input file called `test_input1.xml` with the following content:

  ```
  <Message>test1</Message>
  <Message>testtwo</Message>
  <Message>testthree</Message>
  ```

  Each line ends with a line terminator; on a Windows system, this comprises carriage return and line feed characters (X'0D0A'). Put this file into directory `C:\FileInput\TestDir`.
- A message set. This example uses a message set called `xml1` which uses the XMLNSC parser. Message set `xml1` models messages of the following form:

  ```
  <Message>...</Message>
  ```

Complete the following steps:

Procedure

1. Set the required node properties on the FileInput node. The following table summarizes the FileInput node properties that you should set, which tab they appear on and the value that you should set in order to follow this example:

Tab	Property	Value
Basic	`Input directory`	`C:\FileInput\TestDir`
	`File name or pattern`	`test_input1.xml`
	`Action on successful processing`	`Move to Archive Subdirectory`
	`Replace duplicate archive files`	Selected
Input Message Parsing	`Message domain`	`XMLNSC`
	`Message set`	`xml1`
Polling	`Polling interval`	3
Retry	`Action on failing file`	`Add Time Stamp and Move to Backout Subdirectory`
Records and Elements	`Record detection`	`Delimited`
	`Delimiter`	`DOS or UNIX Line End`
	`Delimiter type`	`Postfix`
FTP	`FTP`	Not selected

2. Deploy the message flow to the broker. See Chapter 11, “Packaging and deploying,” on page 3209.

Results

The following actions occur when you perform these steps:

1. The file is processed. In accordance with the values set in the properties on the **Records and Elements** tab, the FileInput node detects records that are separated by DOS or UNIX end-of-line characters and creates a message for each one that it finds. It propagates three messages to the flow attached to the Out terminal:

- Message 1:
  ```
  <Message>test1</Message>
  ```
- Message 2:
  ```
  <Message>testtwo</Message>
  ```
- Message 3:
  ```
  <Message>testthree</Message>
  ```

2. If a flow is attached to the End of Data terminal, the End of Data message is propagated after the last record in the file has been processed.
3. When processing is complete, the file `test_input1.xml` is moved to the `mqsiarchive` subdirectory, `C:\FileInput\TestDir\mqsiarchive\test_input1.xml`. If a file called `test_input1.xml` already exists in the `mqsiarchive` subdirectory, it is overwritten.
4. If the message flow fails, retry processing is attempted according to the values set in the properties of the FileInput node. In this example task, a time stamp is added to the file name and the file is moved to the `mqsibackout` directory. Here is an example of the path to such a file: `C:\FileInput\TestDir\mqsibackout\20070928_150234_171021_test_input1.xml`.

What to do next

To see the effects of specifying other combinations of values in the `Record detection`, `Delimiter`, and `Delimiter type` properties of the FileInput node, see "Controlling how files are separated into records" on page 1848.

The following samples also show how to use this node:

- Batch Processing
- WildcardMatch

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Routing or enriching a message based on the contents of a file:

The FileRead node can route or enrich messages based on the contents of the file.

When developing the message flow you can specify the name and location of the file to be read. You can override these values at run time based on the contents of a message.

The node complements the existing FileInput and FileOutput nodes. The FileRead node reads a file in the middle of a message flow.

Using the node to route messages

A message is routed by using the contents of a file colocated with WebSphere Message Broker or on a network file system. The message from the source system is routed to a target system by using an external routing file. No response is expected.

The basic flow of events is as follows:

- WebSphere Message Broker receives a message through an input node.
- The WebSphere Message Broker message flow interrogates the contents of a message to identify routing key information.
- If the file consists of more than one record, you need to determine:
  - Where the first record starts. Unless you specify an offset byte, the node starts reading the file at the first byte.
  - How each record ends (fixed-sized, delimited, or parsed.)
  - Which record to propagate. You can use any combination of information from the input message and the file in deciding this. All records from the specified start point are read until a record is found that matches the record selection expression, this record is then propagated. Examples include:

    The third record, as identified by the local environment field `$OutputLocalEnvironment/File/Read/RecordNumber=3`. In this example, the first record is fully read and the expression evaluates to false. The second record is then fully read and the expression evaluates to false. When the third record is fully read, the expression evaluates to true and the record is propagated. No further records are read.

    A key field in the input message matches a key field in the file `$InputRoot/XMLNSC/FromMQInputMessage/Record1 = $ResultRoot/XMLNSC/FromFile/Record5`. In this example, records are read from the file until the value of the Record5 element of the record matches the value of the Record1 element of the incoming message. The location of the record in the file determines how many records the node must read before successfully matching the record selection expression.
- Within the message flow you can implement a local cache of records to reduce the performance cost of reading multiple static records. For an example of how to implement a local cache, see the following sample:
  - Message Routing
- You can choose to take information from the file, and copy it to the outgoing message. The copy can be a subset of the data, and can be copied to any location in the message or the local environment.
- A target application receives the routed message.

For information about how to process messages based on the contents of an XML or CSV file, see the following sample:

- Message Routing

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

Related reference:

"FileOutput node" on page 4430
Use the FileOutput node to write messages to files.

Combining a WebSphere MQ message with an XML file using the contents of the message to identify which file to use:

Combine an incoming message with the contents of an XML file, using fields in the message to determine which file to use.

Before you begin

Before you start: Put a file on the file system that is local to the broker, for the FileRead node to read. Here is an example of the file contents:

```
<Data>Purchase details</Data>
```

In this example, the contents of the data in the data tag are inserted into the incoming message. Any valid XML structures can be added to this section.

Make a note of the path to the file. For example: `c:\temp\FileRead\task3.xml` or `/tmp/FileRead/task3`.

Create the following queues on the broker queue manager:

- FILEREAD.TASK3.IN1
- FILEREAD.TASK3.OUT1

Detailed information about configuring the node is given on the property panels for the node, in the WebSphere Message Broker Toolkit.

Procedure

1. Create a message flow that contains an MQInput node, a FileRead node, and an MQOutput node.
2. Wire the terminals as follows:
   a. Wire the Out terminal of the MQInput node to the In terminal of the FileRead node.

b. Wire the Out terminal of the FileRead to the In terminal of the MQOutput node.

3. Configure the MQInput node:
   a. On the Basic panel, set the Queue name to `FILEREAD.TASK3.IN1`
   b. On the Input Message Parsing panel set the domain to `XMLNSC`.
4. Configure the FileRead node.
   a. On the Basic panel, set the directory and file name to refer to the XML file. For example: `c:\temp\FileRead` and `task3.xml` or `/tmp/FileRead` and `task3`.
   b. Configure the Result panel:
      1) Set the Result data location to `$ResultRoot/XMLNSC/Data`
      2) Set the Output data location to `$InputRoot/XMLNSC/Data`
   c. Configure the Input Message Parsing panel:
      1) Set the Domain to `XMLNSC`
5. Configure the MQOutput node:
   a. On the Basic panel, set the Queue name to `FILEREAD.TASK3.OUT1`
6. Deploy the message set and message flow.
7. Change the Directory and Name fields to the correct location of the file, and then put the following XML message onto queue FILEREAD.TASK2.IN1:

```
<Invoice>
  <Directory>c:\temp\FileRead</Directory>
  <Name>task2.xml</Name>
  <Data/>
</Invoice>
```

Results

The broker routes the message to the queue FILEREAD.TASK3.OUT1 and inserts data from the file into the Data field of the output message:

```
<Invoice>
  <Directory>c:\temp\FileRead</Directory>
  <Name>task2.xml</Name>
  <Data>Purchase details</Data>
</Invoice>
```

Related concepts:

"Routing or enriching a message based on the contents of a file" on page 1837
The FileRead node can route or enrich messages based on the contents of the file.

Related reference:

"FileRead node" on page 4444
Use the FileRead node to read one record, or the entire contents of a file, from within a message flow.

Record selection expressions:

The record selection expression is used to select a record from a file to propagate to the rest of the flow.

Each record in turn is compared to the expression, and the first one to evaluate to true is propagated to the **Out** terminal. You can set the expression to any valid XPath expression that returns a Boolean value. The expression is not used when `Whole File` is selected as the `Record Detection` option.

Correlation names used in the expression

You can use any of the following correlation names in the expression:

InputRoot and InputLocalEnvironment
The Input names refer to the incoming message that enters the node through the **In** terminal

ResultRoot
The ResultRoot name refers to the message created by using the current record in the file.

OutputRoot
The OutputRoot name refers to the message that is propagated if the expression evaluates to true. This action is identical to ResultRoot, unless the Output data location or Result data location have been changed to copy the Result message found in the file to a different location in the outgoing message.

OutputLocalEnvironment
The OutputLocalEnvironment contains the normal local environment which is propagated down the **Out** terminal and contains useful information like the number of the record and its offset.

Any combination of data in these correlation names can be used, along with any valid XPath expression, to determine whether to propagate the record.

Examples

Expression is:

```
$InputRoot/XMLNSC/Invoice/AccountNumber=$ResultRoot/XMLNSC/Data/Key
```

In this example, each record is a valid XML document. The FileRead node reads each record from the file. In the incoming message the FileRead node compares the field /Data/Key to the field /Invoice/AccountNumber. If the record matches, it is propagated to the **Out** terminal.

Expression is:

```
$OutputLocalEnvironment/File/Read/RecordNumber=5
```

The FileRead node reads each record from the file and compares the record number to 5. The record is propagated when it reaches the fifth record.

Building an outgoing message by using an incoming message combined with a record from a file

The FileRead node reads a record from a file and combines it with the message coming in to the node. By default, it replaces the message with the contents of the record read from the file. However, by using properties on the Result panel, you can choose how to combine the incoming message and file record contents. The node has three logical trees:

Input The Input message assembly contains all the data in the incoming message and is the basis for the propagated record.

Result The Result message assembly contains the record read from the file.

Output
The Output message assembly is the actual object propagated from the node.

By default, the Output message assembly is constructed by copying the Input message assembly to the Output message assembly. The data part of the Output message assembly is then replaced by the contents of the Result message assembly and the OutputLocalEnvironment is updated with details of what happened in the node.

The following Result panel properties can be used to modify this behavior:

Result data location
Specifies which part of the read record is copied to the Output message. By default, the Result data location copies everything from ResultRoot but it can be changed to copy only part of the record. For example: ResultRoot.XMLNSC.Invoice.Name just copies the name field from the selected record to the output message.

Output data location
Specifies where the record is copied to in the outgoing message. By default, the Output data location copies everything to OutputRoot. The location specified can be in the data part of the message (under ResultRoot) or in any other Output tree like OutputLocalEnvironment. For example: To copy the resulting record to a field in the message body OutputRoot.XMLNSC.Invoice.Data or to copy the result to local environment OutputRoot.Variables.Invoice.data.

Copy local environment
Causes the local environment to be copied from the InputLocalEnvironment. If the Copy local environment option is not selected, the InputLocalEnvironment is used directly without copying. This option allows nodes before the FileRead node to see changes to the Local environment.

For example, the following options copy the name field from a record to the output going message. The rest of the Output message is based on the input message:

```
Result data location= ResultRoot.XMLNSC.Invoice.Name
Output data location= OutputRoot.XMLNSC.Invoice.Name
```

The following options copy the message body from a record to the output going local environment. The Output message is the same as the input message:

```
Result data location= ResultRoot.XMLNSC.Invoice
Output data location= OutputLocalEnvironment.Variables.Invoice
```

Use the FileRead node to read one record, or the entire contents of a file, from

within a message flow.

Reading a file on a remote FTP or SFTP directory:

Use a FileInput node to read a file in a directory on a remote FTP or SFTP server and then propagate messages that are based on the contents of that file.

Before you begin

Before you start:

This example is an extension of the example described in "Using a local file as input for your message flow" on page 1834 and it describes how to use a FileInput node in a message flow. The instructions assume that you are using a Windows operating system and that you have created a message flow containing a FileInput node. You also require the following resources:

- An FTP or SFTP server. Ensure that an FTP or SFTP server exists, with the following settings:

  Server *ftpserver.hursley.abc.com*

  Port *21* (for FTP) or *22* (for SFTP)

  Working directory
  /ftpfileinput

  Userid
  myuserid

  Password
  mypassword

  These values are for the purposes of this example only. If you use other values, record them so that you can set the appropriate values during the task.
- A security identity. Use the **mqsisetdbparms** command to define a security identity called *myidentity* for your user and password details.

  If you want to connect to an FTP server, the security identity must have an `ftp::` prefix, to enable the file nodes to find the identity definition. For example, use the following command for a broker called *MyBroker*:

  ```
  mqsisetdbparms MyBroker -n ftp::myidentity -u myuserid -p mypassword
  ```

  If you want to connect to an SFTP server, the security identity must have an `sftp::` prefix, as shown in the following example:

  ```
  mqsisetdbparms MyBroker -n sftp::myidentity -u myuserid -p mypassword
  ```

  You can also configure a connection to an SFTP server to use public key authentication, by specifying an SSH identity file and pass phrase, instead of a password. For example:

  ```
  mqsisetdbparms MyBroker -n sftp::myidentity -u myuserid -i identity_file -r passphrase
  ```

  For more information about configuring connections to an SFTP server, see "Transferring files securely by using SFTP" on page 1864.
- An input file. To follow this example scenario, create an input file called `test_input1.xml` with the following content:

  ```
  <Message>test1</Message>
  <Message>testtwo</Message>
  <Message>testthree</Message>
  ```

Each line ends with a line terminator that is suitable for the system on which the FTP or SFTP server is found. Do not put this file in the input directory but, instead, put it in the FTP or SFTP server directory `/ftpfileinput`.

- A message set. This example uses a message set called *xml1*, which uses the XMLNSC parser. Message set *xml1* models messages of the following form:

  ```
  <Message>...</Message>
  ```

About this task

Complete the following steps:

Procedure

1. Set the required node properties on the FileInput node. The following table summarizes the FileInput node properties that you must set, the tab on which they are displayed, whether they are mandatory, and the required values.

Tab	Property	Value
Basic	`Input directory`	`C:\FileInput\TestDir` If the input directory does not exist, no files are processed, even if you are processing files over FTP or SFTP.
	`File name or pattern`	`test_input1.xml`
	`Action on successful processing`	`Move to Archive Subdirectory`
	`Replace duplicate archive files`	Selected
Input Message Parsing	`Message domain`	`XMLNSC`
	`Message set`	`xml1`
Polling	`Polling interval`	3
Retry	`Action on failing file`	`Add Time Stamp and Move to Backout Subdirectory`
Records and Elements	`Record detection`	`Delimited`
	`Delimiter`	`DOS or UNIX Line End`
	`Delimiter type`	`Postfix`
FTP	`Remote transfer`	Selected
	`Transfer protocol`	`FTP or SFTP`
	`Remote server and port`	`ftpserver.hursley.abc.com`
	`Security identity`	`myidentity`
	`Server directory`	`/ftpfileinput`
	`Transfer mode`	`ASCII` (for FTP only)
	`Scan delay`	`45`

   If you used other values for your FTP or SFTP server resource, enter those values. The settings used here are identical to those used in the example in "Using a local file as input for your message flow" on page 1834, except that the `Remote transfer` property has been selected and there are now properties on the **FTP** tab. If you clear the `Remote transfer` property, the node operates as it does in the example in "Using a local file as input for your message flow" on page 1834; the properties on the **FTP** tab remain set but are ignored.
2. Deploy the message flow to the broker. See Chapter 11, "Packaging and deploying," on page 3209.

Results

The following actions occur when you perform these steps:

1. The file `test_input1.xml` is transferred from the FTP or SFTP server directory (`/ftpfileinput`) to the local directory (`C:\FileInput\TestDir`). The file is deleted from the FTP or SFTP server directory.
2. The FileInput node detects records that end with a DOS or UNIX line end and creates a message for each one that it finds, as defined by the properties on the **Records and elements** tab. The node propagates three messages to the message flow that is attached to the Out terminal:
   - Message 1:

     ```
     <Message>test1</Message>
     ```
   - Message 2:

     ```
     <Message>testtwo</Message>
     ```
   - Message 3:

     ```
     <Message>testthree</Message>
     ```
3. If a node is attached to the End of Data terminal, the End of Data message is propagated after the last record in the file has been processed.
4. When processing is complete, the file `test_input1.xml` is moved to the `mqsiarchive` subdirectory `C:\FileInput\TestDir\mqsiarchive`. If a file called `test_input1.xml` exists in the `mqsiarchive` subdirectory, it is overwritten.
5. If the message flow fails, retry processing is attempted according to the values set in the properties of the FileInput node. In this example task, a time stamp is added to the file name and the file is moved to the `mqsibackout` directory. Here is an example of the path to such a file: `C:\FileInput\TestDir\mqsibackout\20070928_150234_171021_test_input1.xml`.

   If an error occurs on the FTP side, stating that access is denied, a 0–byte file is created and moved to the mqsibackout directory. A 0–byte file is created in the mqsibackout directory for every FTP attempt that fails.

Because the `Remote transfer` property is selected, the FTP scan delay of 45 seconds overrides the polling interval of 3 seconds.

What to do next

For more information, see "Controlling how files are separated into records" on page 1848, which shows the effects of specifying other combinations of values in the `Record detection`, `Delimiter`, and `Delimiter type` properties of the FileInput node.

The following samples also show how to use this node:
- Batch Processing
- WildcardMatch

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Receiving a file by WebSphere MQ File Transfer Edition:

Use the FTEInput node to receive files from an existing WebSphere MQ File Transfer Edition network.

Before you begin

Before you start:

1. Read about WebSphere MQ File Transfer Edition.
2. Prepare the environment.

About this task

Complete the following steps to create an FTEInput node message flow using the default settings. The task includes some optional steps for additional configuration, but detailed information about configuring the FTEInput node is given on the property panels for the node, in the WebSphere Message Broker Toolkit.

Procedure

1. Drag an FTEInput node onto a message flow and wire its Out terminal to an output node of your choice.
2. Optional: To process only a defined subset of files sent to an agent, configure the Basic panel. This action allows multiple FTEInput nodes in the same execution group to receive specific files, depending on the directory or file filters specified.

   You can also specify whether, after processing, the file should be left in its directory, renamed, or deleted.

3. To change how the node handles a message flow failure, configure the Retry panel.
4. Optional: To change how records are identified in the input file, configure the `Record detection` property on the Records and Elements panel. For example, you might want to specify that a record is fixed length, and set the record length.
   a. If you set the `Record detection` property to anything other than `Whole File`, drag an additional output node to the flow, such as the MQOutput node. Wire the End of Data terminal on the FTEInput node to the In terminal of the MQOutput node, as shown in the following figure:

   The node connected to the End of Data terminal receives an empty message when the last record in the file is read.
5. Optional: To process the file based on details of the transfer, place a node such as the Route node after the FTEInput node. Details of the transfer are stored in the local environment, at `LocalEnvironment.FTE`.
6. Add the flow to a broker archive (BAR) file and deploy the BAR file.
7. Optional: Change the coordination queue manager; see "Preparing the environment for WebSphere MQ File Transfer Edition nodes" on page 740. The queue manager for the broker is the default coordination queue manager. The default might be adequate for testing; for production, consider changing it. A warning is written to the log if the coordination queue manager is not changed from the default.

Receiving a file using IBM Sterling Connect:Direct:

Use the CDInput node to receive files from an IBM Sterling Connect:Direct network.

Before you begin

Before you start:

1. Read "IBM Sterling Connect:Direct overview and concepts" on page 1810.

About this task

MultipleCDInput nodes can be deployed to the same execution group, or to different execution groups in the same broker. Multiple CDInput nodes can read files transferred to the same directory without contention. Each file is processed only once, even if the nodes are deployed to separate execution groups, or different brokers.

On z/OS, when the CDInput node receives notification of the arrival of a dataset that it should process, the node copies that dataset into Unix System Services temporarily, before processing.

Complete the following steps to create a CDInput node message flow using the default settings. The task includes some optional steps for additional configuration, but detailed information about configuring the CDInput node is given on the property panels for the node, in the WebSphere Message Broker Toolkit. The default settings assume that you have a Connect:Direct server running on the same machine as the broker, and that you are using the default ports.

Procedure

1. Drag a CDInput node onto a message flow and wire its Out terminal to an output node of your choice.
2. Optional: To process only a defined subset of files, configure the Basic panel. This action allows multiple CDInput nodes in the same execution group to receive specific files, depending on the directory or file filters specified.

   You can also specify whether, after processing, the file is left in its directory, renamed, or deleted.
3. To change how the node handles a message flow failure, configure the Retry panel.
4. Optional: To change how records are identified in the input file, configure the `Record detection` property on the Records and Elements panel. For example, you might want to specify that a record is fixed length, and set the record length.
   a. If you set the `Record detection` property to anything other than `Whole File`, drag an additional output node to the flow, such as the MQOutput node. Wire the End of Data terminal on the CDInput node to the In terminal of

the MQOutput node. The node connected to the End of Data terminal receives an empty message when the last record in the file is read.

5. Optional: To process the file based on details of the transfer, place a node such as the Route node after the CDInput node. Details of the transfer are stored in the local environment, at `LocalEnvironment.CD`.
6. Setup the *username* and *password* that is required for the CDInput node to connect to the primary Connect:Direct server using the "**mqsisetdbparms** command" on page 3954.
7. Add the flow to a broker archive (BAR) file and deploy the BAR file.

   For information on how to use configurable services with IBM Sterling Connect:Direct, see "Advanced configuration properties when using IBM Sterling Connect:Direct nodes" on page 727.
8. Use IBM Sterling Connect:Direct to send a file to the local Connect:Direct server. The CDInput node processes this file.

Controlling how files are separated into records:

Set the `Record detection` and other properties on node **Records and Elements** tabs to read files in different formats.

The following examples are based on the examples described in "Using a local file as input for your message flow" on page 1834 and "Reading a file on a remote FTP

or SFTP directory" on page 1842. In each case, the input file to use, the property settings, and the expected results are described.

The examples, which describe using the FileInput node, can be applied to the FTEInput node, with the following provisos:

- The FTEInput node has no Basic tab.
- FTP and SFTP are not used to transmit files to an FTEInput node.

The examples can also be applied to the FileRead node, with the following provisos:

- The FileRead node propagates only one record from the file and, by default, this record is the first record in the file. The FileRead node can be configured to propagate a specific record. For more information see "Routing or enriching a message based on the contents of a file" on page 1837.
- FTP and SFTP are not used to transmit files to an FileRead node.

Example 1. Records are separated by a DOS or UNIX line end

This example is identical to the one described in "Using a local file as input for your message flow" on page 1834 or "Reading a file on a remote FTP or SFTP directory" on page 1842. Create an input file called `test_input1.xml` with the following content:

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

Each line ends with a line terminator.

The properties to set are:

Tab	Property	Value
Records and Elements	`Record detection`	`Delimited`
	`Delimiter`	`DOS or UNIX Line End`
	`Delimiter type`	`Postfix`

The FileInput node detects records that end with a DOS or UNIX line end and creates a message for each one that it finds.

The result is the propagation of three messages, as follows:

- Message 1:

  ```
  <Message>test1</Message>
  ```
- Message 2:

  ```
  <Message>testtwo</Message>
  ```
- Message 3:

  ```
  <Message>testthree</Message>
  ```

The DOS or UNIX line end is not part of any propagated message.

Example 2. Records are separated by a custom delimiter

Create an input file called `test_input2.xml` with the following content:

```
<Message>test01</Message>,<Message>test001</Message>,<Message>test0001</Message>
```

There must be no line terminator at the end of this file data; the XMLNSC parser ignores the line terminator if it is present.

In addition to the property settings described in "Using a local file as input for your message flow" on page 1834 or "Reading a file on a remote FTP or SFTP directory" on page 1842, set these properties:

Tab	Property	Value
Basic	File name or pattern	test_input2.xml
Records and Elements	Record detection	Delimited
	Delimiter	Custom Delimiter
	Custom delimiter	2C
	Delimiter type	Infix

The hexadecimal X'2C' represents a comma in ASCII. On other systems, you must use a different hexadecimal code.

The FileInput node detects the comma character and uses it to separate records. Because the value of the Delimiter type property is Infix, a comma is not required at the end of the file.

The result is the propagation of three messages, as follows:

- Message 1:
  <Message>test01</Message>
- Message 2:
  <Message>test001</Message>
- Message 3:
  <Message>test0001</Message>

The comma character is not part of any propagated message. There are no commas in the bodies of the message in this example; if the message bodies did contain commas, the records would be split at those points resulting in incorrectly formed messages being propagated to the rest of the flow.

Example 3. Records are separated by a fixed number of bytes

Create an input file called test_input3.xml with the following content:

```
<Message>123456789</Message><Message>abcdefghi</Message><Message>rstuvwxyz</Message>
```

There must be no line terminator at the end of this file.

In addition to the property settings described in "Using a local file as input for your message flow" on page 1834 or "Reading a file on a remote FTP or SFTP directory" on page 1842, set these properties:

Tab	Property	Value
Basic	File name or pattern	test_input3.xml
Records and Elements	Record detection	Fixed Length
	Length	28

The FileInput node splits the input file into records each 28 bytes long.

The result is the propagation of three messages, as follows:

- Message 1:

  ```
  <Message>123456789</Message>
  ```

- Message 2:

  ```
  <Message>abcdefghi</Message>
  ```

- Message 3:

  ```
  <Message>rstuvwxyz</Message>
  ```

Each message is 28 bytes long. If the file contains trailing bytes, for example a carriage return-line feed pair, a further message containing these bytes is propagated; the trailing bytes might or might not be recognized by the message domain, message set, and message type assigned to parse the message.

Example 4. Records are whole files

Create an input file called `test_input4.xml` with the following content:

```
<Message>Text string of a length decided by you, even including line
terminators, as long as it only contains this tag at the end.</Message>
```

There must be no line terminator at the end of this file; if there is one, it has no effect.

In addition to the property settings described in "Using a local file as input for your message flow" on page 1834 or "Reading a file on a remote FTP or SFTP directory" on page 1842, set these properties:

Tab	Property	Value
Basic	`File name or pattern`	`test_input4.xml`
Records and Elements	`Record detection`	`Whole File`

The FileInput node does not split the file; it propagates all of the content of the file as a single record to be parsed by the message domain, message set, and message type as specified on the node. In this example, you are using the XMLNSC parser and message set `xml1`, so the message is recognized.

The result is the propagation of one message, as follows:

- Message 1:

```
<Message>Text string of a length decided by you, even including line terminators, as long as
it only contains this tag at the end.</Message>
```

Trailing bytes (for example, line terminators) are included.

Example 5. Records are recognized as separate messages by the parser specified in the `Message domain` property

Create an input file called `test_input5.xml` with the following content:

```
<Message>Text string of a length decided by you  </Message><Message>and another</Message>
<Message>and another on a new line</Message>
```

Line terminators at the end of this file, or at the end of lines, are acceptable.

In addition to the property settings described in "Using a local file as input for your message flow" on page 1834 or "Reading a file on a remote FTP or SFTP directory" on page 1842, set these properties:

Table 13.

Tab	Property	Value
Basic	`File name or pattern`	`test_input5.xml`
Records and Elements	`Record detection`	`Parsed Record Sequence`

The FileInput node defers to the parser to determine the record boundaries. In this example, message set `xml1` in domain XMLNSC must recognize the complete `<Message>` XML format. XMLNSC absorbs trailing white space (for example, line terminators).

The result is the propagation of three messages, as follows:

- Message 1:

```
<Message>Text string of a length decided by you  </Message>
```

- Message 2:

```
<Message>and another</Message>
```

- Message 3:

```
<Message>and another on a new line</Message>
```

Trailing white space (for example, line terminators) are included in the messages.

Use the CDOutput node when using IBM Sterling Connect:Direct with WebSphere Message Broker.

"FileOutput node" on page 4430
Use the FileOutput node to write messages to files.

Writing a file to your local file system:

Use a FileOutput node to write a file to a specified directory on your local file system.

Before you begin

This example shows you how one combination of values in the `Record definition`, `Delimiter`, and `Delimiter type` properties result in the creation of a file from multiple messages. The example describes the FileOutput node of a message flow and assumes that the rest of the flow has been developed. It is also assumed that a Windows system is being used. To complete this example task, you must first have added a FileOutput node to a message flow. You must also ensure that the following messages are produced by the flow preceding the FileOutput node:

- Three input messages, which are sent, in this order, to the In terminal of the FileOutput node:
  - Message 1:

    ```
    <Message>test1</Message>
    ```
  - Message 2:

    ```
    <Message>testtwo</Message>
    ```
  - Message 3:

    ```
    <Message>testthree</Message>
    ```

  These messages can be produced, for example, by the XMLNSC domain with a message set which recognizes XML with the following form:

  ```
  <Message>...</Message>
  ```
- A final message, which is sent to the Finish File terminal of the FileOutput node after the first three messages have been sent:

  ```
  <thiscanbe>anything</thiscanbe>
  ```

Complete the following steps:

Procedure

1. Set the required node properties on the FileOutput node. The following table summarizes the FileOutput node properties that you must set, on which tab they appear, and the value that you must set in order to follow this example:

Tab	Property	Value
Basic	Directory	C:\FileOutput\TestDir
	File name or pattern	test_output1.xml
	Output file action	Time Stamp, Archive and Replace Existing File (or Create if File does not Exist)
	Replace duplicate archive files	Selected
Records and Elements	Record definition	Record is Delimited Data
	Delimiter	Broker System Line End
	Delimiter type	Postfix
FTP	FTP	Cleared

2. Deploy the message flow to the broker. See Chapter 11, "Packaging and deploying," on page 3209.
3. Send the first three messages to the In terminal of the FileOutput node.
4. Send the final message to the Finish File terminal of the FileOutput node.

Results

The following actions occur when you perform these steps:

1. The file is processed. In accordance with the values set in the properties of the FileOutput node, the node generates one record per message with a local file system line terminator after each one. The file contains the following data, each line terminated by a carriage return (X'0D') and line feed (X'0A') pair of characters (on a Windows system):

   ```
   <Message>test1</Message>
   <Message>testtwo</Message>
   <Message>testthree</Message>
   ```

2. Records are accumulated in file test_output1.xml in the C:\FileOutput\TestDir\mqsitransit directory. When the final message is sent to the Finish File terminal, the file is moved to the output directory, C:\FileOutput\TestDir directory.
3. If a file of the same name exists in the output directory, the existing file is renamed and moved to the mqsiarchive directory. For example, the following file might be created:

   ```
   C:\FileOutput\TestDir\mqsiarchive\20081124_155346_312030_test_output1.xml
   ```

   If a file of this name exists in this archive directory, it is overwritten in accordance with the Replace duplicate archive files property selected on the FileOutput node.

What to do next

See "Setting the Record definition property for the FileOutput and FTEOutput nodes" on page 1861 to see the results of running this task with different values set in the Record definition, Delimiter, and Delimiter type properties of the FileOutput node.

The following samples also show how to use this node:

- File Output
- Batch Processing
- WildcardMatch

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Writing a file to a remote FTP or SFTP server:

Use a FileOutput node to write a file to a directory on a remote FTP or SFTP server.

Before you begin

This example shows you how one combination of values in the `Record definition`, `Delimiter`, and `Delimiter type` properties result in the creation of a file from multiple messages. The example is an extension of the example described in "Writing a file to your local file system" on page 1853, and describes the use of a FileOutput node in a message flow.

These instructions assume that you are using a Windows system, and that you have already created a message flow containing a FileOutput node. You also require the following resources:

- An FTP or SFTP server. Ensure that an FTP or SFTP server exists with the following settings, so that you can follow this example scenario:

Server *ftpserver.hursley.abc.com*

Port *21* (for FTP) or *22* (for SFTP)

Working directory
/ftpfileoutput

User ID
myuserid

Password
mypassword

These values are for the purposes of this example only. If you use other values, record them so that you can set the appropriate values when you follow the instructions in this task.

- A security identity. Use the **mqsisetdbparms** command to define a security identity called *myidentity* for your user and password details.

  If you want to connect to an FTP server, the security identity must have an `ftp::` prefix, to enable the file nodes to find the identity definition. For example, use the following command for a broker called *MyBroker*:

  ```
  mqsisetdbparms MyBroker -n ftp::myidentity -u myuserid -p mypassword
  ```

  If you want to connect to an SFTP server, the security identity must have an `sftp::` prefix, as shown in the following example:

  ```
  mqsisetdbparms MyBroker -n sftp::myidentity -u myuserid -p mypassword
  ```

  You can also configure a connection to an SFTP server to use Public Key authentication, by specifying an SSH identity file and pass phrase, instead of a password. For example:

  ```
  mqsisetdbparms MyBroker -n sftp::myidentity -u myuserid -i identity_file -r passphrase
  ```

  For more information about configuring connections to an SFTP server, see "Transferring files securely by using SFTP" on page 1864.

- The following messages, which must be produced by the message flow preceding the FileOutput node:
  - Three input messages. These messages are sent, in this order, to the In terminal of the FileOutput node:
    - Message 1:

      ```
      <Message>test1</Message>
      ```

    - Message 2:

      ```
      <Message>testtwo</Message>
      ```

    - Message 3:

      ```
      <Message>testthree</Message>
      ```

    These messages can be produced, for example, by the XMLNSC domain with a message set that recognizes XML, in the following form:

    ```
    <Message>...</Message>
    ```

  - A final message sent to the Finish File terminal of the FileOutput node after the first three messages have been sent:

    ```
    <thiscanbe>anything</thiscanbe>
    ```

Complete the following steps:

Procedure

1. Set the required node properties on the FileOutput node. The following table summarizes the FileOutput node properties that you must set, the tabs on which they are displayed, and the values that are used in this example:

Tab	Property	Value
Basic	Directory	C:\FileOutput\TestDir
	File name or pattern	test_output1.xml
	Output file action	Time Stamp, Archive and Replace Existing File (or Create if File does not Exist)
	Replace duplicate archive files	Selected
Records and Elements	Record definition	Record is Delimited Data
	Delimiter	Broker System Line End
	Delimiter type	Postfix
FTP	Remote transfer	Selected
	Transfer protocol	FTP or SFTP
	Remote server and port	ftpserver.hursley.abc.com
	Security identity	myidentity
	Server directory	/ftpfileoutput
	Transfer mode	ASCII (for FTP only)
	Retain local file after transfer	Selected

   If you used other values for your FTP or SFTP server resource, use those values. The settings used here are identical to those settings used in the example in "Writing a file to your local file system" on page 1853 except that the Remote transfer property has been selected and there are now properties on the **FTP** tab. If you clear the Remote transfer property, the node operates as it does in the example in "Writing a file to your local file system" on page 1853; the properties on the **FTP** tab remain set but are ignored.

   You can override the Remote server and port property on the node by setting a value in the local environment. For more information, see "Local environment overrides for the FileOutput node" on page 4443.

2. Deploy the message flow to the broker. See Chapter 11, "Packaging and deploying," on page 3209.
3. Send the first three messages to the In terminal of the FileOutput node.
4. Send the final message to the Finish File terminal of the FileOutput node.

Results

The following actions occur when you perform these steps:

1. The file is processed. The FileOutput node generates one record per message with a local file system line terminator after each one. The file contains the following data, with each line terminated by a carriage return (X'0D') and line feed (X'0A') pair of characters (on a Windows system):

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

2. Records are accumulated in file `test_output1.xml` in the `C:\FileOutput\TestDir\mqsitransit` directory. When the final message is sent to the Finish File terminal, the file is moved to the remote FTP or SFTP server directory (because the `Remote transfer` property is selected). As a result, the file `/ftpfileoutput/test_output1.xml` is created.
3. If a file with the same name exists in the remote FTP or SFTP server directory, the existing file is overwritten.

   If the remote FTP server is not running on a Windows system and the `Transfer mode` property is set to `ASCII`, the character encoding and line terminator characters might be modified after transfer. For example, on a z/OS FTP server, the ASCII text is typically converted to EBCDIC, and the line terminator character pairs are replaced by EBCDIC new line characters (X'15'). Other FTP servers might treat ASCII transfers differently. If you are using SFTP, the `Transfer mode` property is ignored and files are sent as Binary files.
4. Because the `Retain local file after transfer` property is selected, the local file is not deleted but is moved from the `mqsitransit` subdirectory to the output directory, `C:\FileOutput\TestDir`. If a file with the same name exists in the output directory, the existing file is renamed and moved to the `mqsiarchive` directory. For example, the following file might be created:

   ```
   C:\FileOutput\TestDir\mqsiarchive\20081124_155346_312030_test_output1.xml
   ```

   However, if a file with this name exists in this archive directory, it is overwritten according to the value of the `Replace duplicate archive files` property set on the FileOutput node.

What to do next

For more information, see “Setting the `Record definition` property for the FileOutput and FTEOutput nodes” on page 1861, which shows the results of running this task with different values set in the `Record definition`, `Delimiter`, and `Delimiter type` properties of the FileOutput node.

The following samples also show how to use this node:

- File Output
- Batch Processing
- WildcardMatch

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Sending a file by WebSphere MQ File Transfer Edition:

Send files to an existing WebSphere MQ File Transfer Edition network.

Before you begin

Before you start:

1. Read about WebSphere MQ File Transfer Edition.
2. Get the following information from your WebSphere MQ File Transfer Edition administrator:
   - The name of the remote WebSphere MQ File Transfer Edition agent to which the file is to be sent.
   - The name of the destination queue manager.
   - The name of the output file.
3. Create a message flow that contains an input node.

About this task

Detailed information about configuring the FTEOutput node is given on the property panels for the node, in the WebSphere Message Broker Toolkit.

Procedure

1. Drag an FTEOutput node onto the message flow, and wire its In terminal to the input node.
2. On the Basic panel, set values for the `Destination agent` and `Destination file name` properties. Configuring just these two properties is enough if you want to send all the input message tree as a single record in the output file.
3. Optional: On the Basic panel, set a value for the `Destination queue manager` property. The default destination queue manager is the queue manager for the broker.
4. Optional: To specify a location in the input message tree for the data to be sent, configure the `Data location` property on the "Request properties" panel.

5. Optional: To change how records are placed in the output file, configure the `Record definition` property on the "Record definition" panel. For example, you might want to specify that a record is fixed length, and set the record length.
   a. If you set the `Record definition` property to anything other than `Record is Whole File`, drag a node such as the MQOutput node to the flow, and wire its Out terminal to the Finish File terminal on the FTEOutput node, as shown in the following figure:

   The node connected to the Finish File terminal must have logic to determine the last record in the file.
6. Optional: To set properties for the transfer dynamically, place a node such as the Compute node or Mapping node before the FTEOutput node. You can override the following properties:
   - `Destination agent`
   - `Destination file directory`
   - `Destination file name`
   - `Destination queue manager`
   - `Job name`
   - `Overwrite files on destination`

   Configure the node to write the overrides to the `LocalEnvironment.Destination.FTE` subtree.
7. Add the flow to a broker archive (BAR) file and deploy the BAR file.
8. Optional: Change the coordination queue manager; see “Preparing the environment for WebSphere MQ File Transfer Edition nodes” on page 740. The queue manager for the broker is the default coordination queue manager. The default might be adequate for testing; for production, consider changing it. A warning is written to the log if the coordination queue manager is not changed from the default.

Related reference:

“FTEOutput node” on page 4466
Use the FTEOutput node to write messages to files by using the WebSphere MQ File Transfer Edition.

Setting the `Record definition` property for the FileOutput and FTEOutput nodes:

Set the properties on the**Records and Elements** tab of the node to write files in different formats.

The following examples are based on those described in “Writing a file to your local file system” on page 1853 and “Writing a file to a remote FTP or SFTP server” on page 1855. The FTEOutput does not archive, and files are transferred using WebSphere MQ File Transfer Edition, rather than FTP or SFTP. In all examples, it is assumed that the same messages are sent to the FileOutput node; three to the In terminal and one to the Finish File terminal:

- Three input messages which are sent, in this order, to the In terminal of the FileOutput node:
  - Message 1:

    ```
    <Message>test1</Message>
    ```
  - Message 2:

    ```
    <Message>testtwo</Message>
    ```
  - Message 3:

    ```
    <Message>testthree</Message>
    ```

  These messages can be produced, for example, by the XMLNSC domain with a message set which recognizes XML with the following form:

  ```
  <Message>...</Message>
  ```
- A final message which is sent to the Finish File terminal of the FileOutput node after the first three messages have been sent. It does not matter what this message contains.

The following examples describe the contents of the file or files produced; the disposition of the files created is as in the “Writing a file to your local file system” on page 1853 and “Writing a file to a remote FTP or SFTP server” on page 1855 topics.

Example 1. Records written are separated by a DOS or UNIX line end

This example is identical to the one described in “Writing a file to your local file system” on page 1853 or “Writing a file to a remote FTP or SFTP server” on page 1855. Specify the node's properties as described in “Writing a file to your local file system” on page 1853 or “Writing a file to a remote FTP or SFTP server” on page 1855.

These properties result in one file being written. The file contains three records each terminated by a local system line terminator. On a Windows system, this is a carriage return (X'0D') line feed (X'0A') pair of characters; on UNIX systems it is X'0A'.

```
<Message>test1</Message>
<Message>testtwo</Message>
<Message>testthree</Message>
```

Example 2. Records written are separated by a custom delimiter

In addition to the property settings described in "Writing a file to your local file system" on page 1853 or "Writing a file to a remote FTP or SFTP server" on page 1855, set these properties on the **Records and Elements** tab:

Property	Value
Record definition	Record is Delimited Data
Delimiter	Custom Delimiter
Custom delimiter	0D0A
Delimiter type	Postfix

The hexadecimal X'0D0A' represents a carriage return character followed by a line feed character. On a Windows system, this results in a file identical to the one created in Example 1. On other systems, the result might differ from the result in Example 1; Example 1 uses local system line end characters, whereas Example 2 always puts the X'0D0A' sequence at the end of each line.

Example 3. Records written are padded to a fixed length

In addition to the property settings described in "Writing a file to your local file system" on page 1853 or "Writing a file to a remote FTP or SFTP server" on page 1855, set these properties on the **Records and Elements** tab:

Property	Value
Record definition	Record is Fixed Length Data
Length (bytes)	30
Padding bytes (hexadecimal)	2A

The hexadecimal character X'2A' represents an asterisk character in ASCII.

The length of each incoming message is 24 bytes, 26 bytes, and 28 bytes respectively. The required fixed length of each record is 30 bytes. Each record is therefore padded by an extra 6 bytes, 4 bytes, and 2 bytes respectively, using the hexadecimal character X'2A'.

One file is written. It contains a single line:

```
<Message>test1</Message>******<Message>testtwo</Message>****<Message>testthree</Message>**
```

Example 4. Records written are not separated by delimiters or padding

In addition to the property settings described in "Writing a file to your local file system" on page 1853 or "Writing a file to a remote FTP or SFTP server" on page 1855, set this property on the **Records and Elements** tab:

Property	Value
Record definition	Record is Unmodified Data

The records are concatenated with no padding or delimiters.

One file is written with the following content:

```
<Message>test1</Message><Message>testtwo</Message><Message>testthree</Message>
```

There are no trailing bytes or line terminators.

Example 5. Records are written as whole files

In addition to the property settings described in "Writing a file to your local file system" on page 1853 or "Writing a file to a remote FTP or SFTP server" on page 1855, set this property on the **Records and Elements** tab:

Property	Value
Record definition	Record is Whole File

Three files are created, each containing one record:

- File 1:

  ```
  <Message>test1</Message>
  ```

- File 2:

  ```
  <Message>testtwo</Message>
  ```

- File 3:

  ```
  <Message>testthree</Message>
  ```

Each of these files is created with the same name, one by one, in the mqsitransit directory. If you are following the example in "Writing a file to a remote FTP or SFTP server" on page 1855, each file is transferred to the remote FTP server. However, because each file overwrites the previous one, only the third file remains when the task is complete.

After optional transfer, if a copy is retained, each file is moved to the output directory, `C:\FileOutput\TestDir`. In accordance with the properties on the FileOutput node as described in "Writing a file to your local file system" on page 1853 or "Writing a file to a remote FTP or SFTP server" on page 1855, the second file moved displaces the first file from the output directory which is moved to the mqsiarchive subdirectory with a time stamp added to the file name. When the third file is moved to the output directory, it displaces the second file, causing it to be moved to the mqsiarchive subdirectory and renamed. The final result is files similar to these:

```
C:\FileOutput\TestDir\mqsiarchive\20071101_165346_312030_test_output1.xml
C:\FileOutput\TestDir\mqsiarchive\20071101_165347_312030_test_output1.xml
C:\FileOutput\TestDir\test_output1.xml
```

being File 1, File 2, and File 3 respectively. If FTP processing was enabled, File 3 would also be in the remote FTP server directory and called `test_output1.xml`.

Transferring files securely by using SFTP

You can transfer files securely by using the Secure File Transfer Protocol (SFTP), which enables file transfer by using the Secure Shell (SSH) protocol.

Use the properties on the FTP tab of the FileInput and FileOutput nodes to configure the secure transfer of files.

You can also use the FtpServer configurable service to configure other SFTP properties, including the cipher to be used for SFTP communication, compression level, and strict known host checking.

See the following topics for more information about configuring secure file transfer:

- "Configuring SFTP file transfer"
- "Known host checking" on page 1866

Configuring SFTP file transfer:

Use an FtpServer configurable service to specify the Secure File Transfer Protocol (SFTP) settings for a message flow, and to override the SFTP settings that are specified on the FileInput and FileOutput nodes.

About this task

The settings that you specify by using an FtpServer configurable service are read and validated when the message flow starts, and are used to configure any SFTP connections that are made for the node. The configurable service can override any or all of the remote transfer properties on the **FTP** tab of the FileInput and FileOutput nodes. For more information about the settings that you can specify with an FtpServer configurable service, see "FtpServer configurable service properties" on page 3794.

You can configure strict host key checking and specify your own known hosts file, or you can turn off strict host key checking and use the known hosts files that are created and managed by the broker.

Multiple configurable services can specify the same host and port, even with different known hosts files. FTP defaults to port 21 and SFTP defaults to port 22, which is the SSH default port. If you set the port and specify an FTP connection to an SFTP server (or specify an SFTP connection to an FTP server) a connection error occurs and a message is added to the event log.

You can use the FtpServer configurable service to configure the following SFTP settings:

- Cipher used for SSH/SFTP communication
- Compression level
- Strict known host checking
- Protocol (FTP/SFTP) for nodes to use for remote file transfer
- Location of a known hosts file when strict known host checking is set to Yes

Procedure

1. Use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command to create an FtpServer configurable service with the required parameter values. For more information about creating the FtpServer configurable service, see "FtpServer configurable service properties" on page 3794.
2. In the FileInput and FileOutput nodes, specify the name of the FtpServer configurable service in the **Remote server and port** property on the **FTP** tab. Use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** and **mqsireportproperties** commands to change or view the properties of the configurable service.

Known host checking:

Use known host checking to control which hosts the broker can connect to, and to verify the identity of those hosts.

Known host checking enables the broker to protect the messages in the message flow from unauthorized attempts to intercept the data (sometimes known as *man-in-the-middle attacks*). Known hosts files contain the SSH keys of the hosts to which the broker can connect. On z/OS systems, known hosts files and SSH identity files are stored in EBCDIC format, and on other operating systems they are stored in ASCII format.

Before it connects to a host to receive or transfer a file (using the FileInput or FileOutput nodes), the broker checks the host key against the keys that are stored in the known hosts file. If the host key does not match an existing entry for the host in the known hosts file, the connection fails. If the host is new (and has no entry in the known hosts file), the result depends on whether strict known host checking is turned on or off.

You can specify whether strict known host checking is turned on or off by setting the **strictHostKeyChecking** parameter of either the **mqsicreateconfigurableservice** command or the FtpServer configurable service. For more information about the settings that you can specify with an FtpServer configurable service, see "FtpServer configurable service properties" on page 3794.

Strict known host checking

When strict known host checking is turned on (by setting the **strictHostKeyChecking** parameter to `Yes`), the broker connects only to known hosts with valid SSH host keys that are stored in the known hosts file. If you use strict known host checking, you must create your own known hosts file, in OpenSSH format, containing the SSH keys of your trusted hosts. You specify the location of

your known hosts file using the **knownHostsFile** parameter of the **mqsicreateconfigurableservice** command. When the broker attempts to make a connection to a host, it checks the host key against the contents of the known hosts file. If the key is not in the known hosts file, the connection fails and a BIP3371 error occurs.

You can have multiple known hosts files and specify a different one for each node or configurable service. The known hosts files that you provide for strict known host checking are not modified by the broker.

Non-strict known host checking

When strict known host checking is turned off (by setting the **strictHostKeyChecking** parameter to `No`) the broker connects only to known hosts with valid keys or to new hosts to which it has not connected before. If the broker attempts to connect to a new host (to which it has not connected previously), the broker makes the connection, accepts the host's SSH key, and stores it in the known hosts file. When the broker tries to connect to the same host on subsequent occasions, the host key is checked against the key stored in the known hosts file, and, if the key matches, the connection is made. However, if the host key is different from the one stored in the known hosts file, the connection attempt fails and a BIP3371 error occurs.

When strict known host checking is turned off, the known hosts file is managed by the broker. One broker-managed known hosts file exists for each execution group.

BIP3371 error message

The BIP3371 error message might indicate that there has been an unauthorized attempt to intercept a message. However, the connection failure (and resulting BIP3371 error message) might be caused by a change to the host's SSH key at some time following its first connection to the broker. For example, if the SSH server is reinstalled, it is assigned a new key, which is not found in the known hosts file and is therefore not accepted by the broker. As a result, the connection fails and the BIP3371 error message is shown.

If you know that the SSH host key has changed (as a result of a recent SSH server reinstallation, for example), you can solve the connection failure by modifying the known hosts file:

1. Stop the message flow.
2. Edit the known hosts file:
   - If you have strict known host checking turned on, correct the entry for the host in the known hosts file that you specified in the **knownHostsFile** parameter of the **mqsicreateconfigurableservice** command.
   - If you have strict known host checking turned off, remove the host's entry from the broker-managed known hosts file. The known hosts file is in the `\components\`*`BROKERNAME-NAME`*`\`*`EG-UID`*`\config\known_hosts` subdirectory of the directory in which WebSphere Message Broker is installed. For example, on Windows the default directory is `C:\Documents and Settings\All Users\Application Data\IBM\MQSI\components\`*`BROKERNAME-NAME`*`\`*`EG-UID`*`\config\known_hosts`. On UNIX systems the default directory is `/var/mqsi/components/`*`BROKERNAME-NAME`*`/`*`EG-UID`*`/config/known_hosts`.

     When the broker attempts to reconnect, it adds the new host key to the known hosts file.

3. Restart the message flow.

Managed file transfers using WebSphere MQ File Transfer Edition

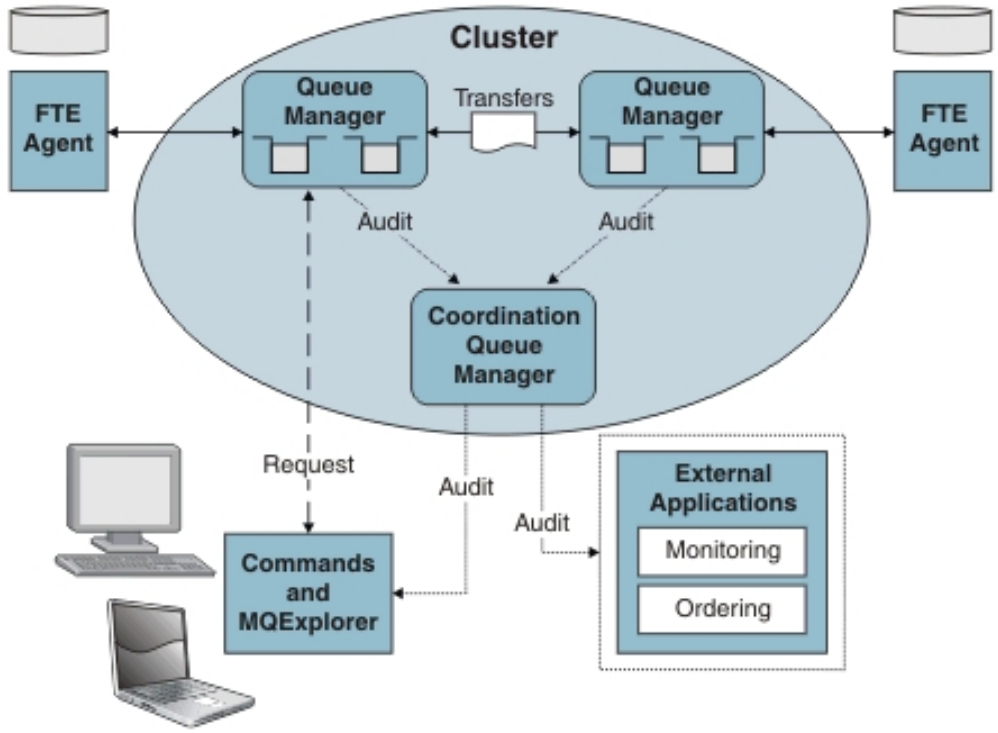
Transfer files, with file transfer metadata, in a timely and reliable manner.

- Transfer metadata is supported, providing more flexible file processing.
- Transfers are timely.
- The audit trail is complete between the broker and the remote agent.
- Resource statistics are available.

About WebSphere MQ File Transfer Edition

WebSphere MQ File Transfer Edition V7.0 delivers a reliable managed file transfer solution for moving files between IT systems without the need for programming. Files that are larger than the maximum individual WebSphere MQ message size can be moved. A log of file movements demonstrates that business data in files is transferred with integrity from source file system to destination file system.

Using the WebSphere MQ File Transfer Edition nodes offers seamless integration with your existing WebSphere MQ File Transfer Edition network. The following diagram shows a typical WebSphere MQ File Transfer Edition network:



The main components and concepts of WebSphere MQ File Transfer Edition are:

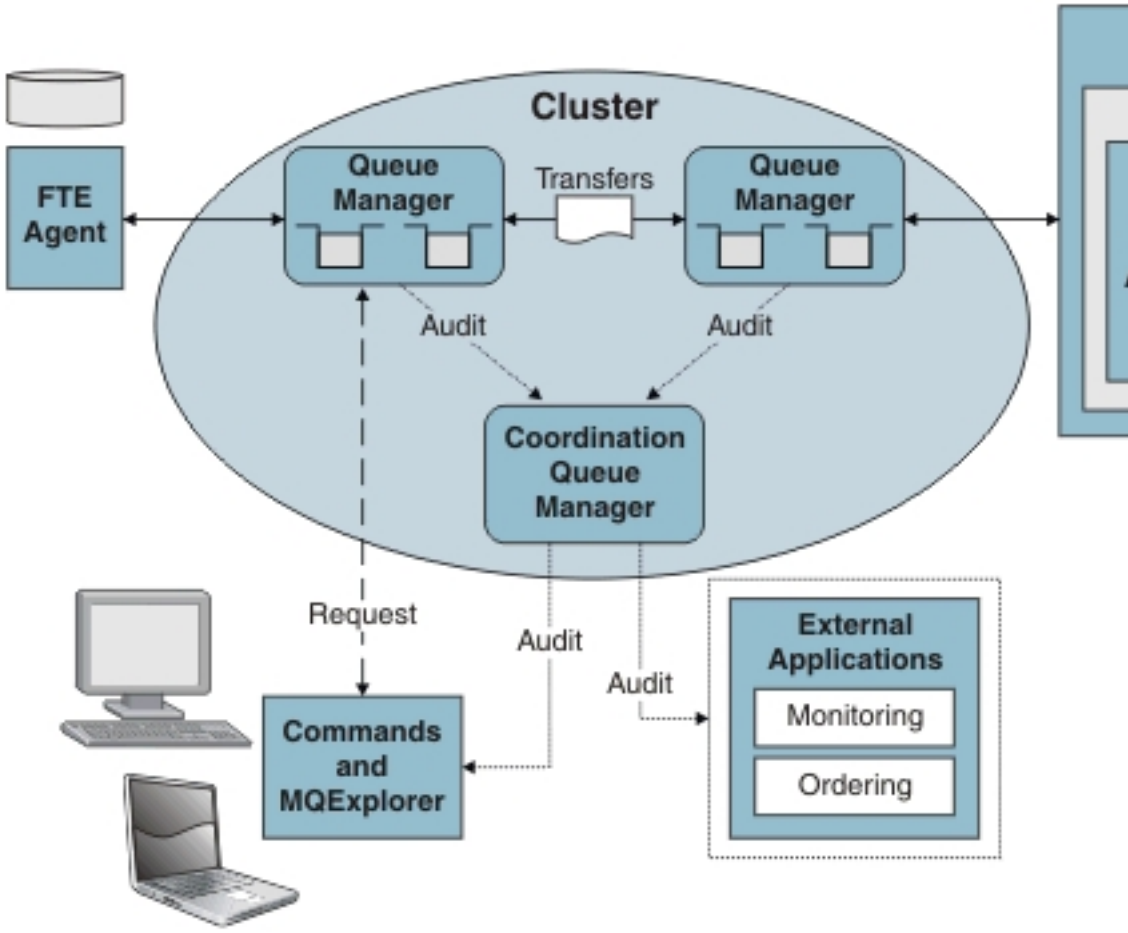
agent A process that forms the end point of a transfer (source or destination). An agent is a WebSphere MQ application, and is connected to one queue manager. Many agents can be connected to the same queue manager. Operational commands can be sent to an agent (for example, to request a transfer) by putting an XML message on a particular queue on the agent's queue manager.

coordination queue manager
One queue manager in the topology takes on the responsibility of the coordination queue manager. All agents register with the coordination queue manager and also send audit information about each transfer. The coordination queue manger is responsible for publishing that audit information to external monitoring applications.

transfer
A transfer is a movement of one or more files from one agent to another. The transfer goes direct from one agent's queue manager to the other agent's queue manager, not via the coordination queue manager. The transfer takes place even if the coordination queue manager is not running.

transfer log
The WebSphere MQ Explorer plug-in tool includes a Transfer Log view that subscribes to the coordination queue manager for the audit information. The view displays information about every transfer that occurs in a given topology.

How WebSphere Message Broker fits in



agent

An agent runs in each execution group that has deployed flows containing WebSphere MQ File Transfer Edition nodes. The agent is responsible for receiving and initiating all WebSphere MQ File Transfer Edition transfers. The agent name is derived from *Broker.ExecutionGroup*; the name is not configurable. See "Preparing the environment for WebSphere MQ File Transfer Edition nodes" on page 740 for restrictions on agent names.

You do not need to start or stop this agent; if a flow containing WebSphere MQ File Transfer Edition nodes is deployed, the agent is running. The agent is stopped only when the execution group is stopped. The broker queue manager is used as the queue manager for the agent.

coordination queue manager

The broker queue manager is the default coordination queue manager. You can specify a different coordination queue manager by using the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command. You must configure your coordination queue manager as a coordination queue manager. See the WebSphere File Transfer Edition Information Center for details.

transfer

Multiple FTEOutput nodes can be deployed to the same execution group, or to different execution groups in the same broker. FTEOutput nodes can

send one file per transfer. Each file can have multiple records. Each record can have multiple elements. Transfers from the FTEOutput are non-blocking; an error occurs if another transfer is outstanding with the same file name.

Multiple FTEInput nodes can be deployed to the same execution group, or to different execution groups in the same broker. Multiple FTEInput nodes can read files transferred to the same directory without contention. Each file is processed only once, even if the nodes are deployed to separate execution groups, or different brokers.

When sending a file, you can dynamically set the following properties:

- `Destination agent`
- `Destination file directory`
- `Destination file name`
- `Destination queue manager`
- `Job name`
- `Overwrite files on destination`

Put a node such as the Compute node or Mapping node before the FTEOutput node.

When receiving files, you can apply filters. If an execution group has more than one FTEInput node, each node receives only the appropriate files. You can also determine what happens after the file has been processed (the file is left in its existing destination directory, left with a timestamp added, or deleted). See the Basic tab on the node for details.

You can combine the FTEInput and FTEOutput nodes to create a request and reply flow. See the sample for details.

Using elements in the local environment, you can call a program on the destination agent before starting the transfer, or when the transfer is finished. See "LocalEnvironment.Destination.FTE fields" on page 1826 for details.

Overview of using WebSphere MQ File Transfer Edition nodes

You do not need to configure the WebSphere MQ File Transfer Edition code that runs in the broker. Operational tools in WebSphere Message Broker Explorer are provided to create transfers. The following nodes are provided:

FTEOutput

FTEInput

Take the following steps to use the nodes to send or receive data across an existing WebSphere MQ File Transfer Edition network:

1. Create a flow that includes one of the WebSphere MQ File Transfer Edition nodes.
2. Configure the node.
3. For production purposes, change the coordination queue manager from the broker queue manager; see "Preparing the environment for WebSphere MQ File Transfer Edition nodes" on page 740.
4. Deploy the flow.

Monitoring the license usage of WebSphere MQ File Transfer Edition in WebSphere Message Broker

A message is written to the system log for every execution group that has a WebSphere MQ File Transfer Edition node deployed.

Initiating a managed file transfer using IBM Sterling Connect:Direct

Use a CDOutput node to send a file from a specified directory on your primary Connect:Direct server (PNODE) to a filename and directory on a secondary Connect:Direct server (SNODE).

Before you begin

This topic describes use of the CDOutput node in a message flow and assumes that the rest of the flow has been developed, for example, an MQInput to a CDOutput node.

Multiple CDOutput nodes can be deployed to the same execution group, or to different execution groups in the same broker. CDOutput nodes can send one file per transfer. Each file can have multiple records; each record can have multiple elements. Transfers from the CDOutput node are non-blocking.

Complete the following steps:

Procedure

1. Set the required node properties on the CDOutput node.

   If you set the `Destination file name` only, and leave all the other options at their default values, the file is transferred:

   - From the primary Connect:Direct server (PNODE) back to itself
   - Into the default transfer directory using the default process name.

   Additionally, the file is created if it does not exist, or replaced if it already exists.

The following table summarizes the CDOutput node properties that you can set, on which tab they appear, and a value that you can select:

Tab	Property	Value
Basic	Process name	You can use any name you want for the process. Note, however, that the name must be a maximum of eight characters and cannot contain any spaces.
	SNODE	The secondary Connect:Direct server to which the file is being transferred.
	Destination file directory	TestDir on secondary Connect:Direct server (SNODE).
	Destination file name	Filename on secondary Connect:Direct server (SNODE).
	Disposition	RPL
	Transfer mode	Text mode

2. Setup the *username* and *password* that is required for the CDOutput node to connect to the primary Connect:Direct server using the "**mqsisetdbparms** command" on page 3954.
3. Deploy the message flow to the broker. See Chapter 11, "Packaging and deploying," on page 3209.
4. Send the file to the In terminal of the CDOutput node.

Results

The following actions occur when you perform these steps:

1. The file is constructed in accordance with the values set in the properties of the CDOutput node.
2. The file is staged in the local file system and then a command is sent to the Connect:Direct server to cause the transfer to occur.
3. If a file of the same name exists in the selected directory on the secondary Connect:Direct server, the processing of the existing file is determined by the value of the *Disposition* property; in this example, the file is replaced.

   Once the transfer has completed the local, staged file is deleted.

Note, that when sending a file, you can dynamically set the following properties:

- Secondary Connect:Direct server (SNODE)
- Process name
- Accounting data
- Destination file directory
- Destination file name
- Copy from options
- Copy to options

You have complete control of the Copy statements.

For example:

```
LocalEnvironment.Destination.CD.Copy.To.Option.PERMISS = '777'
```

causes IBM Sterling Connect:Direct to set the permissions on the destination file to `777` (or `RWX RWX RWX`) if the destination file is on a UNIX operating system, or within Unix System Services on z/OS.

However, if you enter an incorrect format, a syntax error is detected when the process script is submitted and this causes an error to be thrown in the node.

For example:

```
LocalEnvironment.Destination.CD.Copy.To.Option.PERMISS = '7xddd'
```

causes a syntax error because `'7xddd'` is not of the format `nnn`. When an error occurs the process script is available in the exception thrown and the user trace.

Tip: To help you with problem determination, you can view the script generated by the CDOutput node by turning on user trace.

WebSphere Service Registry and Repository

The WebSphere Service Registry and Repository (WSRR) is a central repository of entities. A wide range of entities can be stored and retrieved, including user-defined concepts and definitions related specifically to Web services, such as WSDL services, service interfaces, and associated policies.

You can configure a message flow to dynamically retrieve resources from WSRR at run time, and to use and expose those resources in the message flow. You can therefore defer the decision about which resources you want to use until run time, rather than deciding at deployment time.

WSRR has specific support for many of the document types associated with Web services, including generic XML documents, WSDL, and SCDL. For example, when you load a WSDL document into WSRR it also identifies and stores its individual logical components, such as the service and port type.

Use the WSRR nodes (the RegistryLookup and EndpointLookup nodes) to create message flows that retrieve data dynamically from WSRR. Data is retrieved according to search criteria defined by node properties, possibly supplemented or overridden by local environment definitions. The retrieved data is placed in the local environment tree, which makes the data available to subsequent nodes. The input message received by the node is propagated to the output terminal unchanged.

Use the RegistryLookup node to submit generic queries to WSRR. Entities returned by the query are stored in the ServiceRegistry output tree in the local environment. You can also specify that details of the relationships between the returned entities and other entities that they reference are represented in the ServiceRegistry output tree.

Use the EndpointLookup node to submit queries for Web service endpoints. This node is tailored to retrieve WSDL port definitions that implement a specified WSDL portType. The details of service endpoints that match the specified criteria are placed in the ServiceRegistry output tree in the local environment. If the node is configured to return a single matching service endpoint, the Web service URL destination used by the SOAP and HTTP request nodes is also overridden in the local environment. If the node is configured to return all matching service endpoints, the local environment is not set up automatically for the SOAP and HTTP request nodes. In this case the local environment tree might contain data for multiple service endpoints, and the message flow interprets and uses this information.

Set the configuration parameters for the WSRR nodes to specify how WebSphere Message Broker interfaces with your WSRR server.

- Use the **connectionTimeout** parameter to set a system-wide connection timeout for queries that are issued by the EndpointLookup and RegistryLookup nodes. If a query result is not returned from the WSRR server before the connection timeout period expires, the configured error handling is invoked.
- Use the **needCache** parameter to enable the WebSphere Message Broker WSRR cache. The cache is used to store results from queries that are issued by the EndpointLookup and RegistryLookup nodes.
- If the WebSphere Message Broker WSRR cache is enabled, use the **timeout** parameter to set a system-wide cache timeout. The cache timeout controls how long results from queries that are stored in the cache are used before the query is reissued.

If your WebSphere Message Broker application is running on Sun Solaris 10 on SPARC, you might need to increase the number of file descriptors. If there are not enough file descriptors, you might fail to get a response to a WSRR query within the configured timeout period. In addition, the service trace might contain one or

more java.lang.SecurityExceptions related to com.ibm.ws.tcp.channel.impl.ChannelSelector, and an abend file might be produced.

For information about the specific levels of WSRR that are supported with WebSphere Message Broker, see WebSphere Message Broker Requirements.

Configuration parameters for the WebSphere Service Registry and Repository nodes

These parameters affect the broker configuration when interfacing with WebSphere Service Registry and Repository (WSRR).

The following table describes the parameters used by the **mqsichangeproperties** command to configure the `DefaultWSRR` object of the `Service Registries` configurable service.

Configuration Setting Name	Default value	Description
`endpointAddress`	For all versions of WSRR: `http://hostname:9080/WSRRCoreSDO/services/WSRRCoreSDOPort`	Endpoint of the WSRR server. Where *hostname:port* is host address and port of your WSRR server. To connect to a secure WSRR, specify `https://` instead of `http://`. For more information, see "Accessing a secure WSRR repository" on page 1884. For information about the specific levels of WSRR that are supported with WebSphere Message Broker, see WebSphere Message Broker Requirements.
`timeoutConnection`	`180`	The WSRR connection timeout period in seconds. The default value is `180` seconds. Set a value that is sufficiently long for complex queries to complete.

For more information about WSRR endpoint addresses, see WSRR Web service interface URLs.

The following table describes the parameters for Cache that are configured by using the **mqsichangeproperties** command.

Configuration Setting Name	Default value	Description
needCache	True	Enable WebSphere Message Broker WSRR cache.
timeout	100000000	The timeout value for the cache. The cache expiry time in milliseconds. (The default value of 100000000 milliseconds is approximately 27.8 hours).
predefinedCacheQueries	None	A list of semicolon-separated WSRR XPath query expressions with which to initialize the WebSphere Message Broker WSRR cache at startup. These WSRR XPath query expressions are defined by the WSRR SOAP interface query expression language, and can include an optional depth specifier extension.

The following table describes the parameters for Cache Notification that are configured by using the **mqsichangeproperties** command.

Configuration Setting Name	Default value	Description
enableCacheNotification	False	Enable WebSphere Message Broker WSRR Cache Notification.
refreshQueriesAfterNotification	True	When a notification is received from WSRR, if refreshQueriesAfterNotification is set to True, the cache is updated with the new version of the object immediately; if False, the cache is updated on the next request.
connectionFactoryName	jms/SRConnectionFactory	The name of the WSRR WebSphere Application Server JMS provider JMS connection factory for Cache Notification.
initialContextFactory	com.ibm.websphere.naming.WsnInitialContextFactory	The name of the WSRR WebSphere Application Server JMS provider JMS context factory for Cache Notification.
locationJNDIBinding	iiop://*hostname*:2809/	The URL to the WebSphere Application Server JMS provider JNDI bindings, where *hostname* is variable.
subscriptionTopic	jms/SuccessTopic	The topic name used to receive WebSphere Application Server JMS provider Cache Notification.

For information about accessing a secure WSRR server, see "Accessing a secure WSRR repository" on page 1884.

The supplied configurable services, and the configurable services that you create, are defined by their names and properties. You can use the supplied services.

"EndpointLookup node" on page 4407
Use the EndpointLookup node to retrieve service endpoint information held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. Depending on the node configuration, the Web service URL destination used by the SOAP and HTTP request nodes can also be set. The input message is not modified.

"RegistryLookup node" on page 4646
Use the RegistryLookup node to retrieve any type of entity held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. The input message is not modified.

Displaying the configuration parameters for the WebSphere Service Registry and Repository nodes

Use the **mqsireportproperties** command to display all of the configuration parameters of the default WebSphere Service Registry and Repository (WSRR) profile, `DefaultWSRR`.

About this task

The `DefaultWSRR` is a `Service Registries` configurable service that is supplied for each broker, see "Configurable services properties" on page 3766.

For information about the specific levels of WSRR that are supported with WebSphere Message Broker, see WebSphere Message Broker Requirements.

To display the configuration parameters of the default WSRR profile `DefaultWSRR`, complete the following steps:

Procedure

1. Ensure that the broker is running. If it is not, use the **mqsistart** command to start it.
2. Enter the following command (where MB7BROKER is the name of your broker):

   ```
   mqsireportproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR -r
   ```

   where:

   -c specifies the configurable service (in this case, ServiceRegistries)
   -o specifies the name of the object (in this case, DefaultWSRR)
   -r specifies that all property values of the object are displayed, including the child values if appropriate.

Results

The command produces a response similar to this:

```
ReportableEntityName=''
ServiceRegistries
  DefaultWSRR=''
    connectionFactoryName = 'jms/SRConnectionFactory'
    connectionTimeout = '120'
    endpointAddress = 'http://fill.in.your.host.here:9080/WSRRCoreSDO/services/WSRRCoreSDOPort'
    initialContextFactory = 'com.ibm.websphere.naming.WsnInitialContextFactory'
    locationJNDIBinding = 'iiop://localhost:2809/'
    needCache = 'true'
    predefinedCacheQueries = ''
    refreshQueriesAfterNotification = 'true'
    subscriptionTopic = 'jms/SuccessTopic'
    timeout = '10000000'
```

Changing the configuration parameters for the WebSphere Service Registry and Repository nodes

Use the **mqsichangeproperties** command to change the configuration parameters of the `DefaultWSRR` configurable service.

About this task

`DefaultWSRR` is a configurable service object that is supplied for each broker, it defines the WebSphere Service Registry and Repository (WSRR) configuration parameters. `DefaultWSRR` has a configurable service type of `ServiceRegistries`.

For details about configuration parameters that affect WSRR use, see "Configuration parameters for the WebSphere Service Registry and Repository nodes" on page 1877.

To update the configuration parameters of the `DefaultWSRR` configurable service perform the following steps:

Procedure

1. Ensure that the broker is running. If it is not, use the **mqsistart** command to start it.
2. Enter the following command (which applies to all versions of WSRR) to change the `endpointAddress` value and point to your WebSphere Service Registry and Repository server:

   ```
   mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
   -n endpointAddress
   -v http://localhost:9080/WSRR6_1/services/WSRRCoreSDOPort
   ```

   where:

   -c specifies the configurable service type
   (in this case, `ServiceRegistries`)
   -o specifies the name of the configurable service object
   (in this case, `DefaultWSRR`)
   -n specifies the names of the properties to be changed
   (in this case, `endpointAddress`)
   -v specifies the values of properties defined by the **-n** parameter
   (in this case,
   `http://localhost:9080/WSRR6_1/services/WSRRCoreSDOPort`)

For information about the specific levels of WSRR that are supported with WebSphere Message Broker, see WebSphere Message Broker Requirements.

3. (Optional) Enter the following command to change the cache `timeout` value:

```
mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
-n timeout -v 3600000
```

where:

-c specifies the configurable service type
(in this case, `ServiceRegistries`)
-o specifies the name of the configurable service object
(in this case, `DefaultWSRR`)
-n specifies the names of the properties to be changed
(in this case, `timeout`)
-v specifies the values of properties defined by the **-n** parameter
(in this case, 3600000 milliseconds to provide WSRR cache expiry timeout of 1 hour)

4. (Optional) Enter the following command to change the `connectionTimeout` value:

```
mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
-n connectionTimeout -v 240
```

where:

-c specifies the configurable service type
(in this case, `ServiceRegistries`)
-o specifies the name of the configurable service object
(in this case, `DefaultWSRR`)
-n specifies the names of the properties to be changed
(in this case, `connectionTimeout`)
-v specifies the values of properties defined by the **-n** parameter
(in this case, 240 seconds to provide connection timeout for WSRR queries of 4 minutes)

5. (Optional) Enter the following command to preload the cache at broker startup with the results of specific queries:

```
mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
-n predefinedCacheQueries
-v "//*[@name=&apos;ConceptA1&apos;]"
```

where:

-c specifies the configurable service type
(in this case, `ServiceRegistries`)
-o specifies the name of the configurable service object
(in this case, `DefaultWSRR`)
-n specifies the names of the properties to be changed
(in this case, `predefinedCacheQueries`)
-v specifies the values of properties defined by the **-n** parameter
(in this case a simple full depth WSRR XPath query on the entity `ConceptA1`, `"//*[@name=&apos;ConceptA1&apos;]"`).

Note that single quotation marks in the WSRR query must be replaced by `&apos;)`

Multiple queries can be specified by delimiting them with ';'

For example, to perform a full depth query on the entities named `ConceptA1` and `ConceptB2` use:

```
-v "//*[@name=&apos;ConceptA1&apos;];//*[@name=&apos;ConceptB2&apos;]"
```

When a specific value for the `Depth Policy` property is used on a RegistryLookup node the same depth must be specified in the **predefinedCacheQueries** property by using an optional extension to the query expression of the form `depth=n`.
For the `Depth Policy` value of `MatchOnly` use `depth=0`.
For the `Depth Policy` value of `MatchPlusImmediate` use `depth=1`.
For the `Depth Policy` values of `MatchPlusAll` or `MatchShowReluse` `depth=-1`, which is the default value.

For example, the following query retrieves an XSD `MsgDef.xsd` with no related entities, the entity `ConceptA1` and its immediately related entities, and the entity `ServiceA2` and all entities related to it:

```
-v "//*[@name=&apos;MsgDef.xsd&apos;]{depth=0};
//*[@name=&apos;ConceptA1&apos;]{depth=1};
//*[@name=&apos;ServiceA2&apos;]"
```

Individual queries can use the full power of the WSRR query language:

```
-v "/WSRR/WSDLService/ports[binding/portType
[@name=&apos;DemoCustomer&apos;
and @namespace=&apos;http://demo.sr.eis.ibm.com&apos;]]"
```

Use the Broker User Trace to obtain the WSRR XPath query string that is issued when a RegistryLookup or EndpointLookup node is invoked.

Alternatively, use parameter `-p` instead of **-v** to specify a file from which the **mqsichangeproperties** command reads the property values:

```
mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
-n endpointAddress
-p config.xml
```

The following conditions apply when you use the **-p** parameter:

- The parameter is used to specify the location and name of a file from which the command reads the property values.
- The parameter can be used to set only a single property. Therefore, the **-n** parameter must specify only a single property name, not a comma-separated list of property names.
- White space characters (including line feed, carriage return, and end of file characters) are preserved when read from a file that is specified by using the **-p** parameter

See "Configurable services properties" on page 3766 for further detail.

6. Restart the broker, by using the **mqsistop** command to stop the broker, followed by the **mqsistart** command to start it.

Accessing a secure WSRR repository

To access a secure WebSphere Service Registry and Repository (WSRR) repository, set the configuration parameters by using the **mqsichangeproperties** command.

About this task

You must connect over HTTPS, not HTTP, which is specified in the `endpointAddress` configuration parameter of the default WSRR profile, `DefaultWSRR`.

For more information about the `endpointAddress` configuration parameter, see "Configuration parameters for the WebSphere Service Registry and Repository nodes" on page 1877.

To access a secure WebSphere Service Registry and Repository, enter the following sequence of commands:

Procedure

1. Ensure that the broker is running. If it is not, use the **mqsistart** command to start it.
2. Use the ServiceRegistries configurable service to configure the broker to use HTTPS to communicate with the WSRR server. You can view the current configuration parameters for the ServiceRegistries configurable service by using the following command:

   ```
   mqsireportproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR -r
   ```

where:

-c specifies the configurable service (in this case, ServiceRegistries)
-o specifies the name of the object (in this case, DefaultWSRR)
-r specifies that all property values of the object are displayed, including the child values, if appropriate.

To change the endpointAddress configuration parameter to specify HTTPS and the secure port for the DefaultWSRR of the ServiceRegistries configurable service, use the following command. The endpointAddress applies to the version of WSRR (for more information, see "Configuration parameters for the WebSphere Service Registry and Repository nodes" on page 1877).

```
mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
-n endpointAddress
-v https://localhost:9443/WSRR6_1/services/WSRRCoreSDOPort
```

where:

-c specifies the configurable service (in this case, ServiceRegistries)
-o specifies the name of the object (in this case, DefaultWSRR)
-n specifies the names of the properties to be changed
(in this case, endpointAddress)
-v specifies the values of properties defined by the **-n** parameter
(in this case, https://localhost:9443/WSRR6_1/services/WSRRCoreSDOPort)

For information about the specific levels of WSRR that are supported with WebSphere Message Broker, see WebSphere Message Broker Requirements.

3. Configure the broker keystore to contain your WSRR server certificate keys; for a discussion of digital certificates, see "Digital certificates" on page 356. Obtain these certificate keys from the installation of the WebSphere Application Server that hosts your WSRR server. The broker uses a single keystore, therefore, if your broker also implements WS-Security, HTTPS, or SSL-secured WebSphere MQ, you might need to merge the provided keys into an existing keystore file. The broker keystore is configured by using the **mqsichangeproperties** command to change configuration parameters for the broker. Display the current configuration parameters of the broker by using the following command:

   ```
   mqsireportproperties MB7BROKER -o BrokerRegistry -r
   ```

   where:

   -o specifies the name of the object (in this case, BrokerRegistry)
   -r specifies that all property values of the object are displayed, including the child values, if appropriate.

   To change the brokerKeystoreFile configuration parameters for the broker, use the following command:

   ```
   mqsichangeproperties MB7BROKER -o BrokerRegistry
   -n brokerKeystoreFile -v C:\WSRR\SSL\ClientKeyFile.jks
   ```

   where:

   -o specifies the name of the object (in this case, BrokerRegistry)
   -n specifies the names of the properties to be changed (in this case, brokerKeystoreFile
   -v specifies the values of properties defined by the **-n** parameter
   (in this case, C:\WSRR\SSL\ClientKeyFile.jks)

4. Configure the broker truststore to contain signer certificates for your WSRR server. As described previously for the keystore, the broker uses a single

truststore, therefore certificates might need to be merged into an existing truststore file. The broker truststore is configured by using the **mqsichangeproperties** command. To change the brokerTruststoreFile configuration parameters for the broker, use the following command:

```
mqsichangeproperties MB7BROKER -o BrokerRegistry
-n brokerTruststoreFile -v C:\WSRR\SSL\ClientTrustFile.jks
```

where:

-o specifies the name of the object
(in this case, BrokerRegistry)
-n specifies the names of the properties to be changed
(in this case, brokerTruststoreFile)
-v specifies the values of properties defined by the **-n** parameter
(in this case, C:\WSRR\SSL\ClientTrustFile.jks)

5. Stop the broker by using the **mqsistop** command. You must stop the broker to complete the following step.
6. Set the WebSphere Application Server user name and password by using the following command:

   ```
   mqsisetdbparms MB7BROKER -n DefaultWSRR::WSRR -u wasuser -p waspass
   ```

   where:

   -n specifies the name of the data source
   (in this case, DefaultWSRR::WSRR)
   -u specifies the user ID to be associated with this data source (in this case, wasuser)
   -p specifies the password to be associated with this data source (in this case, waspass)
7. Set the brokerKeystore user name and password by using the following command:

   ```
   mqsisetdbparms MB7BROKER -n brokerKeystore::password -u dummy -p WebAS
   ```

   where:

   -n specifies the name of the data source (in this case, brokerKeystore::password)
   -u specifies the user ID to be associated with this data source (in this case, dummy)
   -p specifies the password to be associated with this data source (in this case, WebAS)
8. Set the brokerTrustStore user name and password by using the following command:

   ```
   mqsisetdbparms MB7BROKER -n brokerTruststore::password -u dummy
   -p WebAS
   ```

   where:

   -n specifies the name of the data source (in this case, brokerTruststore::password)
   -u specifies the user ID to be associated with this data source (in this case, dummy)
   -p specifies the password to be associated with this data source (in this case, WebAS)
9. To use cache notification with your secure WSRR server, you must specify a valid user ID and password for the broker to use when connecting to the WSRR JMS cache notification topic. To set the user ID and password that the broker will use to make the JMS cache notification connection, use the following command:

   ```
   mqsisetdbparms MB7BROKER -n jms::DefaultWSRR@jms/SRConnectionFactory
   -u userid -p password
   ```

where:

-n specifies the name of the data source
(in this case, `jms::DefaultWSRR@jms/SRConnectionFactory`)
-u specifies the user ID to be associated with this data source
(in this case, *userid*)
-p specifies the password to be associated with this data source
(in this case, *password*)

Note: When using WebSphere Application Server Version 8.0, the default IIOP secure setting must be set to SSL-supported to enable the JMS cache notification. For more information about setting IIOP security, go to the WebSphere Application Server, Network Deployment (Distributed platforms and Windows), Version 8.0 information center, and read the topic "Common Secure Interoperability Version 2 transport inbound settings"; see WebSphere Application Server information center, Version 8.0.

10. Restart the broker by using the **mqsistart** command.

Caching artifacts from the WebSphere Service Registry and Repository

WebSphere Message Broker saves the data it retrieves from the WebSphere Service Registry and Repository (WSRR) in a local cache.

The WSRR nodes, EndpointLookup and RegistryLookup, can retrieve data that was stored in the Broker WSRR cache by a previous query, improving performance and message throughput. The first occurrence of each query is always sent to WSRR. By default, this activity occurs when a WSRR node first issues a specific query, although it is possible to pre-populate the cache, when the broker starts, by using the queries described here.

Configuring the WSRR Cache

The cache is configured individually for each broker by using the WebSphere Message Broker Explorer or the **mqsichangeproperties** command; for details, see "Configurable services properties" on page 3766.

You can configure the cache in the following ways:

- **Disabling the cache**

  Disable the cache by setting the `needCache` parameter to `false`. By default, the cache is enabled, but the WSRR nodes can operate without the cache. If the cache is disabled, every query that is issued by the node is sent to WSRR, ensuring that the results of the query always reflect the current contents of the registry. This activity can affect performance.

- **Preloading the cache**

  Preload the cache by setting the `predefinedCacheQueries` parameter. By default, no items are preloaded in the cache and the first occurrence of every query is sent to WSRR. You can specify predefined queries that are executed when the broker starts, or when a message flow containing WSRR flows is first deployed, populating the cache for use by subsequent WSRR nodes. By specifying predefined queries, performance might be affected at startup, rather than on the first occurrence of a query at run time. The predefinedCacheQueries parameter is a list of WSRR XPath query expressions separated by semicolons, each with an optional depth specification. The user trace shows the WSRR XPath query expression generated by a WSRR node.

- **Changing the cache expiry timeout value**

  Change the cache expiry timeout value by setting the `timeout` parameter. The cached results of a query are discarded after the specified time has elapsed. The

next occurrence of the query is sent to WSRR and the new result is entered in the cache. If the contents of the registry are likely to change frequently, you can specify a shorter expiry timeout value so that changes are picked up quicker. This activity affects performance as more queries are sent to WSRR.

- **Enabling cache notification**

  Enable cache notification by setting the `enableCacheNotification` parameter to `true` and by setting the `initialContextFactory` and `locationJNDIBinding` properties appropriately for your WSRR server. By default, cache notification is disabled. Cache notification is a more flexible method than expiry timeout for refreshing cached data because it allows individual WSRR entities to be refreshed at the time they are modified in WSRR.

  If cache notification is enabled, the cache subscribes to events occurring in WSRR and is notified when an object is updated or deleted in WSRR. The object is discarded from the cache. If the `refreshQueriesAfterNotification` parameter is set to `true`, the cache is updated with the new version of the object immediately. If the `refreshQueriesAfterNotification` parameter is set to `false`, the cache is updated the next time a relevant query is issued by a WSRR node.

modified.

Setting up cache notification:

Use the **mqsichangeproperties** command to enable cache notification, so that the cache is notified of events occurring in WebSphere Service Registry and Repository (WSRR).

About this task

WSRR publishes notification events by using WebSphere Application Server. Cache notification allows the cache to subscribe to these events.

To enable cache notification complete the following steps to change the relevant properties on the configurable service DefaultWSRR, and to add a user ID and password if you are connecting to a secure WebSphere Application Server:

Procedure

1. Ensure that the broker is running. If it is not, use the **mqsistart** command to start it.
2. Issue the **mqsichangeproperties** command to change the enableCacheNotification property to true. For example:

   ```
   mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
   -n enableCacheNotification -v true
   ```

   where:

   -c specifies the configurable service (in this case, ServiceRegistries)
   -o specifies the name of the object (in this case, DefaultWSRR)
   -n specifies the names of the properties to be changed
   (in this case, enableCacheNotification)
   -v specifies the values of properties defined by the **-n** parameter
   (in this case, true)
3. Issue the **mqsichangeproperties** command to change the locationJNDIBinding property to the value that you require for your WSRR server. For example:

   ```
   mqsichangeproperties MB7BROKER -c ServiceRegistries -o DefaultWSRR
   -n locationJNDIBinding -v iiop://localhost:2809/
   ```

   where:

   -c specifies the configurable service (in this case, ServiceRegistries)
   -o specifies the name of the object (in this case, DefaultWSRR)
   -n specifies the names of the properties to be changed
   (in this case, locationJNDIBinding)
   -v specifies the values of properties defined by the **-n** parameter
   (in this case, iiop://localhost:2809/)
4. If you are connecting to a secure WebSphere Application Server you must use a user ID and password. To set the user ID and password follow these steps:
   a. Stop the broker by using the **mqsistop** command.
   b. Issue the **mqsisetdbparms** command to set up your user ID and password. For example:

      ```
      mqsisetdbparms MB7BROKER -n jms::DefaultWSRR@jms/SRConnectionFactory
      -u userid -p password
      ```

      where:

-n specifies the name of the data source
(in this case, jms::DefaultWSRR@jms/SRConnectionFactory)
-u specifies the user ID to be associated with this data source
(in this case, *userid*)
-p specifies the password to be associated with this data source
(in this case, *password*)

c. Restart the broker by using the **mqsistart** command.

Use the **mqsichangeproperties** command to modify broker properties and properties of broker resources.

Dynamically defining the search criteria

You can use the RegistryLookup and EndpointLookup nodes to issue WebSphere Service Registry and Repository (WSRR) queries specified in the local environment.

The RegistryLookup and EndpointLookup nodes issue WSRR queries at run time and save the resulting data in the local environment. You can specify the queries at design time by using node properties to define the search criteria. Both nodes require at least one query property to be defined before you can deploy the message flow. However, you can specify the search criteria at run time in the local environment, either supplementing or overriding the node properties.

The following table defines the local environment overrides for WSRR queries. These fields must be set in

OutputLocalEnvironment.ServiceRegistryLookupProperties by a preceding transformation node, such as a Compute node.

Setting	Description
Name	This setting overrides the Name property on the node; for example, with an ESQL Compute node: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Name = 'DemoCustomer';` This setting relates to the PortType Name property on the EndpointLookup node. Therefore, to set the PortType Name property, use the Name setting in the local environment.
Namespace	This setting overrides the Namespace property on the node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Namespace = 'http://mb.sr.eis.ibm.com';` This setting relates to the PortType Namespace property on the EndpointLookup node. Therefore, to set the PortType Namespace property, use the Namespace setting in the local environment.
Version	This setting overrides the Version property on the node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Version = '1.0';` This setting relates to the PortType Version property on the EndpointLookup node. Therefore, to set the PortType Version property, use the Version setting in the local environment.
MatchPolicy	This setting overrides the Match Policy property on the node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.MatchPolicy = 'One';` Valid values are One and All.
DepthPolicy	This setting overrides the Depth Policy property on the RegistryLookup node; for example: `SET OutputLocalEnvironment.ServiceRegistryLookupProperties.DepthPolicy = 'MatchOnly';` Valid values are: • MatchOnly for Return matched only (Depth = 0) • MatchShowRel for Return matched showing immediate relationships (For compatibility only) • MatchPlusImmediate for Return matched plus immediate related entities (Depth = 1) • MatchPlusAll for Return matched plus all related entities (Depth = -1) The MatchShowRel property provides compatibility with versions of WebSphere Message Broker before Version 6.1.0.4, by using the output format that was used in those previous versions. This option is deprecated, and should not be used if you are creating a new message flow. Consider migrating existing message flows to use one of the other options.

Setting	Description

UserProperties	This setting overrides the `User Properties` property on the node. You can specify more than one user-defined property in the local environment; for example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.UserProperties.property1 = 'value1';`
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.UserProperties.property2 = 'value2';`
	
	You can remove a user-defined property from the local environment by setting its value to NULL; for example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.UserProperties.property1 = NULL;`
	
	You can use the node properties editor at design time to specify ESQL paths or XPath expressions to read the value for a user property at run time from a field in the message tree. However, the override values that you set in the local environment are the string values that are used in the query.

Classification	This setting overrides the `Classification` property on the node; for example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Classification = 'http://www.ibm.com/xmlns/prod/serviceregistry/6/0/governance/DefaultLifecycle#InitialState0';`
	
	You can specify more than one classification in the local environment. For example:
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Classification[1] = 'http://www.ibm.com/xmlns/prod/serviceregistry/6/0/governance/DefaultLifecycle#InitialState0';`
	`SET OutputLocalEnvironment.ServiceRegistryLookupProperties.Classification[2] = 'http://www.ibm.com.policy/GovernancePolicyDomain';`

These parameters affect the broker configuration when interfacing with WebSphere Service Registry and Repository (WSRR).

EndpointLookup node output

Use an EndpointLookup node to retrieve the endpoint addresses for WSDL service definitions held in WebSphere Service Registry and Repository (WSRR).

The input message is not changed by the EndpointLookup node. Instead, the local environment is updated to contain details of the endpoints retrieved by the query specified by the node and any local environment overrides.

You can configure the EndpointLookup node to dynamically set the service endpoint address for services that will be invoked by a subsequent SOAP or HTTP request node. The EndpointLookup node sets the destination URL in the local environment overrides for those nodes. See the following sample for an example of how to do this:

- WebSphere Service Registry and Repository Connectivity

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

EndpointLookup node output if the `Match Policy` property is set to `One`

If the `Match Policy` property of the node is set to `One`, theEndpointLookup node inserts the endpoint URL retrieved by the query into the local environment in an ITService entry in the local environment under ServiceRegistry, and sets the destination overrides for the SOAP and HTTP request nodes that can be connected directly to its output terminal. The following locations are updated:

- `LocalEnvironment.Destination.SOAP.Request.Transport.HTTP.WebServiceURL`
- `LocalEnvironment.Destination.HTTP.RequestURL`

These settings override the Web service URL property of the SOAPRequest, SOAPAsyncRequest, and HTTPRequest nodes, allowing a dynamic call to a Web service provider.

The following example shows typical output from the EndpointLookup node when the Match Policy is set to One. (Other entries might exist in the local environment depending on previous processing in the flow.)

```
<LocalEnvironment>
  <Destination>
    <SOAP>
      <Request>
        <Transport>
          <HTTP>
            <WebServiceURL>http://localhost:9081/DemoCustomerWeb/
              services/DemoCustomer</WebServiceURL>
          </HTTP>
        </Transport>
      </Request>
    </SOAP>
    <HTTP>
      <RequestURL>http://localhost:9081/DemoCustomerWeb/
        services/DemoCustomer
    </RequestURL>
   </HTTP>
  </Destination>
  <ServiceRegistry>
    <ITService>
      <Endpoint>
        <Address>http://localhost:9081/DemoCustomerWeb/
          services/DemoCustomer</Address>
        <PortType>
          <name>DemoCustomer</name>
          <namespace>http://demo.sr.eis.ibm.com</namespace>
          <version>1.0</version>
        </PortType>
        <Property>
          <name>policy</name>
          <value>RM</value>
        </Property>
        <Property>
          <name>country</name>
          <value>China</value>
        </Property>
        <Classification>http://eis.ibm.com/ServiceRegistry/
          GenericObjecttypes#Routing</Classification>
      </Endpoint>
    </ITService>
  </ServiceRegistry>
</LocalEnvironment>
```

EndpointLookup node output if the Match Policy property is set to All

If the Match Policy is set to All the EndpointLookup node writes an ITService entry in the local environment location ServiceRegistry for each endpoint retrieved by the query.

The following example shows typical output from the EndpointLookup node when the Match Policy is set to All. (Other entries might exist in the local environment depending on previous processing in the flow.)

```
<LocalEnvironment>
  <ServiceRegistry>
    <ITService>
      <Endpoint>
```

```
        <Address>http://localhost:9081/DemoCustomerWeb/
          services/DemoCustomer</Address>
        <PortType>
          <name>DemoCustomer</name>
          <namespace>http://demo.sr.eis.ibm.com</namespace>
          <version>1.0</version>
        </PortType>
        <Property>
          <name>policy</name>
          <value>RM</value>
        </Property>
        <Property>
          <name>country</name>
          <value>China</value>
        </Property>
        <Classification>http://eis.ibm.com/ServiceRegistry/
          GenericObjecttypes#Routing</Classification>
      </Endpoint>
    </ITService>
    <ITService>
      <Endpoint>
        <Address>http://localhost:9081/DemoCustomerWeb/
          services/DemoCustomer2</Address>
        <PortType>
          <name>DemoCustomer2</name>
          <namespace>http://demo.sr.eis.ibm.com</namespace>
          <version>1.0</version>
        </PortType>
      </Endpoint>
    </ITService>
  </ServiceRegistry>
</LocalEnvironment>
```

RegistryLookup node output

Use the RegistryLookup node to retrieve any type of entity held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. The input message is not modified.

This topic contains the following sections:
- "Setting the Depth Policy property"
- "Local environment output tree" on page 1898
- "Migrating a message flow that uses the MatchShowRel option" on page 1900
- "Examples" on page 1900

Setting the `Depth Policy` property

The `Depth Policy` property on the RegistryLookup node specifies how much data is returned for each matched entity. The following table shows the valid values.

`Depth Policy` property value	**Local environment override value**	**Data returned**
`Return matched only (Depth = 0)`	`MatchOnly`	Just the matched entities
`Return matched showing immediate relationships (For compatibility only)`	`MatchShowRel`	The matched entities and additional references
`Return matched plus immediate related entities (Depth = 1)`	`MatchPlusImmediate`	The matched entities and the immediate related child entities
`Return matched plus all related entities (Depth = -1)`	`MatchPlusAll`	The matched entities and all the related child entities

Use `MatchShowRel` for compatibility with versions of WebSphere Message Broker before Version 6.1.0.4. The local environment output for `MatchShowRel` is shown in Example 1 and follows the format that was used in those previous versions. However, the `MatchShowRel` option is deprecated, and provided only for compatibility with previous versions. Do not use `MatchShowRel` if you are creating a new message flow, and consider migrating existing message flows to use one of the other options.

Use the MatchOnly option to retrieve just the individual entities matched by the search criteria. This option is efficient, however the local environment output does not contain any information about entities related to the matched entities.

Use the MatchPlusImmediate option to retrieve the entities matched by the search criteria, and the related child entities. This option offers a useful compromise, allowing you to access the immediate relations of the matched entities, while still restricting the total amount of data retrieved.

Use one of the MatchOnly or MatchPlusImmediate options when migrating a message flow that uses the deprecated MatchShowRel option. If your original message flow used the relationship information in the matched entities, use the MatchPlusImmediate option. See "Migrating a message flow that uses the MatchShowRel option" on page 1900.

Use the MatchPlusAll option to retrieve the entities matched by the search criteria, and all the related child entities. Use this option only if your message flow needs access to more than the immediate relations of the matched entities, because it retrieves considerably more data than the MatchPlusImmediate option, see "Local environment output tree."

Local environment output tree

The local environment output tree has a different format when the deprecated MatchShowRel option of the Depth Policy property is used. The following table describes the differences in the local environment output tree format.

MatchOnly, MatchPlusImmediate, and MatchPlusAll options	**MatchShowRel option**
The ServiceRegistry folder element is owned by the XMLNSC compiler.	No owning parser on the ServiceRegistry folder element, and each Entity element is owned by the XMLNS parser
The ServiceRegistry tree does not use unnecessary namespaces.	Namespaces are attached to all UserDefined folder elements, meaning that the path specified must declare and use the relevant namespace to access fields within these folders.
The ServiceRegistry tree is optimized through use of the XMLNSC parser.	The output tree contains a number of XML declaration, pcdata, and white space elements that have no business significance.
In WSRR, binary data is represented as a GenericDocument with a content attribute. The content attribute is represented in the local environment as XMLNSC type Attribute+base64Binary, (0x03000160). You can access the unencoded binary data directly as Entity.content. However, because of the special XMLNSC element type, the data is automatically base64 encoded if the tree is serialized.	Binary content is represented as a base64 encoded character string in the content attribute. The message flow must invoke a Java method to decode the value if the original binary data is required.

MatchOnly, MatchPlusImmediate, and MatchPlusAll options	**MatchShowRel option**
The retrieved entities are not modified to add any user properties.	The matched Entities appear in the local environment with a user property called `WSRREncoding`. This property has no specific significance to message flow processing. If there is a user property called `WSRREncoding` defined for the entity, the defined value is used, otherwise the `WSRREncoding` property is added with `value="DEFAULT"`.

The `MatchPlusImmediate` and `MatchPlusAll` options result in a graph of entities being returned when WSRR executes the query. Each entity in the graph can refer to other entities. There are two types of relationship that cannot be expressed directly in a hierarchical tree:

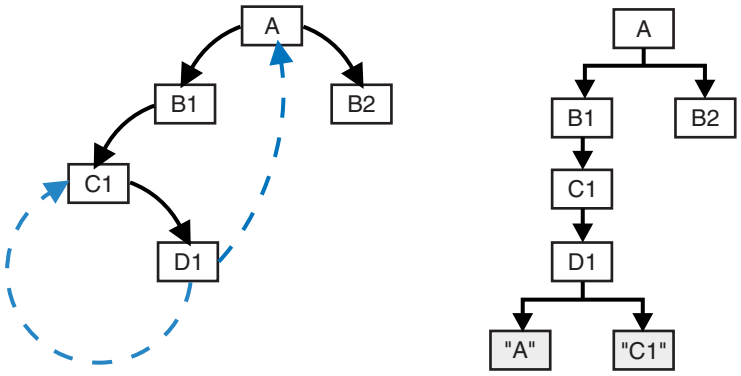
- Cyclic references - a graph can contain an entity from which you can follow relationships that arrive back at the same entity.
- Multiple references - a graph can contain an entity that is referenced by multiple entities.

The representation of these relationships in the local environment output tree is described in the following text.

The WSRR graph is represented in the local environment output tree as follows:

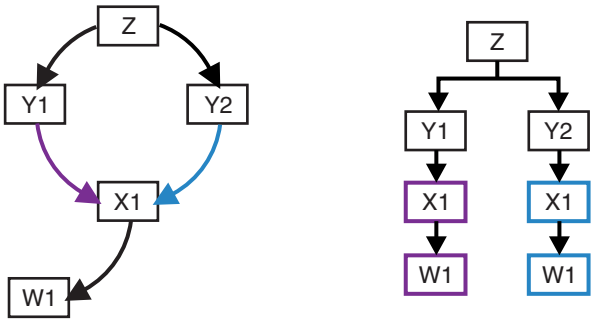
- The matched entities that are returned in the WSRR graph are represented as Entity elements as the first children of the LocalEnvironment.ServiceRegistry. The properties of the matched entities are represented as child elements.
- A matched entity can contain references to other entities. If `MatchPlusImmediate` is set, these references are represented as Entity child elements of the matched entity. If `MatchPlusAll` is set, the same rule is applied recursively to these children.
- Cyclic references - if an entity references another entity that is one of its ancestors in the WSRR graph, the referenced entity is represented as an EntityRef element. An EntityRef element does not represent the target entity directly, but provides information to identify it. This prevents the possibility of entering cyclic loops when navigating the tree.

  The following diagram shows references from entity D1 in the graph to entities C1 and A that are ancestral; therefore, Entity D1 in the message tree contains EntityRef elements for A and C1.



- Multiple references - if an entity in the WSRR SDO graph is referenced by more than one other entity, it is represented as a separate Entity element in the message tree each time it is referenced. The Entity element is cloned, along with any entities that it refers to.

  The following diagram shows that entity X1 in the graph is referenced by entities Y1 and Y2, so Entity X1 and Entity W1 that it references are modeled twice in the message tree.



Migrating a message flow that uses the `MatchShowRel` option

When you migrate an existing message flow that uses the deprecated `MatchShowRel` option of the `Depth Policy` property, the local environment output tree will have a different format. The table shown earlier describes the differences in the local environment output tree formats, and indicates what you must modify in the message flow to access the data in the updated format; see "Local environment output tree" on page 1898.

Examples

The following examples show typical output from the RegistryLookup node:

- Example 1 shows the full RegistryLookup node output in two cases for a query that returns two versions of a concept entity. In both cases the `Match Policy` property is set to `All`. In the first case the `Depth Policy` property is set to `Return matched plus immediate related entities (Depth = 1)` , and in the second case the `Depth Policy` property is set to `Return matched only, showing immediate relationships (For compatibility only)`. This example also shows example ESQL to read elements of the output. See "RegistryLookup node output: example 1" on page 1901
- Example 2 shows the structure of RegistryLookup node output for all possible values of the `Depth Policy` property for a query on a concept entity that has a number of user relationships to other concept entities. See "RegistryLookup node output: example 2" on page 1906
- Example 3 shows the structure of RegistryLookup node output for a query on an entity having metadata relationships and user-defined relationships, using a `Depth Policy` property value of `Return matched plus all related entities (Depth = -1)` . See "RegistryLookup node output: example 3" on page 1909.

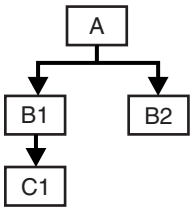
Use the EndpointLookup node to retrieve service endpoint information held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. Depending on the node configuration, the Web service URL destination used by the SOAP and HTTP request nodes can also be set. The input message is not modified.

"RegistryLookup node" on page 4646
Use the RegistryLookup node to retrieve any type of entity held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. The input message is not modified.

RegistryLookup node output: example 1:

Example showing the full RegistryLookup node output in two cases for a query that returns two versions of a concept entity. In both cases the `Match Policy` property is set to `All`. In the first case the `Depth Policy` property is set to `Return matched plus immediate related entities (Depth = 1)` , and in the second case the `Depth Policy` property is set to `Return matched only, showing immediate relationships (For compatibility only)`. This example also shows example ESQL to read elements of the output.

This example shows the ServiceRegistry message tree that is stored in the LocalEnvironment when an entity called ConceptA1 is retrieved from WebSphere Service Registry and Repository (WSRR). ConceptA1 is defined in WSRR with 2 versions: 1.0 which is deprecated, and 2.0 which is classified as initial state. Additional properties and relationships have been added to the 2.0 version. The following diagram shows the relationships between the elements in the message tree.



The following message trees show the different values of the `Depth Policy` property.

- `Depth Policy` property set to `Return matched plus immediate related entities (Depth = 1)`

  The following ESQL was used to create a serialization of the output of the ServiceRegistry node:

  ```
  SET OutputRoot.XMLNSC.Result.ServiceRegistry =
    InputLocalEnvironment.ServiceRegistry;
  ```

The ServiceRegistry folder element is owned by the XMLNSC parser so you can invoke a like parser tree copy to OutputRoot.XMLNSC. The following XML, which has been formatted, is produced when writing this output root tree.

```

</ServiceRegistry>
```

The following ESQL shows how to retrieve the values from the ServiceRegistry message tree in the LocalEnvironment when the Depth Policy property is set to Return matched plus immediate related entities (Depth = 1).

```
DECLARE c1 CHARACTER;

-- Following sets c1 to "ConceptA1" by indexing the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].name;
-- Following sets c1 to "2.0" by indexing the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].version;
-- Following sets c1 to "property1" by indexing the first
--   userDefinedProperties within the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].
  userDefinedProperties[1].name;
-- Following sets c1 to "value1 for v2" by indexing the first
--   userDefinedProperties within the first entity
SET c1 = InputLocalEnvironment.ServiceRegistry.Entity[1].
  userDefinedProperties[1].value;
```

- Depth Policy property set to Return matched showing immediate relationships (For compatibility only)

  The following ESQL was used to create a serialization of the output of the ServiceRegistry node:

  ```
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputLocalEnvironment.ServiceRegistry.Entity[]);
  ```

```
WHILE I < J DO
  SET OutputRoot.XMLNS.ServiceRegistry.Entity[I] =
    InputLocalEnvironment.ServiceRegistry.Entity[I];
  SET I = I + 1;
END WHILE;
```

The ServiceRegistry folder does not have an owning parser so you must navigate to the ""elements and initiate a like-parser-copy to the XMLNS owned output root tree. The following XML is produced when writing this output root tree.

```
<ServiceRegistry>
  <Entity
    xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"

"EndpointLookup node" on page 4407
Use the EndpointLookup node to retrieve service endpoint information held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. Depending on the node configuration, the Web service URL destination used by the SOAP and HTTP

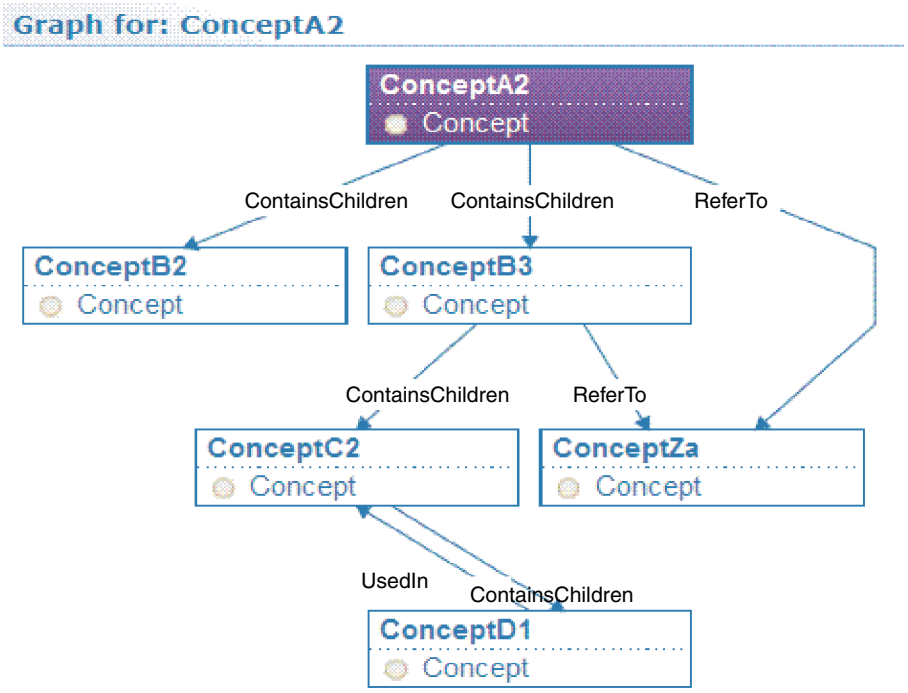
request nodes can also be set. The input message is not modified.

"RegistryLookup node" on page 4646
Use the RegistryLookup node to retrieve any type of entity held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. The input message is not modified.

RegistryLookup node output: example 2:

Example showing the structure of RegistryLookup node output for all possible values of the `Depth Policy` property for a query on a concept entity that has a number of user relationships to other concept entities.

This example shows the ServiceRegistry message trees that are stored in the LocalEnvironment when the Concepts shown in the following WebSphere Service Registry and Repository graph are retrieved. The graph has been annotated with the relationship names to clarify the elements in the message tree.



The following ServiceRegistry message trees have some elements replaced by `...` to emphasis the structure of the tree. Likewise, the bsrURIs have been truncated.

The following shows the message trees for each possible value of the `Depth Policy` property:

- `Return matched only (Depth = 0)`

```
ServiceRegistry
  Entity
    type   = sdo:GenericObject
    bsrURI = a2e62137a605
    name   = ConceptA2
    ...
```

- `Return matched showing immediate relationships (For compatibility only)`. The entities contain elements showing the details of relationships, but only provide a list of the bsrURIs for the related child entities.

  This value of the `Depth Policy` property is deprecated, so you should use of the other options. The output tree structure produced when using this value is not compatible with those from the other values for the `Depth Policy` property. In particular, note the namespace qualifications.

```
ServiceRegistry
  Entity
    type   = sdo:GenericObject
    bsrURI = a2e62137a605
    name   = ConceptA2
    ...
    ns1:userDefinedRelationships
      name    = ContainsChildren
      targets = b2f73637f6e8 b3de6036e1af
    ns1:userDefinedRelationships
      name    = ReferTo
      targets = zac084d6b804
```

- `Return matched plus immediate related entities (Depth = 1)`. The entities contain elements showing the details of relationships, and the details of the related child entities.

```
ServiceRegistry
  Entity
    type   = GenericObject
    bsrURI = a2e62137a605
    name   = ConceptA2
    ...
    userDefinedRelationships
      name = ContainsChildren
      targetEntities
        Entity
          bsrURI = b2f73637f6e8
          name   = ConceptB2
          ...
        Entity
          bsrURI = b3de6036e1af
          name   = ConceptB3
          ...
          userDefinedRelationships
            name    = ContainsChildren
            targets = c26e43ac45a
          userDefinedRelationships
            name    = ReferTo
            targets = zac084d6b804
    userDefinedRelationships
      name = ReferTo
      targetEntities
        Entity
          bsrURI = zac084d6b804
          name   = ConceptZa
          ...
```

- `Return matched plus all related entities (Depth = -1)`. The entities contain elements showing the details of relationships, and the details of the all related child entities. ConceptD1 uses an EntityRef element to refer to its ancestor ConceptC2. ConceptZa appears twice in the tree as it is referenced by both ConceptA2 and ConceptB3.

```
ServiceRegistry

WebSphere Broker Adapters Transport

WebSphere Broker Adapters Transport is a service that connects applications to Enterprise Information Systems (such as SAP Software, PeopleSoft Enterprise, and Siebel Business Application systems).

You can use the WebSphere Broker Adapters Transport to support the following operations:

- Accept input from an SAP, Siebel, or PeopleSoft application.
- Send requests to an SAP, Siebel, JD Edwards, or PeopleSoft application.
- Send a reply to an SAP synchronous callout.
- Route IDocs to separate message flows.

These operations are implement by the following built-in nodes:
- SAPInput node
- SAPRequest node
- SAPReply node
- SiebelInput node
- SiebelRequest node
- PeopleSoftInput node
- PeopleSoftRequest node
- JDEdwardsRequest node

Use the input nodes to accept input from an EIS, along with a matching reply node if the EIS needs a response. Use the request nodes to send requests to an EIS.

To use the WebSphere Broker Adapters Transport, you must deploy a message flow that contains one or more WebSphere Adapters nodes.

The following topics contain more information about working with WebSphere Adapters:

- "Connecting to Enterprise Information Systems" on page 1912
- "WebSphere Adapters nodes" on page 1914
- "Developing message flows that use WebSphere Adapters" on page 2033

Related concepts:

WebSphere Adapters nodes

A WebSphere Adapters node is a message flow node that is used to communicate with Enterprise Information Systems (EIS), such as SAP, Siebel, JD Edwards, and PeopleSoft.

The following terms are associated with WebSphere Adapters:

EIS Enterprise information system. This term is used to describe the applications that form an enterprise's existing system for handling company-wide information. An enterprise information system offers a well-defined set of services that are exposed as local or remote interfaces or both. Enterprise Resource Planning (ERP) and Customer Relationship Management (CRM) are typical enterprise information systems.

EMD Enterprise Metadata Discovery. A specification that you can use to examine an EIS and get details of business object data structures and APIs. An EMD stores definitions as XML schemas by default, and builds components that can access the EIS. In WebSphere Message Broker you use the Adapter Connection wizard to examine an EIS.

Business object
In a development or production environment, a set of XML schema attributes that represents a business entity (such as an invoice) and the definition of actions that can be performed on those attributes (such as the create and update operations).

The WebSphere Adapters support two modes of communication:

- **Inbound**: An event is generated on the EIS and the adapter responds to the event by sending a message to the message broker. The WebSphere Adapters input nodes support inbound communication. When the EIS sends an event to the adapter, a message is propagated from the WebSphere Adapters input node. For example, use an SAPInput node to accept input from an SAP application.
- **Outbound**: The message broker uses the adapter to send a request to the EIS. The WebSphere Adapters request nodes support outbound communication.

When a message is propagated to the WebSphere Adapters request node, the adapter sends a request to the EIS. For example, use an SAPRequest node to send requests to an SAP application.

The WebSphere Adapters nodes need an adapter component to access the EIS. The input nodes need an inbound adapter component, which allows the EIS to invoke the message flow when an event occurs. The request nodes need an outbound adapter component, which is used by the message flow to invoke a service in the EIS.

The WebSphere Adapters nodes also need a message set to ensure that the WebSphere Message Broker messages that are propagated to and from the nodes reflect the logical structure of the data in the EIS.

SAP, Siebel, JD Edwards, and PeopleSoft adapters are supported by the following message flow nodes in WebSphere Message Broker:

- SAPInput node
- SAPRequest node
- SAPReply node
- SiebelInput node
- SiebelRequest node
- PeopleSoftInput node
- PeopleSoftRequest node
- JDEdwardsRequest node
- JDEdwardsInput node

The TwineballInput and TwineballRequest nodes are sample nodes with their own sample EIS. You can use the Twineball nodes to see how adapters nodes work. You cannot use the Twineball nodes to connect to the external SAP, Siebel, and PeopleSoft EIS systems.

You can configure the Websphere Adapters nodes by using properties on the nodes, or by using a configurable service. For example, you can use a configurable service to specify the connection details for the EIS. For more information, see “Configurable services properties” on page 3766.

To effectively maintain the pool of connections to the EIS, you can set a connection timeout value on a configurable service. For more information, see “Configuring EIS connections to expire after a specified time” on page 726.

The SAPRequest node can also use an identity that is present on an input message, and propagate it to SAP, by using the `Propagate` property on the security profile that is defined on the node. For more information, see “Identity and security token propagation” on page 426.

The mode in which your broker is working can affect the number of execution groups and message flows that you can deploy, and the type of node that you can use. For example, in Remote Adapter Deployment mode, only adapter-related features are enabled, and the types of node that you can use, and the number of execution groups that you can create, are limited. For more information about the available modes of operation, see “Operation modes” on page 48.

For more information about support for adapters on different operating systems, see WebSphere Message Broker Requirements.

Overview of WebSphere Adapter for SAP Software:

With WebSphere Adapter for SAP Software you can create integrated processes that include the exchange of information with an SAP server, without special coding.

By using the adapter, an application component (the program or piece of code that performs a specific business function) can send requests to the SAP server (for example, to query a customer record in an SAP table or to update an order document) or receive events from the server (for example, to be notified that a customer record has been updated). The adapter creates a standard interface to the applications and data on the SAP server so that the developer of the application component does not have to understand the lower-level details (the implementation of the application or the data structures) on the SAP server.

WebSphere Adapter for SAP Software complies with the Java Connector Architecture (JCA) 1.5, which standardizes the way in which application components, application servers, and Enterprise Information Systems (EIS), such as an SAP server, interact with each other.

The adapter, which you generate with the Adapter Connection wizard, uses a standard interface and standard data objects. The adapter takes the standard data object sent by the application component and calls the SAP function. The adapter then returns a standard data object to the application component. The application component does not have to deal directly with the SAP function; it is the SAP adapter that calls the function and returns the results.

For example, the application component that requested the list of customers sends a standard business object with the range of customer IDs to the SAP adapter. The application component receives, in return, the results (the list of customers) in the form of a standard business object. The adapter completes all the interactions directly with the SAP function.

Similarly, the message flow might want to know about a change to the data on the SAP server (for example, a change to a particular customer). You can generate an adapter component that listens for such events on the SAP server and notifies message flows with the update. In this case, the interaction begins at the SAP server.

For more information, see "Technical overview of Adapter for SAP Software" on page 1918.

Technical overview of Adapter for SAP Software:

WebSphere Adapter for SAP Software provides multiple ways to interact with applications and data on SAP servers. Outbound processing (from an application to the adapter to the SAP server) and inbound processing (from the SAP server to the adapter to an application) are supported.

WebSphere Adapter for SAP Software connects to SAP systems running on SAP Web application servers. The adapter supports Advanced Event Processing (AEP) and Application Link Enabling (ALE) for inbound processing, and the Business Application Programming Interface (BAPI), AEP, ALE, and Query Interface for SAP Systems (QISS) for outbound processing. You set up the adapter to perform outbound and inbound processing by using the Adapter Connection wizard to generate business objects based on the services it discovers on the SAP server.

For outbound processing, the adapter client invokes the adapter operation to create, update, or delete data on the SAP server or to retrieve data from the SAP server.

For inbound processing, an event that occurs on the SAP server is sent from the SAP server to the adapter. The ALE inbound and BAPI inbound interfaces start event listeners that detect the events. Conversely, the Advanced event processing interface polls the SAP server for events. The adapter then delivers the event to an endpoint, which is an application or other consumer of the event from the SAP server.

You configure the adapter to perform outbound and inbound processing by using the Adapter Connection wizard to create a message set project that includes the interface to the SAP application as well as business objects based on the functions or tables that it discovers on the SAP server.

Overview of the outbound processing interfaces

WebSphere Adapter for SAP Software provides multiple interfaces to the SAP server for outbound processing.

- Through its BAPI interfaces, the adapter issues remote function calls (RFCs) to RFC-enabled functions, such as a Business Application Programming Interface (BAPI) function. These remote function calls create, update, or retrieve data on an SAP server.
  - The BAPI interface works with individual BAPIs (simple BAPIs). For example, you might want to check to see whether specific customer information exists in an SAP database.
  - The BAPI work unit interface works with ordered sets of BAPIs. For example, you might want to update an employee record. To do so, you use three BAPIs:
    1. To lock the record (to prevent any other changes to the record)
    2. To update the record
    3. To have the record approved
  - The BAPI result set interface uses two BAPIs to select multiple rows of data from an SAP database.

  BAPI calls are useful when you need to perform data retrieval or manipulation and a BAPI or RFC function that performs the task already exists.

  Simple BAPIs can be sent through the synchronous RFC, asynchronous transactional RFC, or asynchronous queued RFC protocol.
  - With synchronous RFC, both the adapter and the SAP server must be available when the call is made from the adapter to the SAP server. The adapter sends a request to the SAP server and waits for a response.
  - With asynchronous transactional RFC, a transaction ID is associated with the call from the adapter to the SAP server. The adapter does not wait for a response from the SAP server. Only the transaction ID is returned to the message flow.
  - With asynchronous queued RFC, the call from the adapter is delivered to a predefined queue on the SAP server. As with asynchronous RFC, a transaction ID is associated with the call, and the adapter does not wait for a response from the SAP server.

    This interface is useful when the event sequence must be preserved.
- The Query interface for SAP Software retrieves data from specific SAP application tables. It can return the data or check for the existence of the data. You can use this type of interaction with SAP if you need to retrieve data from an SAP table without using an RFC function or a BAPI.

- With the Application Link Enabling (ALE) interface, you exchange data using SAP Intermediate Data structures (IDocs). For outbound processing, you send an IDoc or a packet of IDocs to the SAP server.

  The ALE interface, which is particularly useful for batch processing of IDocs, provides asynchronous exchange. You can use the queued transactional (qRFC) protocol to send the IDocs to a queue on the SAP server. The qRFC protocol ensures the order in which the IDocs are received. It is often used for system replications or system-to-system transfers.
- With the ALE pass-through IDoc interface, the adapter sends the IDoc to the SAP server with no conversion of the IDoc. The message tree contains a BLOB field that represents the IDoc.
- With the Advanced event processing interface, you send data to the SAP server. The data is then processed by an ABAP handler on the SAP server.

Overview of the inbound processing interfaces

WebSphere Adapter for SAP Software provides the following interfaces to the SAP server for inbound processing.

- Through its BAPI inbound interface, the adapter listens for events and receives notifications of RFC-enabled function calls from the SAP server.
  - With synchronous RFC, both the adapter and the SAP server must be available when the call is made from the SAP server to the adapter. The adapter sends the request to a predefined application and returns the response to the SAP server.
  - With asynchronous transactional RFC, the event is delivered to the adapter even if the adapter is not available when the call is made. The SAP server stores the event on a list of functions to be invoked and continues to attempt to deliver it until the adapter is available.

    You also use asynchronous transaction RFC if you want to deliver the functions from a predefined queue on the SAP server. Delivering the files from a queue ensures the order in which the functions are sent.

    If you select assured once-only delivery, the adapter uses a data source to persist the event data received from the SAP server. Event recovery is provided to track and recover events in case a problem occurs when the adapter attempts to deliver the event to the endpoint.
- With the ALE inbound processing interface, the adapter listens for events and receives one or more IDocs from the SAP server. As with ALE outbound processing, ALE inbound processing provides asynchronous exchange.

  You can use the qRFC interface to receive the IDocs from a queue on the SAP server, which ensures the order in which the IDocs are received.

  If you select assured once-only delivery, the adapter uses a data source to persist the event data, and event recovery is provided to track and recover events in case a problem occurs when the adapter attempts to deliver the event to the endpoint.
- With the ALE pass-through IDoc interface, the SAP server sends the IDoc through the adapter to the endpoint with no conversion of the IDoc. The message tree contains a BLOB field that represents the IDoc.
- The Advanced event processing interface polls the SAP server for events. It discovers events waiting to be processed. It then processes the events and sends them to the endpoint. For more information, see "The Advanced event processing interface" on page 1987.

How the adapter interacts with the SAP server

The adapter uses the SAP Java Connector (SAP JCo) API to communicate with SAP applications. An application sends a request to the adapter, which uses the SAP JCo API to convert the request into a BAPI function call. The SAP system processes the request and sends the results to the adapter. The adapter sends the results in a response message to the calling application.

The Adapter Connection wizard (SAP):

The Adapter Connection wizard is a tool that you use to create services. The Adapter Connection wizard establishes a connection to the SAP server, discovers services (based on search criteria that you provide), and generates business objects, interfaces, and import or export files, based on the services that are discovered.

By using WebSphere Message Broker, you establish a connection to the SAP server to browse the metadata repository on the SAP server. The SAP metadata repository, which is a database of the SAP data, provides a consistent and reliable means of access to that data.

You specify connection information (such as the user name and password needed to access the server), and you specify the interface that you want to use (for example, BAPI). The service metadata that is associated with that interface is displayed. You can then provide search criteria and select the information (for example, you can list all BAPIs that relate to "CUSTOMER" by using the search filter with "BAPI_CUSTOMER*", then select one or more BAPIs).

The result of running the Adapter Connection wizard is an adapter connection project and a message set project that contain the interfaces and business objects as well as the adapter.

The Adapter Connection wizard also produces an import file (for outbound processing) or an export file (for inbound processing).

- The import file contains the managed connection factory property settings that you provide in the wizard.
- The export file contains the activation specification property settings you provide in the wizard.

The BAPI interfaces:

The WebSphere Adapter for SAP Software supports outbound processing for simple BAPIs, BAPI units of work, and BAPI result sets. In outbound processing, message flows call BAPIs and other RFC-enabled functions on the SAP server. The adapter supports inbound processing for simple BAPIs only. In inbound processing, the SAP server sends an RFC-enabled function (such as a BAPI function) through the adapter to an endpoint.

For example, you want to build a service that creates a new customer on the SAP server. You run the Adapter Connection wizard to discover the BAPI_CUSTOMER_CREATEFROMDATA function, and the wizard generates the business-object definition for BAPI_CUSTOMER_CREATEFROMDATA, as well as other Service Component Architecture (SCA) service resources. During BAPI outbound processing, the adapter receives the service request and converts the data into a BAPI invocation.

BAPI interface (simple BAPIs)

A simple BAPI performs a single operation, such as retrieving a list of customers. The adapter supports simple BAPI calls by representing each with a single business object schema.

Simple BAPIs can be used for outbound or inbound processing. You can specify synchronous RFC processing or asynchronous transactional RFC (tRFC) processing when you configure a module for a simple BAPI. In addition, for outbound processing, you can specify asynchronous queued RFC (qRFC) processing, in which BAPIs are delivered to a predefined queue on the SAP server.

- In synchronous RFC processing, the SAP server and the adapter must be available during processing.
  - In outbound processing, the message flow sends a request, then waits for a response from the SAP server.
  - In inbound processing, the SAP server sends a request through the adapter to an endpoint and waits for a response from the adapter.
- In asynchronous tRFC outbound processing, the adapter associates a transaction ID with the function call to the SAP server. The adapter does not wait for a response from the SAP server. If the delivery is unsuccessful, the message flow can use the SAP transaction ID (TID) to make the request again. The TID is a field in your message.
- In asynchronous tRFC inbound processing, the adapter does not have to be available when the SAP server runs the function call. The function call is placed on a list of functions to be invoked, and the call is attempted until it is successful.

  To send function calls from a user-defined outbound queue on the SAP server, you also specify asynchronous tRFC inbound processing.
- In asynchronous qRFC outbound processing, the process is similar to asynchronous tRFC outbound processing. A TID is associated with the function call, and the adapter does not wait for a response from the SAP server. In addition, the BAPIs are delivered to a predefined queue on the SAP server. By sending BAPIs to the predefined queue, you can ensure the order in which they are delivered.

BAPI work unit interface

A BAPI work unit consists of a set of BAPIs that are processed in sequence to complete a task. For example, to update an employee record in the SAP system, the record needs to be locked before being updated. This task is accomplished by calling three BAPIs, in sequence, in the same work unit. The following three BAPIs illustrate the kind of sequence that forms such a unit of work:
- BAPI_ADDRESSEMP_REQUEST
- BAPI_ADDRESSEMP_CHANGE
- BAPI_ADDRESSEMP_APPROVE

The first BAPI locks the employee record, the second updates the record, and the third approves the update. The advantage of using a BAPI unit of work is that the message flow can request the employee record change with a single call, even though the work unit consists of three separate functions. In addition, if SAP requires that the BAPIs be processed in a specific sequence for the business flow to complete correctly, the work unit supports this sequence.

BAPI result set interface

BAPI result sets use the GetList and GetDetail functions to retrieve an array of data from the SAP server. The information that is returned from the GetList function is used as input to the GetDetail function.

For example, if you want to retrieve information on a set of customers, you use BAPI_CUSTOMER_GETLIST, which acts as the query BAPI, and BAPI_CUSTOMER_GETDETAIL, which acts as the result BAPI. The BAPIs perform the following steps:

1. The BAPI_CUSTOMER_GETLIST call returns a list of keys (for example, CustomerNumber).

2. Each key is mapped dynamically to the business object for BAPI_CUSTOMER_GETDETAIL.
3. BAPI_CUSTOMER_GETDETAIL is processed multiple times, so that an array of customer information is returned.

You use the Adapter Connection wizard to discover the BAPI_CUSTOMER_GETLIST and BAPI_CUSTOMER_GETDETAIL functions and build the key relationship between the two BAPIs. The wizard then generates business object definitions for these BAPIs as well as other SCA service resources. At run time, the client sets the values in the BAPI_CUSTOMER_GETLIST business object, and the adapter returns the corresponding set of customer detail records from the SAP server.

For more information, see the following topics.

Outbound processing for the BAPI interface:

In BAPI outbound processing, a message flow sends a request to the SAP server. For BAPI units of work and BAPI result sets, processing is handled synchronously (the message flow waits for a response from the SAP server). For simple BAPIs, you can request that processing be handled synchronously or asynchronously (the message flow does not wait for a response from the SAP server).

For BAPI units of work and BAPI result sets, the processing is handled as described in "Synchronous RFC." For simple BAPIs, you make a selection, during configuration, about the type of remote RFC call you want to make.

Synchronous RFC

If you select **Synchronous RFC** (the default) during configuration for a simple BAPI, or if you are using BAPI units of work or BAPI result sets, the following processing steps occur:

1. The adapter receives a request from a message flow in the form of a BAPI business object.
2. The adapter converts the BAPI business object to an SAP JCo function call.
3. The adapter uses the Remote Function Call (RFC) interface to process the BAPI or RFC function call in the SAP application.
4. After passing the data to the SAP server, the adapter handles the response from SAP and converts it back into the business object format required by the message flow.
5. The adapter then sends the response back to the message flow.

Asynchronous transactional RFC

If you select **Asynchronous transactional RFC** during configuration, the following processing steps occur:

1. The adapter receives a request from a message flow in the form of a BAPI business object.
2. The adapter checks the business object to see whether the SAP transaction ID attribute has a value assigned. (The SAP transaction ID (TID) is a field in your message.)
   - If the SAP transaction ID attribute has a value, the adapter uses that value during processing.
   - If the attribute does not have a value, the adapter makes a call to the SAP server and gets a transaction ID from the SAP server.
3. The adapter converts the BAPI business object to an SAP JCo function call.
4. The adapter uses the transactional Remote Function Call (tRFC) protocol to make the call to the SAP server.

The adapter does not wait for a response from the SAP server.

5. After the function data is passed to the SAP application, control returns to the adapter.
   - If the call to the SAP server fails, the SAP server throws an ABAPException.
   - If the call to the SAP server succeeds but contains invalid data, no exception is returned to the adapter. For example, if the adapter sends a request that contains an invalid customer number, the adapter does not respond with an exception indicating that no such customer exists.
6. The request node builds a message tree that contains the transaction ID as one of the fields.

Asynchronous queued RFC

If you select **Asynchronous queued RFC** during configuration, the following processing steps occur:

1. The adapter receives a request from a message flow in the form of a BAPI business object.
2. The adapter checks the business object to see whether the SAP transaction ID attribute has a value assigned. (The SAP transaction ID (TID) is a field in your message.)
   - If the SAP transaction ID attribute has a value, the adapter uses that value during processing.
   - If the attribute does not have a value, the adapter makes a call to the SAP server and gets a transaction ID from the SAP server.
3. The adapter converts the BAPI business object to an SAP JCo function call.
4. The adapter uses the tRFC protocol to make the call to the specified queue on the SAP server.

   The adapter does not wait for a response from the SAP server.
5. After the function data is passed to the SAP application, control returns to the adapter.
   - If the call to the SAP server fails, the SAP server throws an ABAPException.
   - If the call to the SAP server succeeds but contains invalid data, no exception is returned to the adapter. For example, if the adapter sends a request that contains an invalid customer number, the adapter does not respond with an exception indicating that no such customer exists.
6. The request node builds a message tree that contains the transaction ID as one of the fields.

SAP BAPI transaction commit:

When the SAP adapter is used with the BAPI interface, you must consider certain factors when you design transactional flows.

You can configure message flows to be transactional so that updates to resources such as databases can be coordinated; changes are committed or rolled back together within the same transaction. This transactional coordination can be extended to external system updates, such as SAP databases, when you use the BAPI interface with SAPRequest nodes.

The SAP adapter can control whether it waits for SAP to commit the updates synchronously, or issues a commit and returns while the SAP commit happens asynchronously. You can determine this behavior by using the **Use wait parameter before calling BAPI commit** parameter on the Configure Objects pane of the Adapter Connection wizard. The adapter relies on the transactionality setting of the message flow to determine whether to issue the commit call.

BAPIs with implicit commit

In earlier releases of SAP, some BAPIs were coded with a commit. From SAP Release 4.0A onwards, it is more effective for BAPIs to issue a separate

BAPI_TRANSACTION_COMMIT to force the update, instead of doing commit work. By using this method, BAPI calls can be made before the work is committed as a batched unit of work. To find out if a BAPI is coded with a commit, see the documentation for the BAPI.

Message flow transactionality

When the `Transaction mode` property on the SAPRequest node is set to `Yes`, the adapter is instructed to issue the SAP commit on completion of the message flow in line with other database commits. You can set the **`Use wait parameter before calling BAPI commit`** parameter in the Adapter Connection wizard that determines whether the commit is synchronous or asynchronous.

If the `Transaction mode` property on the SAPRequest node is set to `No`, the adapter does not issue an SAP commit and the parameter that you set on the Adapter Connection wizard has no relevance. However, the commit can still be issued as part of a BAPI work unit COMMIT verb (to which the property on the wizard does apply) or a call to the BAPI_TRANSACTION_COMMIT (to which the property on the wizard does not apply).

The following rules apply when you set the `Transaction mode` property on the SAPRequest node.

- Set `Transaction mode` to `No` if the following conditions apply:
  - The BAPIs already have commits
  - A BAPI_TRANSACTION_COMMIT is called by an SAPRequest node
  - A BAPI work unit includes a BAPI_TRANSACTION_COMMIT or the COMMIT verb is added on the Configure Objects pane of the Adapter Connection wizard

  If the BAPIs are coded with commits and you set `Transaction mode` to `Yes`, the BAPI is called as part of the same transaction as those from other SAPRequest nodes in the same flow and using the same adapter. Therefore, any BAPIs that were called previously in this message flow are committed.
- Set `Transaction mode` to `Yes` if the following conditions apply:
  - The BAPI needs to be committed (that is, the BAPI is not coded with a commit)
  - The BAPI work unit needs to be committed and does not include a BAPI_TRANSACTION_COMMIT or the COMMIT verb

  If you set `Transaction mode` to `No`, the BAPI is not committed now or at the end of the message flow; it is not guaranteed ever to be committed.

The following scenarios illustrate the visibility of the updates made to an SAP system, and show how to use the adapter to avoid uncertainty when data is being committed by an external system.

- Scenario 1: Business partner and relationship processing in a single flow
- Scenario 2: Order create and query application processing with two flows

Scenario 1: Business partner and relationship processing in a single flow:

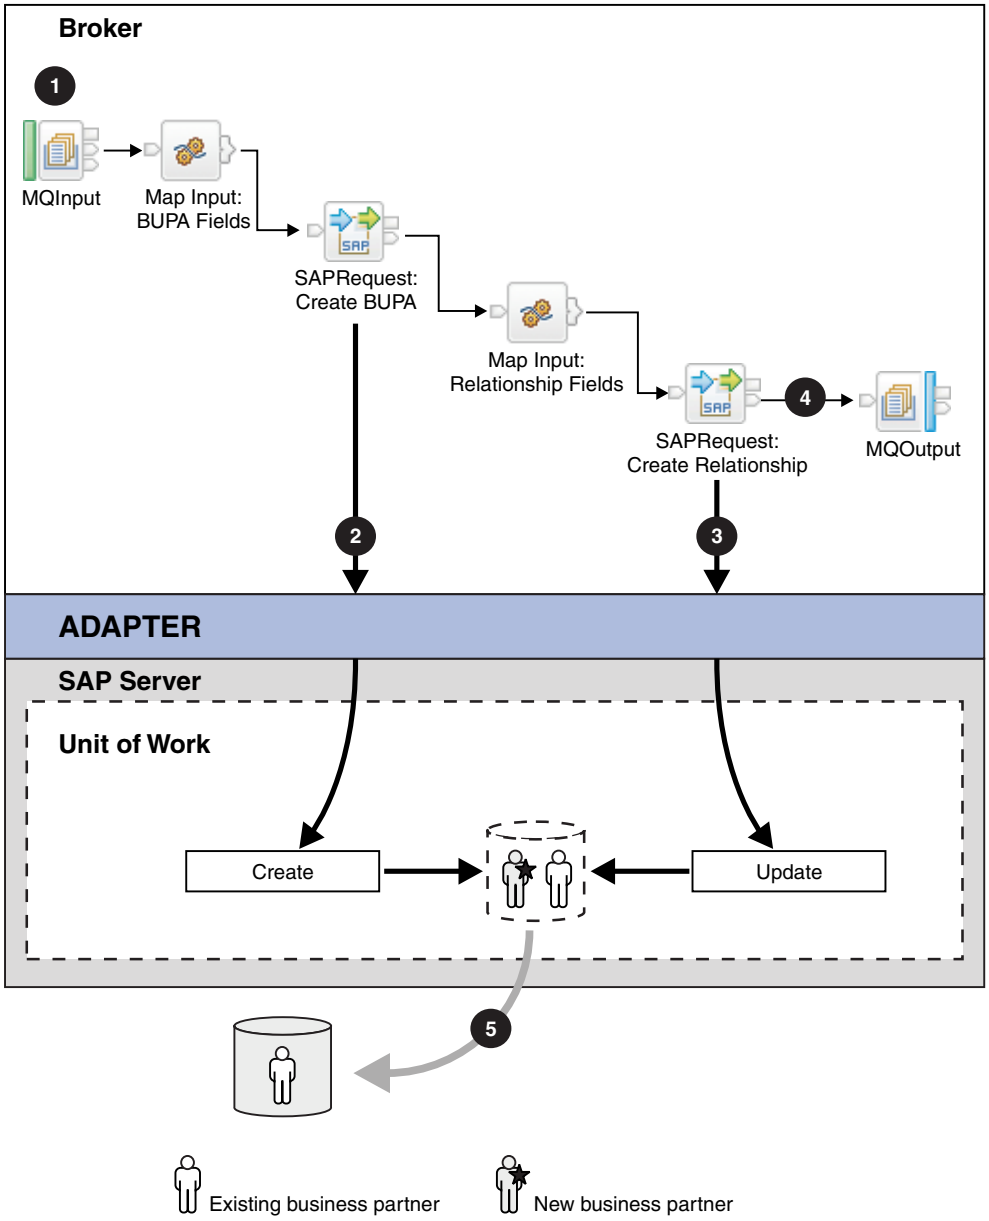
You must set the `Transaction mode` property appropriately on an SAPRequest node when you are processing in a single message flow.

This scenario is one of two examples that illustrate the concepts that are described in "SAP BAPI transaction commit" on page 1928; see also "Scenario 2: Order create and query application processing with two flows" on page 1933.

In this scenario, a message flow is used to create a business partner, and a new relationship with an existing partner by using two BAPI calls:

```
BAPI_BUPA_CREATE_FROM_DATA
BAPI_BUPR_RELATIONSHIP_CREATE
```

The message flow consists of two SAPRequest nodes with the `Transaction mode` property set to `Yes` on both nodes to allow commit or rollback in case of exceptions. When the `Transaction mode` property is set to `Yes`, the message flow's final commit takes place at the end of the flow when the adapter requests SAP to commit the order.



1. An application triggers the transactional flow that creates the business partner.
2. The SAPRequest node submits a BUPA creation and returns the business partner number. The commit happens when the message flow completes because the node participates in a message flow level transaction.
3. The second SAPRequest node attempts to create a relationship between an existing business partner and the new business partner; however, SAP has not yet committed the creation of the new business partner to the database.

   If the same adapter is used for both BAPIs, the adapter ensures a single connection to SAP because both nodes have to participate in the same logical work unit. The single connection means that the BUPA creation is visible to the relationship update call (3 in the diagram), even though the flow transactionality has yet to initiate the commit.

   If the `Transaction mode` property were set to `Yes` on the create BUPA call, but `No` on the create relationship call, the adapter would need to use two different connections to SAP; that is, the transactional properties of the connections

would be different. The create relationship call would therefore fail because the new business partner would not be visible until the message flow and the transactional commit have completed.

4. The MQOutput node puts an MQ message on the output queue pending transactional commit.
5. The message flow completes and the broker begins to commit all the resources involved in that flow, including SAP (5 in the diagram). The updates are committed in SAP.

This scenario illustrates the ability of the broker to use its transactional control of the message flow to provide the necessary information to the SAPRequest nodes to carry out related processing, even though the external SAP system is committing the work asynchronously.

Scenario 2: Order create and query application processing with two flows:

You must set the `Transaction mode` property appropriately on an SAPRequest node when you are processing by using separate message flows.

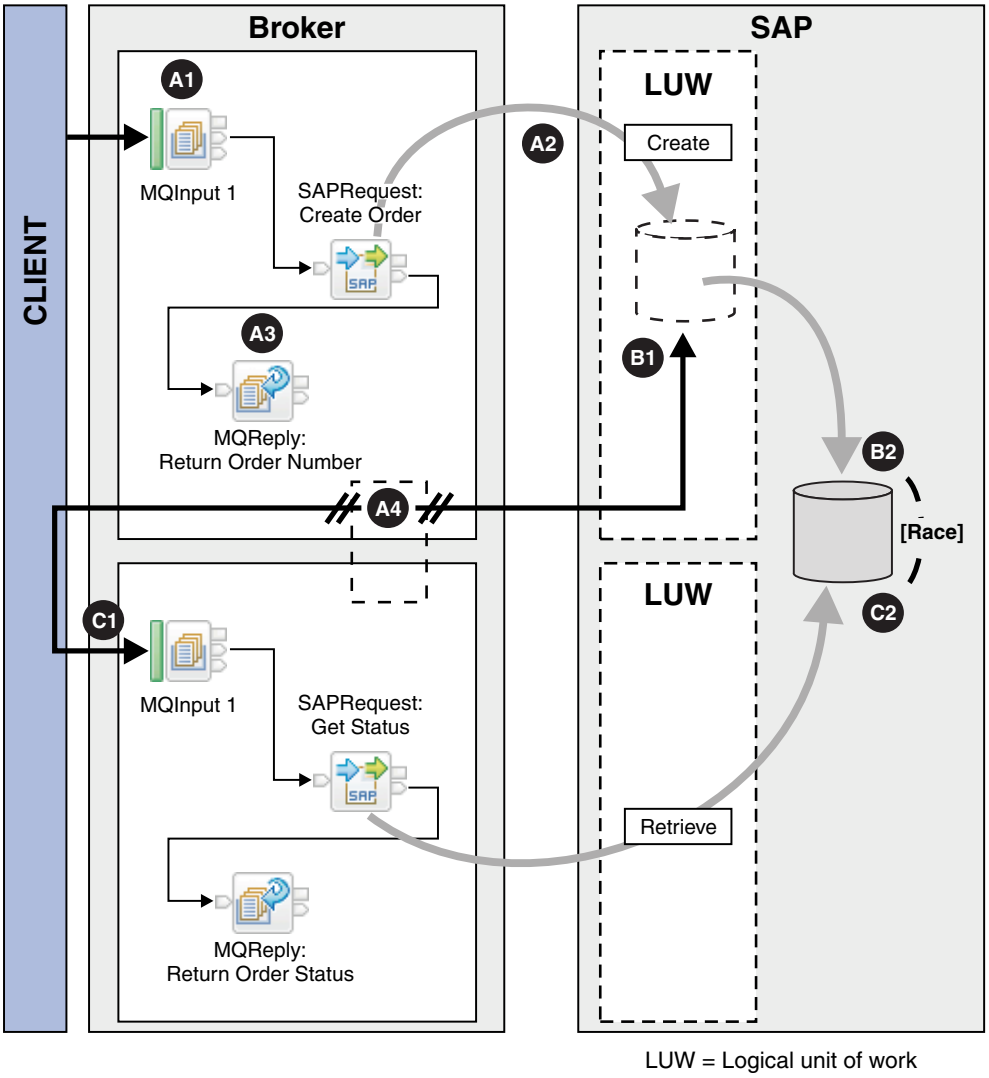
This scenario is one of two examples that illustrate the concepts that are described in "SAP BAPI transaction commit" on page 1928; see also "Scenario 1: Business partner and relationship processing in a single flow" on page 1930.

In this scenario, two message flows are used to issue a sales order create and a subsequent sales order check by using two BAPI calls:

```
BAPI_SALESORDER_CREATEFROMDAT2
BAPI_SALESORDER_GETSTATUS
```

For example, a user queries an order after a purchase has been made by using a Web-based application. The result of the query is closely linked to the asynchronous or synchronous behavior of the order creation steps carried out by the external SAP server.

In the following asynchronous example (the default behavior), the query might fail and the user receives a negative acknowledgment for the order that has been created.



BAPI Create Order message flow

A1. An application triggers the transactional message flow that creates a sales order.

A2. The SAPRequest node submits an order creation and returns the order registration number. The commit happens when the message flow completes because the node participates in a message flow level transaction.

A3. The MQReply node puts an MQ message on the output queue pending transactional commit.

A4. The message flow completes and the broker begins to commit all the resources involved in that flow, including SAP and the MQReply node call. The order number is available to the user application.

The following two processes occur simultaneously, and effectively race each other to complete.

SAP Commits processing asynchronously	**BAPI Get Order Status message flow**

BAPI Create Order message flow

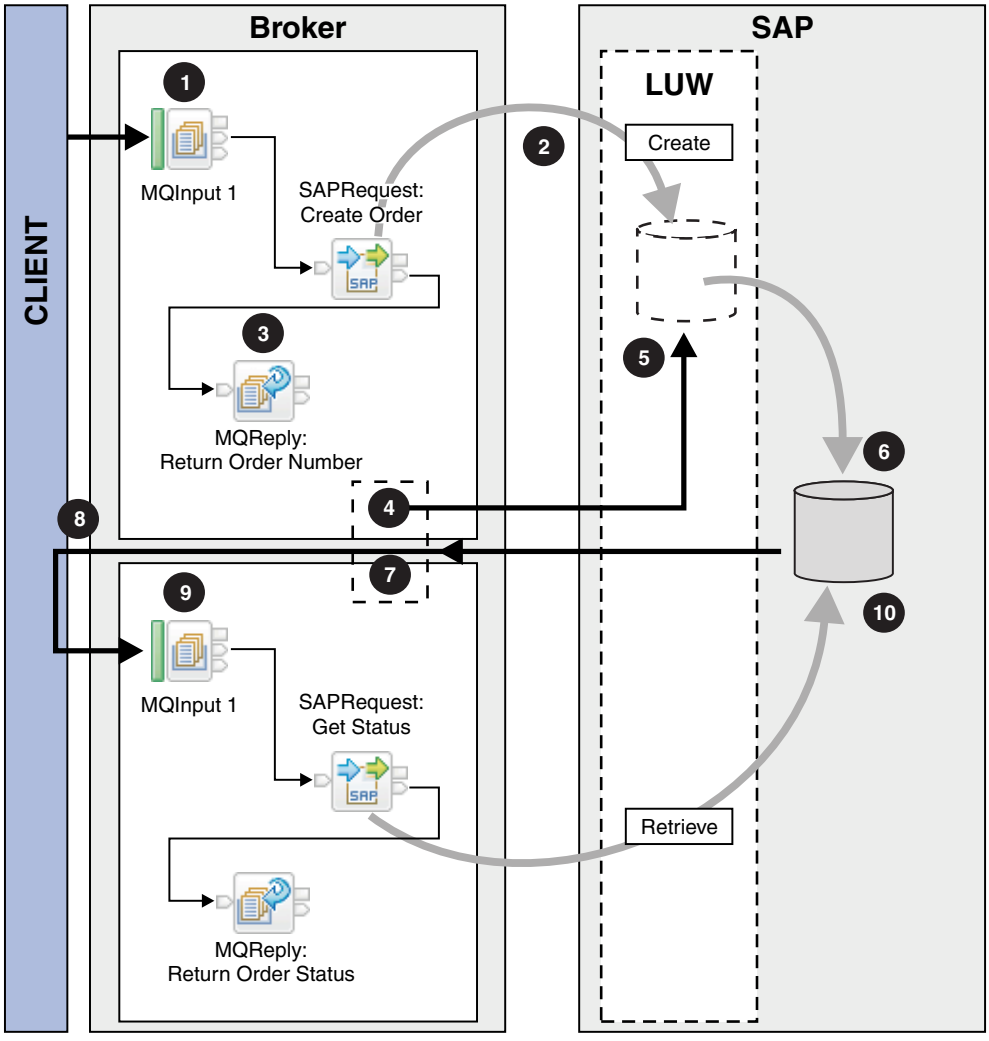
B1. The SAP commit begins.
B2. The SAP commit completes.
C1. A request for an order status query is made.
C2. The SAPRequest node requests the order.

Because of the asynchronous commit, two outcomes are possible when the order is queried:

- The order is not found because SAP has not completed the order commit.
- The order is found but only if SAP has committed the order before the query is made.

You can avoid this uncertainty by configuring the adapter to perform the commit synchronously; set the **Use wait parameter before calling BAPI commit** parameter on the adapter connection wizard to `True`, and set the `Transaction mode` property on the SAPRequest node to `Yes`.

In the following synchronous example, the query is successful and the user receives a positive acknowledgment for the order that has been created.



BAPI Create Order message flow

1. An application triggers the transactional message flow that creates the sales order.
2. The SAPRequest node submits an order creation and returns the order registration number. The commit happens when the message flow completes because the node participates in the a message flow level transaction.
3. The MQReply node puts an MQ message on the output queue pending transactional commit.
4. The message flow completes and the broker begins to commit all the resources involved in that flow, including SAP.

SAP Commits processing synchronously

5. The SAP commit begins.
6. The SAP commit completes.
7. The adapter hands control back to the broker.
8. The MQReply node call is committed, therefore the order number is available to the user application.

BAPI Get Order Status message flow

9. A request for an order status query is made.
10. The SAPRequest node requests the order.

SAP has completed the order commit; therefore, the order query is successful.

"SAPReply node" on page 4682
Use the SAPReply node to send a reply to an SAP synchronous callout. Use this node with an SAPInput node to implement a message flow that acts as a remote function call (RFC) destination.

Synchronous and asynchronous RFC:

For BAPI inbound and outbound processing, you can specify that the processing be handled synchronously (in which both the message flow and the adapter must be available during processing) or asynchronously (in which the adapter does not have to be available when the message flow makes the function call). In synchronous processing, the message flow waits for a response from the adapter. In asynchronous processing, the SAP application does not wait for a response and the adapter does not have to be available when the SAP application makes the function call.

For diagrams that illustrate synchronous and asynchronous RFC, see "BAPI inbound scenarios" on page 1943.

The BAPI interface has two sets of activation specification properties (one for synchronous RFC and one for asynchronous RFC), which you use to set up inbound processing. You specify values for the properties with the Adapter Connection wizard.

The sequence of processing actions that result from an inbound request differ, depending on the selection you make during configuration from the **SAP Remote Function Call (RFC) type** list.

Synchronous RFC

If you select **Synchronous RFC** (the default) during configuration, the following processing steps occur:

1. The adapter starts event listeners, which listen for an RFC-enabled function event (which you specified with the RFCProgramID property) on the SAP server.

2. The RFC-enabled function event is pushed to the adapter by way of the event listeners.
3. The adapter resolves the operation and business object name using the received RFC-enabled function name.
4. The adapter sends the business object to an endpoint in a synchronous manner.
5. The adapter receives the response business object from the endpoint.
6. The adapter maps the response business object to an RFC-enabled function and returns it to the SAP server.

The adapter does not listen for events until the endpoint is active and available.

Asynchronous transactional RFC

If you select **Asynchronous Transactional/Queued RFC** during configuration, the following processing steps occur:

1. A client on the SAP server invokes an RFC-enabled function call on the adapter.

   Note: To send the RFC-enabled functions from a queue on the SAP server, the client program on the SAP server delivers the events to a user-defined outbound queue.

   A transaction ID is associated with the call.

   The calling program on the SAP server does not wait to see whether the call to the adapter was successful, and no data is returned to the calling program.
2. The RFC-function call is placed on a list of functions to be delivered.

   You can see the event list by entering transaction code SM58 on the SAP server
3. The RFC-function call is invoked on the adapter. If the adapter is not available, the call remains in the list on the SAP server, and the call is repeated at regular intervals until it can be processed by the adapter.

   When the SAP server successfully delivers the call event, it removes the function from the list.
4. If you selected **Ensure once-only event delivery**, the adapter sets the transaction ID in the event persistent table.

   This is to ensure the event is not processed more than once.
5. The adapter resolves the operation and business object name using the received RFC-enabled function name.
6. The adapter sends the business object to an endpoint.

   If you are sending functions from a user-defined queue on the SAP server, the functions are delivered in the order in which they exist on the queue. You can see the contents of the queue by entering transaction code SMQ1 on the SAP server.
7. If the delivery is successful, and if you selected **Ensure once-only event delivery**, the adapter removes the transaction ID from the event persistent table.

   If a failure occurs when the adapter attempts to deliver the business object, the transaction ID remains in the event table. When another event is received from the SAP server, the following processing occurs:
   a. The adapter checks the transaction ID.
   b. If the event matches an ID in the table, the adapter processes the failed event once; it does not send the event with the duplicate ID, thereby ensuring that the event is processed only once.

Passing parameters and reporting errors:

The BAPI interface is defined by its input parameters (IMPORT), output parameters (EXPORT), and tables.

After the Adapter Connection wizard has discovered the BAPI interface, the wizard creates a message set that contains an element and a type for the definition of that interface. Each of the import or export parameters has a corresponding field, which has an associated type that can be simple or complex. Tables are represented in the message type definition as repeating complex structures (maxOccurs = -1).

BAPIs are also defined by the messages (error, warning, or success) that they can return. These messages are typically returned in an export parameter (for example, BAPIRETURN). Most BAPIs have this parameter in common, although the type of the parameter can vary. For example, its type can be:

- BAPIRETURN
- BAPIRET1
- BAPIRET2

These structures are similar, except for a few fields that have been added in later versions.

To send an error back to the calling SAP program, use the BAPIReturn structure that was specified as one of the export parameters when the BAPI was defined. Messages are returned in the Return export parameter. You can use the transaction code SE91 for message maintenance.

For more information, see Return Parameters (Error Handling) in the BAPI Programming Guide Reference on the SAP Help Portal.

As well as the application level errors, which can be reported by the Return export parameter, system or communication failures also exist, which indicate to SAP that the function could not be called or did not complete.

BAPI inbound scenarios:

In SAP, you can call functions in other applications or SAP systems that are registered with SAP as remote function call (RFC) servers. In WebSphere Message

Broker, you can register the SAP adapter with SAP as an RFC server so that it accepts synchronous and asynchronous calls from SAP.

Integrating SAP with a system with a synchronous interface:
In SAP, a BAPI interface is a function call. If a system is connected to SAP as an RFC server, you can use the BAPI interface to define the interface where a program running in SAP can call an external system. The external system is identified in SAP by its RFCDestination value, which is bound to a program ID in SAP administration. The program ID is specified by the external system when it first connects to SAP.

By using the WebSphere Adapter for SAP, a message flow can connect to SAP as an RFC Server by configuring the adapter with the relevant program ID and deploying the message flow to the broker. After deployment, the message flow can receive synchronous function calls by using the BAPI interface.

The reply identifier

The BAPI import parameters are received by the adapter and propagated from an SAPInput node as a message tree structure. The BAPI export parameters are propagated to an SAPReply node as a message tree structure. The adapter then sends back the export parameters to the calling SAP program. In this case, the SAPReply node is typically in the same flow as the SAPInput node. The SAPInput node provides a unique ID (the reply identifier) for each BAPI call. The reply identifier is propagated to the SAPReply node (in the local environment) to indicate to which BAPI call it is replying.

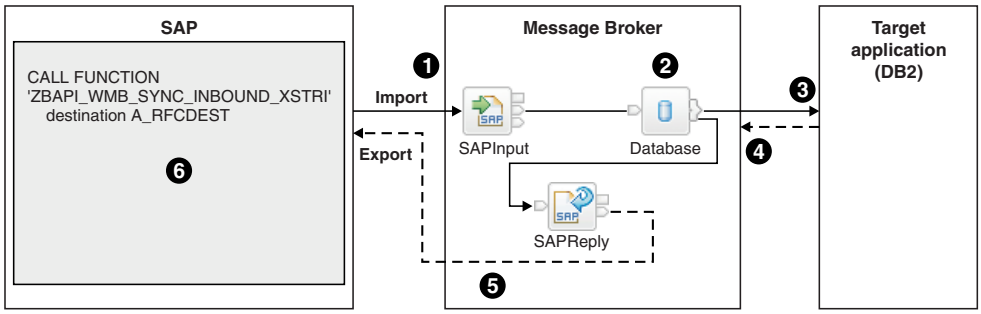
If no reply identifier exists in the local environment, the SAPReply node automatically uses the reply identifier from the SAPInput node that triggered the current execution of the message flow. If the flow is triggered by anything but an SAPInput node, or if a break occurs in the flow, an error is issued. An unhandled exception in the message flow causes a system failure in SAP.

Even if the BAPI does not expect any output parameters, the (empty) message must be propagated to the SAPReply node.

You can process two concurrent callouts from SAP by configuring the message flow with an additional instance.

Scenario 1

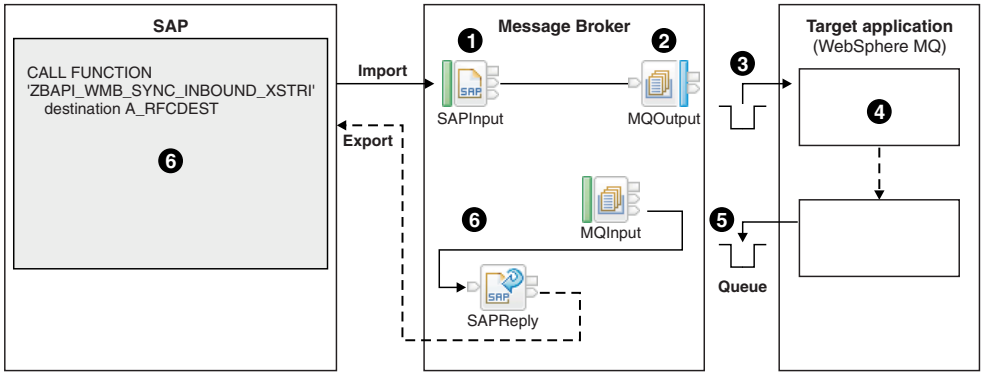
The following diagram represents a message flow where WebSphere Message Broker provides a link between SAP and a target application (in this case, DB2) The SAP program requires reply data, therefore it blocks further processing until the call completes.



1. The SAP program makes a BAPI call to WebSphere Message Broker.
2. WebSphere Message Broker converts the call to an SQL call.
3. WebSphere Message Broker passes the call on to DB2.
4. DB2 processes the SQL and returns the result to WebSphere Message Broker.
5. WebSphere Message Broker converts the SQL result to a BAPI reply and sends the reply to SAP.
6. The SAP program processes the next line of code.

Scenario 2

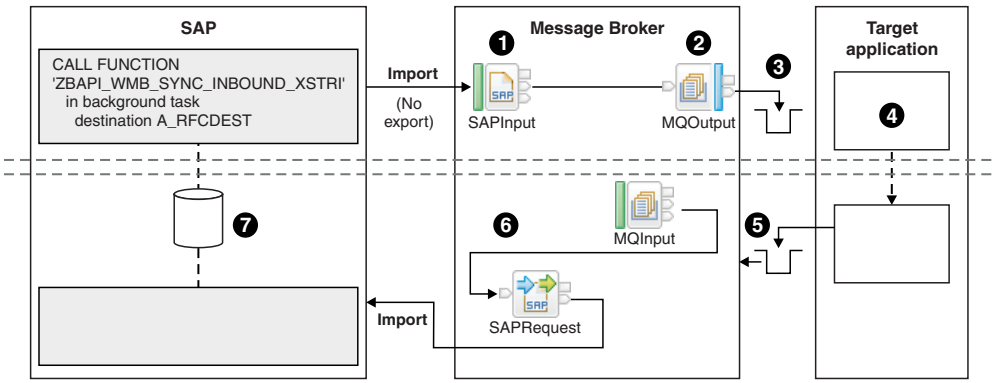
The following diagram also represents a message flow where the SAP program requires reply data, but in this scenario, calls between WebSphere Message Broker and the target application (in this case, WebSphere MQ) are asynchronous. The SAP system blocks further processing until the call completes. When you use the SAPReply node in a different flow from the SAPInput node, deploy the SAPReply node in the same execution group as the SAPInput node.



1. The SAP program makes a BAPI call to WebSphere Message Broker.
2. WebSphere Message Broker converts the import parameters into a message format that is understood by the target application.
3. WebSphere Message Broker puts that message on a request queue.
4. The target application gets the request message from the queue, processes it, and puts a reply message on the reply-to queue.
5. WebSphere Message Broker gets the reply message from the queue.
6. WebSphere Message Broker converts the reply message to BAPI export parameters and sends the reply to SAP.

Scenario 3

The following diagram represents an asynchronous call from SAP to WebSphere Message Broker, and an asynchronous call from WebSphere Message Broker to a target application. This scenario shows how you can combine the inbound processing that is described in this topic with outbound processing to achieve the same result as in scenarios 1 and 2. For more information about outbound processing, see “Outbound processing for the BAPI interface” on page 1926.



1. The SAP program makes a BAPI call to WebSphere Message Broker, stores relevant information in a database table, and continues to process the next line of code.
2. WebSphere Message Broker converts the import parameters into a message format that is understood by the target application.
3. WebSphere Message Broker puts that message on a request queue.
4. The target application gets the request message from the queue and processes it.
5. WebSphere Message Broker gets the reply message from the queue.
6. The SAPRequest node sends the message to the SAP program, requesting an update in SAP.
7. The SAP program refers to the information that is stored in the database table and makes the requested update.

Errors and warnings

- If an SAPReply node is deployed but no SAPInput node is deployed to that execution group, a warning is written to syslog or the Windows Event Viewer.
- If the SAPReply node is provided with a reply identifier that does not correspond to any BAPI call in this execution group, an error is issued.
- If the same reply identifier is sent to two SAPReply nodes, the second node receives an error message.
- If an SAP program tries to call a BAPI that is using the RFCDestination value of the broker, but that BAPI was not discovered for that adapter, an error is written to syslog or the Windows Event Viewer, and a failure message is sent back to the calling SAP program.

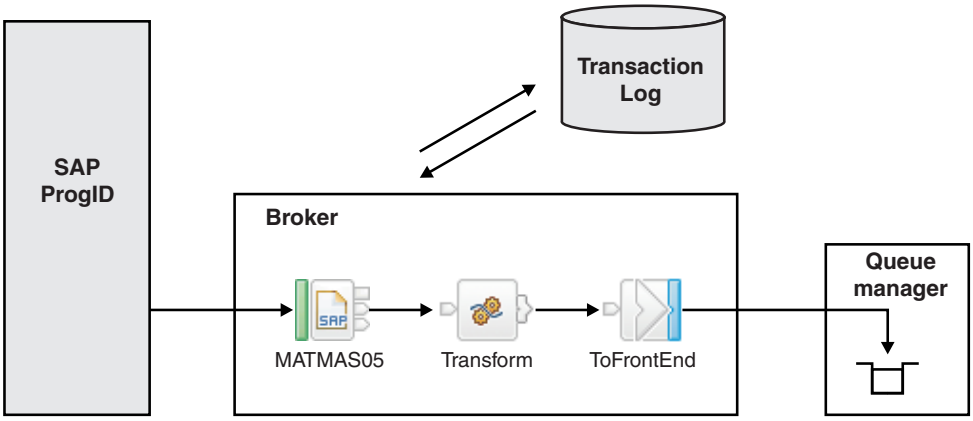
SAP high availability:

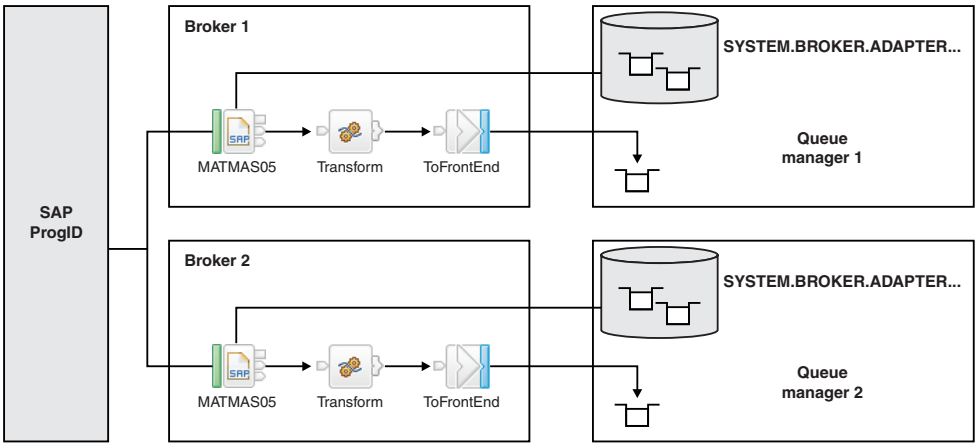
You can configure WebSphere Message Broker to withstand software or hardware failures when working with SAP, so that WebSphere Message Broker is available for as much of the time as possible.

In WebSphere Message Broker , the tRFC protocol between SAP and WebSphere Message Broker (acting as the RFC server) ensures that IDocs and tRFC BAPI calls are delivered exactly once. This behavior is possible because each delivery has an

associated transaction ID (TID). WebSphere Message Broker monitors the progress of a delivery until SAP confirms a successful delivery. If the connection is lost or WebSphere Message Broker fails before that confirmation is issued, SAP attempts to redeliver the message. By keeping a persistent record (in the TID store or transaction log), the broker can ensure integrity and avoid a duplicate delivery.



When two `.inadapter` components, with the same RFC program ID, are deployed to two brokers, two connections to the same RFC server are visible to SAP. If the connection is lost to one of the brokers, SAP might attempt to redeliver to the other broker. The brokers have separate TID stores, therefore, the second broker accepts the redelivery, even though the first broker might have processed some (or all) of the IDocs in the packet.



In WebSphere Message Broker Version 7.0, you can move the TID store to a remote queue manager that can be shared between two brokers. To avoid a single point of failure, make this third queue manager a WebSphere MQ high availability, multi-instance queue manager. For instructions, see “Setting up SAP for high availability” on page 2057.

SAP adapter scalability and performance:

You can improve performance by configuring the number of listeners on the adapter and the number of additional instances on the message flow to prevent delays when processing synchronous calls from SAP.

The SAP inbound adapter receives synchronous calls from SAP. The adapter has a property called `Number of listeners`, which controls the maximum number of concurrent calls by configuring the adapter to have a particular number of threads listening to the SAP program ID. The listeners send the input parameters of these calls to the SAPInput node for processing, and the output parameters are sent to the SAPReply node.

When the listener receives a call from SAP, it blocks processing until a message flow instance that contains the SAPInput node is available. When a message flow instance has become available, and has started to process the import parameters, the listener again blocks processing until a message that contains the export parameters is propagated to an SAPReply node.

The amount of time that elapses between the SAPInput node sending the message and the SAPReply node receiving the reply message can be affected by the additional instances property on the message flow. To avoid delays in processing, tune the maximum number of listeners and the number of additional instances for the message flow that contains the SAPInput and SAPReply nodes. You can configure the number of additional instances at message flow level or on the SAPInput node itself.

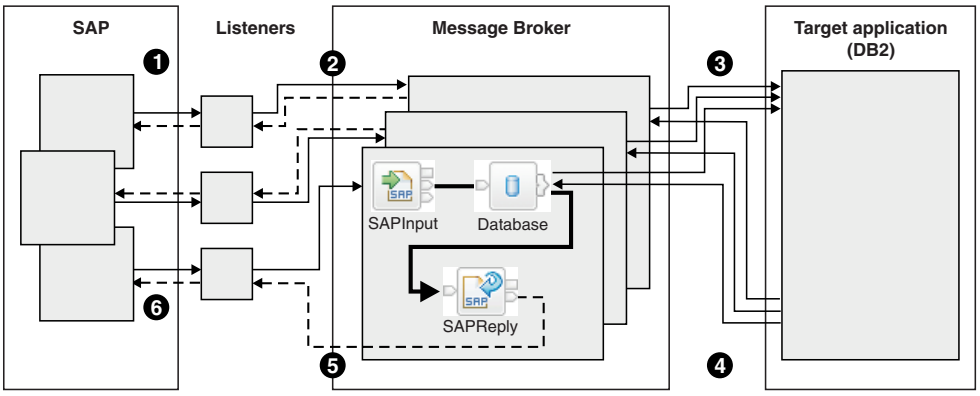
Restrictions

The number of listeners is limited by the SAP configuration. In SAP transaction SMQS, you can view and change the maximum connections property for each RFC destination. Configuring a number of listeners greater than the maximum number of connections has no effect.

For each additional instance of the message flow, extra resources are used by each node in the flow, depending on the types of node in the flow.

Scenarios

The following diagram illustrates a basic scenario, where the number of listeners is equal to the number of additional instances of the message flow; in this case, the scenario has been configured with three listeners and three message flow instances.



1. SAP makes three calls, each of which is received by a listener.
2. Each of the listeners sends the input parameters of each call to the SAPInput node in one of three instances of the message flow.
3. Each message flow instance sends its message to the target application.

4. The target application processes the messages and returns replies to the message flow instances.
5. The SAPReply node in each message flow instance sends the reply message to the listener that received the original call.
6. Each listener returns the reply message to the appropriate SAP program.

The SAPReply node can be in the same message flow as the SAPInput node, as illustrated in the previous example. However, in the following scenario, the SAPReply node is in a different flow from the SAPInput node. The SAPReply node must be deployed in the same execution group as the SAPInput node.

1. SAP makes three calls, each of which is received by a different listener.
2. Each of the listeners sends the input parameters of each call to a message flow that contains an SAPInput node.
3. The message flow puts the message onto a queue for the target application.
4. The target application gets the messages from the queue and processes them.
5. The target application puts the messages onto a queue.
6. A second message flow that contains an SAPReply node gets the messages from the queue and processes them.
7. The SAPReply node sends the reply messages to the appropriate listeners.
8. Each listener returns a reply message to the appropriate SAP program.

In this scenario, the message flow has low latency compared to the time taken by the entire scenario. Therefore, you can limit the resources that are used by the message flow containing the SAPInput node by configuring fewer additional instances for this message flow. One instance of the message flow, as in the example, can service many listeners because the message flow propagates the import parameters quickly for processing.

The following scenarios are also possible.

- A single message flow contains an SAPReply node but it is used to reply to several SAPInput nodes. After the message has been propagated to the SAPReply node, the listener sends the reply back to SAP and is therefore ready to receive another call from SAP. However, the current instance of the message flow is still busy processing the nodes downstream from the SAPReply node. In this case, increase the number of instances on the message flow that contains the SAPReply node.
- After propagating to the SAPReply node, other nodes in the message flow perform extra processing. In this case, increase the number of instances on the message flow that contains the SAPReply node, even when it is the same flow that contains the SAPInput node.

  This scenario might have an undesirable effect on the integrity of your data. If an exception occurs after the SAPReply node, resources that are updated by the message flow (for example, database tables or WebSphere MQ queues) might be rolled back. However, the reply has been sent back to SAP already and cannot be rolled back. If this behavior is not appropriate, you can improve data integrity by ensuring that the SAPReply node is the final node in the message flow.

For information about how to tune the SAP adapter, see “Tuning the SAP adapter for scalability and performance” on page 3278.

These properties are available for review and update when you select the **Manage and Configure** tab for the broker archive file.

Business objects for the BAPI interface:

A business object is a structure that consists of data, the action to be performed on the data, and additional instructions for processing the data.

For outbound processing, the broker uses business objects to send data to SAP or obtain data (through the adapter) from SAP. The broker sends a business object to the adapter, and the adapter converts the data in the business object to a format that is compatible with an SAP API call. The adapter then runs the SAP API with this data.

For inbound processing, the SAP server sends a BAPI function call through the adapter to an endpoint. The adapter converts the BAPI function call into a business object.

The adapter uses the BAPI metadata that is generated by the Adapter Connection wizard to construct a business-object definition. This metadata contains BAPI-related information such as the operation of the business object, import parameters, export parameters, table parameters, transaction information, and dependent or grouped BAPIs.

The BAPI business-object definition that is generated by the Adapter Connection wizard is modeled on the BAPI function interface in SAP. The business-object definition represents a BAPI function, such as a BAPI_CUSTOMER_GETLIST function call.

If you change the BAPI interface, you must run the Adapter Connection wizard again to rebuild the business object definition.

How business-object definitions are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

Business object structure

The structure of a BAPI business object depends on the interface type (simple BAPI, BAPI work unit, or BAPI result set).

For more information, see the following topics.

Business object structure for a simple BAPI:

A business object for a simple BAPI call reflects a BAPI method or function call in SAP. Each business object property maps to a BAPI parameter. The metadata of each business-object property indicates the corresponding BAPI parameter. The operation metadata determines the correct BAPI to call.

For a simple BAPI that performs Create, Update, Retrieve, and Delete operations, each operation is represented by a business object, with the business objects being grouped together in a wrapper.

The business object wrapper can be associated with multiple operations, but for a simple BAPI, each business object is associated with only one operation. For example, while a wrapper business object can contain BAPIs for Create and Delete operations, BAPI_CUSTOMER_CREATE is associated with the Create operation, not the Delete operation.

The BAPI business objects are children of the business object wrapper, and, depending on the operation to be performed, only one child object in this wrapper needs to be populated at run time in order to process the simple BAPI call. Only one BAPI, the one that is associated with the operation to be performed, is called at a time.

If you select **Asynchronous Transactional RFC** (for outbound or inbound processing) or **Asynchronous Queued RFC** (for outbound processing) , the BAPI wrapper business object also contains a transaction ID. The transaction ID is used to resend the BAPI call if the receiving system is not available at the time of the initial call.

Business object structure for a BAPI work unit:

A business object that represents a BAPI work unit (also known as a BAPI transaction) is a wrapper object that contains multiple child BAPI objects. Each child BAPI object in the wrapper object represents a simple BAPI.

The adapter supports a BAPI work unit by using a top-level wrapper business object that consists of multiple child BAPIs, each one representing a simple BAPI

in the sequence. The BAPI wrapper object represents the complete work unit, while the child BAPI objects contained in the BAPI wrapper object represent the individual operations that make up the work unit.

Business object structure for a BAPI result set:

The top-level business object for a result set is a wrapper that contains a GetDetail business object. The GetDetail business object contains the results of a query for SAP data. The GetDetail business object also contains, as a child object, the query business object. The query business object represents a GetList BAPI. These two BAPIs work together to retrieve information from the SAP server.

The ALE interfaces:

The SAP Application Link Enabling (ALE) interface and ALE pass-through IDoc interface enable business process integration and asynchronous data communication between two or more SAP systems or between SAP and external systems. The data is exchanged in the form of Intermediate Documents (IDocs).

The adapter supports outbound and inbound processing by enabling the exchange of data in the form of business objects.

- For inbound processing, SAP pushes the data in IDocs to the SAP adapter. The adapter converts the IDocs to business objects and delivers them to the endpoint.
- For outbound processing, the SAP adapter converts the business object to an IDoc and delivers it to SAP.

To use the ALE interface or ALE pass-through IDoc interface for inbound processing, make sure that your SAP server is properly configured (for example, you must set up a partner profile and register an SAP RCF program ID to listen for events).

Application systems are loosely coupled in an ALE integrated system, and the data is exchanged asynchronously.

IDocs

Intermediate Documents (IDocs) are containers for exchanging data in a predefined (structured ASCII) format across system boundaries. The IDoc type indicates the SAP format that is to be used to transfer the data. An IDoc type can transfer several message types (the logical messages that correspond to different business processes). IDocs can be used for outbound and inbound processing. The SAP adapter supports the basic and extension type of IDocs.

For example, if an application developer wants to be notified when a sales order is created on the SAP server, the developer runs the Adapter Connection wizard to discover the ORDERS05 IDoc on the SAP server. The wizard then generates the business object definition for ORDERS05. The wizard also generates other resources, such as an EIS export component and Service Component Architecture (SCA) interfaces.

IDocs are exchanged for inbound and outbound events, and IDocs can be exchanged either as individual documents or in packets.

The processing of IDoc data depends on whether you are using the ALE interface or the ALE pass-through IDoc interface.

- **ALE interface**

  For outbound processing, the adapter uses the IDoc business object to populate the appropriate RFC-enabled function call made to the SAP server.

  For inbound processing, IDocs can be sent from the SAP server as parsed or unparsed documents

  – For parsed documents, the adapter parses the IDoc and creates a business object that reflects the internal structure of the IDoc.
  – For unparsed IDocs, the adapter processes the IDoc but does not convert the data portion of the IDoc.
- **ALE pass-through IDoc interface**

For both outbound and inbound processing, the adapter does no conversion of the IDoc, which is useful when the client wants to perform the IDoc parsing.

Transactional RFC processing

The adapter uses transactional RFC (tRFC) to assure delivery and to ensure that each IDoc is exchanged only once with SAP. The tRFC component stores the called RFC function in the database of the SAP system with a unique transaction identifier (TID). The TID is a field in your message.

The message flow must determine how to store the SAP transaction ID and how to relate the SAP transaction ID to the data being sent to the adapter. When the events are successful, the message flow should not resubmit the event associated with this TID again to prevent the processing of duplicate events.

- If the message flow does not send an SAP transaction ID with the business object, the adapter returns one after running the transaction.
- If the message flow has an SAP transaction ID, it must populate the SAP transaction ID property in the business object with that value before running the transaction.

The SAP transaction ID can be used for cross-referencing with a global unique ID that is created for an outbound event. You can create the global unique ID for managing integration scenarios.

Queued RFC processing

The adapter uses qRFC (queued transactional RFC) to ensure that IDocs are delivered in sequence to a queue on the SAP server or are received in sequence from the SAP server. Additional threads can increase the throughput of a message flow but you should consider the potential effect on message order. To maintain message order, ensure that your message flow is single threaded.

Outbound processing for the ALE interface:

The adapter supports outbound processing (from the adapter to the SAP server) for the ALE interface and the ALE pass-through IDoc interface. ALE uses IDocs for data exchange, and the adapter uses business objects to represent the IDocs.

The following list describes the sequence of processing actions that result from an outbound request that uses the ALE interface and ALE pass-through IDoc interface.

The message flow that makes the request uses the interface information that was generated by the Adapter Connection wizard.

1. The adapter receives a request, which includes an IDoc business object, from a message flow.

   For pass-through IDocs, the Message tree contains a BLOB field that represents the IDoc. No separate IDoc business object exists for pass-through IDocs.
2. The adapter uses the IDoc business object to populate the appropriate RFC-enabled function call used by the ALE interface.
3. The adapter establishes an RFC connection to the ALE interface and passes the IDoc data to the SAP system. If you are using the qRFC protocol, the adapter passes the IDoc data in the order specified in the wrapper business object to the specified queue on the SAP server.

4. After passing the data to SAP, the adapter performs one of the following steps:
   - If the call is not managed by a local transaction that uses the broker's Local Transaction Manager, the adapter releases the connection to SAP and does not return any data to the caller. When no exceptions are raised, the outbound transaction is considered successful. You can verify whether the data is incorporated into the SAP application by inspecting the IDocs that have been generated in SAP.
   - If the call is managed by a local transaction that uses the broker's Local Transaction Manager, the adapter returns the transaction ID.

     The adapter uses the tRFC protocol to support J2C local transactions.

Inbound processing for the ALE interface:

The adapter supports inbound processing (from the SAP server to the adapter) for the ALE interface and the ALE pass-through IDoc interface.

When you are configuring a module for the ALE interface or the ALE pass-through interface, you indicate whether the IDocs are sent as a packet and, for the ALE interface, you can specify whether they are sent parsed or unparsed. You make these selections in the Adapter Connection wizard. When you use the ALE pass-through IDoc interface, the Message tree contains a BLOB field that represents the IDoc. No separate IDoc business object exists for pass-through IDocs.

The following list describes the sequence of processing actions that result from an inbound request using the ALE interface.
1. The adapter starts event listeners to the SAP server.
2. Whenever an event occurs in SAP, the event is sent to the adapter through the event listeners.
3. The adapter converts the event into a business object before sending it to the endpoint.

The adapter uses the event recovery mechanism to track and recover events in case of abrupt termination. The event recovery mechanism uses a data source for persisting the event state.

The following table provides an overview of the differences between the ALE interface and the ALE pass-through IDoc interface for inbound processing.

Interface	When to use	SplitIDoc = true	SplitIDoc = false	Parsed IDoc = true
ALE inbound	This interface converts the raw incoming IDocs to business objects, which are readily consumable by the client at the endpoint.	On receiving the IDoc packet from SAP, the adapter converts the IDocs to business objects, one by one, before sending each one to the endpoint.	On receiving the IDoc packet from SAP, the adapter converts the IDocs in the packet as one business object before sending it to the endpoint.	The incoming IDoc is only partially parsed (the control record of the IDoc is parsed but the data record is not). The client at the endpoint is responsible for parsing the data record.
ALE pass-through IDoc	This interface wraps the raw incoming IDoc in a business object before delivering it to the client at the endpoint. The client is responsible for parsing the raw IDoc.	On receiving the IDoc packet from SAP, the adapter wraps each raw IDoc in a business object before sending the objects, one by one, to the endpoint.	On receiving the IDoc packet from SAP, the adapter wraps the raw IDoc packet in a business object before sending it to the endpoint.	This attribute is not applicable to the ALE pass- through IDoc interface. (Neither the control record nor the data record of the IDoc is parsed.)

Event error handling:

WebSphere Adapter for SAP Software provides error handling for inbound ALE events by logging the errors and attempting to restart the event listener.

When the adapter detects an error condition, it performs the following actions:

1. The adapter logs the error information in the syslog (on Linux and UNIX systems), Windows Event Viewer, or user trace log.
2. The adapter attempts to restart the existing event listeners.

   The adapter uses the activation specification values for RetryLimit and RetryInterval.

   - If the SAP application is not active, the adapter attempts to restart the listeners for the number of times configured in the RetryLimit property.
   - The adapter waits for the time specified in the RetryInterval parameter before attempting to restart the event listeners.
3. If the attempt to restart the event listeners fails, the adapter performs the following actions:
   - The adapter logs the error condition in the syslog (on Linux and UNIX systems), Windows Event Viewer, or user trace log.
   - The adapter cleans up the existing ALE event listeners.
   - The adapter starts new event listeners.

   The adapter uses the values of the RetryLimit and RetryInterval properties when starting the new event listeners.
4. If all the retry attempts fail, the adapter logs the relevant message and CEI events and stops trying to recover the ALE event listener.

   You must restart the adapter or Service Component Architecture (SCA) application in this case.

Event processing for parsed IDoc packets:

An inbound event can contain a single IDoc or multiple IDocs, with each IDoc corresponding to a single business object. The multiple IDocs are sent by the SAP server to the adapter in the form of an IDoc packet. You can specify, during adapter configuration, whether the packet can be split into individual IDocs or whether it must be sent as one object (non-split).

Event processing begins when the SAP server sends a transaction ID to the adapter. The following sequence occurs.

1. The adapter checks the status of the event and takes one of the following actions:
   - If this is a new event, the adapter stores an EVNTID (which corresponds to the transaction ID) along with a status of `0` (Created) in the event recovery table.
   - If the event status is `-1` (Rollback), the adapter updates the status to `0` (Created).
   - If the event status is `1` (Executed), the adapter returns an indication of success to the SAP system.
2. The SAP system sends the IDoc to the adapter.
3. The adapter converts the IDoc to a business object and sends it to the endpoint.

   For single IDocs and non-split IDoc packets, the adapter can deliver objects to endpoints that support transactions as well as to endpoints that do not support transactions.

- For endpoints that support transactions, the adapter delivers the object as part of a unique XA transaction. When the endpoint processes the event and the transaction is committed, the status of the event is updated to 1 (Executed).

  The endpoint must be configured to support XA transactions.
- For endpoints that do not support transactions, the adapter delivers the object to the endpoint and updates the status of the event to 1 (Executed). The adapter delivers the business object without the quality of service (QOS) that guarantees once-only delivery.

4. For split packets only, the adapter performs the following tasks:
   a. The adapter updates the BQTOTAL column (or table field) in the event recovery table to the number of IDocs in the packet. This number is used for audit and recovery purposes.
   b. The adapter sends the business objects to the message endpoint, one after the other, and updates the BQPROC property to the sequence number of the IDoc it is working on. The adapter delivers the objects to the appropriate endpoint as part of a unique XA transaction (a two-phase commit transaction) controlled by the application server.
   c. When the endpoint receives the event and the transaction is committed, the adapter increments the number in the BQPROC property.

      The message endpoint must be configured to support XA transactions.If the adapter encounters an error while processing a split IDoc packet, it can behave in one of two ways, depending on the IgnoreIDocPacketErrors configuration property:
      - If the IgnoreIDocPacketErrors property is set to `false`, the adapter stops processing any additional IDocs in the packet and reports errors to the SAP system.
      - If the IgnoreIDocPacketErrors property is set to `true`, the adapter logs an error and continues processing the rest of the IDocs in the packet. The status of the transaction is marked 3 (InProgress). In this case, the adapter log shows the IDoc numbers that failed, and you must resubmit those individual IDocs separately. You must also manually maintain these records in the event recovery table.

      This property is not used for single IDocs and for non-split IDoc packets.
   d. The SAP system sends a COMMIT call to the adapter.
   e. After the adapter delivers all the business objects in the IDoc packet to the message endpoint, it updates the event status to 1 (Executed).
   f. In case of abrupt interruptions during IDoc packet processing, the adapter resumes processing the IDocs from the current sequence number. The adapter continues updating the BQPROC property, even if IgnoreIDocPacketErrors is set to `true`. The adapter continues the processing in case you terminate the adapter manually while the adapter is processing an IDoc packet.
5. If an exception occurs either while the adapter is processing the event or if the endpoint generates an exception, the event status is updated to `-1` (Rollback).
6. If no exception occurs, the SAP server sends a CONFIRM call to the adapter.
7. The adapter deletes the records with a 1 (Executed) status and logs a common event infrastructure (CEI) event that can be used for tracking and auditing purposes.

Event processing for unparsed IDocs:

Unparsed IDocs are passed through, with no conversion of the data (that is, the adapter does not parse the data part of the IDoc). The direct exchange of IDocs in the adapter enables high-performance, asynchronous interaction with SAP, because the parsing and serializing of the IDoc occurs outside the adapter. The consumer of the IDoc parses the IDoc.

The adapter processes the data based on whether the packet IDoc is split or non-split and whether the data needs to be parsed.

- The adapter can process packet IDocs as a packet or as individual IDocs. When an IDoc is received by the adapter from SAP as a packet IDoc, it is either split and processed as individual IDocs, or it is processed as a packet. The value of the SplitIDocPacket metadata at the business-object level determines how the IDoc is processed.

  For split IDocs, the wrapper contains only a single, unparsed IDoc object.
- The Type metadata specifies whether the data should be parsed. For unparsed IDocs, this value is `UNPARSEDIDOC`; for parsed IDocs, the value is `IDOC`. This value is set by the Adapter Connection wizard.

Unparsed data format

In the fixed-width format of an unparsed IDoc, the segment data of the IDoc is set in the IDocData field of the business object. It is a byte array of fixed-length data.

The entire segment length might not be used. The adapter pads spaces to the fields that have data; the rest of the fields are ignored, and an end of segment is set. The end of segment is denoted by a null value.

The following figure shows a segment with fields demarcated by the '|' symbol for reference.

Figure 2. Example of a segment before processing

When the adapter processes this segment into unparsed data, it takes into account only those fields that have data in them. It maintains the field width for each segment field. When it finds the last field with data, it appends a null value to mark the end of segment.

Figure 3. Example of a segment after processing

The next segment data processed as unparsed data would be appended after the null value.

Limitations

The unparsed event feature introduces certain limitations on the enterprise application for a particular IDoc type.

- The enterprise application supports either parsed or unparsed business-object format for an IDoc type or message type.
- For an IDoc type, if you select unparsed business-object format for inbound, you cannot have inbound and outbound interfaces in the same EAR file, because outbound is based on parsed business objects.
- The DummyKey feature is not supported for unparsed IDocs.

IDoc status updates:

To monitor IDoc processing, you can configure the adapter to update the IDoc status.

When the adapter configuration property UpdateStatus is set to `true` (indicating that an audit trail is required for all message types), the adapter updates the IDoc status of ALE business objects that are retrieved from the SAP server. After the event is sent to the message endpoint, the adapter updates the status of the IDoc in SAP to indicate whether the processing succeeded or failed. Monitoring of IDocs applies only to inbound processing (when the IDoc is sent from the SAP server to the adapter).

The adapter updates a status IDoc (ALEAUD) and sends it to the SAP server.

An IDoc that is not successfully sent to the endpoint is considered a failure, and the IDoc status is updated by the adapter. Similarly, an IDoc that reaches the endpoint is considered successfully processed, and the status of the IDoc is updated.

The status codes and their associated text are configurable properties of the adapter, as specified in the activation specification properties and shown in the following list:

- SuccessCode
- FailureCode
- SuccessText
- FailureText

Perform the following tasks to ensure that the adapter updates the standard SAP status code after it retrieves an IDoc:

- Set the UpdateStatus configuration property to `true` and set values for the SuccessCode and FailureCode configuration properties.
- Configure the inbound parameters of the partner profile of the logical system in SAP to receive the ALEAUD message type. Set the following properties to the specified values:

Table 14. Inbound properties of the logical system partner profile

SAP property	**Value**
Basic Type	ALEAUD01
Logical Message Type	ALEAUD
Function module	IDOC_INPUT_ALEAUD
Process Code	AUD1

Pass-through support for IDocs, and MQSeries link for R/3 link migration:

Both the inbound and outbound SAP adapters support a pass-through mode for IDocs.

In this mode, the bit stream for the IDoc is provided without any form of parsing. The bit stream can then be used directly in a message flow, and parsed by other parsers, or sent unchanged over transports.

Use the Adapter Connection wizard to select pass-through support: on the Configure settings for adapter pane, select `ALE pass-through IDoc` as the interface type.

A business object is created that contains one field, which is the bit stream of the IDoc. You can transform this business object in a Compute node to an MQSeries link for R/3 format message, as shown in the following example.

```
DECLARE ns NAMESPACE
'http://www.ibm.com/xmlns/prod/websphere/j2ca/sap/sapmatmas05';

CREATE COMPUTE MODULE test4_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
```

```
  CALL CopyMessageHeaders();
  -- CALL CopyEntireMessage();
  set OutputRoot.MQSAPH.SystemNumber = '00';
  set OutputRoot.BLOB.BLOB =
InputRoot.DataObject.ns:SapMatmas05.IDocStreamData;
  RETURN TRUE;
 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER;
  SET J = CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;

 CREATE PROCEDURE CopyEntireMessage() BEGIN
  SET OutputRoot = InputRoot;
 END;
END MODULE;
```

You can also create a request business object from an MQSeries link for R/3 message, as shown in the following example.

```
CREATE COMPUTE MODULE test4_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
  set
OutputRoot.DataObject.ns:SapMatmas05.IDocStreamData =
InputRoot.BLOB.BLOB;
  RETURN TRUE;
 END;
END MODULE;
```

The name of the SapMatmas05 element depends on selections that you make when you run the Adapter Connection wizard.

ALE pass-through IDoc business object structure:

During ALE processing, the adapter exchanges business objects with the SAP application.

The message tree contains a BLOB field that represents the IDoc. The BLOB field is modelled as a HexBinary type in the XSD file. The message tree contains the stream data (the BLOB field), which is the entire data of the IDoc. The transaction ID, iDoc type, and queue name fields contain information about that data and how it has been transferred.

The transaction ID (SAPTransactionID) is used to ensure once-only delivery of business objects, and the queue name (qRFCQueueName) specifies the name of the queue on the SAP server to which the IDocs should be delivered. If you are not using transaction IDs or queues, these properties are blank.

Generic IDoc routing:

By using the SAPInput node in passthrough mode, WebSphere Message Broker can receive any IDoc and route it according to IDoc type.

The message set for a generic IDoc in ALE passthrough mode contains four fields. Three of these fields are control information:

- The transaction ID
- The queue name (if qRFC is used)
- The name of the IDoc type

The fourth field is a hexBinary field that contains the entire IDoc in a raw, unparsed format. You can use the DataObject parser to parse this raw format to a full logical structure of a specific IDoc if you provide a message set that contains the definition for that IDoc type. To parse raw IDocs, you must use an MQInput node with the `Message domain` property set to `DataObject`, and the `Message format` property set to `SAP ALE IDoc`.

When passthrough mode is not used, the message set contains a fully parsed IDoc structure. These structures are specific to each IDoc, therefore the message set must have a type defined for every IDoc that could be received by the `.inadapter` component. This message set is determined by the RFC Program ID that is configured on the adapter and the ALE or RFC configuration on the SAP side. This behavior can affect how message models are managed.

Whenever you need to develop message flows in isolation, where each flow is to handle a different type of IDoc, the ALE parsed mode is not appropriate because all flows have a common denominator (the message set), which needs to be changed whenever a new IDoc type is added.

By using the generic passthrough mode, you can create a routing message flow that uses the IDoc type field of the generic IDoc model to separate WebSphere MQ queues, for example. You can create message flows that deal with each different IDoc type. If the set of discovered IDocs is extended, you can create a message flow and a message set (which contains just the new IDoc), then deploy them, without the need to change existing message flows or message sets.

By using this method, you can also use a single RFC program ID to receive all IDoc types, while still allowing individual IDoc processing.

For instructions about how to route generic IDocs, see "Routing IDocs to separate message flows" on page 2055.

For more information about the pattern that is used in the task, see Data distribution SAP to WebSphere MQ: one-way (for IDoc). You can view patterns in the information center by using the links only when you use the information center that is integrated with the WebSphere Message Broker Toolkit, or when you use the online information center.

ALE business objects:

A business object is a structure that consists of data, the action to be performed on the data, and additional instructions for processing the data. The adapter client uses business objects to send data to SAP or to obtain data (through the adapter) from SAP.

The adapter uses the IDoc metadata that is generated by the Adapter Connection wizard to construct a business-object definition. This metadata contains ALE-related information such as segment information, field names, and an indication of whether the business object handles a single IDoc or an IDoc packet.

The Message tree contains a BLOB field that represents the IDoc.

How business-object definitions are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

For more information, see the following topics.

- "ALE business object structure" on page 1979
- "Transaction ID support" on page 1981

ALE business object structure:

During ALE processing, the adapter exchanges business objects with the SAP application. The business object represents an individual IDoc or an IDoc packet. This business object is a top-level wrapper object that contains one or more IDoc child objects, each one corresponding to a single IDoc. The same business object format is used for inbound and outbound processing.

Wrapper business object

The wrapper business object contains a transaction ID, a queue name, and one or more IDoc business objects. The transaction ID (SAPTransactionID) is used to ensure once-only delivery of business objects, and the queue name (qRFCQueueName) specifies the name of the queue on the SAP server to which the IDocs should be delivered. If you are not using transaction IDs or queues, these properties are blank.

For individual IDocs, the wrapper business object contains only one instance of an IDoc business object. For IDoc packets, the wrapper business object contains multiple instances of an IDoc business object.

IDoc business object

The IDoc business object contains the following objects:

- The control record business object contains the metadata required by the adapter to process the business object.
- The data record business object contains the business object data to be processed by the SAP application and the metadata required for the adapter to convert it to an IDoc structure for the RFC call.

Dummy keys are not used in WebSphere Message Broker.

Unparsed IDocs

For an unparsed IDoc, in which the data part of the IDoc is not parsed by the adapter, the IDoc business object contains a dummy key, a control record, and the IDoc data. The IDoc data is of hexBinary type and represents the whole data record containing segments in binary content.

Use the SAPRequest node to send requests to an SAP application.

Transaction ID support:

An SAP transaction ID (TID) is contained in the ALE wrapper business object and is therefore available as a field in the message tree. You can use transaction ID support to ensure once-only delivery of ALE objects.

The most common reason for using transaction ID support is to ensure once and only once delivery of data. The SAP transaction ID property is always generated by the Adapter Connection wizard.

The message flow must determine how to store the SAP transaction ID and how to relate the SAP transaction ID to the data being sent to the adapter. When the events are successful, the message flow should not resubmit the event associated with this TID again to prevent the processing of duplicate events.

- If the message flow does not send an SAP transaction ID with the business object, the adapter returns one after executing the transaction.
- If the message flow has an SAP transaction ID, it needs to populate the SAP transaction ID property with that value before executing the transaction.

The SAP transaction ID can be used for cross-referencing with a global unique ID that is created for an outbound event. The global unique ID is something you can create for managing integration scenarios.

Query interface for SAP Software:

The Query interface for SAP Software (QISS) provides you with the means to retrieve data from application tables on an SAP server or to query SAP application tables for the existence of data. The adapter can perform hierarchical data retrieval from the SAP application tables.

Query interface for SAP Software supports outbound interactions for read operations (RetrieveAll and Exists) only. You can use this interface in local transactions to look up records before write operations (Create, Update, or Delete). For example, you can use the interface as part of a local transaction to do an existence check on a customer before creating a sales order. You can also use the interface in non-transaction scenarios.

Query interface for SAP Software supports data retrieval from SAP application tables, including hierarchical data retrieval from multiple tables. The interface supports static as well as dynamic specification of `where` clauses for the queries.

The Adapter Connection wizard finds the application data tables in SAP, interprets the hierarchical relationship between tables, and constructs a representation of the tables and their relationship in the form of a business object. The wizard also builds a default `where` clause for the query.

You can control the depth of the data retrieval, as well as the amount of information, by using the maxRow and rowsSkip properties.

Query interface for SAP software (QISS) supports hierarchical data retrieval from the SAP application tables. By using this interface, the adapter can determine the

existence of data in SAP application tables, or retrieve all the data in SAP application tables. For example, to check if customer Bob exists in SAP system, the Adapter Connection wizard can be run to discover the SAP application table KNA1. The wizard then generates the business object for KNA1 along with other SCA service artifacts. At run time, the SAPRequest node passes the KNA1 business object to the adapter to call the QISS interface, the adapter retrieves the table data from SAP, and returns the result to the node.

Outbound processing for the query interface for SAP Software:

You use the Query interface for SAP Software for outbound processing only.

The message flow that makes the request uses the interface information that was generated by the Adapter Connection wizard.

The following list describes the sequence of processing actions that result from an outbound request that uses the query interface for SAP Software.

1. The adapter receives a request, which includes a table object, from a message flow.

   The query business object can be in a container business object, or it can be received as a table business object.
2. The adapter determines, from the table object sent with the query, the name of the table to examine.
3. The adapter determines the columns to retrieve or examine.
4. The adapter determines the rows to retrieve or examine.
5. The adapter responds.
   - For a RetreiveAll operation, the adapter returns a result set in the form of a container of query business objects, which represent the data for each row retrieved from the table. If the query is received as a table business object (not inside a container), the rows are returned one at a time, as they are retrieved.
   - For the Exists operation, the adapter returns an indication of whether the data exists in the SAP table.
   - If no data exists, the adapter generates an exception.

Business objects for the query interface for SAP Software:

A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The input to the Query interface for SAP Software is a table business object. The table business object represents the columns in a table on the SAP server. The adapter uses the table business object to obtain data from tables on the SAP server.

How data is represented in business objects

The adapter uses metadata that is generated by the Adapter Connection wizard to construct a business-object definition.

The data in the business object represents the columns of the associated table in SAP.

How business objects are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

Business object structure

The table business object can be part of a container.

The table business object contains columns selected from the specified SAP table.

In addition to column information, the table business object also contains a query business object as the last parameter.

The properties of the query business object are sapWhereClause, sapRowsSkip, and sapMaxRows:

- The sapWhereClause property retrieves information from SAP tables. The default value is populated by the Adapter Connection wizard. The space character is used as the delimiter to parse the sapWhereClause.
- The sapMaxRows property is the maximum number of rows to be returned. The default value is `100`.
- The sapRowsSkip property is the number of rows to skip before retrieving data. The default value is `0`.

The tables can be modeled as hierarchical business objects. You specify the parent-child relationship of the tables in the Adapter Connection wizard.

Tables are linked by a foreign key to form parent-child relationships. The child table business object has a foreign key that references a property in the parent query business object.

In the KNA1 business object, notice the reference to SapAdrc, a child business object. The SapAdrc table object has a column named AddressNumber. This column has an associated property (ForeignKey) that contains a reference to the parent business object.

The return from the Query interface for SAP Software call for a RetrieveAll operation is a container of table objects.

The Advanced event processing interface:

The Advanced event processing interface of the WebSphere Adapter for SAP Software is used for both inbound and outbound processing.

For inbound processing, it polls for events in SAP, converts them into business objects, and sends the event data as business objects to WebSphere Message Broker.

For outbound processing, the adapter processes events sent from an application to retrieve data from or update data in the SAP server.

Outbound processing for the AEP interface:

During outbound processing, business object data is converted into an ABAP handler function, which is called on the SAP server. When the data is returned by the ABAP handler function, the data is converted to a business object, and the business object is returned as a response.

The following list describes the sequence of processing actions that result from an outbound request that uses the Advanced event processing interface.

1. The adapter receives the Advanced event processing record, which contains business data along with the metadata.
2. The Advanced event processing interface of the adapter uses the metadata of the business object to obtain the type of IDoc specified and to reformat the business object data into the structure of that IDoc.
3. After it reformats the data, the adapter passes the business object data to an object-specific ABAP handler (based on the operation), which handles the integration with an SAP native API.

4. After the object-specific ABAP handler finishes processing the business object data, it returns the response data in IDoc format to the adapter, which converts it to the business object.
5. The adapter returns the results to the caller.

For more information, see the following topics.

ABAP handler overview:

An ABAP handler is a function module that gets data into and out of the SAP application database. For each business object definition that you develop, you must support it by developing a custom ABAP handler.

ABAP handlers are in the SAP application as ABAP function modules. ABAP handlers are responsible for adding business-object data into the SAP application database (for Create, Update, and Delete operations) or for using the business-object data as the keys to retrieving data from the SAP application database (for the Retrieve operation).

You must develop operation-specific ABAP handlers for each hierarchical business object that must be supported. If you change the business object definition, you must also change the ABAP handler.

An ABAP handler can use any of the SAP native APIs for handling the data. The following list contains some of the native APIs.

- Call Transaction

  Call Transaction is the SAP-provided mechanism for entering data into an SAP system. Call Transaction guarantees that the data adheres to the SAP data model by using the same screens an online user sees in a transaction. This process is commonly referred to as *screen scraping*.
- Batch data communication (BDC)

  Batch Data Communication (BDC) is an instruction set that SAP can follow to process a transaction without user intervention. The instructions specify the sequence in which the screens in a transaction are processed and which fields are populated with data on which screens. All of the elements of an SAP transaction that are exposed to an online user have identifications that can be used in a BDC.
- ABAP SQL

  ABAP SQL is the SAP proprietary version of SQL. It is database-independent and platform-independent, so that whatever SQL code you write, you can run it on any database and platform combination that SAP supports. ABAP SQL is similar in syntax to other versions of SQL and supports all of the basic database table commands such as update, insert, modify, select, and delete. For a complete description of ABAP SQL, see your SAP documentation.

  By using ABAP SQL, an ABAP handler can modify SAP database tables with business-object data for create, update, and delete operations. It can also use the business-object data in the where clause of an ABAP select statement as the keys.

  Do not use ABAP SQL to modify SAP tables, because it might corrupt the integrity of the database. Use ABAP SQL only to retrieve data.
- ABAP Function Modules and Subroutines

  From the ABAP handler, you can call ABAP function modules or subroutines that implement the required function.

The adapter provides the following tools to help in the development process:

- The adapter includes the Call Transaction Recorder wizard to assist you in developing the ABAP handlers that use call transactions or BDC sessions.
- The Adapter Connection wizard generates the required business objects and other resources for Advanced event processing. The business objects are based on IDocs, which can be custom or standard.
- The adapter provides samples that you can refer to for an understanding of the Advanced event processing implementation.

ABAP handler creation:

For each IDoc object definition that you develop, you must support it by developing a custom ABAP handler.

You can use either standard IDocs or custom IDocs for the Advanced event processing interface. After defining the custom IDoc for an integration scenario, create an ABAP handler (function module) for each operation of the business object that must be supported.

Each function should have the following interface to ensure that adapter can call it:

```
*" IMPORTING
*" VALUE(OBJECT_KEY_IN) LIKE /CWLD/LOG_HEADER-OBJ_KEY OPTIONAL
*" VALUE(INPUT_METHOD) LIKE BDWFAP_PAR-INPUTMETHD OPTIONAL
*" VALUE(LOG_NUMBER) LIKE /CWLD/LOG_HEADER-LOG_NR OPTIONAL
*" EXPORTING
*" VALUE(OBJECT_KEY_OUT) LIKE /CWLD/LOG_HEADER-OBJ_KEY
*" VALUE(RETURN_CODE) LIKE /CWLD/RFCRC_STRU-RFCRC
*" VALUE(RETURN_TEXT) LIKE /CWLD/LOG_HEADER-OBJ_KEY
*" TABLES
*" IDOC_DATA STRUCTURE EDID4
*" LOG_INFO STRUCTURE /CWLD/EVENT_INFO
```

The following table provides information about the parameters:

Table 15. Interface parameters

Parameter	Description
OBJECT_KEY_IN	Should be no value.
INPUT_METHOD	Indicates whether the IDoc should be processed in a dialog (that is, through Call Transaction). Possible values are: " " - Background (no dialog) "A" - Show all screens "E" - Start the dialog on the screen where the error occurred "N" Default
LOG_NUMBER	Log Number.
OBJECT_KEY_OUT	Customer ID returned from the calling transaction.
RETURN_CODE	0 - Successful. 1 - Failed to retrieve. 2 - Failed to create, update, or delete.
RETURN_TEXT	Message describing the return code.
IDOC_DATA	Table containing one entry for each IDoc data segment. The following fields are relevant to the inbound function module: Docnum - The IDoc number. Segnam - The segment name. Sdata - The segment data.

Table 15. Interface parameters (continued)

Parameter	Description
LOG_INFO	Table containing details regarding events processed with either a success or error message.

Call Transaction Recorder wizard:

The adapter provides the Call Transaction Recorder wizard to assist you in developing the ABAP handlers that use call transactions or BDC sessions.

The Call Transaction Recorder wizard enables you to generate sample code for call transactions to facilitate development. It generates sample code stubs for each screen that is modified during the recording phase.

To access this wizard, enter the /CWLD/HOME transaction in the SAP GUI.

The following example is sample code that is generated by the wizard. You can adopt this code in the ABAP Handler.

```
* Customer master: request screen chnge/displ cent.
perform dynpro_new using 'SAPMF02D' '0101' .

* Customer account number
perform dynpro_set using 'RF02D-KUNNR' '1' .

* Function Command
perform dynpro_set using 'BDC_OKCODE' '/00' .

* Function Command
perform dynpro_set using 'BDC_OKCODE' '/00' .

* Customer master: General data, CAM address, communication
perform dynpro_new using 'SAPMF02D' '0111' .

* Title
perform dynpro_set using 'SZA1_D0100-TITLE_MEDI' 'Mr.' .

* Function Command
perform dynpro_set using 'BDC_OKCODE' '=UPDA' .

* Call Transaction
Call Transaction 'XD02' using bdcdata
    mode input_mode
   update 'S'
  messages into bdc_messages.
```

The wizard does not generate the required business object. You use the Adapter Connection wizard to generate the business object.

Inbound processing for the AEP interface:

The adapter uses the Advanced event processing interface to poll for events on the SAP server, to process the events, and to send them to an endpoint.

The following list describes the sequence of processing actions that result from an inbound request that uses the Advanced event processing interface.

1. A triggered event enters the event table with an initial status of prequeued.
2. When the adapter polls for events, the status of the event changes from prequeued to queued if there are no database locks for the combination of the user who created the event and the event key.
3. After the event is retrieved from the event table, the status of the event is updated to InProgress.

   If locks exist, the status of the event is set to locked and the event is requeued into the queue. Every event with a prequeued or locked status is updated with every poll. You can configure the polling frequency by using the Poll Frequency property.
4. After preprocessing all prequeued events, the adapter selects the events.

   The property Poll Quantity determines the maximum number of events returned for a single poll call.
5. For each event, the adapter uses the remote function specified for the Retrieve operation to retrieve the data and send it to the endpoint.

If the AssuredOnceDelivery property is set to true, an XID value is set for each event in the event store. After each event is picked up for processing, the XID value for that event is updated in the event table.

If, before the event is delivered to the endpoint, the SAP connection is lost or the application is stopped, and the event is consequently not processed completely, the XID column ensures that the event is reprocessed and sent to the endpoint. After the SAP connection is reestablished or the adapter starts up again, it first checks for events in the event table that have a value in the XID column. It then processes these events first and then polls the other events during the poll cycles.

6. After each event is processed, it is updated or archived in the SAP application.

   When the event is processed successfully, it is archived and then deleted from the event table.

   The adapter can also filter the events to be processed by business object type. The filter is set in the Event Filter Type property. This property has a comma-delimited list of business object types, and only the types specified in the property are picked for processing. If no value is specified for the property, no filter is applied and all the events are picked up for processing.

Event detection:

Event detection refers to the collection of processes that notify the adapter of SAP application object events. Notification includes, but is not limited to, the type of the event (object and operation) and the data key required for the external system to retrieve the associated data.

Event detection is the process of identifying that an event was generated in the SAP application. Typically, adapters use database triggers to detect an event. However, because the SAP application is tightly integrated with the SAP database, SAP allows very limited access for direct modifications to its database. Therefore, the event-detection mechanisms are implemented in the application transaction layer above the database.

Adapter-supported event detection mechanisms

The four event-detection mechanisms that are supported by the adapter are described in the following list:

- Custom Triggers, which are implemented for a business process (normally a single SAP transaction) by inserting event detection code at an appropriate point in the SAP transaction
- Batch programs, which involve developing an ABAP program containing the criteria for detecting an event
- Business workflows, which use the object-oriented event detection capabilities of SAP
- Change pointers, a variation of business workflows, which use the concept of change documents to detect changes for a business process

All these event-detection mechanisms support real-time triggering and retrieval of objects. In addition, custom triggers and batch programs provide the ability to delay the retrieval of events. An event whose retrieval is delayed is called a future event.

Each event detection mechanism has advantages and disadvantages that need to be considered when designing and developing a business object trigger. Keep in mind that these are only a few examples of event detection mechanisms. There are many different ways to detect events.

After you determine the business process to support (for example, sales quotes or sales orders) and determine the preferred event-detection mechanism, implement the mechanism for your business process.

When implementing an event detection mechanism, it is a good idea to support all of the functions for a business process in one mechanism. This limits the effect in the SAP application and makes event detection easier to manage.

Event table

Events that are detected are stored in an SAP application table. This event table is delivered as part of the ABAP component. The event table structure is as follows.

Table 16. Event table fields

Name	Type	Description
event_id	NUMBER	Unique event ID that is a primary key for the table.
object_name	STRING	Business object name.
object_key	STRING	Delimited string that contains the keys for the business object.
object_function	STRING	Operation corresponding to the event (Delete, Create, or Update).
event_priority	NUMBER	Any positive integer to denote the priority of the event.
event_time	DATE	Date and time when the event was generated.
event_status	NUMBER	Event processing status. Possible values are: 0 - Ready for poll 1 - Event delivered 2 - Event prequeued 3 - Event in progress 4 - Event locked -1 - Event failed
Xid	STRING	Unique XID (transaction ID) value for assured-once delivery.
event_user	STRING	User who created the event.
event_comment	STRING	Description of the event.

Event triggers:

After an event is identified by one of the event-detection mechanisms, it is triggered by one of the adapter-delivered event triggers. Event triggers can cause events to be processed immediately or in the future.

The function modules that trigger events are described in the following list.

- /CWLD/ADD_TO_QUEUE

  This function module triggers events to the current event table for immediate processing.
- /CWLD/ADD_TO_QUEUE_IN_FUTURE

  This function module triggers events to the future event table to be processed at a later time.

Both functions are for real-time triggering.

Current event table

If the event will be triggered in real-time, /CWLD/ADD_TO_QUEUE_AEP commits the event to the current event table (/CWLD/EVT_CUR_AEP).

Specifically, it adds a row of data for the object name, verb, and key that represents the event.

Future event table

If an event needs to be processed at a future date, the processing that is described in the following list occurs.

1. A custom ABAP handler calls /CWLD/ADD_TO_QUEUE_IN_FUTURE_AEP with the event.
2. The /CWLD/ADD_TO_QUEUE_IN_FUTURE_AEP module commits the event to the future event table (/CWLD/EVT_FUT_AEP). Specifically, it adds a row of data for the object name, verb, and key that represents the event. In addition, it adds a Date row
3. The adapter-delivered batch program /CWLD/SUBMIT_FUTURE_EVENTS_AEP reads the future event table.
4. If scheduled to do so, the batch program retrieves events from the future event table.
5. After it retrieves an event, the batch program calls /CWLD/ADD_TO_QUEUE_AEP.
6. The /CWLD/ADD_TO_QUEUE_AEP module triggers the event to the current event table.

/CWLD/ADD_TO_QUEUE_IN_FUTURE_AEP uses the system date as the current date when it populates the Date row of the future event table.

Business objects for the Advanced Event Processing (AEP) interface:

During advanced event processing, the adapter exchanges business objects with the SAP application.

How data is represented in business objects

Advanced event processing business objects are based on custom IDocs, standard IDocs, or extension IDocs available in the SAP system.

How business-object definitions are created

You create business-object definitions by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business-object definitions to represent them. It also generates other resources that are needed by the adapter, such as the interface information that indicates the input and output parameters.

For custom interfaces that you want to support, you must first define the custom IDoc in the SAP system. You can then use the Adapter Connection wizard to discover this custom IDoc and build the required resources, including the business-object definition.

Overview of WebSphere Adapter for Siebel Business Applications:

With WebSphere Adapter for Siebel Business Applications, you can create integrated processes that exchange information with a Siebel application, without special coding.

Use the WebSphere Adapter for Siebel Business Applications to create integrated processes that exchange information with a Siebel application. With the adapter, an application can send requests to the Siebel Business Applications server or receive notifications of changes from the server.

The adapter creates a standard interface to the applications and data on the Siebel Business Applications server, so that the application developer does not need to understand the lower-level details (the implementation of the application or the data structures) on the Siebel Business Applications server. An application, for example, can send a request to the Siebel Business Applications server, to query or update an Account record, represented by a Siebel business component instance. It can also receive events from the server; for example, to be notified that a customer record has been updated. This behavior provides you with improved business workflow and processes to help manage your customer relations.

WebSphere Adapter for Siebel Business Applications complies with the Java Connector Architecture (JCA). JCA standardizes the way application components, application servers, and Siebel applications, such as Siebel Business Applications server, interact with each other.

The adapter configuration, which you generate with the Adapter Connection wizard, uses a standard interface and standard data objects. The adapter takes the standard data object sent by the application component and calls the Siebel Business Applications function. The adapter then returns a standard data object to the application component. The application component does not have to deal directly with the Siebel Business Applications function; it is the Siebel Business Applications adapter that calls the function and returns the results.

For example, the application component that needs the list of customers sends a standard business object with the range of customer IDs to Adapter for Siebel Business Applications. In return, the application component receives the results (the list of customers) in the form of a standard business object. The application component does not need to know how the function worked or how the data was structured. The adapter completes all the interactions with the Siebel Business Applications function.

Similarly, the message flow might want to know about a change to the data on the Siebel Business Applications server (for example, a change to a particular customer). You can generate an adapter component that polls for such events on the Siebel Business Applications server and notifies message flows of the update. In this case, the interaction begins at the Siebel Business Applications server.

Technical overview of the Adapter for Siebel Business Applications:

WebSphere Adapter for Siebel Business Applications supports the exchange of information between your existing applications and Siebel Business Applications. The adapter supports Siebel entities, including business objects, business components, and business services. This enables you to create business processes that exchange data.

The adapter supports outbound processing (requests for data or services from an application to the Siebel application) and inbound processing (event notification from a Siebel application server to an application).

With Adapter for Siebel Business Applications, you can use existing or newly-created applications that run in a supported runtime environment to send requests for data and services to Siebel Business Applications.

You can also add event-generation triggers to Siebel business objects to have notifications of events, such as the creation, update, and deletion of a record, sent to one or more of your applications.

For more information, see the following topics.

Outbound processing for Siebel Business Applications:

WebSphere Adapter for Siebel Business Applications supports synchronous outbound processing. This means that when the component sends a request in the form of a WebSphere business object hierarchy to the adapter, the adapter processes the request and returns a WebSphere business object hierarchy that represents the result of the operation.

When the adapter receives a WebSphere business object hierarchy, the adapter processes it as follows:

1. The adapter extracts metadata from the WebSphere business object hierarchy.
2. It identifies the appropriate Siebel objects to access (for example, Siebel business objects and business components, or Siebel business services, integrations objects, and integration components) depending on the objects against which the artifacts were generated.
3. The adapter extracts the outbound operation to perform from the WebSphere business object hierarchy.
4. After accessing the required Siebel objects, the adapter retrieves, updates, deletes, or creates a Siebel business component hierarchy or performs the corresponding business service method on the integration component hierarchy.
5. If there are updates (Create, Update, Delete), the adapter populates that Siebel object (business or integration component hierarchy) with data from the hierarchy of WebSphere business objects.

Supported Outbound Operations

WebSphere Adapter for Siebel Business Applications supports the outbound operations shown in the following table.

Table 17. Supported outbound operations

Operation	Description
Create	Creates the business component.
Delete	Deletes the business component and its children.
Exists	Checks for the existence of incoming business objects. The output business object, "ExistsResult" will be returned with the boolean value populated.
Retrieve	Specifies the value of the business component.
RetrieveAll	Retrieves multiple instances of the same business component and populates it as the container object.

Table 17. Supported outbound operations (continued)

Operation	Description
Update	Updates the Siebel application with the incoming business object.

Inbound processing for Siebel Business Applications:

WebSphere Adapter for Siebel Business Applications supports asynchronous inbound processing, which means that the adapter polls the Siebel Business Applications at specified intervals for events. When the adapter detects an event, it converts the event data into a business object and sends it to the component.

Before inbound processing can occur, a Siebel event business component must be created in the Siebel application (IBM2 for Siebel version 7.x and IBM_EVENT for Siebel version 8) and its name specified against the corresponding property in the adapter activation specification.

When the adapter detects an event for Siebel event business components or integration components, it processes the event by retrieving the updated data for the Siebel event business component or integration component and converting it into a business object. The adapter then sends the business object to the event business component. For example, if an event business component (an account) is updated, an event trigger adds an event record to the event business component. The adapter polls the event business component, retrieves the event record, and processes it.

When the adapter finds an event for a Siebel event business component, it processes the event in the following way:

1. The adapter retrieves the event information from the Siebel event business component.
2. The adapter retrieves the corresponding event business component instance hierarchy.
3. The adapter populates the associated WebSphere business object or business graph (if it was generated) with the values that it retrieves from the event business component.
4. The adapter sends a notification to each registered application.

If an inbound event in the event table fails or is invalid, the event status is updated to -1, which indicates an error in processing the event, and a resource exception message is issued that explains the reason for the error.

Event store for Siebel Business Applications:

The event store is a persistent cache where event records are saved until the polling adapter can process them. To keep track of inbound events as they make their way through the system, the adapter uses an event store.

The creation, update, or deletion of an event record in the Siebel business application is an 'event'. Each time a business object is created, updated, or deleted, the adapter updates the status of the event in an event store.

For example, if you have a customer component and a new customer has just been added to it, this signals an update. If the adapter is configured to receive the events about the new update, there are triggers attached to the Siebel end and connected to the customer component. The triggers add a record to the event business component. The record contains information about the new customer, such as the customer ID. This information is stored in the object key. The object key is the unique identifier that provides the key name and value of the event business component that was updated (for example, `Id=1-20RT`). The object name is the WebSphere business-object name that represents the customer component (for example, `Account`). The adapter retrieves this event and the new customer information that relates to it. It then processes the event and delivers it to the export component.

During inbound processing, the adapter polls the event business components from the event store at regular intervals. Each time it polls, a number of events are processed by the adapter. Events are processed in ascending order of priority and ascending order of the event time stamp. In each poll cycle, new events are picked up. The adapter retrieves the value set in the object key field for the event and loads the business object that corresponds to it. The business object is created from the retrieved information and is delivered to the export components.

If you set the activation specification property AssuredOnceDelivery to `true`, a transaction ID (XID) value is set for each event in the event store. After the event is retrieved for processing, the XID value for it is updated in the event store and displayed in the XID column in the event business component. The event is then delivered to its corresponding export component, and the status is updated to show that the event has been successfully delivered. If the application is stopped or the event is not processed completely, the XID column is filled with a value. This ensures that the event is reprocessed and sent to the export component. After the connection is reestablished or the adapter starts again, the adapter checks for events in the event store that have a value in the XID column. The adapter processes these events first, then polls the other events during the poll cycles.

The adapter can either process all events or process events filtered by business-object type. You set the filter through the activation specification property, EventTypeFilter. This property contains a comma-delimited list of business-object types. Only the types specified in the property are processed. If the EventTypeFilter property is not set, all of the events are processed. If the FilterFutureEvents property is set to `true`, the adapter filters events based on the time stamp. The adapter compares the system time in each poll cycle to the time stamp on each event. If an event is set to occur in the future, it is not processed until that time.

After an event is successfully posted and delivered to the export component, the entry is deleted from the event store. Failed events (posting and delivery to the export component is unsuccessful), remain in the event store and are marked `-1`. This prevents duplicate processing.

Event store structure for Siebel business objects and business components

The `IBM2` event business component stores information about the event. The information stored is used by the resource adapter during event subscription to build the corresponding business object and send it to the registered export components. The information that is stored, and the structure of the event store used by the adapter, are shown in the following table.

Table 18. Event store structure for `IBM2` Siebel event business objects and business components

Field	Description	Example
Description	Any comment associated with the event.	Account Create Event
Event ID	The ID of the event row.	Automatically generated unique ID in Siebel (for example: `1-XYZ`)
Event timestamp	The time stamp for the event. The format is in *mm/dd/yyyy hh:mm:ss*	*02/24/2007 11:37:56*
Event type	The type of event.	Create, Update, or Delete
Object key	A unique identifier of the business-object row for which the event was created. It is a name-value pair consisting of the name of the property (key name) and value.	ID=1-20RT
Object name	The name of the business object for which the event was detected.	`IOAccountPRMANIICAccount`
Priority	The event priority.	1
Status	The event status. This is initially set to the value for a new event and updated by the adapter as it processes the event. The status can have one of the following values: • 0: Identifies a new event. • 1: Identifies an event that has been delivered to an export component. • -1: An error occurred while processing the event. This column cannot contain a null value.	0

Table 18. Event store structure for IBM2 Siebel event business objects and business components (continued)

Field	Description	Example
XID	The transaction ID. This is to ensure assured once-only delivery.	None

Event store structure for Siebel business services

The event is retrieved from the IBM2 event business component and the information is used to retrieve the event business component.

Table 19. Event store structure for IBM2 Siebel business services

Field	Description	Example
Description	Any comment associated with the event.	Account PRM ANI Event
Event ID	The ID of the event row.	Automatically generated unique ID in Siebel (for example: 1-XYZ)
Event timestamp	The time stamp for the event. The format is in *mm/dd/yyyy hh:mm:ss*	*02/24/2007 11:37:56*
Event type	The type of event.	Create, Update, or Delete
Object key	A unique identifier of the business-object row for which the event was created. It is a name value pair consisting of the name of the property (key name) and value.	Name=TestName;Location=BGM, where 'Name' and 'Location' are the keys in the integration component. 'TestName' and 'BGM' are the values specified, and ; is the event key delimiter.
Object name	The name of the business object for which the event was detected.	IOAccountPRMANIICAccount
Priority	The event priority.	1
Status	The event status. This is initially set to the value for a new event and updated by the adapter as it processes the event. The status can have one of the following values: • 0: Identifies a new event. • 1: Identifies an event that has been delivered to an export component. • -1: An error occurred while processing the event. This column cannot contain a null value.	0
XID	The transaction ID. This is to ensure 'assured once delivery'.	None

Business objects for Siebel Business Applications:

To send data or obtain data from Siebel Business Applications, the adapter uses business objects. A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The data can represent either a business entity, such as an invoice or an employee record, or unstructured text.

How business objects are created

You create business objects by using the Adapter Connection wizard, which connects to the application, discovers data structures in the application, and generates business objects to represent them. It also generates other resources that are needed by the adapter.

The Siebel business objects are created with long names by default. To generate business objects with shorter names, select **Generate business objects with shorter names** on the Configure Objects screen of the Adapter Connection wizard. For more information, see "Naming conventions for business objects representing Siebel business services" on page 4095.

Business object structure

The adapter supports business objects that are hierarchically structured. The top-level business object must have a one-to-one correspondence with the Siebel business component, and collections that occur in the top-level object are children of it. Information about the processed object is stored in the application-specific information for the object and each of its attributes.

Adapter Connection wizard (Siebel):

The Adapter Connection wizard is a tool that you use to configure your adapter. The wizard establishes a connection to the Siebel server, discovers business objects and services (based on search criteria you provide), and generates business objects based on the services discovered.

By using the Adapter Connection wizard, you establish a connection to the Siebel server to browse the metadata repository on the Siebel server. You also specify connection information, such as the Connection URL, user name, and password needed to access the server.

The result of running the wizard is a message set project that contains the Siebel business objects and services along with the adapter.

Overview of WebSphere Adapter for PeopleSoft Enterprise:

With the adapter for PeopleSoft Enterprise you can create integrated processes that exchange information with PeopleSoft Enterprise through a standard interface. This interface shields the message flow developer from having to understand the lower level details about implementation of the application or data structures used on the PeopleSoft Enterprise server.

With the adapter, a message flow can send a request, for example to a PeopleSoft Enterprise database to query a record in an HR table, or it can receive events from the server, such as notification that an employee record has been updated.

WebSphere Adapter for PeopleSoft Enterprise complies with the Java Connector Architecture (JCA), which standardizes the way application components, application servers, and enterprise information systems, such as a PeopleSoft Enterprise server, interact with each other.

The adapter component, which you generate with the Adapter Connection wizard uses a standard interface and standard data objects. The adapter component takes the standard data object sent by the message flow and calls the PeopleSoft function. It then returns a standard data object to the message flow. The message flow does not have to deal directly with the PeopleSoft function; it is the adapter component that calls the function and returns the results.

For example, the message flow that requested the list of employees sends a standard business object with the range of skill codes to the PeopleSoft adapter component. The message flow receives, in return, the results (the list of employees) in the form of a standard business object. The adapter component completes all the interactions directly with the PeopleSoft function.

Similarly, the message flow might need to be notified about a change to the data on the PeopleSoft Enterprise server (for example, a change to the skills set of a particular employee). You can generate an adapter component that listens for such events on the PeopleSoft Enterprise server and notifies message flows with the update. In this case, the interaction begins at the PeopleSoft Enterprise server.

For more information, see “Technical overview of the WebSphere Adapter for PeopleSoft Enterprise” on page 2015.

Technical overview of the WebSphere Adapter for PeopleSoft Enterprise:

The adapter supports the exchange of business data between the PeopleSoft Enterprise server and WebSphere Message Broker. It does so by connecting to two layers of PeopleTools application programming interface classes that reveal the underlying business data for integration.

The Adapter for PeopleSoft Enterprise establishes bidirectional connectivity with the PeopleSoft Enterprise server by connecting to two PeopleTools application programming interfaces as follows:

1. The adapter accesses the primary API layer to create a session instance and to connect to the application server through the Jolt port.
2. The adapter then accesses the PeopleSoft Component Interface API, which reveals underlying business objects, logic, and functions.

In PeopleSoft, a component is a set of pages grouped together for a business purpose (such as an employee profile), and a component interface is an API that provides synchronous access to a component from an external application. After the adapter connects to the component interface, the following entities are exposed to the adapter and available for integration:

- All business objects in the component interface definition
- PeopleCode methods associated with the underlying components
- Records, except searches and menu-specific processing options

Outbound processing for PeopleSoft Enterprise:

The Adapter for PeopleSoft Enterprise supports synchronous outbound request processing. Synchronous outbound processing means that when the message flow sends a request in the form of a business object to the adapter, the adapter processes the request and returns a business object representing the result of the operation to the message flow.

When the adapter receives a WebSphere business object hierarchy, adapter processes it as follows:

1. The adapter extracts metadata from the WebSphere business object hierarchy that identifies the appropriate PeopleSoft component interface to access.
2. The adapter extracts the outbound operation to perform from the WebSphere business object hierarchy.
3. After the adapter accesses the component interface, it sets the keys from values specified in the business objects. If key values are not generated, for example with a create operation, the PeopleSoft application generates key fields.
4. After it retrieves the PeopleSoft objects, the adapter instantiates an existing component interface to delete, retrieve, update, or create a component interface.

5. If there are updates (Create, Update), the adapter populates the component interface with data from the WebSphere business object hierarchy. If there are Deletes, the adapter populates the component interface only with StatusColumnName and value information.

For Create and Update operations, the adapter processes attributes in the order defined in the business object. For example, if there is a complex attribute between two simple attributes, the adapter processes the simple attribute at the first position, the complex attribute followed by the simple attribute. After the changes are made, the component interface is saved to commit the data to the PeopleSoft database.

Supported outbound operations

WebSphere Adapter for PeopleSoft Enterprise supports the following outbound operations:

Table 20. Supported outbound operations

Operation	Description
Create	Creates the business object.
Delete	Deletes the business object and its children. Because the adapter supports only logical deletes, objects are marked as deleted but not removed.
Exists	Checks for the existence of incoming business objects.
Retrieve	Retrieves the PeopleSoft component, and maps component data onto the business object hierarchy.
RetrieveAll	Retrieves multiple instances of the PeopleSoft component, and maps component data onto the business object hierarchy.
Update	Updates the corresponding PeopleSoft component with the incoming business object.

Inbound processing for PeopleSoft Enterprise:

The WebSphere Adapter for PeopleSoft Enterprise supports inbound event processing.

Inbound event processing means that the adapter polls the PeopleSoft Enterprise server at specified intervals for events. When the adapter detects an event, it converts the event data into a business object and sends it to the message flow.

To use inbound event processing, you must create a custom event project in PeopleSoft, as described in "Creating a custom event project in PeopleTools" on page 2083.

For more information, see "Event store for PeopleSoft Enterprise" on page 2019.

Event store for PeopleSoft Enterprise:

The event store is a table that holds events that represent data changes until the polling adapter can process them. The adapter uses the event store to keep track of event entities.

To use inbound processing, you must use PeopleTools Application Designer to create a custom project for event notification. The custom project uses two PeopleCode functions that determine the way future events are processed, and the custom project creates the event store the adapter needs for inbound processing. Each time a business object is created, updated, or deleted, the PeopleCode function used in the project and then added to the component interface inserts a new record in the event store, with the appropriate object name, keys, and status value.

With inbound processing, the adapter polls the event entities from the event store at configured poll intervals. In each poll call, a configured number of events are processed by the adapter. The order of event processing is based on the ascending order of priority and the ascending order of the event time stamp. The events with the status, Ready for poll (0), are picked up for polling in each poll cycle. The adapter uses the object name and object key to retrieve the corresponding business object.

If you set the activation specification property AssuredOnceDelivery to `true`, an XID (transaction ID) value is set for each event in the event store, and it is used to ensure that an event is delivered only once to the target application. After an event is obtained for processing, the XID value for that event is updated in the event store. The event is then delivered to its corresponding export component, and its status is updated to show that event delivery has been completed. If the application is stopped before the event can be delivered to the export component

or if delivery has failed, the event might not be processed completely. In this case, the XID value represents in-progress status, and the XID column ensures that the event is reprocessed and sent to the export component. Once the database connection is re-established or the adapter starts again, the adapter checks for events in the event table that have a value in the XID column of Ready for Poll (0). The adapter processes these events first, and then polls the other events during the poll cycles.

The adapter uses special processing for events that have status code (99), which indicates that they will occur in the future. During a poll cycle, when the adapter retrieves events with a future status, the adapter compares the system time with the time stamp on each event. If the event time is earlier than or equal to the system time, the adapter processes the event and changes the event status to Ready for Poll (0).

If you want to the adapter to process future status events in the present time, use the function `IBM_PUBLISH_EVENT` instead of `IBM_FUTURE_PUBLISH_EVENT`. Doing so means that the event is identified as Ready to Poll (0) instead of Future (99).

As events are retrieved and processed from the event store, the status of the event changes to reflect the cycle, as shown in the following table:

Table 21. Event status values

Status short name	Description	Event table value
Error processing event	An error occurred during event processing.	-1
Ready for poll	The event has not yet been picked up by the adapter. The event is ready to be picked up.	0
Success	The event has been delivered to the event manager.	1
Deleted	The event has been processed successfully and is removed from the event store.	4
Future Events	These events should be processed at a future date.	99

Business objects for PeopleSoft Enterprise:

To send data or obtain data from PeopleSoft Enterprise, the adapter uses business objects. A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The data can represent either a business entity, such as an invoice or an employee record, or unstructured text.

How business objects are created

You create business objects by using the Adapter Connection wizard. The wizard connects to the application, discovers data structures in the application, and generates business objects to represent them. It also generates other resources that are needed by the adapter.

Business object structure

The adapter supports business objects that are hierarchically structured. The top-level business object must have a one-to-one correspondence with the PeopleSoft component interface, and collections that occur in the top-level object are children of it. Information about the processed object is stored in the application-specific information for the object and each of its attributes.

The following table describes the attributes that form a business object.

Attribute property	Description
Name	Indicates the name of the business object attribute.
Type	Indicates the type of the Business Object attribute. The adapter uses character mapping between PeopleSoft component property types and the generated business object attribute types. PeopleSoft component property types map to generated attribute types in the following manner: CHAR maps to attribute type String NUMBER maps to attribute type BigDecimal LONG maps to attribute type Long SIGN maps to attribute type BigDecimal DATE maps to attribute type Date TIME maps to attribute type Time DTTM maps to attribute type DateTime
Key	Child business objects have their own keys that have the primary key application-specific information. They also inherit keys from their parent business object.
Cardinality	Single cardinality for simple attributes; multiple cardinality for container attributes.

Overview of WebSphere Adapter for JD Edwards EnterpriseOne:

With the WebSphere Adapter for JD Edwards EnterpriseOne, you can create integrated processes that include the exchange of information with a JD Edwards EnterpriseOne server, without special coding.

The adapter provides a standard interface that eliminates the need for the component to understand the lower-level implementation details or data structures of the application. By using the adapter, a component (the program or piece of code that performs a specific business function) can send requests to the JD Edwards EnterpriseOne server (for example, to query a customer record in a table or to update an order document).

WebSphere Adapter for JD Edwards EnterpriseOne complies with the Java 2 Platform, Enterprise Edition (J2EE) Connector Architecture (JCA). JCA standardizes the way in which application components, application servers, and Enterprise Information Systems (EIS), such as a JD Edwards EnterpriseOne server, interact with each other. WebSphere Adapter for JD Edwards EnterpriseOne makes it possible for JCA-compliant application servers to connect to and interact with the JD Edwards EnterpriseOne server. Clients running on the JCA-compliant server can then communicate with the JD Edwards EnterpriseOne server in a standard way (by using business objects or JavaBeans).

Suppose a medium-sized retail company uses JD Edwards EnterpriseOne to coordinate most of its business operations. JD Edwards EnterpriseOne includes a business function that can return a real-time list of inventory items for its 100 stores located across the United States. An application component might be able to use this business function as part of an overall business process. For example, an employee of a retail company can access the real-time list of available inventory items, therefore providing correct, real-time information to a customer.

Technical overview of the WebSphere Adapter for JD Edwards EnterpriseOne:

The IBM WebSphere Adapter for JD Edwards EnterpriseOne provides a way for applications to interact with data on JD Edwards EnterpriseOne applications.

The adapter processes requests using one of two types of business objects: business functions and XML Lists. A business function is a business object container that can contain one or many business objects that can be processed as a single transaction. An XML List is a single business object that can query a table and return multiple records.

You create business objects by using the Adapter Connection wizard. The business objects that are generated by the Adapter Connection wizard have predefined business object definitions.

Outbound processing (JD Edwards):

The WebSphere Adapter for JD Edwards EnterpriseOne supports synchronous outbound request processing. When the adapter receives a request from the module, in the form of a business object, the adapter processes the request and returns the result, when applicable, in a business object.

The adapter processes requests by using one of two types of business object: business functions and XML Lists. A business function is a business object container that can contain one or many business objects, which can be processed as a single transaction. An XML List is a single business object that can query a table and return multiple records. The component sends a request in the form of a WebSphere business object hierarchy to the adapter, the adapter processes the request, and returns a WebSphere business object hierarchy that represents the result of the operation.

When the adapter receives a WebSphere business object hierarchy, the adapter processes it in the following way.

1. The adapter extracts metadata from the WebSphere business object hierarchy.
2. The adapter identifies the appropriate JD Edwards EnterpriseOne objects to access (for example, JD Edwards EnterpriseOne business objects and business components, or JD Edwards EnterpriseOne business function, or JD Edwards EnterpriseOne XML List) depending on the objects against which the artifacts were generated.
3. The adapter extracts the outbound operation to complete from the WebSphere business object hierarchy.

4. After accessing the required JD Edwards EnterpriseOne objects, the adapter retrieves the data for XML List, or completes the corresponding business function method.
5. If updates are involved (Create, Update, Delete), the adapter populates that JD Edwards EnterpriseOne object (business function or XML List hierarchy) with data from the hierarchy of WebSphere business objects.

Supported outbound operations

When the adapter receives a request, it processes the request by using the JD Edwards EnterpriseOne Dynamic Java connector to call either a business function or an XML List.

Business functions support the following types of operation:

- Create
- Delete
- Execute
- Retrieve
- Update

XML Lists support the retrieveAll operation

Operations	Description
Create	Creates the business object.
Delete	Deletes the business object and its children. The adapter supports only logical deletes, therefore objects are marked as deleted but not removed.
Exists	Checks for the existence of incoming business objects.
Retrieve	Retrieves the JD Edwards EnterpriseOne component, and maps component data onto the business object.
RetrieveAll	Retrieves multiple instances of the JD Edwards EnterpriseOne component, and maps component data onto the business object.
Update	Updates the corresponding JD Edwards EnterpriseOne component with the incoming business object.

Inbound processing for JD Edwards EnterpriseOne:

The WebSphere Adapter for JD Edwards EnterpriseOne supports asynchronous inbound processing. The adapter polls the JD Edwards EnterpriseOne server at specified intervals for events. When the adapter receives an event, it converts the event data into a business object and sends the business object to the component.

The WebSphere Adapter for JD Edwards EnterpriseOne supports real-time events. A real-time event is a business transaction that provides information from the JD Edwards EnterpriseOne server that can be used to interoperate with a third-party system. Real-time events can be generated wherever business functions run, such as HTML, WIN32, and enterprise servers. Real-time events are useful for producing notifications in real time. The adapter supports both single and container real-time events.

When the adapter gets a real-time event from the JD Edwards EnterpriseOne transaction server by calling the JD Edwards EnterpriseOne Dynamic Java Connector API, it parses the content of this real-time event and converts it into a business object. The adapter then sends the business object to the event endpoints. For example, if a company is updated, the JD Edwards EnterpriseOne server captures this change immediately, and one real-time event is generated by the JD Edwards EnterpriseOne transaction server. The adapter then communicates with the JD Edwards EnterpriseOne transaction server, retrieves this real-time event, and processes it. After converting it into a business object, the adapter delivers this business object to the event endpoint.

WebSphere Adapter for JD Edwards EnterpriseOne processes events in the following way.

1. The adapter calls the JD Edwards EnterpriseOne Dynamic Java Connector API to get a real-time event.
2. The adapter parses the content of this real-time event.
3. The adapter populates the associated business object with the values that it retrieves from the payload of this real-time event.
4. The adapter sends the generated business object to each registered application.

Before inbound processing can occur, the JD Edwards EnterpriseOne server must be configured to support real-time events.

Event persistence (JD Edwards):

The WebSphere Adapter for JD Edwards EnterpriseOne supports event persistence for inbound processing in case of abrupt termination. Event persistence (or assured-once delivery) is a way to make sure that events are delivered once, and only once, to the endpoint in the case of a failure.

During event processing, the adapter persists the event state in an event store located on the data source. You must set up this data source before you can create the event store. To use the recovery feature, set the `AssuredOnceDelivery` property in the activation specification to `True`. This recovery feature is set to `True` by default.

When a failed event occurs, the adapter tries to deliver the event once more only. If the event fails again, its status is marked as FAILED and the event remains in the event store until it is either deleted manually or has its status changed. If the adapter fails or stops before the event is marked as FAILED, when it recovers, the

adapter retrieves the event from the event store with the stored data and attempts to redeliver the event, marking its status as FAILED only after the default retry limit of one has been exceeded again.

Reference information to refer to when you connect to a JD Edwards EnterpriseOne application.

Event store (JD Edwards):

The event store is a persistent cache where event records are saved until the polling adapter can process them. The adapter uses event stores to record inbound events as they make their way through the system.

Each time a real-time event is received, the adapter updates the status of the event in an event store. The status of each event is continually updated by the adapter for recovery purposes until the events are delivered to the endpoint. If the adapter detects that no event store exists for the inbound module in WebSphere Message Broker, it creates one automatically when the application is deployed to the run time. Each event store that is created by the adapter is associated with a specific inbound module. The adapter does not support multiple adapter modules pointing to the same event store.

When the adapter polls the JD Edwards EnterpriseOne transaction server and receives a real-time event, it creates an entry in the event store for each event that matches the search criteria specified in the activation specification properties. The adapter records the status of each new entry as NEW.

If a real-time event is successfully delivered, the corresponding event store entries are deleted. For failed events, the entries remain in the event store.

Assured once delivery

The JD Edwards EnterpriseOne transaction server provides guaranteed event delivery quality of service. All the real-time events to which the adapter subscribes are delivered to the adapter without any loss. The JD Edwards EnterpriseOne transaction server can send duplicate real-time events to the adapter, therefore the adapter provides assured once event delivery; each event is delivered once and only once. To enable assured once delivery, you must set the `AssuredOnceDelivery` activation specification property to `True`.

When you set the `AssuredOnceDelivery` activation specification property to `True`, the `AutoAcknowledge` activation specification property is set to `False` automatically. You can also set assured once delivery by using the JDEdwardsConnection configurable service; for more information, see "Configurable services properties" on page 3766.

When a real-time event is obtained, it is processed in the following way.

1. The event is delivered to its corresponding endpoint.
2. The event entry is deleted from the event store.
3. An acknowledgment is issued to the JD Edwards EnterpriseOne transaction server.

Business objects for JD Edwards EnterpriseOne:

A business object is a structure that consists of data, the action to be performed on the data, and additional instructions, if any, for processing the data. The data can represent either a business entity, such as an invoice or an employee record, or unstructured text. The adapter uses business objects to send data to or obtain data from the JD Edwards EnterpriseOne server.

How the adapter uses business objects

The WebSphere Adapter for JD Edwards EnterpriseOne uses the JD Edwards EnterpriseOne Dynamic Java Connector APIs to communicate with the JD Edwards EnterpriseOne server. The adapter exchanges information with JD Edwards EnterpriseOne through business functions, XML List calls, and the real-time event mechanism.

How business objects are created

You create business objects by using the Adapter Connection wizard, which connects to the application, discovers data structures in the application, and generates business objects to represent them. It also generates other resources needed by the adapter.

Business object structure

The adapter supports processing of hierarchical business objects. A container business object representing a JD Edwards EnterpriseOne operation is a wrapper object that contains single or multiple child business function objects, also called simple business function objects. Each business function object represents a specific function call in the JD Edwards EnterpriseOne application.

"WebSphere Adapter for JD Edwards EnterpriseOne properties" on page 4146
Reference information to refer to when you connect to a JD Edwards EnterpriseOne application.

The Adapter Connection wizard (JD Edwards):

The Adapter Connection wizard is a tool that you use to create services. The Adapter Connection wizard establishes a connection to the JD Edwards EnterpriseOne server, discovers services (based on search criteria that you provide), and generates business objects, interfaces, and import or export files, based on the services that are discovered.

See the WebSphere Adapter for JD Edwards EnterpriseOne Information Center for further information.

By using WebSphere Message Broker, you establish a connection to the JD Edwards EnterpriseOne server to browse the metadata repository on the JD Edwards EnterpriseOne server.

You specify connection information (such as the user name and password needed to access the server), and you specify the method of operation that you want to use for an outbound or inbound request:

- For an outbound request, you specify either a business function or an XML List.
- For an inbound request, you specify real-time events.

You can then provide search criteria and select the information (for example, by using the search filter with libraries for business functions, or by selecting tables for XML Lists).

The result of running the Adapter Connection wizard is an adapter connection project and a message set project that contain the interfaces and business objects as well as the adapter.

The Adapter Connection wizard also produces an import file (for outbound processing) or an export file (for inbound processing).

- The import file contains the managed connection factory property settings that you provide in the wizard.

- The export file contains the activation specification property settings you provide in the wizard.

WebSphere Adapters technotes

WebSphere Adapters Library web page

Preparing your system to use WebSphere Adapters nodes:

Before you can connect to an Enterprise Information System (EIS), you must prepare your system by adding external software dependencies and configuring the EIS to work with the WebSphere Adapter.

Before you begin

Before you start:

- For general background information, read "WebSphere Adapters nodes" on page 1914
- Check for the latest information about WebSphere Adapters at WebSphere Adapters technotes.
- Check for the latest information about support for adapters on different operating systems at WebSphere Message Broker Requirements.
- Check the mode of your broker, because it can affect the number of execution groups and message flows that you can deploy, and the types of node that you can use. For more information, see "Restrictions that apply in each operation mode" on page 3657 and "Checking the operation mode of your broker" on page 657.
- Enable the WebSphere Adapters nodes in the broker runtime environment; see "Preparing the environment for WebSphere Adapters nodes" on page 717.

- If you want to use the IBM Tivoli License Manager (ITLM), perform the steps in "Activating IBM Tivoli License Manager for WebSphere Adapters" on page 2036.
- To see how the WebSphere Adapters work, look at the following samples:
  - Twineball Example EIS Adapter
  - SAP Connectivity

  You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

About this task

Perform the following steps, in the order shown, to prepare your system to use WebSphere Adapter nodes.

Procedure

- **SAP**
  1. Follow the instructions in "Adding external software dependencies for SAP" on page 2048.
  2. Follow the instructions in "Configuring the SAP server to work with the adapter" on page 2050.
- **Siebel**
  1. Follow the instructions in "Adding external software dependencies for Siebel" on page 2068.
  2. Follow the instructions in "Creating the event store manually" on page 2072.
- **PeopleSoft**
  1. Follow the instructions in "Adding external software dependencies for PeopleSoft" on page 2081.
  2. Follow the instructions in "Creating a custom event project in PeopleTools" on page 2083.
- **JD Edwards**
  1. Follow the instructions in "Adding external software dependencies for JD Edwards EnterpriseOne" on page 2090.

What to do next

After you have prepared your system, connect to an EIS by following the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.

Related concepts:

"WebSphere Adapters nodes" on page 1914

WebSphere Adapters technotes

Activating IBM Tivoli License Manager for WebSphere Adapters:

If you want to use IBM Tivoli License Manager (ITLM), you must activate it for each of the WebSphere Adapters.

About this task

ITLM enables you to monitor the usage of IBM (and other) software products. For more information, see the IBM Tivoli License Manager Information Center or the IBM Tivoli License Manager website.

The following steps describe how to activate the ITLM file for each of the adapters.

Procedure

1. Locate the ITLM directory for the adapter.
   - For SAP: *install_dir*/itlm/SAP
   - For Siebel: *install_dir*/itlm/Siebel
   - For PeopleSoft: *install_dir*/itlm/PeopleSoft
2. Remove the inactive file extension from the file in the ITLM directory so that it ends with .sys2.

Results

After you have performed these steps, when you run ITLM, the adapter is visible.

Related concepts:

"WebSphere Adapters nodes" on page 1914
A WebSphere Adapters node is a message flow node that is used to communicate with Enterprise Information Systems (EIS), such as SAP, Siebel, JD Edwards, and

PeopleSoft.

For information about how to develop message flows that use WebSphere Adapters, see the following topics.

Related reference:

"Directory structures after installation" on page 3633
When you install WebSphere Message Broker components, the installation program creates a structure of subdirectories under the directory that you specified as the installation directory. The exact structure depends on the platform on which you have installed WebSphere Message Broker, and the components that you have installed. If you install the WebSphere Message Broker Toolkit, other directories might be created for IBM Installation Manager, the Shared Resources Directory, and the package group in which you install the toolkit.

Connecting to an EIS by using the Adapter Connection wizard:

Use the Adapter Connection wizard to create the resources that enable the WebSphere Adapters to connect to an Enterprise Information System (EIS).

Before you begin

Before you start:

- Complete the preparatory tasks listed in "Developing message flows that use WebSphere Adapters" on page 2033.
- Before you run the Adapter Connection wizard, gather the information that you need from the system administrator. You need information to connect to the EIS, and information to discover objects. For a list of the information that you might need to gather for each EIS, see the appropriate topic:
  - "Interacting with an SAP application" on page 2046
  - "Interacting with a Siebel application" on page 2066
  - "Interacting with a PeopleSoft application" on page 2080
  - "Interacting with a JD Edwards application" on page 2088

About this task

A message flow that uses one of the WebSphere Adapters requires the following resources:

- One or more message flows that contain one or more WebSphere Adapters nodes
- A message set that contains the XML Schema Definitions (XSD) for each business object in the Enterprise Information System (EIS)
- An adapter component file for the WebSphere Adapter that is being used

The Adapter Connection wizard creates these resources automatically.

You can take an adapter component that was created by using the Adapter Connection wizard, and update it with newly discovered objects from the EIS by running the Adapter Connection - Iterative Discovery wizard. This facility is known as *iterative discovery*. You can either add the new objects without modifying existing objects, or replace existing objects. For more information, see "Enhancing existing adapters with newly discovered objects" on page 2063.

The following steps describe how to connect to an EIS.

Procedure

1. Click **File** > **New** > **Adapter Connection**. The Adapter Connection wizard opens.
2. Follow the instructions in the wizard. To see a description of each field within the wizard, hold the mouse pointer over the field.

   Ensure that inbound and outbound SAP IDocs have different names if they are stored in the same message set. For more information, see "An error is issued when you use the message set that is generated by the Adapter Connection wizard" on page 3431.

   When you have completed the steps in the wizard, the specified message set project contains a message set with a message type for each business object that is to be used, and the specified message flow project references the message set project.

   When the Adapter Connection wizard completes, the WebSphere Message Broker Toolkit displays a message that prompts you to drag the adapter component onto the message flow canvas.
3. Ensure that a message flow is open in the Message Flow editor so that the message flow canvas is available.
4. In the Broker Development view, expand the folders beneath the message set until you see the adapter component, which has a suffix of inadapter or outadapter.
5. Drag the adapter component onto the message flow canvas. The component appears as a message flow node.
6. Configure the node, as described in .
7. When you have developed and saved your message flow, deploy it by following the instructions in "Deploying a message flow that uses WebSphere Adapters" on page 3240.

What to do next

Using configurable services for WebSphere Adapters nodes

WebSphere Adapters nodes can get connection details from either the adapter component or a configurable service. By using configurable services, you can change the connection details for adapters without the need to redeploy the adapters. For more details about creating, changing, reporting, and deleting the configurable services for each EIS, see the appropriate topic:

- "Changing connection details for SAP adapters" on page 719
- "Changing connection details for Siebel adapters" on page 720
- "Changing connection details for PeopleSoft adapters" on page 722
- "Changing connection details for JD Edwards adapters" on page 724

Configuring EIS connections to expire after a specified time:

You can configure connections to SAP, Siebel, and PeopleSoft to expire after a specified time by using a configurable service.

About this task

You can use the connectionIdleTimeout property on a configurable service to control the number of connections to SAP, Siebel and PeopleSoft by closing connections that have not been used for a specified time.

Procedure

Use the **mqsicreateconfigurableservice** command to set up connections that expire when they have not been used for a specified length of time.
In the following example, the SAPConnection configurable service is configured to close connections when they have not been used for 120 seconds.

```
mqsicreateconfigurableservice MB7BROKER -c SAPConnection -o mySAPAdapter.outadapter
-n connectionIdleTimeout -v 120
```

Reference information about the properties that you set for WebSphere Adapters nodes.

Configuring WebSphere Adapters nodes for secondary adapters:

You can deploy the resources that are required to support new methods in an Enterprise Information System (EIS), without affecting any resources that are already deployed, by using primary and secondary adapters and message sets. You must configure the WebSphere Adapters nodes in your message flows to use the secondary adapters.

Before you begin

Before you start:

- Read the concept topic, "WebSphere Adapters deployment" on page 3219.
- Complete the steps in "Preparing your system to use WebSphere Adapters nodes" on page 2034.

About this task

The primary adapter for a WebSphere Adapters node contains its connection information and part of its interface; the secondary adapters contain the rest of the interface. The primary message set contains message model metadata for the parts of the interfaces that are supported by the node; the secondary message sets define the rest of the model.

Complete the following steps to configure a message flow so that it can be extended by secondary adapters and message sets.

Procedure

1. To create a primary adapter and message set, run the Adapter Connection wizard by following the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
2. When the wizard has finished, create a message flow that contains one or more WebSphere Adapters nodes.
3. In the Broker Development view, expand the folders beneath the message set until you see the adapter component, which has a suffix of `.inadapter` or `.outadapter`.
4. Drag the adapter component onto the WebSphere Adapters node in your message flow.
5. On the Basic properties tab of the WebSphere Adapters node, set the `Secondary adapter mode` to `All adapters in execution group`.
6. Save the message flow.

What to do next

Next:

Add the message flow, adapter, and message set to a BAR file, then deploy the BAR file to the execution group. For more information, see "Deploying a message flow that uses WebSphere Adapters" on page 3240.

You have created a message flow that you can enhance in the future when you need to call new services or handle new event types in an EIS. For instructions about how to enhance your message flow, see the following topics:

- "Calling new services from a WebSphere Adapters request node without changing existing deployed resources" on page 2042
- "Handling new event types from a Websphere Adapters input node without changing existing deployed resources" on page 2044

Related concepts:

Calling new services from a WebSphere Adapters request node without changing existing deployed resources:

If your message flow acts as a gateway to an Enterprise Information System (EIS), you can use it to call new services that did not exist when you developed the flow. Therefore, if a new service is provided by the EIS, you do not have to modify and retest the message flow.

Before you begin

Before you start:

- Read the concept topic "WebSphere Adapters deployment" on page 3219.
- Ensure that you have created and deployed a message flow that is configured to use secondary adapters, as described in "Configuring WebSphere Adapters nodes for secondary adapters" on page 2040.

About this task

To use iterative deployment, you can configure an SAPRequest, SiebelRequest, PeopleSoftRequest, or JDEdwardsRequest node to look for a specified operation in all relevant `.outadapter` components that are deployed to the execution group.

Procedure

1. Run the Adapter Connection wizard to create an `.outadapter` component and a message set for the new EIS services.

   You do not need to rediscover existing services. For more information about running the Adapter Connection wizard, see "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
2. Ensure that method names are unique across all primary and secondary adapters that are used by the request node. If they are not unique, edit them by clicking **Edit Operations** on the Service Generation and Deployment Configuration panel of the Adapter Connection wizard.

   The method names correspond to the Service Operation names, which are configured by the Adapter Connection wizard. In most cases, the names are based on the name of the service that is being discovered (for example, the BAPI name in SAP, or the business object and operation name in Siebel). However, in some cases, you must edit them to avoid a clash.

You can set the method name dynamically in the message flow by setting the local environment field `$LocalEnvironment/Adapter/MethodName`.

3. Avoid duplicate method names by using user trace in the following way.
   a. Start user trace by following the instructions in "Starting user trace" on page 3197.
   b. Stop and restart the message flow.
   c. Read user trace by using the **mqsireadlog** command. Message BIP3432 identifies which methods are already defined by currently deployed adapters.

   Alternatively, you can identify the methods that are defined by the adapter by looking at the `Default method` property of the request node. If you have a `.outadapter` component in your workspace, you can drop it onto a message flow to create a request node for the `.outadapter` component. The request node has that adapter set as its primary adapter, and the list of methods that are defined by that adapter are visible in the `Default method` property of the request node.
4. Ensure that the message set that is created does not contain any types that share the same name and namespace of existing message sets. You can change the namespaces of the types on the Adapter Connection wizard by using the Business Object Namespace control.

   Use different namespaces for different message sets. The use of different namespaces is important when working with BAPIs because the BAPI return field typically has the same name for all BAPIs, and its type definition can change depending on the age of the BAPI.

Related concepts:

Handling new event types from a Websphere Adapters input node without changing existing deployed resources:

You can create an event handler to an Enterprise Information System (EIS) to handle new event types that did not exist when you first developed your message flow. Therefore, if a new event is provided by the EIS, you do not have to modify and retest the message flow.

Before you begin

Before you start:

- Read the concept topic "WebSphere Adapters deployment" on page 3219.
- Ensure that you have created and deployed a message flow that is configured to use secondary adapters, as described in "Configuring WebSphere Adapters nodes for secondary adapters" on page 2040.

About this task

To implement an event handler that you can enhance iteratively with new event types (that is, deploy new event types to the event handler), configure an SAPInput node to use secondary adapters. The set of secondary adapters can be extended at operational time without affecting any existing adapters.

Procedure

1. Run the Adapter Connection wizard to create a new `.inadapter` component and a new message set for the new EIS events.

   You do not need to rediscover existing events. For more information about running the Adapter Connection wizard, see "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
2. Ensure that the method names are unique.

   The method names correspond to the Service Operation names. Therefore, when you are choosing or editing the Service Operation names, make sure that they do not clash with those names defined in other adapters that are being used by that node.
3. Avoid duplicate method names by using user trace in the following way.
   a. Start user trace by following the instructions in "Starting user trace" on page 3197.

b. Stop and restart the message flow.
c. Read user trace by using the **mqsireadlog** command. Message BIP3432 identifies which methods are already defined by currently deployed adapters.

4. Ensure that the message set that is created does not contain any types that share the same name and namespace of existing message sets. You can change the namespaces of the types on the Adapter Connection wizard by using the Business Object Namespace control.

   Use different namespaces for different message sets. The use of different namespaces is important when working with BAPIs because the BAPI return field typically has the same name for all BAPIs, and its type definition can change depending on the age of the BAPI.

Interacting with an SAP application:

To interact with an SAP application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

About this task

To connect to an SAP application, the SAP adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the SAP application, then deploy the relevant resources.

Procedure

1. To obtain software dependencies, follow the instructions in "Adding external software dependencies for SAP" on page 2048.
2. Optional: If you are using Application Link Enabling (ALE) processing, register a Remote Function Call (RFC) destination on the SAP server and configure the SAP server, as described in "Configuring the SAP server to work with the adapter" on page 2050.
3. Optional: To set up SAP for high availability, see "Setting up SAP for high availability" on page 2057.
4. Before you run the Adapter Connection wizard, gather the following information from your SAP administrator:
   - SAP system user name
   - SAP system password
   - SAP host name or IP address
   - SAP Client ID (for example, 001)
   - SAP system number (for example, 00)
   - Language code (for example, EN)

   You might also need to gather some specific information from your SAP administrator about the items that you are discovering. For example, if you are discovering IDocs, you need the appropriate information to complete the following fields:
   - IDoc name
   - Version
   - SAP outbound
   - Verbs (create, update, delete)
   - Partner number
   - Message type

   For more information, see "SAP connection properties for the Adapter Connection wizard" on page 4044.
5. To connect to SAP by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
6. Develop your message flow to define the interaction with the SAP application.

   For example, to route IDocs to separate messages, follow the instructions in "Routing IDocs to separate message flows" on page 2055.

7. Optional: To propagate security credentials to an SAP request, see "Propagating security credentials to an SAP request" on page 2065.
8. Deploy the appropriate resources, as described in "Deploying a message flow that uses WebSphere Adapters" on page 3240.
9. Optional: To change connection details for SAP adapters, see "Changing connection details for SAP adapters" on page 719.
10. Optional: To enhance existing adapters with newly discovered objects, see "Enhancing existing adapters with newly discovered objects" on page 2063.

Adding external software dependencies for SAP:

Before you can develop message flows that use WebSphere Adapters nodes, you must add prerequisite files to the runtime environment.

Before you begin

Before you start:

Ensure that you have the relevant prerequisite files for your SAP system. (For information about the versions of files that WebSphere Message Broker supports, see WebSphere Message Broker Requirements.)

- `sapjco3.jar`
- Windows On Windows:
  - `sapjco3.dll`
- z/OS Linux UNIX On z/OS, Linux, and UNIX:
  - `libsapjco3.so`

Download these files for your operating system from the external SAP Web site, SAP Service Marketplace, and save them to a directory, such as `C:\SAP_LIB`. (On Windows, the directory cannot be a mapped network drive on a remote Windows computer; the directory must be local or on a Storage Area Network (SAN) disk.) You must have an SAPNet account to be able to access this Web site.

- Windows On Windows, download the `.dll` files that come with the SAP JCo download.
- z/OS Linux UNIX On z/OS, Linux, and UNIX, download the `.so` and `.o` files that come with the SAP JCo download.

About this task

Locating the SAP support files in the runtime environment

To add the SAP prerequisite files to the runtime environment, take the following steps.

Procedure

- Windows Linux UNIX On Windows, Linux and UNIX:
  1. Ensure that the broker has started.
  2. Either open the Command Console, or open a Windows command prompt and enter **`mqsiprofile`** to initialize the environment.
  3. Enter the following command to display the locations of the prerequisite JAR files and native libraries:

     ```
     mqsireportproperties MB7BROKER -c EISProviders -o AllReportableEntityNames  -r
     ```

     The following example shows what typically is displayed when you run this command:

     ```
     ReportableEntityName=''
      EISProviders
       JDEdwards=''
        jarsURL='default_Path'
        nativeLibs='default_Path'
     ```

```
PeopleSoft=''
 jarsURL='default_Path'
 nativeLibs='default_Path'
SAP=''
 jarsURL='default_Path'
 nativeLibs='default_Path'
Siebel=''
 jarsURL='default_Path'
 nativeLibs='default_Path'
 siebelPropertiesURL=''
Twineball=''
 jarsURL='default_Path'
 nativeLibs='default_Path'
```

4. Set the location of the SAP prerequisite files using the following command:

```
mqsichangeproperties MB7BROKER -c EISProviders -o SAP  -n jarsURL -v C:\SAP_LIB
mqsichangeproperties MB7BROKER -c EISProviders -o SAP  -n nativeLibs -v C:\SAP_LIB
```

5. To check that the values have been set correctly, run the following command:

   ```
   mqsireportproperties  MB7BROKER -c EISProviders -o SAP -r
   ```

   The following example shows what is displayed by the **mqsireportproperties** command.

   ```
   ReportableEntityName=' '
   EISProviders
    SAP=' '
     jarsURL='C:\SAP_LIB'
     nativeLibs='C:\SAP_LIB'

   BIP8071I: Successful command completion.
   ```

6. Restart the broker.

- z/OS On z/OS: Run the **mqsireportproperties** command by customizing and submitting the BIPCHPR utility. For more information about this utility, see "Contents of the broker PDSE" on page 3991.

About this task

Locating the SAP support files through the WebSphere Message Broker Toolkit

To add the SAP prerequisite files through the WebSphere Message Broker Toolkit, take the following steps.

Procedure

- Windows On Windows: When you run the Adapter Connection wizard, you are prompted to specify the paths to the required libraries.
- Linux On Linux: Append the directory that contains the SAP libraries to the LD_LIBRARY_PATH environment variable:

  ```
  LD_LIBRARY_PATH=DIRECTORY_CONTAINING_SAP_LIBRARIES:${LD_LIBRARY_PATH}
  export LD_LIBRARY_PATH
  ```

  You must set this variable either for the whole system, or in the same shell or environment from which the WebSphere Message Broker Toolkit is launched.

What to do next

Next: configure the SAP system to work with the adapter

Configuring the SAP server to work with the adapter:

Before you configure the WebSphere Adapter for SAP Software for Application Link Enabling (ALE) processing, you must register a Remote Function Call (RFC) destination on the SAP server, and configure a receiver port, logical system, distribution model, and partner profile on the SAP server. Ask your system administrator if these items have been configured.

Before you begin

Before you start:

Add the required external software dependencies for SAP.

About this task

Complete the following steps on the SAP server by using the SAP graphical user interface.

Procedure

1. Register an RFC program ID:
   a. Open transaction **SM59** (Display and Maintain RFC Destinations).
   b. Click **Create**.
   c. Type a name for the RFC destination.
   d. In the **Connection Type** field, select **T**.
   e. In the **Activation Type** field, select **Registered Server Program**.
   f. Type a Program ID.

      You use this program ID when you configure the adapter. This value indicates to the SAP gateway which RFC-enabled functions the program ID listens for.
   g. Enter a description in **Description 1**, such as `RFC for Test Sample`.
   h. Enter a description in **Description 2**, such as your name.
   i. Click **MDMP & Unicode**, and set the RFC destination to **Unicode** or **non-Unicode**, depending on the communication type of the target system.

      To avoid errors when you use multiple language settings, set the RFC destination to **Unicode**.
   j. Save your entry.
2. Set up a receiver port:
   a. Open transaction **WE21** (Ports in IDoc processing).
   b. Select **Transactional RFC**, click **Ports**, and click the **Create** icon.
   c. Type a name for the port and click **OK**.
   d. Type the name of the destination that you created in the previous task (or select it from the list).
   e. Save your entry.
3. Specify a logical system:
   a. Open transaction **BD54** (Change View Logical Systems).
   b. Click **New Entries**.
   c. Type a name for the logical system and click the **Save** icon.
   d. If you see the Prompts for Workbench request, click the **New Request** icon. Then enter a short description and click **Save**.
   e. Click the **Continue** icon.
4. Configure a distribution model:
   a. Open transaction **BD64** (Maintenance of Distribution Model).
   b. Click **Distribution Model** > **Switch processing model**.
   c. Click **Create model view**.
   d. Type a name for the model view and click the **Continue** icon.

e. Select the distribution model that you created and click **Add message type**.
f. For outbound processing, type the logical system name that you created in the previous task as **Sender**, and type the logical name of the SAP server as **Receiver**, then select a message type (for example, **MATMAS**) and click the **Continue** icon.
g. Select the distribution model again and click **Add message type**.
h. For inbound processing, type the logical name of the SAP server as **Sender**, and the logical system name that you created in the previous task as **Receiver**, then select a message type (for example, **MATMAS**) and click the **Continue** icon.
i. Save your entry.

5. Set up a partner profile:
   a. Open transaction **WE20** (Partner Profiles).
   b. Click the **Create** icon.
   c. Type the name of the logical system that you created in the earlier task and, for **Partner Type**, select **LS**.
   d. For **Post Processing: permitted agent**, type `US` and your user ID.
   e. Click the **Save** icon.
   f. In the Outbound parameters section, click the **Create outbound parameter** icon.
   g. In the Outbound parameters window, type a message type (for example, `MATMAS05`), select the receiver port that you created in the earlier task, and select **Transfer IDoc immed**.
   h. Click the **Save** icon.
   i. Press **F3** to return to the Partner Profiles view.
   j. In the Inbound parameters section, click the **Create inbound parameter** icon.
   k. In the Inbound parameters window, type a message type (for example, `MATMAS`), and a process code (for example, `MATM`).
   l. Click the **Save** icon.
   m. Press **F3** to return to the Partner Profiles view.
   n. In the Inbound parameters section, click the **Create inbound parameter** icon.
   o. In the Inbound parameters window, type the following values: `ALEAUD` for **Message Type**, and `AUD1` for **Process Code**.
   p. Click the **Save** icon.
   q. Press **F3** to return to the Partner Profiles view.
   r. Click the **Save** icon.

What to do next

Next: connect to an EIS using the Adapter Connection wizard.

Changing connection details for SAP adapters:

SAP nodes can get SAP connection details from either the adapter component or a configurable service. By using configurable services, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a configurable service is created or modified, you must reload the broker or execution group to which the adapter was deployed, by using the **mqsistop** and **mqsistart** commands, or the **mqsireload** command.

Before you begin

Before you start:

- Read "WebSphere Adapters nodes" on page 1914 and "Configurable services" on page 1296 for background information.

About this task

Use the SAPConnection configurable service to change connection details for an SAP adapter. The SAP node reads all connection properties from the adapter component that it is configured to use. If a configurable service exists that has the same name as the node's adapter component, the node uses the values that are

defined in that configurable service to override the corresponding properties from the adapter. If any properties on the configurable service are set to an empty string, the values that are configured in the `.inadapter` or `.outadapter` file are used. The properties of the SAP configurable services are described in "Configurable services properties" on page 3766.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates an SAPConnection configurable service for the SAP adapter *mySAPAdapter.outadapter* that connects to the SAP host `test.sap.ibm.com`, and uses client *001* for the connections into that server:

  ```
  mqsicreateconfigurableservice MB7BROKER -c SAPConnection
  -o mySAPAdapter.outadapter -n applicationServerHost,client
  -v test.sap.ibm.com,001
  ```

  To pick up the new values in the configurable service, restart the execution group and message flow.
- To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. This example changes the connections that are used by the adapter *mySAPAdapter.outadapter*. After you run this command, all adapters connect to the production system (`production.sap.ibm.com`) instead of the test system (`test.sap.ibm.com`):

  ```
  mqsichangeproperties MB7BROKER -c SAPConnection -o mySAPAdapter.outadapter
  -n applicationServerHost -v production.sap.ibm.com
  ```

  To pick up the updated values in the configurable service, restart the execution group and message flow.
- To display all SAPConnection configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

  ```
  mqsireportproperties MB7BROKER -c SAPConnection -o AllReportableEntityNames -r
  ```
- You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

  ```
  mqsideleteconfigurableservice MB7BROKER -c SAPConnection
  -o mySAPAdapter.outadapter
  ```

  You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

Routing IDocs to separate message flows:

You can use a pattern to process IDocs of various kinds with a single RFC program ID without having to redeploy or rediscover existing message sets and adapters, even when adding new types of IDoc.

Before you begin

Before you start:

Read the concept topic about "Generic IDoc routing" on page 1976.

About this task

You can create a routing message flow that contains an SAPInput node. You can use this flow to route the IDocs, based on their type, to separate message flows that deal with each different IDoc type. If the set of discovered IDocs is extended, you can create a message flow and message set, then deploy them, without the need to change existing message flows or message sets.

For more information about the pattern that is used in this task, see Data distribution SAP to WebSphere MQ: one-way (for IDoc). You can view patterns in the information center by using the links only when you use the information center that is integrated with the WebSphere Message Broker Toolkit, or when you use the online information center.

The following instructions describe how to use a pattern to create the resources that you need.

Procedure

1. Open the Patterns Explorer by following the instructions in "Choosing a pattern" on page 1313.
2. Expand the Application Integration category, and the SAP category, then click **MQ one-way (IDoc)** to open the pattern. The pattern specification describes the pattern and how to use it.
3. Click **Create New Instance**.
4. Enter a name and provide the required configuration parameters for the pattern instance, then click **Generate**.

   When the pattern has been generated, the Broker Development view lists the resources that have been generated:
   - A Java project
   - A routing message flow:

   - A message set
   - An `.inadapter` component
5. Add these resources to a BAR file then deploy the BAR file.
6. Use the **mqsisetdbparms** command to set your user name and password for the SAP system. For more information about how to use this command, see "**mqsisetdbparms** command" on page 3954.
7. The pattern also creates a configurable service called `idocpassthrough.inadapter.configurableservice`. Deploy the configurable service by dragging it onto the broker in WebSphere Message Broker Explorer.

Results

Result: The SAP adapter is connected by using the program ID that is specified in the configurable service. The message flow receives an IDoc from SAP and writes it to WebSphere MQ. The ESQL code in the Compute node specifies that the queue name to which the message is written is the same as the IDoc type. You can create separate message flows to process the different types of IDoc.

What to do next

Next: The SAPInput node can route the IDocs according to their type, but it does not parse the binary data BLOB messages that they contain. You can create a message flow that contains an MQInput node, which uses an adapter message set in the DataObject domain to parse the binary data BLOB message into a structured record that WebSphere Message Broker can manipulate. To use the DataObject parser to parse IDocs, you must set the `Message domain` property of the MQInput node to `DataObject`, and set the `Message format` property to `SAP ALE IDoc`. To create the message set, run the Adapter Connection wizard.

Related concepts:

"Generic IDoc routing" on page 1976
By using the SAPInput node in passthrough mode, WebSphere Message Broker can receive any IDoc and route it according to IDoc type.

"The ALE interfaces" on page 1959
The SAP Application Link Enabling (ALE) interface and ALE pass-through IDoc interface enable business process integration and asynchronous data communication between two or more SAP systems or between SAP and external systems. The data is exchanged in the form of Intermediate Documents (IDocs).

"Inbound processing for the ALE interface" on page 1963
The adapter supports inbound processing (from the SAP server to the adapter) for the ALE interface and the ALE pass-through IDoc interface.

"DataObject parser and domain" on page 1114
Use the DataObject domain to parse and write messages for WebSphere Adapters and CORBA applications.

"Patterns" on page 1310
A *pattern* is a reusable solution that encapsulates a tested approach to solving a common architecture, design, or deployment task in a particular context.

Related tasks:

"Configuring the SAP server to work with the adapter" on page 2050
Before you configure the WebSphere Adapter for SAP Software for Application Link Enabling (ALE) processing, you must register a Remote Function Call (RFC) destination on the SAP server, and configure a receiver port, logical system, distribution model, and partner profile on the SAP server. Ask your system administrator if these items have been configured.

Setting up SAP for high availability:

You can configure WebSphere Message Broker to withstand software or hardware failures when working with SAP by moving the transaction ID (TID) store to a remote queue manager that can be shared between two brokers. To avoid a single point of failure, make this queue manager a WebSphere MQ high availability, multi-instance queue manager.

Before you begin

Before you start:

Read the concept topic about "SAP high availability" on page 1947.

About this task

The following topics describe how to set up a WebSphere MQ shared queue on distributed systems or z/OS.

Procedure

- "Setting up a shared queue on distributed systems for the SAP adapter event store"
- "Setting up a shared queue on z/OS for the SAP adapter event store" on page 2061

Related concepts:

"Overview of WebSphere Adapter for SAP Software" on page 1917
With WebSphere Adapter for SAP Software you can create integrated processes that include the exchange of information with an SAP server, without special coding.

Related tasks:

"Defining WebSphere MQ resources" on page 1558
An application client can run on a computer anywhere in the WebSphere MQ network. If your applications use WebSphere MQ facilities to connect to the broker, and to interact with it (by using the MQI and AMI), you must set up the WebSphere MQ resources that they require.

"Using WebSphere MQ cluster queues for input and output" on page 1544
Design your broker network to use WebSphere MQ queues, if appropriate for your business needs.

Related reference:

"WebSphere MQ resources for the broker" on page 585
Each broker depends on a number of WebSphere MQ resources: some are required, others are optional, and depend on your environment and requirements. Some of these resources are created for you, but others you must define for yourself.

"WebSphere Adapter for SAP properties" on page 4024
Reference information to which to refer when you connect to an SAP application.

Setting up a shared queue on distributed systems for the SAP adapter event store:

To achieve high availability when processing SAP messages on distributed systems, you can set up a shared queue for the SAP adapter event store.

About this task

On distributed systems, you can configure the broker to use a remote queue manager to persist the transaction ID (TID) store for SAP transactional RFC (tRFC) data. By using this configuration, two adapters that are deployed to two brokers can share the same TID, and can therefore operate as a single RFC server. This configuration is essential if the adapters have been configured with the same RFC Program ID.

Before the broker can use a remote queue manager as the TID store, you must complete some administration tasks on that queue manager. You must first create the queue for the broker to use as the TID store. Then you must define two

channels for the broker to use to connect to that queue manager: define the server channel on the queue manager, and define a client channel in a file, which you must make available to the broker.

You can use the Run WebSphere MQ Commands (runmqsc) command or WebSphere MQ Explorer to create this client channel definition file on any queue manager. After you have created the file, you must move it from the queue manager to a file system that is accessible to the broker.

To set up a shared queue for the SAP adapter event store, complete the following steps.

Procedure

1. Create the queue SYSTEM.BROKER.ADAPTER.PROCESSED.

   You can create the queue either by using WebSphere MQ Explorer or by running the following command in WebSphere MQ **runmqsc**:

   ```
   DEFINE QLOCAL('SYSTEM.BROKER.ADAPTER.PROCESSED')
   ```

2. Create the server channel.
   a. On the computer that hosts the shared queue manager, create a server channel by running the WebSphere MQ **runmqsc** command and entering the following parameters, where *WSADAPTERS.SAP* is an example of the channel name.

      ```
      DEFINE CHANNEL ('WSADAPTERS.SAP') CHLTYPE (SVRCONN) TRPTYPE(TCP)
      ```

   b. After you have created the channel, start it by using the following command in **runmqsc**:

      ```
      START CHANNEL ('WSADAPTERS.SAP')
      ```

3. Create the client definition file.

   On any queue manager, create a client definition file by running the **runmqsc** command and entering the following parameters, where the following criteria apply:

   - *WSADAPTERS.SAP* is an example of the channel name.
   - *myhost.ibm.com* is an example of the host name of the computer where the queue manager is running. This queue manager is the one on which you created the queue in step 1 and the server channel in step 2. This name is used by the broker to connect to the queue manager, therefore do not use *localhost*.
   - *1414* is an example of the port number where the listener is running on that queue manager.
   - *QMGR* is an example of the queue manager name.
   - You can use any name for the server and client channels, but they must match.
   - Set the CONNAME parameter to the host name or IP address of the computer that hosts the shared queue manager, and the port number of the MQ Listener that is running on that computer. 1414 is the default listener port.

   ```
   DEFINE CHANNEL ('WSADAPTERS.SAP') CHLTYPE (CLNTCONN) CONNAME('myhost.ibm.com(1414)') TRPTYPE(T
   ```

   If the queue manager is running in multi-instance mode, define two channels, one for each instance of the queue manager

4. Move the client definition file to a file system that is accessible by the broker.

- Linux UNIX On Linux and UNIX, you can find this file at `/var/mqm/qmgrs/QMGR_NAME/@ipcc/AMQCLCHL.TAB`.
- Windows On Windows, you can find this file at `C:\Program Files\IBM\WebSphere MQ\Qmgrs\QMGR_NAME\@ipcc\AMQCLCHL.TAB`.

5. Configure the broker.
   a. Create an SAPConnection configurable service for the `.inadapter` component by using the **mqsicreateconfigurableservice** command.
   b. Set the sharedTidStoreClientDefinitionFile parameter of the configurable service to the path of the file that you created in step 3 and moved in step 4.
   c. Set the sharedTidStoreQueueManger parameter to the name of the queue manager for which you created the queue in step 1 and the server channel in step 2.

      For more information about these parameters, see "SAPConnection configurable service" on page 3784.
6. Verify the setup.

   After you have completed these steps, you can verify that the broker is using the queue on the remote queue manager by inspecting user trace. If the setup is successful, message BIP3470 is issued, specifying which queue manager the broker is using as the TID store.

Setting up a shared queue on z/OS for the SAP adapter event store:

To achieve high availability when processing SAP messages on z/OS, you can set up a shared queue for the SAP adapter event store.

Before you begin

Before you start:

Ensure that the queue-sharing group name that you are planning to use does not exist in SYS1.PARMLIB(IEFSSNxX). If the name does exist, choose a different name for the new group.

About this task

You can find the data set members, which are referred to in the following steps, as samples in the `thlqual.SCSQPROC` library, unless stated otherwise. The library is supplied with WebSphere MQ for z/OS.

Procedure

1. Review your DB2 data-sharing requirements. The queue-sharing group is backed by a DB2 data sharing group. Add entries to DB2 for WebSphere MQ by completing the following steps.
   a. Customize the CSQ4INSS data set member with the structure names and ensure that it is included in the CSQINP2 DD concatenation for one queue manager in the queue-sharing group.
   b. To amend the QSGDATA system parameter, amend and rerun the CSQ4ZPRM sample in the format (*Qsgname*,*Dsgname*,*Db2name*,*Db2servers*).
   c. Copy, customize, and run the following sample JCLs. These jobs need to be run only once for each DB2 subsystem or data-sharing group.
      1) Customize and run sample JCL CSQ45CSG to create the storage group that is to be used for the WebSphere MQ database, table spaces, and tables.
      2) Customize and run sample JCL CSQ45CDB to create the database to be used by all queue managers that connect to this DB2 data-sharing group.
      3) Customize and run sample JCL CSQ45CTS to create the table spaces to contain the queue manager and channel initiator tables that are used for queue-sharing groups (created in step i).
      4) Customize and run sample JCL CSQ45CTB to create the twelve DB2 tables and associated indexes. Do not change any of the row names or attributes.
      5) Customize and run sample JCL CSQ45BPL to bind the DB2 plans for the queue manager, utilities, and channel initiator.
      6) Customize and run sample JCL CSQ45GEX to grant execute authority to the respective plans for the user IDs that will be used by the queue

manager, utilities, and channel initiator. The user IDs for the queue manager and channel initiator are the user IDs under which their started task procedures run. The user IDs for the utilities are the user IDs under which the batch jobs can be submitted. For more information about the names of the appropriate plans, see the WebSphere MQ Version 7 Information Center online.

2. Create a queue-sharing group by completing the following steps.
   a. Define the Coupling Facility structures that are used by the queue managers in the queue-sharing group.

      Define the administration and application structures in the Coupling Facility Resource Management (CFRM) policy data set for the z/OS Sysplex that will host the queue sharing group, as shown in the following example, where *MQPU* is the queue-sharing name.

      ```
      STRUCTURE NAME(MQPUCSQ_ADMIN)
      SIZE(20000)
      INITSIZE(10000)
      PREFLIST(PUCF01)

      STRUCTURE NAME(MQPUAPPLICATION1)
      SIZE(20000)
      INITSIZE(10000)
      PREFLIST(PUCF01)
      ```

      For more information about setting up the Coupling Facility, see the WebSphere MQ Version 7 Information Center online.
   b. Define each of the queue-sharing groups to DB2 by using the ADD QSG function of the queue-sharing group utility (CSQ5PQSG). Sample CSQ45AQS is provided in the SCSQPROC library. Run the sample once for each queue-sharing group.
   c. Define each of the queue managers to DB2 by using the ADD QMGR function of the queue-sharing group utility CSQ5PQSG. Sample CSQ45AQM is provided in the SCSQPROC library. Run the sample for every member of a queue-sharing group.
   d. To activate the changes that you have made, stop and start all the queue managers in the group.
3. Define the SAP event store queue in the queue sharing group.

   Typically, creating an event store queue is the most effective method. If you are migrating from a previous broker, ensure that any outstanding SAP requests have been resolved before you move to the new topology.
   a. To create a shared queue, run the following command on one of the queue managers only:

      ```
      DEFINE QL(SYSTEM.BROKER.ADAPTER.SHARED)
      LIKE(SYSTEM.BROKER.ADAPTER.PROCESSED) CFSTRUCT(NEW) QSGDISP(SHARED) SHARE DEFSOPT(SHARED)
      ```
   b. To allow other queue managers that have been added to the group to use the shared queue, delete their locally defined queues by running the following command on each of those queues:

      ```
      DELETE QLOCAL(SYSTEM.BROKER.ADAPTER.PROCESSED) QSGDISP(QMGR)
      ```
4. Configure the broker.
   a. Create an SAPConnection configurable service for the `.inadapter` component by using the **mqsicreateconfigurableservice** command.
   b. Set the sharedTidStoreQueueManger parameter to the name of the queue manager of the broker.

For more information about this parameter, see "SAPConnection configurable service" on page 3784.

5. Verify the setup.

   After you have completed these steps, you can verify that the broker is using the queue as a shared TID store by inspecting user trace. If the setup is successful, message BIP3470 is issued, specifying which queue manager the broker is using as the TID store.

Results

WebSphere Message Broker first attempts to open the SYSTEM.BROKER.ADAPTER.SHARED queue. If that queue is unavailable, WebSphere Message Broker opens the SYSTEM.BROKER.ADAPTER.PROCESSED queue instead. The availability of the SYSTEM.BROKER.ADAPTER.SHARED queue indicates that you are operating in a z/OS high availability environment.

Enhancing existing adapters with newly discovered objects:

In WebSphere Message Broker Version 7.0, you can take an adapter component that was created by using the Adapter Connection wizard, and update it with newly discovered objects from the Enterprise Information System (EIS). This facility is

known as *iterative discovery*. You can either add the new objects without modifying existing objects, or replace existing objects.

Before you begin

Before you start:

The following instructions assume that you have already run the Adapter Connection wizard to discover a set of objects, as described in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037. You can run iterative discovery only on projects that were created in WebSphere Message Broker Version 7.0 or later versions.

About this task

Procedure

1. From the Broker Development view, expand the appropriate message set project folders until you see the .inadapter or .outadapter component.
2. Right-click the adapter component, then click **Iterative discovery**.

   The Adapter Connection - Iterative Discovery wizard opens. The fields in the wizard are populated with the values that you specified when you ran it previously. You can modify these values if anything has changed, such as a password.
3. On the Find and Discover Services page, the objects that you previously discovered and selected for import are shown in the Objects to be imported pane. You can discover and select new objects to import from the Objects discovered by query pane.
4. On the final page of the Adapter Connection - Iterative Discovery wizard, choose from the following options.
   - To add only the new objects that you discovered, select **Add XSDs for new objects and replace .wsdl, .import/.export**. When you click **Finish**, the following results occur:
     - XSD files for the additional objects are added to the adapter component. These files are shown in the New files pane.
     - Updated .wsdl and .import or .export files replace the files already in the adapter component.
     - The XSD files that are being added to the adapter component are also imported into the message set that is associated with the adapter component.

     If you have discovered objects by using the SAP Wrapper or SAP Work Unit options, the XSD files that correspond to the SAP wrapper objects are replaced in the adapter component. These XSD files are also imported into the message set, replacing any files that have the same name. This behavior is because the wrapper objects contain references to the new objects.
   - To replace all existing objects with the objects that you have discovered, select **Replace the contents of .in/.outAdapter with the newly discovered files**. When you click **Finish**, the following results occur:
     - The contents of the .inadapter or .outadapter file in the adapter component are replaced.
     - All discovered XSD files are imported into the message set, replacing any files that have the same name.

   Note:

Select the **Replace the contents of .in/.outAdapter with the newly discovered files** option if you have changed any of the configuration options during rediscovery, or if the interfaces or data structure of objects that you are discovering have changed since the previous discovery.

If you have discovered objects by using the BAPI result set option, the **Add XSDs for new objects and replace .wsdl, .import/.export** option is not available and you see the message: `Incremental discovery is not applicable for the selected option`.

For options that are used in rediscovering SAP objects, and the corresponding restrictions, see "SAP options for rediscovery" on page 4090.

5. Click **Finish**.

In WebSphere Message Broker Version 7.0, you can add newly discovered objects into an existing adapter component without modifying any existing objects. This facility is known as *iterative discovery*. You can rediscover certain objects for an inbound or outbound adapter.

"Configuration properties for the WebSphere Adapter for SAP Software" on page 4043
The WebSphere Adapter for SAP Software has several categories of configuration properties, which you set with the Adapter Connection wizard when you generate or create objects and services.

Propagating security credentials to an SAP request:

The SAPRequest node can use an identity that is present in the Properties folder of the message tree structure for the security credentials in a request, by using the `Propagate` property on the security profile that is defined on the node.

About this task

If an SAPRequest node is configured with a security profile, it extracts security tokens from the input message at run time, and propagates an identity to SAP.

Procedure

To propagate an identity to be used for the SAP request security credentials, complete the following steps.

1. Ensure that an appropriate security profile exists for the SAPRequest node, or create a security profile, by following the instructions in "Creating a security profile" on page 433.
2. Use the Broker Archive editor to select a security profile for the SAPRequest node that has identity propagation enabled. For detailed instructions, see "Configuring for identity propagation" on page 492.

Related concepts:

"Identity and security token propagation" on page 426
Identity and security token propagation enables the identity and security tokens (associated with each message) to be propagated throughout a message flow, and on to target applications through output or request nodes.

"WebSphere Adapters nodes" on page 1914
A WebSphere Adapters node is a message flow node that is used to communicate with Enterprise Information Systems (EIS), such as SAP, Siebel, JD Edwards, and PeopleSoft.

Related tasks:

"Configuring for identity propagation" on page 492
To enable a message flow to perform identity propagation, the input nodes must extract the identity and the output node must propagate it.

Reference information about the properties that you set for WebSphere Adapters nodes.

Interacting with a Siebel application:

To interact with a Siebel application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

About this task

To connect to a Siebel application, the Siebel adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the Siebel application, then deploy the relevant resources.

Procedure

1. To obtain software dependencies, follow the instructions in "Adding external software dependencies for Siebel" on page 2068.
2. To configure the Siebel application to work with the adapter, create an event table and a Siebel business object, as described in "Configuring the Siebel application to work with the adapter" on page 2070.
3. Optional: To connect to a Siebel server in a clustered environment, see "Connecting to a clustered Siebel environment" on page 2078.
4. Optional: To connect to different versions of Siebel, see "Connecting to different versions of Siebel" on page 2077.
5. Before you run the Adapter Connection wizard, gather the following information from your Siebel administrator:
   - Siebel user name
   - Siebel password
   - Siebel host name or IP address
   - Language code

   For more information, see "Siebel connection properties for the Adapter Connection wizard" on page 4099.
6. To connect to Siebel by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
7. Develop your message flow to define the interaction with the Siebel application.
8. Deploy the appropriate resources, as described in "Deploying a message flow that uses WebSphere Adapters" on page 3240.
9. Optional: To change connection details for Siebel adapters, see "Changing connection details for Siebel adapters" on page 720.

Related concepts:

Adding external software dependencies for Siebel:

Before you can develop message flows that use WebSphere Adapters nodes, you must add prerequisite files to the runtime environment.

Before you begin

Before you start:

Ensure that you have the relevant prerequisite files for your Siebel system.

- Siebel Business Applications Versions 7.5 and earlier
  - `SiebelJI_`*`language code`*`.jar` (for example, `SiebelJI_enu.jar`)
  - `SiebelJI_Common.jar`
- Siebel Business Applications Versions 7.7x, 7.8x, and 8.0
  - `Siebel.jar`
  - `SiebelJI_`*`language code`*`.jar` (for example, `SiebelJI_enu.jar`)

Download these files from the Siebel application, and save them to a directory, such as `C:\Siebel_LIB.` (On Windows, the directory cannot be a mapped network drive on a remote Windows computer; the directory must be local or on a Storage Area Network (SAN) disk.)

The sample resources that you need to set up the Siebel system so that it can communicate with the broker are in the following directory: *`install_dir`*`\ResourceAdapters\Siebel_7.0.0\samples`.

About this task

Locating the Siebel support files in the runtime environment on Windows

To add the Siebel prerequisite files to the runtime environment, take the following steps.

Procedure

1. Ensure that the broker has started.
2. Either open the Command Console, or open a Windows command prompt and enter **`mqsiprofile`** to initialize the environment.

3. Enter the following command to display the locations of the prerequisite JAR files and native libraries:

   ```
   mqsireportproperties MB7BROKER -c AllTypes -o AllReportableEntityNames  -r
   ```

   The following example shows what typically is displayed when you run this command:

   ```
   ReportableEntityName=''
    EISProviders
     JDEdwards=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     PeopleSoft=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     SAP=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     Siebel=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
      siebelPropertiesURL=''
     Twineball=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
   ```

4. Set the location of the Siebel prerequisite files by using the **mqsichangeproperties** command; for example:

```
mqsichangeproperties MB7BROKER -c EISProviders -o Siebel -n jarsURL -v C:\Siebel_LIB
mqsichangeproperties MB7BROKER -c EISProviders -o Siebel -n nativeLibs -v C:\Siebel_LIB
```

5. Optional: To connect to a server in a clustered environment, complete the following steps.

   a. If you do not already have a `siebel.properties` file, create one with a `siebel.conmgr.virtualhosts` property that lists the Siebel servers in the cluster. The `siebel.conmgr.virtualhosts` property is the only property in the `siebel.properties` file that WebSphere Message Broker supports. The server names are represented by a comma separated list in the format *hostname:port*.

   b. Set the location of the `siebel.properties` file by using the **mqsichangeproperties** command; for example:

```
mqsichangeproperties MB7BROKER -c EISProviders -o Siebel -n siebelPropertiesURL
-v C:\siebel.properties
```

   Information message BIP3427 indicates if a `siebel.properties` file is being used, and error message BIP3428 indicates if a problem occurs when attempting to access the `siebel.properties` file.

6. Optional: To connect to different versions of Siebel, follow the instructions in "Connecting to different versions of Siebel" on page 2077.

7. To check that the values have been set correctly, run the following command:

   ```
   mqsireportproperties MB7BROKER -c EISProviders -o Siebel -r
   ```

   The following example shows what is displayed by the **mqsireportproperties** command.

   ```
   ReportableEntityName=' '
   EISProviders
    Siebel=' '
     jarsURL='C:\Siebel_LIB'
   ```

```
    nativeLibs='C:\Siebel_LIB'
    siebelPropertiesURL=''

BIP8071I: Successful command completion.
```

8. Restart the broker.

What to do next

Next: configure the Siebel application to work with the adapter.

"SiebelRequest node" on page 4745
Use the SiebelRequest node to interact with a Siebel application.

Configuring the Siebel application to work with the adapter:

To configure the Siebel application, create an event table and a Siebel business object.

Before you begin

Before you start:

1. Add the required external software dependencies for Siebel.
2. Before you configure the Siebel application to work with WebSphere Adapter for Siebel Business Applications, you must create a user name and password so that the Adapter Connection wizard can connect to Siebel Business Applications to perform outbound operations, and retrieve Siebel business objects and services.

   You perform this task on the Siebel server, therefore ensure that you are familiar with the Siebel tools that are required to complete it. For information about using Siebel tools, refer to the Siebel tools documentation.

   To open Siebel Sales Enterprise on your local database, you must have administrative privileges.

About this task

To configure the Siebel application, you must create an event table and a Siebel business object. WebSphere Message Broker contains resources that help you to create the event components and triggers. This topic describes how to use those resources. You can also create the event table and Siebel business object manually; for more information, see "Creating the event store manually" on page 2072.

Procedure

1. Locate the scripts folder at *install_dir*/WMBT700/ResourceAdapters/Siebel_7.0.0.3_IF08/scripts.

   The scripts folder contains two folders: Siebel7.x.x and Siebel8.0. Each version has an Event_pkg folder, which contains a `.sif` file and a number of `.js` scripts. You use the `.sif` file to create the event components; it can add business objects, views, and all other Siebel objects to the Siebel repository. The `.js` scripts help you to create Siebel triggers.
2. To use the `.sif` file:
   a. Open Siebel tools and click **Tools** > **Import**.
   b. Import the `.sif` file.
   c. Merge the differences between the `.sif` file and the Siebel repository.
   d. Recompile the repository into a Siebel repository file (`.srf` file).
3. Use the `.js` scripts to create Siebel triggers. The provided samples show how to create entries in the inbound table when new Account objects are created.

Creating the event store manually:

To configure the Siebel application, create an event table and a Siebel business object.

About this task

"Configuring the Siebel application to work with the adapter" on page 2070 describes how to use the samples that are supplied with WebSphere Message Broker to configure the Siebel application. This topic describes how to create the event store manually.

The following steps describe how to create the event store to be used for inbound operations in the Siebel application. You can substitute all references to Siebel Sales Enterprise with the name of the Siebel application that you are using.

Procedure

1. Create a project called IBM, and lock the project with Siebel tools.
2. Using the object wizard, create an event table called CX_IBM_EVENT in which to store the events.
   a. In the event table, create the columns that are shown in the following table.

Column Name	Type	Length	Data Type	Required	Nullable	Status
DESCRIPTION	Data (public)	255	Varchar	No	Yes	Active

Column Name	Type	Length	Data Type	Required	Nullable	Status
EVENT_ID	Data (public)	30	Varchar	Yes	No	Active
EVENT_TYPE	Data (public)	20	Varchar	Yes	No	Active
OBJECT_KEY	Data (public)	255	Varchar	Yes	No	Active
OBJECT_NAME	Data (public)	255	Varchar	Yes	No	Active
PRIORITY	Data (public)	10	Varchar	No	Yes	Active
STATUS	Data (public)	20	Varchar	Yes	No	Active
XID	Data (public)	255	Varchar	Yes	No	Active

b. Create a new business component called IBM Event.
c. Create a new time stamp called Field Event, and map it to the CREATED column from CX_IBM_EVENT. Make the Type of this field DTYPE_UTCDATETIME.
d. Create a new business object called IBM Event.
e. Associate the IBM event business component to the IBM Event business object.
f. Create an applet called IBM Event List Applet, and base it on the IBM Event business component that you have created.
g. Create a view called IBM Event List View, and base it on the IBM Event business object that you have created.
h. Create a screen called IBM Event Screen, and associate it with the IBM Event List View in the Siebel tools.

3. Create a page tab.
   a. Click **Start Application** > **Siebel Sales Enterprise**.
   b. Right-click the **Page** tab, and click **New Record**.
   c. Specify IBM Event as the screen name, and IBM Event for the **Text - String Override** field.
   d. Leave the **Inactive** field blank.
4. Create a new business object called Schema Version for your IBM project and associate it with the Schema Version business component.
   a. Apply the physical schema for the new tables to your local database by querying for the new table, CX_IBM_EVENT_Q and selecting the current query to create a physical schema. Leave the table space and index space blank.
   b. Click **Activate** to activate the new schema.
5. Add or modify the Siebel VB or e-scripts for the business component that corresponds to the business objects that are used at your site. Siebel scripts trigger event notification for business objects. Samples are located in the Samples folder in your adapter installation.
6. Create a new Siebel repository file by compiling the updated and locked projects on your local database. The new repository file has an extension of `.srf`.
7. Create and populate a new responsibility.
   a. Open Siebel Sales Enterprise on your local database.
   b. Create a new responsibility called IBM Responsibility for IBM Event List View.
   c. Add the employees or teams who are responsible for reviewing events to the newly created IBM Responsibility.

d. Create a user name called IBMCONN (or another user name to be used by the adapter later). Add the user name to the newly created IBM Responsibility and also to the Administrative Responsibility.

8. Test the application in your local environment to ensure that you can see the IBM Event List View. An event is generated in the view after you create a record in the supported object. As part of the test, create a new Account business component instance in Siebel. Confirm that a new Account event is shown in the IBM Event List View (assuming that you have added the e-script trigger to the Account business component). If a new Account event is not displayed in the view, check for an error and fix it. For more information on the errors that might be generated, check either the Siebel support site or Siebel documentation.
9. When the test that you perform in Step 8 is successful, add your new and updated projects to your development server.
10. Activate the new table in the development server.
11. Compile a new Siebel repository (`.srf`) file on the server.
12. Back up the original repository file on the server.
13. Stop the Siebel server and replace the original repository file with the newly created one.
14. Restart the Siebel server.

Changing connection details for Siebel adapters:

Siebel nodes can get Siebel connection details from either the adapter component or a configurable service. By using configurable services, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a configurable service is created or modified, you must reload the broker or execution group to which the adapter was deployed, by using the **mqsistop** and **mqsistart** commands, or the **mqsireload** command.

Before you begin

Before you start:

- Read "WebSphere Adapters nodes" on page 1914 and "Configurable services" on page 1296 for background information.

About this task

Use the SiebelConnection configurable service to change connection details for a Siebel adapter. The Siebel node reads all connection properties from the adapter component that it is configured to use. If a configurable service exists that has the same name as the adapter component of the node, the node uses the values that are defined in that configurable service to override the corresponding properties from the adapter. If a configurable service is being used, all properties that are exposed by the configurable service are taken from the configurable service. The only properties that are taken from the adapter are those that you cannot set on the configurable service. The properties of the Siebel configurable service are described in "Configurable services properties" on page 3766.

You can also connect to different versions of Siebel by creating a custom EISProviders configurable service and setting the location of the appropriate library files. For more information, see "Connecting to different versions of Siebel" on page 2077.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates a SiebelConnection configurable service for the Siebel instance that is running on *my.siebel.qa.com*:

```
mqsicreateconfigurableservice MB7BROKER -c SiebelConnection -o mySiebelAdapter.outadapter
-n connectString -v "siebel://my.siebel.qa.com/SBA_80/SSEObjMgr_enu"
```

To pick up the new values in the configurable service, restart the execution group and message flow.

- To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. This example changes the connections that are used by the adapter *mySiebelAdapter.outadapter*. After you run this command, all adapters connect to the production system (`my.siebel.production.com`) instead of the test system (`my.siebel.qa.com`):

```
mqsichangeproperties MB7BROKER -c SiebelConnection -o mySiebelAdapter.outadapter -n connectString
-v "siebel://my.siebel.production.com/SBA_80/SSEObjMgr_enu"
```

To pick up the updated values in the configurable service, restart the execution group and message flow.

- To display all SiebelConnection configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

```
mqsireportproperties MB7BROKER -c SiebelConnection -o AllReportableEntityNames -r
```

- You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

```
mqsideleteconfigurableservice MB7BROKER -c SiebelConnection -o mySiebelAdapter.outadapter
```

You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

Connecting to different versions of Siebel:

You can access multiple versions of Siebel from a single broker by using different versions of the client libraries.

About this task

You can connect to different versions of Siebel by creating a custom EISProviders configurable service and setting the location of the appropriate library files. You can then configure an execution group so that all Siebel nodes use this custom configurable service. Therefore, you can connect to different versions of a Siebel server from two different execution groups in the same broker.

You can complete this task by using the command line, the WebSphere Message Broker Explorer, or the Administration API for WebSphere Message Broker (CMP API). For more information about using the WebSphere Message Broker Explorer, see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644. For more information about using the CMP API, see "Developing applications that use the Administration API" on page 956. This topic describes how to connect to different versions of Siebel by using the command line.

Procedure

1. For each version of Siebel to which you want to connect, create a custom EISProviders configurable service by using the **mqsicreateconfigurableservice** command, as shown in the following example.

```
mqsicreateconfigurableservice MB7BROKER -c EISProviders -o EISProvidersName -n jarsURL -v "c:\siebelclient\"
```

   The **-o** parameter specifies the name of the EIS provider, and the **-n** and **-v** parameters are used to specify the file location of the EIS provider JAR files.

2. Configure your execution group to use the custom EISProviders configurable service by using the **mqsichangeproperties** command, as shown in the following example.

```
mqsichangeproperties MB7BROKER –e ExecutionGroupLabel –o ComIbmSiebelManager –n EISProviders –v EISProvidersName
```

3. Restart the execution group by using the **mqsistartmsgflow** command, or in the WebSphere Message Broker Toolkit by right-clicking the execution group and clicking **Start**.
4. Deploy message flows to the appropriate execution group.

"WebSphere Adapter for Siebel properties" on page 4092
Reference information to refer to when you connect to a Siebel application.

Connecting to a clustered Siebel environment:

To connect to a Siebel server in a clustered environment, use a `siebel.properties` file.

Before you begin

Before you start:

Ensure the external software dependencies for Siebel have been set up, as described in "Adding external software dependencies for Siebel" on page 2068.

About this task

To connect to a Siebel server in a clustered environment, use the `siebel.conmgr.virtualhosts` property in the `siebel.properties` file to list the Siebel servers in the cluster.

The `siebel.conmgr.virtualhosts` property is used to list groups of servers with the same function. An incoming call attempts to connect to each server in a group in turn.

The only property in the `siebel.properties` file that WebSphere Message Broker supports is `siebel.conmgr.virtualhosts`. Information message BIP3427 indicates if a `siebel.properties` file is being used, and error message BIP3428 indicates if a problem occurs when attempting to access the `siebel.properties` file.

When the list of servers has been set up in the `siebel.properties` file, you specify the location of the file by using a configurable service, as described in the following steps.

Procedure

1. If you do not already have a `siebel.properties` file, create one with a `siebel.conmgr.virtualhosts` property that lists the Siebel servers in the cluster. Servers are listed by using a comma separated list in the format *hostname:port*.
2. Set the location of the `siebel.properties` file by using the **mqsichangeproperties** command; for example:

```
mqsichangeproperties MYBROKER -c EISProviders -o Siebel -n siebelPropertiesURL
-v C:\siebel.properties
```

Interacting with a PeopleSoft application:

To interact with a PeopleSoft application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

About this task

To connect to a PeopleSoft application, the PeopleSoft adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the PeopleSoft application, then deploy the relevant resources.

Procedure

1. To obtain software dependencies, follow the instructions in "Adding external software dependencies for PeopleSoft" on page 2081.
2. To configure the PeopleSoft application to work with the adapter, create a custom event project, as described in "Creating a custom event project in PeopleTools" on page 2083.
3. Before you run the Adapter Connection wizard, gather the following information from your PeopleSoft administrator:
   - PeopleSoft user name
   - PeopleSoft password
   - PeopleSoft host name or IP address
   - Port number (for example, 9000)
   - Language code (for example, ENG)

   For more information, see "PeopleSoft connection properties for the Adapter Connection wizard" on page 4132.
4. To connect to PeopleSoft by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
5. Develop your message flow to define the interaction with the PeopleSoft application.
6. Deploy the appropriate resources, as described in "Deploying a message flow that uses WebSphere Adapters" on page 3240.
7. Optional: To change connection details for PeopleSoft adapters, see "Changing connection details for PeopleSoft adapters" on page 722.

Related concepts:

Adding external software dependencies for PeopleSoft:

Before you can develop message flows that use WebSphere Adapters nodes, you must add prerequisite files to the runtime environment.

Before you begin

Before you start:

Ensure that you have the relevant prerequisite files for your PeopleSoft system.

- `psjoa.jar`
- A JAR file that contains the component interface API classes

Save both support files to a directory such as `C:\PeopleSoft_LIB.` (On Windows, the directory cannot be a mapped network drive on a remote Windows computer; the directory must be local or on a Storage Area Network (SAN) disk.) You can find the `psjoa.jar` file in the following location on the PeopleSoft Application Server: *`peopleTools_installation_directory`*`\web\PSJOA\psjoa.jar`. Use PeopleTools to generate the component interface JAR file for your business objects.

The sample resources that you need to set up the PeopleSoft system so that it can communicate with the broker are in *install_dir*\ResourceAdapters\PeopleSoft_7.0.0\samples.

About this task

Locating the PeopleSoft support files in the run time on Windows

To add the PeopleSoft prerequisite files to the run time, complete the following steps.

Procedure

1. Ensure that the broker has started.
2. Either open the Command Console, or open a Windows command prompt and enter **mqsiprofile** to initialize the environment.
3. Enter the following command to display the locations of the prerequisite JAR files and native libraries:

   ```
   mqsireportproperties MB7BROKER -c AllTypes -o AllReportableEntityNames  -r
   ```

   The following example shows what typically is displayed when you run this command:

   ```
   ReportableEntityName=''
    EISProviders
     JDEdwards=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     PeopleSoft=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     SAP=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     Siebel=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
      siebelPropertiesURL=''
     Twineball=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
   ```

4. Set the location of the PeopleSoft prerequisite files by using the following command:

```
mqsichangeproperties MB7BROKER -c EISProviders -o PeopleSoft -n jarsURL -v C:\PeopleSoft_LIB
```

5. To check that the values have been set correctly, run the following command:

   ```
   mqsireportproperties MB7BROKER -c EISProviders -o PeopleSoft -r
   ```

   The following example shows what is displayed by the **mqsireportproperties** command.

   ```
   ReportableEntityName=' '
   EISProviders
    PeopleSoft=' '
     jarsURL='C:\PeopleSoft_LIB'

   BIP8071I: Successful command completion.
   ```

6. Restart the broker.

What to do next

Next: create a custom event project in PeopleTools.

Creating a custom event project in PeopleTools:

The WebSphere Adapter requires an event project in PeopleSoft to perform asynchronous inbound event processing. Use PeopleTools to create the custom event project.

Before you begin

Before you start:

Add the required external software dependencies for PeopleSoft.

About this task

If your environment requires inbound event support, you must use a custom event project in PeopleSoft. A sample event project, IBM_EVENT_V600, is provided with the adapter. You can modify and use and the sample project, or you can create your own project by using PeopleTools. If you create your own project, make sure that you complete the following steps.

Procedure

1. Use PeopleTools Application Designer to create and name a new project.
2. Create the fields for the new project as described in the following table:

Field name	Field description
IBM_EVENT_ID	A numeric value that is retrieved from IBM_FETCH_ID record. This value is a unique ID for the event.
IBM_OBJECT_NAME	The name of the corresponding business graph.
IBM_OBJECT_KEYS	The get key property names in the Component Interface, followed by the key values in name-value pairs. This information is used for the component's retrieval from the EIS.
IBM_EVENT_STATUS	If the event is ready to be polled, the status is set to 0 and the IBMPublishEvent function is called.
IBM_OBJECT_VERB	The verb that is set on the business object graph that contains the retrieved business object.
IBM_EVENT_DTTM	The date on which the event is created. For a future dated event, this is the effective date.
IBM_NEXT_EVENT_ID	The field that has the latest event ID under the record IBM_FETCH_ ID. This field is incremented for each event that is added to the IBM_EVENT_TBL, and it populates the IBM_EVENT_ID field in that table.
IBM_XID	The transaction ID that is needed to provide assured event delivery.

3. Create a record named IBM_EVENT_TBL and add to it all the fields that you have just created, except IBM_NEXT_EVENT_ID.
4. Create a record named IBM_FETCH_ID and add to it only the IBM_NEXT_EVENT_ID field.
5. Open the IBM_FETCH_ID record, select the IBM_NEXT_EVENT_ID field, view the PeopleCode, and select **fieldformula.**
6. Copy the PeopleCode for a custom event project from "PeopleCode for a custom event project" on page 4125 to the project that you are creating.

7. Create a page under your project that contains the fields of the IBM_EVENT_TBL record at level 0. The page can have any name.
8. Create a component under your project that contains the page that you have just created. The component can have any name.
9. Create a Component Interface against this component and give it any name. Confirm that you want to default the properties that are based on the underlying component definition.
10. Build the entire project, selecting all create options.
11. Test and confirm that the Component Interface works, by using the Component Interface tester.
12. Generate the Java APIs for the Component Interface, then add the generated classes to the adapter classpath. For complete information about building a PeopleTools project and testing the PeopleSoft Component Interface, refer to PeopleSoft documentation.

Changing connection details for PeopleSoft adapters:

PeopleSoft nodes can get PeopleSoft connection details from either the adapter component or a configurable service. By using configurable services, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a configurable service is created or modified, you must reload the broker or execution group to which the adapter was deployed, by using the **mqsistop** and **mqsistart** commands, or the **mqsireload** command.

Before you begin

Before you start:

- Read "WebSphere Adapters nodes" on page 1914 and "Configurable services" on page 1296 for background information.

About this task

Use the PeopleSoftConnection configurable service to change connection details for a PeopleSoft adapter. The PeopleSoft node reads all connection properties from the adapter component that it is configured to use. If a configurable service exists that has the same name as the node's adapter component, the node uses the values that are defined in that configurable service to override the corresponding properties from the adapter. If a configurable service is being used, all properties that are exposed by the configurable service are taken from the configurable service. The only properties that are taken from the adapter are those that you cannot set on the configurable service. The properties of the PeopleSoft configurable service are described in "Configurable services properties" on page 3766.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates a PeopleSoftConnection configurable service for the PeopleSoft instance that is running on *my.peoplesoft.qa.com*:

```
mqsicreateconfigurableservice MB7BROKER -c PeopleSoftConnection -o myPeopleSoftAdapter.outadapter
-n hostName,port -v "my.peoplesoft.qa.com",9000
```

  To pick up the new values in the configurable service, restart the execution group and message flow.
- To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. This example changes the connections that are used by the adapter *myPeopleSoftAdapter.outadapter*. After you run this command, all adapters connect to the production system (`my.peoplesoft.production.com`) instead of the test system (`my.peoplesoft.qa.com`):

```
mqsichangeproperties MB7BROKER -c PeopleSoftConnection -o myPeopleSoftAdapter.outadapter -n hostName
-v "my.peoplesoft.production.com"
```

To pick up the updated values in the configurable service, restart the execution group and message flow.

- To display all PeopleSoftConnection configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

```
mqsireportproperties MB7BROKER -c PeopleSoftConnection -o AllReportableEntityNames -r
```

- You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

```
mqsideleteconfigurableservice MB7BROKER -c PeopleSoftConnection -o myPeopleSoftAdapter.outadapter
```

You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

Interacting with a JD Edwards application:

To interact with a JD Edwards application, obtain external software dependencies, run the Adapter Connection wizard, develop a message flow, then deploy the relevant resources.

Before you begin

Before you start:

Gather the following information from your JD Edwards administrator; you will need this information when you run the Adapter Connection wizard.

- JD Edwards EnterpriseOne environment name
- JD Edwards user name
- JD Edwards password
- The role that is associated with the user name

To find objects in the JD Edwards system, you use the Adapter Connection wizard to run a query to discover business functions or XML lists. Ask your JD Edwards administrator about the available business function libraries or XML list tables. To complete the wizard, you need to know the table type and the attributes to specify in the query. For more information, see JD Edwards connection properties for the Adapter Connection wizard.

You need the following information to complete the system connection information in the Adapter Connection wizard. You can find this information in the `jdbj.ini` file that is included with the external JD Edwards resource files.

```
[JDBj-BOOTSTRAP SESSION]
user=user
password=***
environment=JDEenv
role=*ALL
```

Connecting to a DB2 database

If you are connecting to a DB2 database, the JDBC driver file that is required for DB2 can be found in the JDBC driver files table (see "Adding external software dependencies for JD Edwards EnterpriseOne" on page 2090). The `jdbj.ini` file contains the following example entries, which have been configured by the JD Edwards administrator:

```
[JDBj-BOOTSTRAP DATA SOURCE]

databaseType=W

[JDBj-JDBC DRIVERS]

UDB=COM.ibm.db2.jdbc.app.DB2Driver
```

Connecting to an Oracle database

If you are Connecting to an Oracle database, the JDBC driver files that are required for Oracle can be found in the JDBC driver files table (see "Adding external software dependencies for JD Edwards EnterpriseOne" on page 2090). The `jdbj.ini` file contains the following example entries, which have been configured by the JD Edwards administrator:

```
[JDBj-JDBC DRIVERS]
ORACLE=oracle.jdbc.driver.OracleDriver

[JDBj-ORACLE]
tns=tnsnames.ora
```

About this task

To connect to a JD Edwards application, the JD Edwards adapter requires certain files and libraries. You must store these files so that they are accessible to the Adapter Connection wizard. The wizard creates various resources, such as an adapter component and message flow. After you have completed the wizard, you can develop a message flow to define the interaction with the JD Edwards application, then deploy the relevant resources.

Procedure

1. To obtain software dependencies, follow the instructions in "Adding external software dependencies for JD Edwards EnterpriseOne" on page 2090.
2. To connect to JD Edwards by using the Adapter Connection wizard, and create a message flow, follow the instructions in "Connecting to an EIS by using the Adapter Connection wizard" on page 2037.
3. Develop your message flow to define the interaction with the JD Edwards application.
4. Deploy the appropriate resources, as described in "Deploying a message flow that uses WebSphere Adapters" on page 3240.
5. Optional: To change connection details for JD Edwards adapters, see "Changing connection details for JD Edwards adapters" on page 724.

Use the JDEdwardsRequest node to interact with a JD Edwards EnterpriseOne server.

Adding external software dependencies for JD Edwards EnterpriseOne:

Before you can develop message flows that use WebSphere Adapters nodes, you must add prerequisite files to the runtime environment.

Before you begin

Before you start:

Obtain the relevant prerequisite files for your JD Edwards EnterpriseOne system from your JD Edwards EnterpriseOne administrator. The necessary files are listed in the following table. The software dependencies differ, depending on which version of JD Edwards EnterpriseOne Tools you use.

JD Edwards EnterpriseOne Tools, version 8.9 (SP1, SP2), 8.93	**JD Edwards EnterpriseOne Tools, version 8.94**	**JD Edwards EnterpriseOne Tools, version 8.95, 8.96**	**JD Edwards EnterpriseOne Tools, version 8.97, 8.98**

JDBC driver files

Database	JDBC driver files	Implementation class
Oracle	tsnames.ora classes12.zip	oracle.jdbc.driver.OracleDriver
SQLServer	sqljdbc.jar	com.ibm.microsoft.sqlserver.jdbc.SQLServerDriver
AS/400	jt400.jar	com.ibm.as400.access.AS400JDBCDriver
DB2 Type-2 (JDK 1.4/1.5)	db2java.zip	com.ibm.db2.jdbc.app.DB2Driver
DB2 Type-4 (JDK 1.4/1.5)	db2jcc.jar db2jcc_license_cu.jar	com.ibm.db2.jcc.DB2Driver
DB2 Type-4 (JDK 1.6)	db2jcc4.jar	com.ibm.db2.jcc.DB2Driver

Copy the external dependency files to a temporary location. For example, copy them to `C:\temp\JDE_dependencies\`.

Tip: The Adapter Connection wizard can browse the JDBC driver files more easily if they are stored in their own folder. For example, if you are using an Oracle database server, you put the `tnsnames.ora` and `classes12.zip` files in the following location: `C:\temp\JDE_dependencies\`.

About this task

Locating the JD Edwards support files in the runtime environment on Windows

To add the JD Edwards prerequisite files to the runtime environment, complete the following steps.

Procedure

1. Ensure that the broker has started.
2. Either open the Command Console, or open a Windows command prompt and enter **mqsiprofile** to initialize the environment.
3. Enter the following command to display the locations of the prerequisite JAR files:

   ```
   mqsireportproperties MB7BROKER -c AllTypes -o AllReportableEntityNames  -r
   ```

   The following example shows what typically is displayed when you run this command:

   ```
   ReportableEntityName=''
    EISProviders
     JDEdwards=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     PeopleSoft=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     SAP=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     Siebel=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
     Twineball=''
      jarsURL='default_Path'
      nativeLibs='default_Path'
   ```

4. Set the location of the JD Edwards prerequisite files by using the following command:

```
mqsichangeproperties MB7BROKER -c EISProviders -o JDEdwards -n jarsURL
-v C:\temp\JDE_dependencies\
mqsichangeproperties MB7BROKER -c EISProviders -o JDEdwards -n nativeLibs
-v C:\temp\JDE_dependencies\
```

5. To check that the values have been set correctly, run the following command:

   ```
   mqsireportproperties MB7BROKER -c EISProviders -o JDEdwards -r
   ```

   The following example shows what is displayed by the **mqsireportproperties** command.

   ```
   ReportableEntityName=' '
   EISProviders
    JDEdwards=' '
     jarsURL='C:\temp\JDE_dependencies'
     nativeLibs='default_Path'

   BIP8071I: Successful command completion.
   ```

6. Restart the broker.

Use the JDEdwardsRequest node to interact with a JD Edwards EnterpriseOne server.

Changing connection details for JD Edwards adapters:

JD Edwards nodes can get JD Edwards EnterpriseOne connection details from either the adapter component or a configurable service. By using configurable services, you can change the connection details for adapters without the need to redeploy the adapters. To pick up new values when a configurable service is created or modified, you must reload the broker or execution group to which the adapter was deployed, by using the **mqsistop** and **mqsistart** commands, or the **mqsireload** command.

Before you begin

Before you start:

- Read "WebSphere Adapters nodes" on page 1914 and "Configurable services" on page 1296 for background information.

About this task

Use the JDEdwardsConnection configurable service to change connection details for a JD Edwards adapter. The JD Edwards node reads all connection properties from the adapter component that it is configured to use. If a configurable service exists that has the same name as the nodes adapter component, the node uses the values that are defined in that configurable service to override the corresponding properties from the adapter. If a configurable service is being used, all properties that are exposed by the configurable service are taken from the configurable service. The only properties that are taken from the adapter are the ones that you

cannot set on the configurable service. The properties of the JD Edwards configurable service are described in "Configurable services properties" on page 3766.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates a JDEdwardsConnection configurable service to connect to the DV7333 development Environment for a user with the Role of administrator.

```
mqsicreateconfigurableservice MYBROKER -c JDEdwardsConnection -o myJdedwardsAdapter.outadapter
-n Environment,Role -v "dv7333,administrator"
```

  To pick up the new values in the configurable service, restart the execution group and message flow.
- To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. This example changes the connection that is used by the adapter *myJdedwardsAdapter.outadapter* to connect to the PD7333 production Environment. After you run this command, all adapters connect to the production Environment (PD7333) instead of the development system (DV7333).

```
mqsichangeproperties MYBROKER -c JDEdwardsConnection -o myJdedwardsAdapter.outadapter -n Environment,Role
-v PD7333,administrator
```

  To pick up the updated values in the configurable service, restart the execution group and message flow.
- To display all JDEdwardsConnection configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

```
mqsireportproperties MYBROKER -c JDEdwardsConnection -o AllReportableEntityNames -r
```

- You can delete a configurable service that has been created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

```
mqsideleteconfigurableservice MYBROKER -c JDEdwardsConnection -o myJdedwardsAdapter.outadapter
```

  You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

Working with WebSphere Process Server

WebSphere Process Server is a business integration server that uses Service Component Architecture (SCA) to present all business transactions in a service-oriented way in its runtime environment. WebSphere Message Broker can accept requests from WebSphere Process Server, and can also call service components on WebSphere Process Server.

About this task

The topics in this section describe what SCA is, and how you can configure your message flows to use SCA to interoperate with WebSphere Process Server.

- "Working with Service Component Architecture (SCA)"
- "Service Component Architecture (SCA) overview" on page 2096
- "Interoperability with WebSphere Process Server" on page 2097
- "SCA nodes" on page 2101
- "Using Broker SCA definitions to configure message flows" on page 2102

- "Message flows for Service Component Architecture (SCA)" on page 2105

Working with Service Component Architecture (SCA)

Start here to find out how you can use SCA to allow interoperability with WebSphere Process Server Version 6.2.

SCA is a specification that describes a model for building applications and systems using a service-oriented architecture (SOA).

WebSphere Message Broker provides built-in message flow nodes that allow interoperability with WebSphere Process Server. These nodes support inbound and outbound scenarios with WebSphere Process Server. In an inbound scenario, a service component in WebSphere Process Server can send a request to WebSphere

Message Broker. In an outbound scenario, a message flow in WebSphere Message Broker can send a synchronous or asynchronous request to WebSphere Process Server.

The nodes are configured by a Broker SCA definition. You can create a Broker SCA definition in two ways:

- From an SCA import or SCA export component that is defined in WebSphere Integration Developer Version 6.2 and imported into WebSphere Message Broker.
- From a WebSphere Message Broker message set.

The SCA nodes cannot be used without a Broker SCA definition to configure them.

If you want to call services available on WebSphere Message Broker, you must either:

- Import an SCA import component from WebSphere Integration Developer and create a message flow that uses an SCAInput node, or
- Generate an inbound Broker SCA definition and export the `.insca` file to WebSphere Integration Developer

If you want to call a service in WebSphere Process Server, you must either:

- Import an SCA export component from WebSphere Integration Developer and configure a message flow using the Broker SCA definition that is created, or
- Generate an outbound Broker SCA definition and export the `.outsca` file to WebSphere Integration Developer

When designing message flows with SCA, you must select a suitable transport (also called a *binding*). The SCA nodes support these transports:

- WebSphere MQ Enterprise transport
- WebSphere Broker HTTP transport with SOAP

Important: The SCA nodes do not support the SCA binding in WebSphere Integration Developer, which is used only for SCA invocations between modules running within WebSphere Process Server.

The following topics describe how to work with SCA:

- "Service Component Architecture (SCA) overview"
- "Message flows for Service Component Architecture (SCA)" on page 2105

Service Component Architecture (SCA) overview

Service Component Architecture (SCA) is a specification that describes a model for building applications and systems using a service-oriented architecture (SOA).

SCA simplifies the creation and integration of business applications that are built using an SOA by separating business logic from its implementation so that you can focus on assembling an integrated application without knowing details of its implementation.

SCA divides the steps of building a service-oriented application into two major parts:

- The implementation of components that provide services and use other services.
- The assembly of these service components to build the business application.

Service components can be assembled graphically using WebSphere Integration Developer, and the implementation can be added later.

For more information about SCA, see SCA.

WebSphere Process Server is a business integration server that supports solutions that are based on SOA; see "Interoperability with WebSphere Process Server."

"Service Component Architecture (SCA) overview" on page 2096
Service Component Architecture (SCA) is a specification that describes a model for building applications and systems using a service-oriented architecture (SOA).

Interoperability with WebSphere Process Server

WebSphere Process Server is a business integration server that supports solutions based on service-oriented architecture (SOA). It uses Service Component Architecture (SCA) to present all business transactions in a service-oriented way in its runtime environment. WebSphere Message Broker can accept requests from WebSphere Process Server, and can also call service components on WebSphere Process Server.

WebSphere Process Server provides components that can use, or be used by, the services in WebSphere Message Broker. This interoperability is based on SCA, and the SCA nodes provide the facilities that permit operation between the two products.

WebSphere Integration Developer is the development environment for WebSphere Process Server. It is the tool for building and deploying SOA-based integration solutions on WebSphere Process Server.

When designing a solution, the Integration Developer can choose either of the following approaches:

"Starting from WebSphere Integration Developer" on page 2099
Design the applications in WebSphere Integration Developer, export your project as a Project Interchange (PI) file, then import it into WebSphere

Message Broker. For more details, see “Importing and exporting resources in a Project Interchange file” on page 1452.

“Starting from WebSphere Message Broker” on page 2100
Design the applications in WebSphere Message Broker, export the Broker SCA definitions, then import them into WebSphere Integration Developer.

Differences in WSDL definition files

When you compare messages on the wire from WebSphere Message Broker and WebSphere Integration Developer, the root element might be different. WSDL generated by WebSphere Message Broker creates messages whose root element is the element name of the message. In most cases, this element name is the same as the message definition name that is used to generate the WSDL. However in WebSphere Integration Developer, messages are wrapped with an additional element whose name is the same as the name of the operation; consequently, the root element has the name of the operation.

Related tasks:

“Exporting an SCA Import or Export from a Broker SCA definition” on page 2945
You can use the New Message Definition File wizard in the WebSphere Message Broker Toolkit to export SCA import or SCA export components. You must export an SCA import or SCA export if the Broker SCA definition is to be used by WebSphere Integration Developer.

“Generating a Broker SCA definition from a message set” on page 2967
WebSphere Message Broker creates a Broker SCA definition from existing message definitions.

“Importing SCA import or SCA export components” on page 2943
You can use the New Message Definition File wizard in the WebSphere Message Broker Toolkit to import SCA import or SCA export components from WebSphere Integration Developer. You must import an SCA import or SCA export into the workspace to provide a broker SCA definition for use in configuring the SCA nodes.

“Developing SCA applications for non-XML data” on page 2103
The SCA nodes allow non-XML data to be sent and received from WebSphere Process Server by using the WebSphere MQ binding. For example, create a message model from a COBOL copybook, and use that message model to parse messages received from WebSphere Process Server.

Related reference:

“SCAInput node” on page 4707
Use the SCAInput node with the SCAReply node to process messages from WebSphere Process Server.

“SCAReply node” on page 4726
Use the SCAReply node to send a message from the broker to the originating client in response to a message received by a SCAInput node.

“SCAAsyncRequest node” on page 4690
Use the SCAAsyncRequest node with the SCAAsyncResponse node to construct a pair of message flows that invoke a WebSphere Process Server service component asynchronously.

“SCAAsyncResponse node” on page 4698
Use the SCAAsyncResponse node with the SCAAsyncRequest node to construct a pair of message flows that start a component asynchronously.

Starting from WebSphere Integration Developer:

You can design SOA applications in WebSphere Integration Developer (IBM Integration Designer) that need to call services in WebSphere Message Broker, or be called by services in WebSphere Message Broker

- If you are developing a service on WebSphere Integration Developer and you want WebSphere Message Broker to be able to send requests to it, you create an export component in your WebSphere Integration Developer application.
- If you want to call a WebSphere Message Broker service from your WebSphere Integration Developer application, you create an import component in your application.

After you have created your WebSphere Integration Developer application, you export a PI file, which you can then import into WebSphere Message Broker.

Use the New Message Definition File wizard or the Start from SCA Import or Export Quick Start wizard to import WebSphere Integration Developer export and import components. See "Importing SCA import or SCA export components" on page 2943. Ensure that the import or export components that you import from WebSphere Integration Developer use SOAP 1.1 bindings; a validation error occurs if you attempt to import SCA import components or SCA export components that have been generated with SOAP 1.2 bindings.

Importing the PI file creates the message definition file and the Broker SCA definition files.

If you import a WebSphere Integration Developer import component and create a Broker SCA definition from it, you create a Broker SCA definition with a file extension of `.insca`. The Broker SCA definition contains:

- binding information (in a file with an extension of `.import`)
- WSDL and XSD files that describe the message format

Broker SCA definitions that are created from imported WebSphere Integration Developer import components provide values for properties on the SCAInput node which can then receive requests from WebSphere Process Server.

If you import a WebSphere Integration Developer export component and create a Broker SCA definition from it, you create a Broker SCA definition with a file extension of `.outsca`. This file contains:

- binding information (in a file with an extension of `.export`)
- WSDL and XSD files that describe the message format

Broker SCA definitions that are created from imported WebSphere Integration Developer export components provide values for properties on the SCARequest node, or the SCAAsyncRequest and SCARequest nodes, which can then send requests to WebSphere Process Server.

Related concepts:

"Interoperability with WebSphere Process Server" on page 2097
WebSphere Process Server is a business integration server that supports solutions based on service-oriented architecture (SOA). It uses Service Component Architecture (SCA) to present all business transactions in a service-oriented way in its runtime environment. WebSphere Message Broker can accept requests from WebSphere Process Server, and can also call service components on WebSphere Process Server.

"Starting from WebSphere Message Broker"
You can design SOA applications in WebSphere Message Broker that need to call services in WebSphere Process Server or be called by services in WebSphere Process Server.

Starting from WebSphere Message Broker:

You can design SOA applications in WebSphere Message Broker that need to call services in WebSphere Process Server or be called by services in WebSphere Process Server.

- If you are developing a service on WebSphere Message Broker and you want a WebSphere Integration Developer application to be able to send requests to it, you generate an `.insca` Broker SCA Definition file. You use the Broker SCA Definition file to create an SCAInput node, which can receive requests from WebSphere Process Server. You also export this file from WebSphere Message Broker to the file system or workspace. You can import the exported artifacts into WebSphere Integration Developer. Importing the file into WebSphere Integration Developer creates an Import component in your WebSphere Integration Developer application; to access a service provided by WebSphere Message Broker, connect this Import component in the assembly diagram.
- If you are developing a service on WebSphere Message Broker and you want to access a service on WebSphere Process Server, you generate an `.outsca` Broker SCA Definition file. You use the Broker SCA Definition file to create either:
  - A pair of SCAAsyncRequest and SCAAsyncResponse nodes, for asynchronous operations.
  - A SCARequest node, for operations that are synchronous or one-way.

  The SCAAsyncRequest or SCARequest node sends requests to WebSphere Process Server. You also export this file from WebSphere Message Broker to the file system or workspace. You can import the exported artifacts into WebSphere Integration Developer. Importing the artifacts into WebSphere Integration Developer creates an Export component in your WebSphere Integration Developer application; to receive requests from a broker application, connect this Export component in the assembly diagram.

Use the Generate Broker SCA Definition wizard to generate Broker SCA definitions; see "Generating a Broker SCA definition from a message set" on page 2967.

Use the Export an SCA Import or Export from a Broker SCA definition wizard to export a Broker SCA definition after you have generated it; see "Exporting an SCA Import or Export from a Broker SCA definition" on page 2945.

SCA nodes

SCA nodes support interoperability between WebSphere Message Broker and WebSphere Process Server.

- The SCAInput and SCAReply nodes are analogous to the SOAPInput and SOAPReply nodes, and are used in a message flow that provides an SCA endpoint. These SCA nodes are used to construct a message flow which implements SCA.

  The SCAInput node listens for SCA inbound requests (from WebSphere Process Server to WebSphere Message Broker).

  The SCAReply node sends a reply back to the client that originated the SCA request. See "SCAInput node" on page 4707 and "SCAReply node" on page 4726.

- The SCAAsyncRequest and SCAAsyncResponse nodes are used to construct a pair of message flows that call a WebSphere Process Server service component asynchronously.

  The SCAAsyncRequest node sends an SCA outbound request to a service component that runs in WebSphere Process Server.

  The SCAAsyncResponse node receives the response from a business process that is running in WebSphere Process Server and to which the previous asynchronous request was made. The SCAAsyncResponse node can be in the same message flow or in a separate message flow.

  Calling a WebSphere Process Server service component asynchronously means that the SCAAsyncRequest node sends a request but does not wait for the associated response to be received, although it might wait for an acknowledgment of the request.

  The nodes are used as a pair, and correlate responses and requests. See "SCAAsyncRequest node" on page 4690 and "SCAAsyncResponse node" on page 4698.

- The SCARequest node is used to send a request to WebSphere Process Server. The node is configured using a Broker SCA Definition (`.outsca`) file; depending on the contents of the `.outsca` file, requests are either:
  - Two-way, synchronous; the node sends the request, then blocks until it receives a response, or the timeout period is exceeded.
  - One-way; the node sends a request only.

Using Broker SCA definitions to configure message flows

Use Broker SCA definitions to create and configure SCA nodes in a message flow.

A Broker SCA definition is a broker artifact that has a `.insca` or `.outsca` extension. The artifact contains the following information:

- Binding type and interface information which is present in SCA import or SCA export components
- WSDL that defines the interface
- XSD files that describe the message format

The Broker SCA definition files appear in a folder, named `Broker SCA Definitions`, in the message set project.

A `.insca` file contains an SCA Import component, and is used to configure SCAInput and SCAReply nodes.

A `.outsca` file contains an SCA Export component, and is used to configure SCAAsyncRequest, SCAAsyncResponse, and SCARequest nodes.

To create and configure SCA nodes, drag Broker SCA definitions, which are generated from SCA import or export files, into the message flow editor. This action automatically creates the appropriate nodes, and completes many of the configurable properties of the nodes. The nodes cannot be used if there is no Broker SCA definition with which to configure the nodes.

For Web Services binding, the data defines the service and the port name for the service within the WSDL that is invoked. It also defines an SCA endpoint address, extracted from the WSDL.

For MQ binding, the data defines the WebSphere MQ connection properties, the message binding format, the replyTo destination, and transaction and security information.

Developing SCA applications for non-XML data

The SCA nodes allow non-XML data to be sent and received from WebSphere Process Server by using the WebSphere MQ binding. For example, create a message model from a COBOL copybook, and use that message model to parse messages received from WebSphere Process Server.

About this task

Both WebSphere Message Broker and WebSphere Integration Developer use XML schema to describe the *logical* format of the message to be parsed. Extra information in the form of XML schema annotations is used to describe any *physical* formats that you define for the messages. The physical format describes the precise appearance of the message bit stream during transmission.

In WebSphere Message Broker, using the MRM domain, you can model different physical representations using specific physical formats. These physical formats include *Custom Wire Format* (CWF) and *Tagged Delimited String Format* (TDS). Using the CWF physical format, you can model a message directly from a COBOL copybook.

"Interoperability with WebSphere Process Server" on page 2097 describes how the schema describing the logical format can be exchanged between WebSphere Message Broker and WebSphere Integration Developer. But the XML schema annotations that describe the physical format is not exchanged in those steps. This topic shows how to model the same message in both WebSphere Message Broker

and WebSphere Integration Developer. You create applications in WebSphere Message Broker and WebSphere Process Server that use a message model derived from a COBOL copybook. You can use a similar method for other message models derived from other non-XML data structures such as C Header files.

Starting from WebSphere Integration Developer:
Procedure

1. Import the COBOL copybook into your WebSphere Integration Developer module. See *Creating a business object from a source file* in the WebSphere Integration Developer Information Center.
2. Add the SCA Import or SCA Export to the assembly diagram that has an interface containing operations using message data types that were created from the COBOL copybook.
3. Export the Project Interchange (PI) file from WebSphere Integration Developer.
4. Import the PI file into WebSphere Message Broker using the Importer wizard.
5. Create the Inbound or Outbound SCA message flow from the SCA Definition file that the importer created.
6. Create a second message set and import the **same** COBOL copybook that was used to import into WebSphere Integration Developer.
7. Update the project references for your message flow project so that it also references the second message set.
8. In the message flow, select the **Input message parsing** tab in the SCAInput node, or **Response message parsing** tab in the SCARequest or SCAAsyncRequest node. Change the message domain from BLOB to MRM. Select the second message set that you created in the message set property. Select the relevant message type and message format.
9. Continue developing the rest of the application in WebSphere Message Broker.

Starting from WebSphere Message Broker:
Procedure

1. Create a message set from the COBOL copybook.
2. Generate the Broker SCA definition.
3. Export the SCA component.
4. In WebSphere Integration Developer, import the SCA import or export component and WSDL that have been exported from WebSphere Message Broker. Do not select the XSD files. See *Importing WSDL files* in WebSphere Integration Developer Information Center.
5. In WebSphere Integration Developer, select the import or export component and select the binding tab. For the input data format and output data format, click **Select** and step through the Data Format Transformation wizard; the information required by this wizard is not exported from WebSphere Message Broker.
6. In WebSphere Integration Developer, create the data types in the same module by importing the COBOL copybook. See *Creating a business object from a source file* in WebSphere Integration Developer Information Center.
7. Update the operations in the interface used by the SCA Import or Export so that they use the data types that you created.
8. Continue developing the rest of the application in WebSphere Integration Developer.

Message flows for Service Component Architecture (SCA)

Use the SCA nodes to develop message flows so that WebSphere Message Broker can interoperate with WebSphere Process Server. These nodes support scenarios in which service components that run on WebSphere Process Server either are called from WebSphere Message Broker or call a WebSphere Message Broker message flow.

Message flows that are called by service components in WebSphere Process Server are SCA inbound message flows. Message flows that call service components in WebSphere Process Server are SCA outbound message flows.

Inbound flows use either a SCAInput node, or a pairing of the SCAInput node and SCAReply node to process messages from WebSphere Process Server.

Outbound flows use either a SCARequest node, or a pairing of the SCAAsyncRequest node and SCAAsyncResponse node, to call a service component in WebSphere Process Server.

Related concepts:

"SCA inbound message flows"
SCA inbound message flows are message flows that can be called by a service component running on WebSphere Process Server. By using SCAInput and SCAReply nodes in your message flow, you can process messages from WebSphere Process Server.

"SCA outbound message flows" on page 2107
SCA outbound message flows are message flows that call a service component on WebSphere Process Server. By using an SCARequest node, or a pair of SCAAsyncRequest and SCAAsyncResponse nodes, you can call a service component in WebSphere Process Server.

SCA inbound message flows:

SCA inbound message flows are message flows that can be called by a service component running on WebSphere Process Server. By using SCAInput and SCAReply nodes in your message flow, you can process messages from WebSphere Process Server.

When you want WebSphere Process Server to call services that are provided by WebSphere Message Broker, the SCAInput node acts as an SCA endpoint for the WebSphere Process Server service component. It accepts requests from WebSphere Process Server. The SCAReply node sends replies back to WebSphere Process Server.

Values for many of the properties of the SCAInput node that relate to the WebSphere Process Server binding are provided in the Broker SCA definition. You can generate this in two ways:

- From a message set.
- From an SCA import component imported from WebSphere Integration Developer.

You can put an instance of the SCAInput node into a message flow in either of the following ways:

- Drag a Broker SCA definition with an extension of `.insca` from a message set onto the message flow editor canvas. If the `.insca` file contains only one-way operations, dragging a `.insca` file onto the canvas creates a SCAInput node. Otherwise, a pair of SCAInput and SCAReply nodes is created. If you use this method, many of the values for the properties of the node or nodes are supplied by the Broker SCA definition.
- Drag an instance of the node from the node palette onto the canvas. You then configure the node by dragging a Broker SCA definition with an extension of `.insca` onto the node.

The values for properties that relate to the binding supported by the specific SCA component are automatically supplied to the node from the Broker SCA definition; you do not have to manually provide them.

Use the SCAReply node to send a message from the broker to the originating client in response to a message received by a SCAInput node.

"SCAAsyncRequest node" on page 4690
Use the SCAAsyncRequest node with the SCAAsyncResponse node to construct a pair of message flows that invoke a WebSphere Process Server service component asynchronously.

"SCAAsyncResponse node" on page 4698
Use the SCAAsyncResponse node with the SCAAsyncRequest node to construct a pair of message flows that start a component asynchronously.

"SCARequest node" on page 4719
Use the SCARequest node to send a request to WebSphere Process Server. The node is a synchronous request and response node, and blocks after sending the request until the response is received. The node can also send one-way requests.

SCA outbound message flows:

SCA outbound message flows are message flows that call a service component on WebSphere Process Server. By using an SCARequest node, or a pair of SCAAsyncRequest and SCAAsyncResponse nodes, you can call a service component in WebSphere Process Server.

Many of the properties of the SCAAsyncRequest and SCAAsyncResponse nodes are provided in the Broker SCA definition. You can generate this in two ways:

- From a message set.
- From an SCA export component imported from WebSphere Integration Developer.

The Broker SCA definition contains specific data that relates to the binding supported by the specific SCA component.

You create the appropriate nodes by dragging an outbound Broker SCA definition (`.outsca` file) onto the message flow editor from a message set project.

- If the `.outsca` file contains either a single request-response operation, or more than one operation (one-way or request-response), you are prompted to select the operation. If the chosen operation is request-response, you can also choose whether to invoke the service synchronously or asynchronously. Synchronous invocation is the default value, and creates a SCARequest node. Choosing the asynchronous option creates a pair of SCAAsyncRequest and SCAAsyncResponse nodes.
- If the chosen operation is one-way, synchronous invocation is the only option, and a SCARequest node is created.

Synchronous requests:

Use a SCARequest node when:

- WebSphere Message Broker needs to synchronously invoke a request-response operation.
- WebSphere Message Broker needs to invoke a one-way operation in an application running on WebSphere Process Server.

If the request is request-response, the node sends the request, then blocks until it receives a response, or the timeout period is exceeded. If the timeout period is exceeded, the message received on the input terminal of the SCARequest is propagated to the Failure terminal.

If the request is one-way, the node sends a request only. The message received on the input terminal of the SCARequest node is propagated to the Out terminal.

Asynchronous requests: When WebSphere Message Broker needs to make an asynchronous call to a service component that is provided by WebSphere Process Server, use a message flow, or flows, that contains a pair of SCAAsyncRequest and SCAAsyncResponse nodes. The SCAAsyncRequest node sends a request to a service component running on WebSphere Process Server. The SCAAsyncResponse node receives the response from WebSphere Process Server to a previously made asynchronous request from an SCAAsyncRequest node. Responses are correlated against the original requests.

The SCAAsyncRequest node requests sends a request to a service component running on WebSphere Process Server. The SCAAsyncResponse node receives the response from WebSphere Process Server to a previously made asynchronous request from an SCAAsyncRequest node. Responses are correlated against the original requests.

The SCAAsyncResponse node can be in the same message flow as the SCAAsyncRequest node which makes the request, or it can be in a separate message flow; it must, however, be in the same execution group as the SCAAsyncRequest node.

Transform and enrich messages by using one or more of the techniques described in this section.

Databases overview

Brokers can access *user databases* to manipulate your business data. If you have user databases, you must configure them before you can access them from your message flow.

WebSphere Message Broker supports the databases that are listed in "Supported databases" on page 3591 for user databases. If you configure your message flows to access user databases, you cannot access some of the data types that are supported by these databases. The supported data types are defined in "Data types of values from external databases" on page 5288.

User databases

User databases are the databases in which you store the business data that is processed by message flow applications. Additional local and remote database managers might also be supported for your computer. For more information, see "Supported databases" on page 3591 and "Database locations" on page 3595.

You must set up connections to the user databases so that the broker can access the databases on behalf of its deployed message flows. Both ODBC and JDBC

connections are supported; some restrictions apply on some platforms, as described in the topics in this section. ODBC drivers are supplied and installed with WebSphere Message Broker. JDBC drivers are not supplied by WebSphere Message Broker; you must obtain these files from your database vendor. Supported drivers are listed in "Supported databases" on page 3591.

You can use the **mqsicvp** command as an ODBC test tool; see "Enabling ODBC connections to the databases" on page 668 for further information.

For information about connections to user databases, see "User database connections."

"Data types of values from external databases" on page 5288
How database data types are implicitly cast to ESQL data types.

User database connections:

User databases contain business data that is written and accessed by deployed message flows. You must create connections from the broker to the user database by using ODBC or JDBC.

ODBC connections to databases are managed internally by the broker, and therefore any configurable connection pooling options that are available on the ODBC driver should not be used.

The broker requires a database connection for each data source name (DSN) that is referenced in the message flow, even if different DSNs resolve to the same physical database.

The number of connections to a user database that a broker requires depends on the actions of the message flows that access the database. For each message flow thread, a broker that accesses a user database makes one connection for each data source name (DSN). If a different node on the same thread uses the same DSN, the same connection is used, unless a different transaction mode is used, in which case another connection is required. For further information about transactions, see "Database connections for coordinated message flows" on page 4235.

When you start a broker, and while it is running, it opens connections to WebSphere MQ queues and to databases. The broker makes the connections when it needs to use them, and they remain open until one of the following events occurs:

The message flow has been idle for 1 minute

The message flow is stopped

The broker is stopped

If the message flow contains a DatabaseInput node, at least one database connection remains open while the message flow is running.

Database connections from message flows that are not globally coordinated are released when a flow has no work. For example, a connection is released if the message flow input queue has no messages, and the database has not been accessed for 1 minute.

Linux UNIX Windows On Linux, UNIX, and Windows systems, to avoid breaking global coordination, database connections are released only for message flows that are not globally coordinated.

z/OS On z/OS, database connections for globally coordinated message flows are also released if the database has not been accessed for 1 minute.

To change the default time of 1 minute after which a database connection for an idle message flow is released, use the following command:

```
mqsichangeproperties myBroker -e myExecutionGroup -o ComIbmDatabaseConnectionManager -n maxConnect
```

or the following command, to change the default time for all execution groups:

```
mqsichangeproperties myBroker -o ComIbmDatabaseConnectionManager -n maxConnectionAge -v newValue
```

where *maxConnectionAge* is specified in seconds. If *maxConnectionAge* is set to option -1, database connections are never released until the execution group or broker is stopped.

If you are using DB2 for your database, the default action is to limit the number of concurrent connections to a database to the value of the **maxappls** configuration parameter. The default for **maxappls** is 40. If you believe that the connections that the broker might require exceeds the value for **maxappls**, increase this parameter and the associated **maxagents** parameter to new values based on your calculations.

For z/OS, the number of connections does not change when you use ODBC CAF (Call Attachment Facility) connections or RRSAF (Recoverable Resource Services Attachment Facility). For more information on the number of connections required, see You do not know how many database connections a broker requires.

If you are using another database, check the database documentation for information about connections and the limits or restrictions that might apply.

When a message flow is idle, the execution group periodically releases database connections. Therefore, connections held by the broker reflect its current use of these resources. This situation allows the broker to respond when a database quiesces, if the database manager supports quiescing. Not all databases support the quiesce function, and not all databases quiesce in the same way. Check your database documentation for information about database quiescing.

The number of WebSphere MQ connections a broker requires to its queue manager depends on the actions of the message flows that access the WebSphere MQ resource.

Accessing databases from message flows

Create and configure message flows to access user databases.

Before you begin

Before you start:

Complete the following tasks:

- "Creating a message flow" on page 1431
- "Working with databases" on page 2109

Read the following concept topic:
- "Message flow nodes" on page 1024

Check which databases are supported on which platform, and if any restrictions apply:
- "Supported databases" on page 3591

About this task

You can access a database from a message flow in two ways:

- You can design a message flow that responds to events generated by the database.
- After a flow has already started, you can access the database to read or update information in it. Information from the database can be used to enhance or influence the operation of the message flow.

You can access a database from a message flow by using the following nodes:
- Compute
- Database
- DatabaseInput
- DatabaseRetrieve
- DatabaseRoute
- DataDelete
- DataInsert
- DataUpdate
- Filter
- JavaCompute
- Mapping
- Warehouse

For more details about these nodes, and how to configure them in message flows, see "Built-in nodes" on page 4293.

If you want the actions that the message flow takes against the database to be coordinated with other actions, configure the message flow to support global coordination of transactions. For information about how to complete this task, see "Configuring transactionality for message flows" on page 1290.

To access a database from a message flow:

Procedure

1. Identify the database that you want to access. You can access an existing database, or create a new database for this purpose. See "Data sources on z/OS" on page 4014 for more information about what to call a z/OS user database.

   Create the database you want, or ask your database administrator to create it for you. If you are using DB2 or Oracle databases, some of the samples programs include basic instructions for creating databases, which you can use as a guide. For information about which samples include databases, see "Creating the user databases" on page 661.
2. Define a connection to the data source name (DSN) to enable a connection to the database, if one does not exist:

- Define a JDBC connection if you want to interact with a database directly from a Java application. You can code Java in both a JavaCompute node and in a Java user-defined node.

  For more information, see “Enabling JDBC connections to the databases” on page 683.
- Define an ODBC connection if you want to interact with a database in a node that supports ESQL, including a JavaCompute node in which you use the MbSQLStatement interface.

  For more information, see “Enabling ODBC connections to the databases” on page 668.

3. Authorize the broker to access the database.

   Access to a user database from within a message flow is controlled by user ID and password.

   - Linux UNIX Windows Use the **mqsisetdbparms** command to specify a user ID and password for a specific database, or to set up a default user ID and password.
   - z/OS Use the BIPSDBP JCL in the customization data set `<hlq>.SBIPPROC` to customize the **mqsisetdbparms** command to specify a user ID and password for a specific database, or to set up a default user ID and password.

What to do next

The following samples access databases from message flows:

- Message Routing
- Data Warehouse
- Error Handler
- Airline Reservations

Message Routing and Data Warehouse use Compute nodes to access the database. Error Handler uses Database nodes to access the database, and Airline Reservations uses both Compute and Database nodes.

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

"Data sources on z/OS" on page 4014

Accessing databases from ESQL

Configure your broker and your database to support connections from message flows.

Before you begin

Before you start:

- Create the broker.

You must configure both your broker and your databases to support read, write, and update operations in your message flows.

About this task

- Set the `Data Source` property of each node to the name (that is, the ODBC DSN) of the database that you want to access.
- Configure the broker to be able to connect to the database:
  - Create ODBC data source connections on the system on which the broker is running.
  - Define a user ID and password to be used by the broker to connect to the database:

- If you have used the **mqsisetdbparms** command, or submitted the JCL member BIPSDBP in the customization data set <hlq>.SBIPPROC on z/OS, to set a user ID and password for a particular database, the broker uses these values to connect to the database.
- If you have not set up a specific user ID and password for this database, the broker users the default ID and password set by using the **mqsisetdbparms** command, or the JCL file BIPSDBP.
- If you have not set up a default user ID and password:
  - On Windows, the service user ID and password are used to connect to the database.
  - On z/OS, the broker started task ID is used. The schema used is the one defined for a specific DSN or a default DSN set up by using the **mqsisetdbparms** command. If neither exist, the value of CURRENTSQLID in the BIPDSNAO file is used. If CURRENTSQLID is not set, the schema defaults to the started task user ID for the broker.
  - On other platforms, connection to the database fails.

- Set up the authorization for the user ID to access the database by using the administration facilities provided by the database vendor. If you do not do so, the broker generates an error when the message flow runs.
- All databases accessed from the same node must have the same ODBC functions as the database specified on the Data Source property on that node. This requirement is always satisfied if the databases are of the same type (for example, DB2 or Oracle), at the same release level (for example, release 9.1), and on the same platform. Other database combinations might have the same ODBC functions. If a node tries to access a database that does not have the same ODBC functions as the database specified on the Data Source property on that node, the broker generates an error message.

  You can use the **mqsicvp** command as an ODBC test tool. This test tool can be run against two databases simultaneously, and tells you whether those two datasources are eligible to be used together in the same node.

  The test tool is also useful in displaying any limitations there might be in your datasource, prior to constructing your ESQL; see "Enabling ODBC connections to the databases" on page 668 for further information.
- With a single SELECT FROM clause, you can access only tables that exist in a single database.
- If you access database columns that have names composed of only numeric characters, you must enclose the names in double quotation marks; for example, "0001". Because of this restriction, you cannot use a SELECT * statement, which returns the names without quotation marks; the names are therefore invalid and the broker raises an exception.

For details of the ESQL statements and functions that you can use to access databases, see "Interaction with databases using ESQL" on page 2487.

Extended database support

Use WebSphere Message Broker ODBC Database Extender (IE02) to allow WebSphere Message Broker to support two ODBC database driver managers in the same process space.

Database supported:

solidDB
: solidDB is an in-memory database product from IBM. solidDB V6.5 is supported; for more information see IBM solidDB product family.

See "Supported databases" on page 3591 for a full list of supported operating systems on which the WebSphere Message Broker supports solidDB.

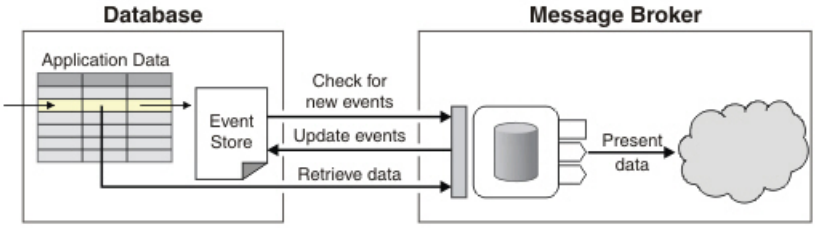
Use the **mqsicvp** command to perform verification tests on a broker, or to verify ODBC connections.

Event-based database integration

Use a DatabaseInput node to respond to events in a database. For example, the broker can keep an external system synchronized with a database by sending updates to the target system whenever data is changed in the database.

The database must record the fact that data has changed in an *event store*, which is typically a database table. The event store is not the same as the application data. The following diagram shows the interaction between the database, event store, and the broker.

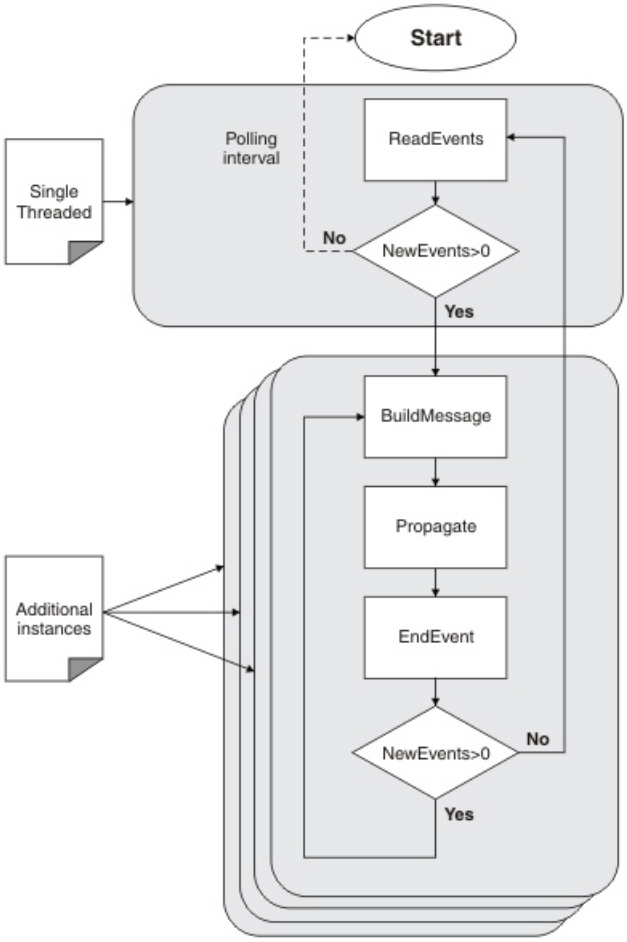


1. A database application changes a database table.
2. The database management system (DBMS) records the change in the event store.
3. The broker polls the event store after the interval specified in the `Polling interval` configuration setting.
4. WebSphere Message Broker retrieves the new or changed data, and updates the event store, so that the data is processed only once.
5. WebSphere Message Broker processes the data, and ultimately presents it to the target application, for example SAP, web services, or CICS Transaction Server for z/OS. The data can be presented in a different logical and physical format, if required.

Implementing: Implementing this scenario involves the following steps:

1. Configuring the database to record events.
2. Determining the format in which the target system must receive the data from these new events.
3. Configuring the broker to detect these events by using the DatabaseInput node. To configure the DatabaseInput node, see "Configuring a DatabaseInput node" on page 2120.
4. Configuring the rest of the message flow to present the data to your target system in the correct format.

The DatabaseInput node: The following diagram shows how the DatabaseInput node works.



When the process starts, ReadEvents checks the event store for new events, which are then used by BuildMessage to build the message. This message is propagated to the message flow and then EndEvent updates the event store to ensure that the event cannot be processed again. When all events have been processed, the broker calls ReadEvents to retrieve any events that have been added since the previous check. If the event store is empty, the broker waits until the polling interval has expired, and then calls ReadEvents again. To avoid contention, the check of the event store is single-threaded.

For each event that is read by ReadEvents, BuildMessage builds the message that is propagated to the message flow. Building the message typically uses the event data to look up data in the application table. The data from the application table is then used to construct the message. When BuildMessage ends, the message is automatically propagated to the message flow. When the message is propagated, the broker starts any downstream nodes that are required to process the message.

After the message has been propagated to the message flow, EndEvent updates the event store to ensure that the event that has just been processed cannot be processed again.

The detailed operation of ReadEvents, BuildMessage, and EndEvent are controlled by ESQL code. The DatabaseInput node contains an ESQL module with sample

code and comments, which you must modify to suit your requirements. For information about modifying the ESQL, see "Configuring a DatabaseInput node."

Transactions and Scaling: The processes that are completed by the DatabaseInput node are split across separate transactions. A new transaction is started when ReadEvents starts. When ReadEvents ends, this transaction is committed and new events are marked for processing. By committing this transaction, any locks put on the database by ESQL code that is run from ReadEvents are released. Then, for each event received by BuildMessage, a new transaction is started. This new transaction is committed after EndEvent finishes.

To scale a DatabaseInput node for many events, change the `Additional instances` property on the **Instances** tab from its default value of `0` to the number of instances that you require. If you are using additional instances, the database must be configured so that multiple applications can read different rows from the application table at the same time. ReadEvents always runs in single-threaded mode to avoid database contention, even if you use additional instances. To improve performance, ReadEvents can read multiple events each time it runs, and these events can be processed at the same time by multiple instances of BuildMessage. The event store must have a primary key, which ReadEvents uses to identify events that are currently being processed. You do not have to write the ESQL in ReadEvents to filter out events that are currently being processed by the message flow.

Configuring a DatabaseInput node:

Create and configure message flows that respond to events in a database.

Before you begin

Before you start:

Read the following topics:
- "Event-based database integration" on page 2118
- "Responding to database updates" on page 2123

Check which databases are supported on which platform, and if any restrictions apply:
- "Supported databases" on page 3591

Ensure that your database is configured to record events (uses an event table), and that you know how to query those events. For information about event tables and triggers, see the DatabaseInput Node sample. You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

z/OS If you use DB2 on z/OS, your user ID (or your user group) requires permission to perform a SELECT on SYSIBM.SYSJAROBJECTS.

Complete the following tasks:
- Add a database definition to the toolkit

About this task

When you drag a DatabaseInput node onto the canvas, WebSphere Message Broker creates an ESQL module that contains boilerplate text. To configure the DatabaseInput node, modify the statements in that module to suit your requirements.

When you double-click the node to modify the ESQL code, the editor displays the Database Event Design tab for the module. Complete the mandatory fields and then click **Generate query**. To view or modify the code, click the Source tab. Code that has been generated is clearly marked by color-coded `--@!{` and `--@!}` comments. Any changes that you make within these comments are lost if you regenerate the code.

Procedure

1. In the WebSphere Message Broker Toolkit, drag a DatabaseInput node onto the canvas, and double-click the node. The Database Event Design tab is displayed. Ensure that the correct module is selected.
2. Complete the Event Table section.
   a. Optional: Complete the `Database schema` property. Leave it blank to use the default runtime schema.
   b. Complete the `Table` property. This property represents the database table used as your event store.
   c. Complete the `Primary key` property. This property represents the primary key of the database table used as the event store.
   d. Complete the `Foreign key to application table` property. This property represents the column in the event table that references the row in the

application table containing the changed data to be processed by the DatabaseInput node. This is typically the primary key of the application table.

e. Optional: Complete the `Status column` property. This property represents the name of a column, if you update a column in the event table to indicate that the event has been processed. Leave blank if you delete events from the event table after processing.

f. Optional: Complete the `New event status value` property. This property represents the value written to the status column when the event is first added. Enclose character values in single quotation marks, for example 'Y'. Enter numbers without quotation marks. For a null value, enter NULL. Check the trigger setting in your database for appropriate values.

g. Optional: Complete the `Processed event status value` property. This property represents the value written to the status column after the event has been processed. Enclose character values in single quotation marks, for example 'Y'. Enter numbers without quotation marks. For a null value, enter NULL. Check the trigger setting in your database for appropriate values.

3. Complete the Application Table section.
   a. Complete the `Table` property. This property represents the table that includes the changed data to be processed by the DatabaseInput node.
   b. Complete the `Primary key` property. This property represents the primary key of the database table used as the application table.
   c. Complete the `Output message element` property. This property represents the output message that will be propagated to the flow.
4. Click **Generate query**.
5. Optional: Click the Source tab to view the code, or add customized code.
6. On the Basic tab of the DatabaseInput node, specify the data source. This data source is the ODBC data source name of the database that contains the tables that you refer to in the ESQL module. See "Enabling ODBC connections to the databases" on page 668.
7. On the Basic tab, ensure that the `ESQL module` property refers to the correct module.
8. Optionally, change values on the other tabs of the node.
9. Configure the rest of the flow to use the message from this node.

What to do next

Configure your target system to receive the message.

Changing the default color of auto-generated text:
Procedure

1. Click **Window** > **Preferences**.
2. In the tree on the left, navigate to **Broker Development** > **ESQL** > **ESQL Editor**.
3. On the Colors tab, select **Auto-generated**, and select the color.

Use the DatabaseInput node to detect events recorded in a database, and to retrieve the data affected by those events.

Responding to database updates:

Implement a message flow that responds to database updates, and presents the data to another application.

Before you begin

Before you start:

- Create an event table (a database table that serves as a transient store for event data).
- Create a trigger on the application data table. The trigger inserts a row into the event store whenever the application data is changed.
- Configure the broker runtime to connect to the database; see "Enabling ODBC connections to the databases" on page 668.

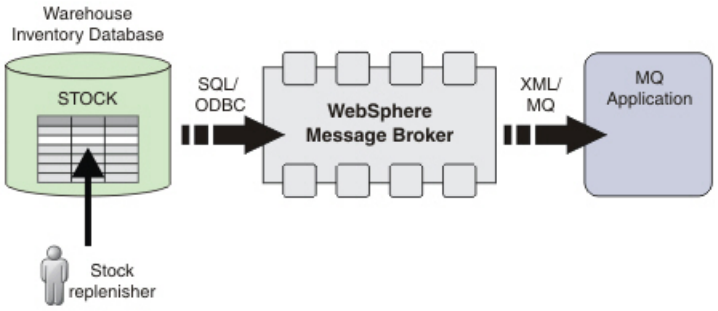
For information about event tables and triggers, see the DatabaseInput Node sample. You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

z/OS If you use DB2 on z/OS, your user ID (or your user group) requires permission to perform a SELECT on SYSIBM.SYSJAROBJECTS.

You do not need experience of ESQL to complete this task.

About this task

Scenario: A retail company uses a relational database to manage its stock inventory. Since a recent acquisition, a new set of applications based on XML and WebSphere MQ are added to the environment. The applications notify interested parties of any changes to the stock levels. The applications have a predefined XSD schema model that describes the input message.



WebSphere Message Broker is used to respond to database updates, and to notify the WebSphere MQ application of these changes.

1. A DatabaseInput node retrieves the data.
2. A transformation node, such as a Compute node or a Mapping node, transforms the data to the target format.
3. An output or request node, such as an MQOutput node, sends the transformed message to the target system.

You will complete the following actions:

1. "Discover the database model"
2. "Create a new message model for the database input" on page 2125
3. "Create the message flow" on page 2125
4. "Test the flow" on page 2126

Discover the database model:

Create a `.dbm` file that you will use to create the message model. You create a data design project, and use a wizard to give WebSphere Message Broker details of your database event store and data table.

Procedure

1. Click **File** > **New** > **DataBase Definition**.
2. Click **New** to create a new data design project, or select an existing data design project from the drop down list.
3. Select the appropriate database type and version, and then click **Next**.
4. Select an existing JDBC connection, or create a connection to your database. If you create a connection, test the connection.
5. Select the database schema that you will use to create the message definition.

6. Select the database elements that you need for the model. You require `Tables` and `Triggers`. The data model is created, and you can see details of the database tables that are described in the chosen schema.

Create a new message model for the database input:

Create a new message schema model file from the discovered data definition if you require a model of the data structure that the database input will present. You need a model if you want to graphically map this input. The model also enables content assistance auto-completion of paths in the ESQL editor if you are transforming the data in ESQL.

Procedure

1. Click **File** > **New** > **Message model**
2. In the **Other** section, select `Database record`, and then click **Next**.
3. Select `Create an XML schema file from a database definition`, and then click **Next**.
4. Navigate to and select the Database definition `.dbm` file that you created during discovery, and then click **Next**.
5. Ensure that the database tables that will be used are selected.
6. Click **Next** and then **Finish**.

Results

The New Message model wizard creates an XML schema message model file in your selected location.

Create the message flow:

Create and configure a flow that consists of a DatabaseInput node, a Mapping node, and an MQOutput node.

You will use the schema file that describes the input message to create a message definition file.

Procedure

1. Create a message flow project that references both the data design project, and the message set project, that you created earlier.
2. Create a message flow, and drag a DatabaseInput node onto the canvas.
3. Configure the node as follows:
   a. Set the **`Data source`** to the ODBC connection that you created earlier.
   b. Follow the instructions in "Configuring a DatabaseInput node" on page 2120 to configure the ESQL procedures to provide details of the event store and application data.
4. To enable graphical mapping from the database data to the output message format, in addition to Creating the new message model for the database input as above, you also require a message model for the target message. This can be a DFDL or XML schema message model as appropriate to your scenario.
5. Drag a Mapping node onto the flow, and configure it.
   a. Set the map source to the message that you defined in "Create a new message model for the database input."
   b. Set the map target to the `TARGET` message that you just defined.

You can use other methods to transform the message; see "Transforming and enriching messages" on page 2227.

6. Drag an MQOutput node onto the canvas, and set the queue manager name and queue name.

Test the flow:

Use the debugger to test the flow.

Procedure

1. Start the debugger, and then add breakpoints to the flow.
2. Deploy the flow.
3. Change the data source, for example by adding a new row. You can change data from within the WebSphere Message Broker Toolkit. Under **Data Source Explorer**, right-click the table and choose **Data** > **Edit**.
4. Use the debugger, and WebSphere Message Broker Explorer, to check that the flow is working correctly.

Related concepts:

"Event-based database integration" on page 2118
Use a DatabaseInput node to respond to events in a database. For example, the broker can keep an external system synchronized with a database by sending updates to the target system whenever data is changed in the database.

"Event tables"
An event table stores information about changes to application tables.

Related tasks:

"Starting the flow debugger" on page 3160
To start the flow debugger, you must attach it to an execution group. When the flow debugger is started, you can introduce test messages to your message flow.

Event tables:

An event table stores information about changes to application tables.

The event table is a database table created by the user, generally within the same schema as the application table for which it stores events. The event table describes the type of change made to an application table, and also contains an identifier for the changed row.

To populate an event table, one or more *triggers* must be created. A trigger is a database construct that can run an SQL script when a predefined action occurs. For example, a trigger can insert a row in the event table when an update in the application table occurs.

For examples of triggers and event tables, see the DatabaseInput Node sample. You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

The following table shows some typical columns in an event table, and the reasons for including them.

Column name	Column function	Example value
EVENT_ID	Required. The primary key, which identifies the event being processed.	1
OBJECT_KEY	Required. The identifying element of the changed row in the application table, typically the element of the row in the primary key column.	cust1
OBJECT_VERB	Optional. The change performed, typically one of CREATE, UPDATE, or DELETE. This event is used to distinguish a DELETE event, where the application table contains no row to retrieve when the message for the flow is built.	CREATE
OBJECT_NAME	Optional. The name of the application table that has changed. This column is required if the DatabaseInput node is being used to support updates to more than one application table.	customer
EVENT_PRIORITY	Optional. The priority of the event. For example, you can ensure that high value transactions are computed first.	1
EVENT_TIME	Optional. The time at which the operation was performed. Generally used for logging or performance monitoring of the flow.	2010-10-19T17:10:00
EVENT_STATUS	Optional. Used to determine if the event has already been processed. Required if the events are not to be deleted or archived after processing.	0
EVENT_COMMENT	Optional. Free-form field, for example, it can be used to store the outcome of the message processing if the event was not deleted after processing.	Processed with exceptions

The column names are examples only. You can use other names. If you have a high-throughput application table, a single row might be changed multiple times between retrieving events from the event table. In this case, only the details of the latest change are picked up by the flow. If a record of intermediate changes is required, include more details in the event table. Also ensure that your event table has enough information about events generated by DELETE operations. Here, because the row in the application table no longer exists, all information required to successfully process the event must be present in the event table.

For example, if a new customer with primary key `cust1` is created in the application table, a row is added to the event table:

EVENT_ID	OBJECT_KEY	OBJECT_VERB
1	cust1	Create

The DatabaseInput node responds to the change, and processes the new row in a message flow.

Processing options on completion

When the message flow has processed an event, the flow can handle the event in the following ways:

- Delete the event. Use this option if you do not want to store the event for future reference.
- Update the status column. Use this option if you want to keep a record of processed events. Your event table must have a status column.
- Archive the event to a separate event table. Use this option if you want to keep a record of events while keeping the event table to a minimal size.

"IMSRequest node" on page 4504
Use the IMSRequest node to send a request to run a transaction on a local or remote IMS system, and wait for a response. IMS Connect must be configured and running on the IMS system.

IBM Information Management System (IMS)

IMS is a message-based transaction manager and hierarchical-database manager for z/OS. External applications can use transactions to interact with applications that run inside IMS.

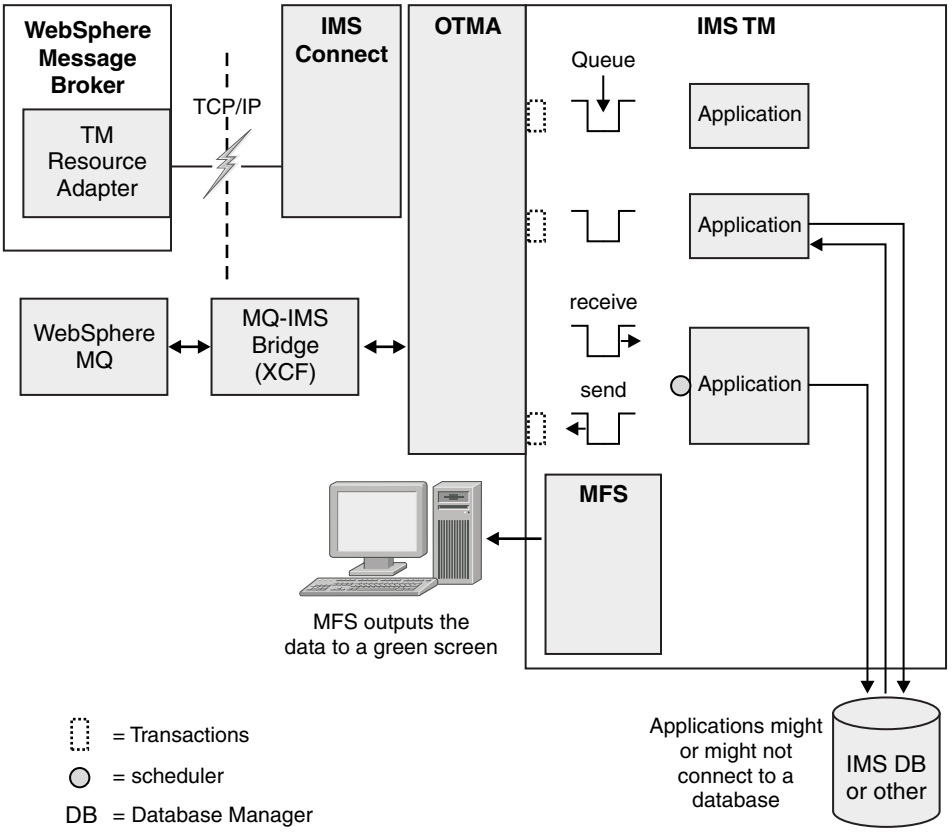
IMS includes two components:

IMS Database Manager (IMS DB)
A database management system for defining database structure, organizing business data, performing queries against the data, and performing database transactions.

IMS Transaction Manager (IMS TM)
A message-based transaction manager for processing input and output messages. IMS TM manages message queuing, security, scheduling, formatting, logging, and recovery.

In addition to these components, IMS Connect manages communications for IMS, connecting one or more clients with one or more IMS systems. IMS Connect also handles workload balancing, and supports the IBM supplied client, the IMS TM resource adapter.

The following diagram shows the layers of communication between WebSphere Message Broker and IMS.



You can also use the following methods to connect to an IMS system:

- **The WebSphere MQ-IMS bridge**

The WebSphere MQ-IMS bridge is a component of WebSphere MQ for z/OS. You can use it to access applications on your IMS system from WebSphere MQ applications. For more information about the WebSphere MQ-IMS bridge, see WebSphere MQ Version 7 Information Center online.

- **The IMS SOAP Gateway**

  The IMS SOAP Gateway is a Web service solution that integrates IMS assets in a Service-Oriented Architecture (SOA) environment. For more information, see IMS SOAP Gateway web page.

For more details about how IMS works with WebSphere Message Broker, see "IMS nodes."

For further information about IMS and its components, see the IBM Information Management Software Library web page, which contains links to the IMS information center and associated IBM Redbooks publications.

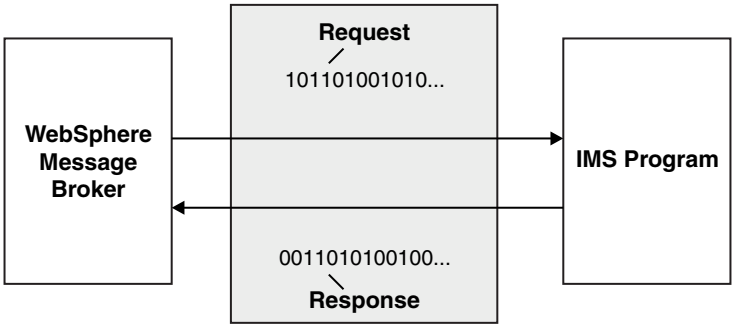
IMS nodes:

WebSphere Message Broker message flows use IMS nodes to call programs that are running in IMS.

The IMS node sends a bit stream to IMS, which schedules one of its programs to process the message. The program generates a message, which IMS sends back to the IMS node, as illustrated in the following diagram.



The bit stream contains the routing information that IMS needs so that it can schedule a program to receive that bit stream. The structure of the bit stream varies

depending on whether it is a request or response bit stream. The structure of the different bit streams are described in the following sections.

Request bit stream

The structure of the request bit stream is illustrated by the following diagram.

- *LLZZ* is a four-byte field. The first two bytes indicate the length of the bit stream, and the other two bytes are reserved for use by IMS.
- The transaction code can contain up to eight characters. If the code contains less than eight characters, the transaction code must be delimited by a space. When the transaction code is less than eight bytes, IMS reads only the transaction code and one space. The response segments do not need to have the transaction name, but an IMS program can add it.
- The rest of the bit stream comprises the data that the IMS program needs.

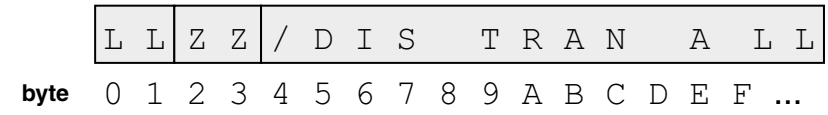
IMS reads the first twelve bytes of the bit stream, but it passes the entire bit stream to the IMS program.

Response bit stream

The structure of the response bit stream is illustrated by the following diagram.

Commands

You can also use bit streams to run commands. The structure of the response bit stream is illustrated by the following diagram.



The first character after LLZZ is the slash (/) character, which is followed by the command verb and any arguments. For commands, the response bit stream has the same format as the response bit stream for transactions: LLZZ is followed by the response data.

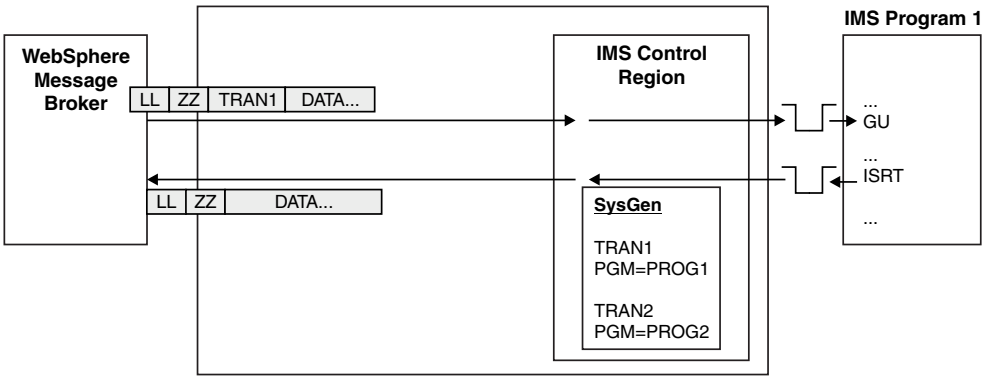
IMS transactions and programs:

The IMS system administrator defines the transactions. For each transaction that is defined, a program name is specified. When you invoke a transaction by using an IMS node, the IMS Control Region determines which program is configured for that transaction, and queues the data for retrieval by that program.



After the program has prepared the response data for the IMS node in the message flow, it inserts that data onto another queue. This output queue is tied to the socket to which WebSphere Message Broker is connected. Therefore, multiple concurrent message flows that are calling the same transaction each have a separate queue to receive the responses.

The IMS program gets messages by issuing a GU (GetUnique) call and it produces messages by issuing an ISRT (Insert) call. These calls are known as *DL/1 calls*. DL/1 is the programming interface to IMS. Other common DL/1 calls are PURG (purge) and GN (GetNext).

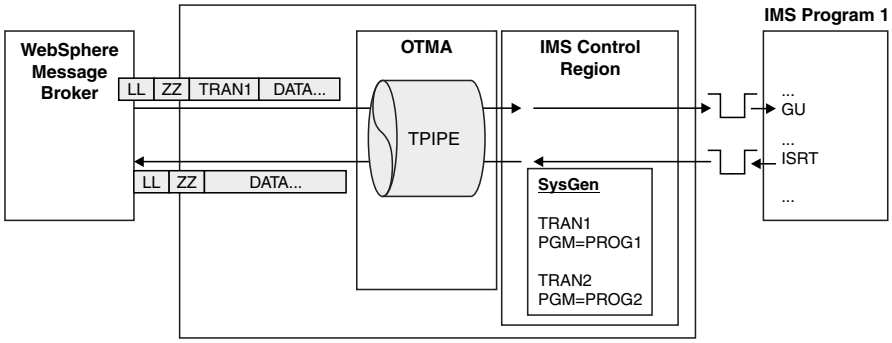
Response models:

The synchronous request and response model is associated with IMS.

Synchronous request and response

In the synchronous request and response model, the entire transmission is returned to the IMS node synchronously.

After the IMS program has prepared the response data for the WebSphere Message Broker message flow, it inserts that data onto a queue. WebSphere Message Broker uses Open Transaction Manager Access (OTMA) to communicate with the IMS program. OTMA helps to correlate the input to the IMS program with the output from the IMS program by using a transaction pipe (TPIPE). Therefore, multiple concurrent message flows that are calling the same transaction each receive the relevant response.



The TPIPE is created automatically. It is not necessary for the name of the TPIPE to be known to WebSphere Message Broker because it uses a mode of operation known as *sharable persistent sockets*, whereby a TPIPE is created automatically for every TCP/IP connection.

The output of a transaction can contain multiple messages. The IMS program inserts then purges each message, as shown in the following diagram. (For multi-segment output, the IMS program inserts multiple messages without purging them.) If the IMS program inserts multiple messages in a single sync point, OTMA correlates all of those messages to the input message and returns them all to the message flow as a single transmission.

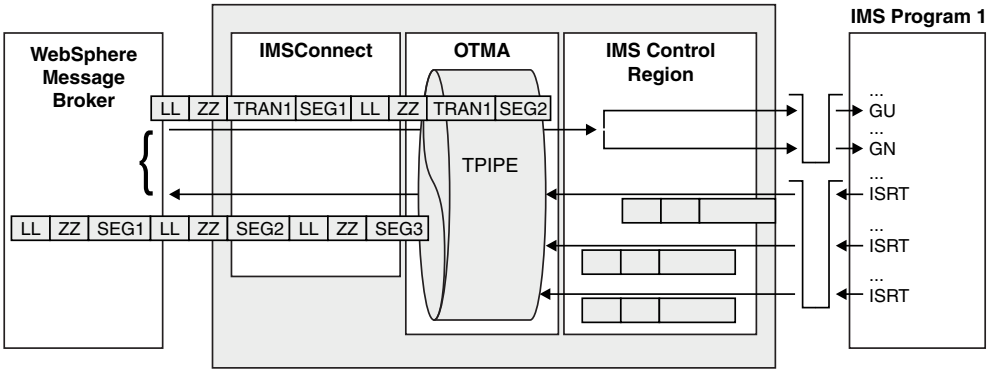
IBM Information Management Software Library web page

IMS message structure:

Each message that is sent to and from IMS can consist of one or more segments. IMS messages often contain multiple segments.

The bit stream that flows between WebSphere Message Broker and the IMS program (also known as the *transmission*) can contain multiple segments. Each segment begins with the LLZZ and Transaction code fields that are described in "IMS nodes" on page 2130. The transmission can contain multiple messages, each one containing multiple segments. The IMS program gets the segments one at a time and typically inserts the output data onto the queue one segment at a time. The IMS program purges the end of a message before it sends the first segment of the next message.

For input messages, each segment includes the LLZZ field. Only the first segment contains the transaction code (Trancode) field. For output messages, each segment includes the LLZZ field. The IMS program gets the segments one at a time. It makes a GetUnique (GU) call to read the first segment of the next message, and a GetNext (GN) call to read the next segment of the current message. The IMS program typically inserts the output data to the queue one segment at a time, and purges the end of a message before it sends the first segment of the next message, as shown in the following diagram.



A COBOL IMS program typically includes a copybook with the data structure definition of each segment. The program logic indicates the order in which the

segments are retrieved and emitted by the program. The WebSphere Message Broker application has two ways to implement this information:
- Model the entire message in MRM.
- Model each segment in MRM but configure the message flow to reflect the application logic in determining the order of these segments.

An IMS transaction's response can have various structures:
- An MRM-CWF structure, such as a message definition that is derived from a COBOL copybook
- An MRM-TDS structure when the output is 3270–based, such as a list of name=value strings
- Another structure, such as XML output from a Java program that is running in an IMS Java Processing Region (JPR)

If the message definition is derived from a COBOL copybook, a message is a sequence of segments, each of which has a model built by importing its copybook. If the output is 3270-based, each segment is a line of output with an MRM-TDS model built by understanding the IMS transaction program's output.

IMS presents program output as one or more messages (typically, one output message per input message), each of which comprises one or more segments. The IMSRequest node presents the message as a single BLOB. You can parse the message into segments and use Filter or Compute nodes to test the shape of the response to determine how to re-parse the segments with ResetContentDescriptor nodes.

You must set the LL and ZZ values on output. The LL value is the entire length of the segment, including the four-byte LLZZ prefix. Therefore, the message flow typically requires an ESQL expression to calculate the LL value. The LLZZ field must use a big-endian encoding 785.

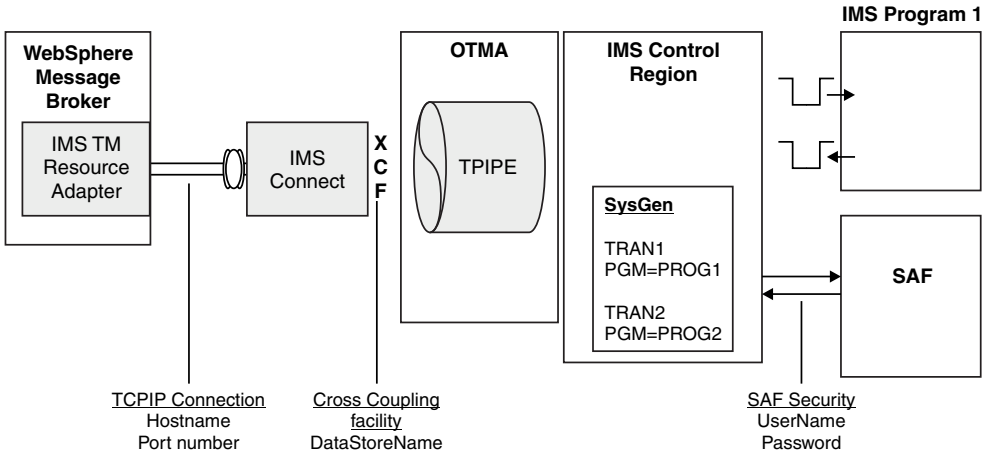
IBM Information Management Software Library web page

IMS connections:

Open Transaction Manager Access (OTMA) is used to provide access to IMS from WebSphere Message Broker.



OTMA uses the z/OS Cross Coupling Facility (XCF) to provide access to IMS from an OTMA client. To access a service through XCF, you must specify a data store name on the IMS node.

IMS Connect is an OTMA client that exposes a TCP/IP interface. WebSphere Message Broker uses the IMS TM Resource Adapter, which connects to IMS through IMS Connect. To connect to IMS Connect, you must specify a host name and port number. If the IMS system is configured to authenticate users by using a System Authorization Facility (SAF) product, such as RACF, you must specify a user ID and password. You can use the **mqsisetdbparms** command to set a user ID and password for an IMSConnect configurable service. For detailed information about how to configure IMS Connect for security, see the *IMS Connect Security Support* topic in the IBM Information Management Software for z/OS Solutions Information Center.

The IMSRequest node can use an identity that is present on an input message, and propagate it to IMS, by using the `Propagate` property on the security profile that is defined for the node. For more information, see “Propagating security credentials to IMS” on page 2144.

Some restrictions exist for the OTMA environment that affect the range of IMS applications with which WebSphere Message Broker can interact. For example, OTMA cannot update the IMS main storage database (MSDB) because it has read only access to the database. For detailed information about the restrictions for the OTMA environment, see the *OTMA restrictions* topic in the IBM Information Management Software for z/OS Solutions Information Center.

Using configurable services for IMS nodes

You can configure IMS nodes to get connection details from a configurable service. For details about creating, changing, reporting, and deleting the configurable services, see “Changing connection information for the IMSRequest node” on page 732.

You can also use the IMSConnect configurable service to configure the IMSRequest node to use Secure Sockets Layer (SSL) protocol. For more information, see “Securing the connection to IMS by using SSL” on page 549.

IBM Information Management Software Library web page

Changing connection information for the IMSRequest node:

You can create a configurable service that the IMSRequest node or message flow refers to at run time for connection information, instead of defining the connection properties on the node or the message flow. The advantage being that you can change the host name, performance, and security values without needing to redeploy your message flow.

Before you begin

Before you start:

- Read "Configurable services" on page 1296 to find out more about configurable services.
- Read "IBM Information Management System (IMS)" on page 2129 for background information.

About this task

Use the IMSConnect configurable service to change the connection information for the IMSRequest node. Two configurable services can connect to the same instance of IMS Connect. The properties of the IMSConnect configurable service are described in "Configurable services properties" on page 3766.

You can use the IMSConnect configurable service to configure the IMSRequest node to use Secure Sockets Layer (SSL) protocol. For more information, see "Securing the connection to IMS by using SSL" on page 549.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates an IMSConnect configurable service for the IMS instance IMSA that is running on `test.ims.ibm.com` port 9999:

  ```
  mqsicreateconfigurableservice MB7BROKER -c IMSConnect -o myIMSConnectService
  -n Hostname,PortNumber,DataStoreName -v test.ims.ibm.com,9999,IMSA
  ```

- To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. This

example changes all the nodes that are configured to use the *myIMSConnectService* configurable service. After you run this command, the IMSRequest node connects to the production system (`production.ims.ibm.com`) instead of the test system (`test.ims.ibm.com`). The command also changes to coded character set identifier (CCSID) to 37.

```
mqsichangeproperties MB7BROKER -c IMSConnect -o myIMSConnectService -n Hostname,CodedCharSetID
-v production.ims.ibm.com,37
```

See "Securing the connection to IMS by using SSL" on page 549 for information about how to turn on SSL support in the broker by setting the `UseSSL` and `SSLEncryptionType` IMSConnect configurable service properties.

- To display all IMSConnect configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

  ```
  mqsireportproperties MB7BROKER -c IMSConnect -o AllReportableEntityNames -r
  ```

- You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

  ```
  mqsideleteconfigurableservice MB7BROKER -c IMSConnect -o myIMSconnectService
  ```

  You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

"IMSRequest node" on page 4504
Use the IMSRequest node to send a request to run a transaction on a local or remote IMS system, and wait for a response. IMS Connect must be configured and running on the IMS system.

Preparing the environment for IMS nodes

Before you can use the IMS nodes, you must set up the broker runtime environment so that you can access the IMS system.

Before you begin

Before you start:

Read "IBM Information Management System (IMS)" on page 2129.

About this task

Complete the following steps to ensure that WebSphere Message Broker can connect to the IMS system.

Procedure

1. Ensure that IMS Connect is installed and started on the IMS system.
2. If you do not want to configure IMS connection properties directly on the IMSRequest node, define a configurable service for each IMS system to which you want to connect.

   For example, to create an IMSConnect configurable service for the IMS instance *IMSA* that is running on *test.ims.ibm.com*, port *9999*, run the **mqsicreateconfigurableservice** command as shown:

   ```
   mqsicreateconfigurableservice MB7BROKER -c IMSConnect -o myIMSConnectService
   -n Hostname,PortNumber,DataStoreName -v test.ims.ibm.com,9999,IMSA
   ```

   For details about how to create, change, and report configurable services, see "Changing connection information for the IMSRequest node" on page 732. You can use the IMSConnect configurable service to configure the IMSRequest node to use Secure Sockets Layer (SSL) protocol. For more information, see "Securing the connection to IMS by using SSL" on page 549.
3. Use the **mqsisetdbparms** command to set security details in the broker store.

   For example, to associate a user ID and password pair with an IMS Connect connection, run the **mqsisetdbparms** command as shown:

   ```
   mqsisetdbparms MB7BROKER -n ims::mySecurityIdentity -u myuserid -p mypassword
   ```

Use the **mqsisetdbparms** command to associate a specific user ID and password (or SSH identity file) with one or more resources that are accessed by the broker.

Securing the connection to IMS by using SSL

Configure the IMSRequest node to communicate with IMS over the Secure Sockets Layer (SSL) protocol by creating a keystore file, and configuring the broker to use SSL.

Before you begin

Before you start:

Set up a public key infrastructure (PKI) at broker level by following the instructions in "Setting up a public key infrastructure" on page 504.

About this task

To configure the IMSRequest node to use SSL, complete the following steps.

Procedure

1. Turn on SSL support in the broker by setting the `UseSSL` and `SSLEncryptionType` properties on the IMSConnect configurable service, as shown in the following example.

   This example changes the IMSRequest node that is configured to use the *myIMSConnectService* configurable service. After you run this command, the IMSRequest node connects to IMS over SSL.

   ```
   mqsichangeproperties MB7BROKER -c IMSConnect -o myIMSConnectService -n
   UseSSL,SSLEncryptionType -v True,Weak
   ```

2. Optional: Develop a message flow that contains a IMSRequest node.
3. Test your configuration.

"IMSRequest node" on page 4504
Use the IMSRequest node to send a request to run a transaction on a local or remote IMS system, and wait for a response. IMS Connect must be configured and running on the IMS system.

Propagating security credentials to IMS

The IMSRequest node can use an identity that is present in the Properties folder of the message tree structure for the security credentials in a request, by using the `Propagate` property on the security profile that is defined for the node.

About this task

If an IMSRequest node is configured with a security profile, it extracts security tokens from the input message at run time, and propagates an identity to IMS.

Procedure

To propagate an identity to be used for the IMS request security credentials, complete the following steps.

1. Ensure that an appropriate security profile exists for the IMSRequest node, or create a security profile, by following the instructions in "Creating a security profile" on page 433.
2. Use the Broker Archive editor to select a security profile for the IMSRequest node that has identity propagation enabled. For detailed instructions, see "Configuring for identity propagation" on page 492.

Related concepts:

"Identity and security token propagation" on page 426
Identity and security token propagation enables the identity and security tokens (associated with each message) to be propagated throughout a message flow, and on to target applications through output or request nodes.

Common Object Request Broker Architecture (CORBA)

The Common Object Request Broker Architecture (CORBA) is a standard defined by the Object Management Group (OMG) that enables software components written in multiple computer languages and running on multiple computers to work together.

CORBA is a standard for distributing objects across networks so that operations on those objects can be called remotely. CORBA is not associated with a particular programming language, and any language with a CORBA binding can be used to call and implement CORBA objects. Objects are described in a syntax called Interface Definition Language (IDL).

CORBA includes four components:

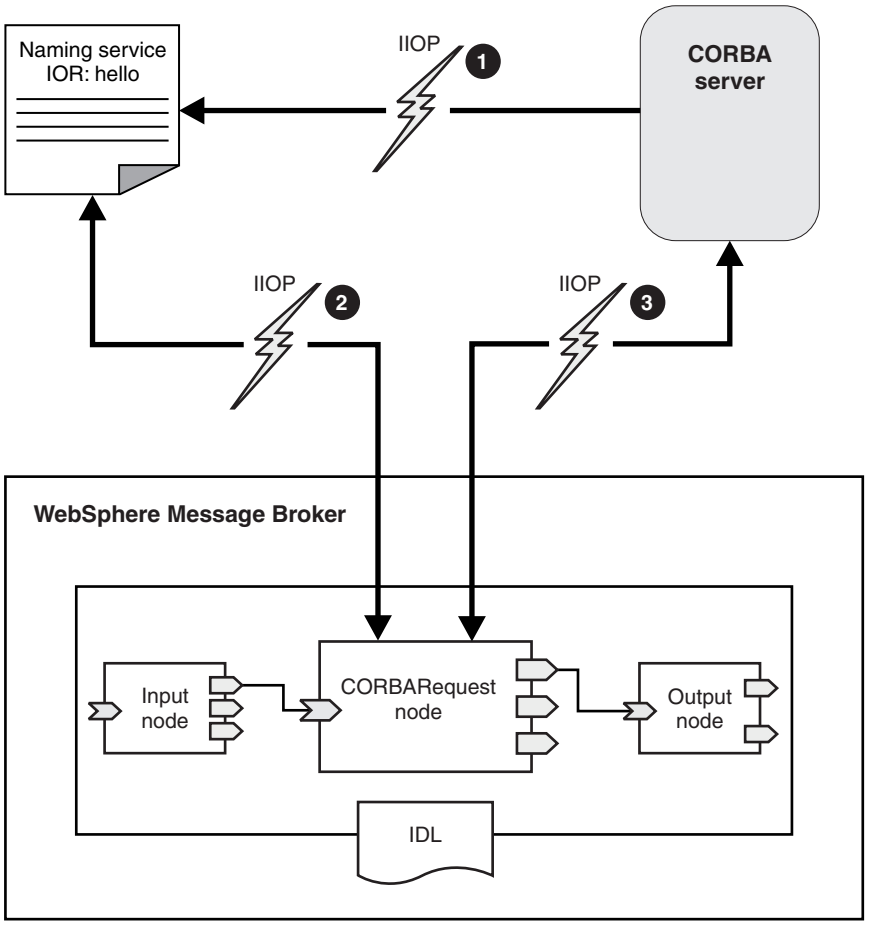
Object Request Broker (ORB)
: The Object Request Broker (ORB) handles the communication, marshaling, and unmarshaling of parameters so that the parameter handling is transparent for a CORBA server and client applications.

CORBA server
: The CORBA server creates CORBA objects and initializes them with an ORB. The server places references to the CORBA objects inside a naming service so that clients can access them.

Naming service
: The naming service holds references to CORBA objects.

CORBARequest node
: The CORBARequest node acts as a CORBA client.

The following diagram shows the layers of communication between WebSphere Message Broker and CORBA.



The diagram illustrates the following steps.

1. CORBA server applications create CORBA objects and put object references in a naming service so that clients can call them.
2. At deployment time, the node contacts a naming service to get an object reference.
3. When a message arrives, the node uses the object reference to call an operation on an object in the CORBA server.

For more details about how CORBA works with WebSphere Message Broker, see "CORBA nodes" on page 2147.

CORBA nodes:

Use CORBA nodes to connect WebSphere Message Broker with CORBA Internet Inter-Orb Protocol (IIOP) applications.

CORBA is a standard for distributing objects across networks so that operations on those objects can be called remotely. CORBA objects are described in Interface Definition Language (IDL) files, and these IDL files are used to configure the CORBA message flow nodes. The IDL file is stored in a message set project, in a folder called CORBA IDLs.

An IDL importer imports the IDL file into the message set project and creates the message definition file (`.mxsd`) in the message set. This message definition file is used for mid-flow validation, ESQL content assist, and the Mapping node.

For each IDL file, a single message definition is created. In the message definition, two messages are created for each operation in the IDL file: one message for the request, and one for the response. The request has a child element for each in and inout parameter; the response has a child element for each inout and out parameter, and a child element named "_return" for the return type of the operation.

The name of these elements is based on the interface name and operation name; for example, for the operation *sayHello* in the Interface *Hello*, the request element is

called *Hello.sayHello*, and the response element is called *Hello.sayHelloResponse*. If the interface is contained in a module, the request and response element names are qualified with the names of the modules. For example, if the operation *sayHello* in the Interface *Hello* is contained in *ModuleB*, which in turn is contained in ModuleA, the response element would be called *ModuleA.ModuleB.Hello.sayHelloResponse*.

When you add a message flow that contains CORBA nodes to a BAR file, all the IDL files that are used by the nodes are added to the BAR file automatically.

The main scenario for connecting WebSphere Message Broker with CORBA applications is described in the following section.

WebSphere Message Broker calls a CORBA server

By using a message flow that includes a CORBARequest node, you can give existing CORBA applications a new external interface; for example, a SOAP interface. The message flow uses the IDL file to configure which operation is called on which interface.

After you have deployed the BAR file, you can start the message flow. A CORBA request is sent by using values from the message tree in the DataObject domain as input parameters. If a response is received, the return type and output parameters are propagated to the Out terminal of the CORBARequest node. You can use the data that is returned from the CORBA application to verify the result from the CORBARequest node.

CORBA support:

The CORBA nodes in WebSphere Message Broker support a set of types and operations in imported IDL files.

WebSphere Message Broker supports the CORBA 2.3.1 specification and uses the Java 6 JRE ORB, and is therefore compatible with any CORBA vendor that is compatible with the JRE ORB.

WebSphere Message Broker currently supports the following CORBA types and operations.

- All primitive types, except bounded strings
- Two-way operations with in, inout, and out parameters
- User-defined exceptions
- Enums
- Modules
- Sequences (sequences must have associated typedefs; anonymous sequences are not supported)
- Structs
- Typedefs
- Comments
- The following preprocessing tokens:
  - #ifndef
  - #endif
  - #define
  - #include

  Other preprocessing tokens are ignored.

When you import an IDL file, supported and unsupported operations are listed. You can import and deploy IDL files that contain unsupported types and operations, but if you try to call one of these unsupported operations, you see an error message.

You cannot import an IDL file that is not valid. During the importing process, if you select an IDL file that is not valid, you see an error message and cannot complete the wizard.

Abstract interfaces and interfaces that contain inheritance are not supported. IDL pragma directives are not supported, but you can include the following pragmas in your IDL file (these pragmas are ignored):

- cpponly
- ID
- init
- localonly
- localonly abstract
- Prefix
- version

Use the CORBARequest node to call an external CORBA application over Internet Inter-Orb Protocol (IIOP).

IDL data types:

When you use the DataObject domain with CORBA, you need to know how XML schema and ESQL types correspond to the types in the IDL file.

Primitive IDL types

The following table shows the mapping between IDL types, XML schema simple types, and ESQL types.

IDL	XML schema	ESQL
boolean	xsd:boolean	BOOLEAN
char	<xsd:simpleType name="char"> <xsd:restriction base="xsd:string"> <xsd:length value="1" fixed="true/> </xsd:restriction> </simpleType>	CHARACTER

IDL	XML schema	ESQL
wchar	<xsd:simpleType name= “wchar”> <xsd:restriction base=”xsd:string”/> </xsd:simpleType>	CHARACTER
double	xsd:double	FLOAT
float	xsd:float	FLOAT
octet	xsd:unsignedByte	INTEGER
long	xsd:int	INTEGER
Long long	xsd:long	INTEGER
short	xsd:short	INTEGER
string	xsd:string	CHARACTER
wstring	xsd:string	CHARACTER
Unsigned short	xsd:unsignedShort	INTEGER
Unsigned long	xsd:unsignedInt	INTEGER
Unsigned long long	xsd:unsignedLong	DECIMAL

Complex IDL types

WebSphere Message Broker supports the following complex IDL types:

- Enums
- Typedefs
- Sequences
- Structures

Each complex type is supported in the following places:

- Return types for operations
- In parameters
- Inout parameters
- Out parameters
- Inside exceptions
- Inside structures
- Inside sequences
- Inside typedefs

The following examples show the mapping between IDL types, XML schema, and XML.

Enums

IDL Enums are mapped to enumerations in XML schema. Enums inside the tree are of type string.

Here is an example IDL file:

```
enum myEnum {A, B, C};
interface example {
 void myoperation(in myEnum input1);
};
```

Here is an example XML schema:

```
<xsd:simpleType name="myEnum">
 <xsd:restriction base="xsd:string">
  <xsd:enumeration value="A"/>
  <xsd:enumeration value="B"/>
  <xsd:enumeration value="C"/>
 </xsd:restriction>
</xsd:simpleType>
```

Here is an XML example:

```
<example.myoperation>
 <input1>A</input1>
</example.myoperation>
```

Sequences and typedefs

IDL typedefs are mapped to XML schema type restrictions. IDL sequences are mapped to XML schema sequence complex types. Sequences can be used only within typedefs.

Here is an example IDL file:

```
Typedef long myLong;
typedef sequence<long> longSeq;
interface example {
 void myoperation(in longSeq input1, inout myLong input2);
};
```

Here is an example XML schema:

```
<xsd:complexType name="longSeq">
 <xsd:sequence>
  <xsd:element name="item" minOccurs="0" maxOccurs="unbounded" type="xsd:int"/>
 </xsd:sequence>
</xsd.complexType>
```

A sequence can be bounded with the syntax sequence<long, 10>, which puts a bound in the XSD file.

Here is an XML example:

```
<example.myoperation>
 <input1>
  <item>10</item>
  <item>11</item>
  <item>12</item>
 </input1>
</example.myoperation>
```

Structures

IDL structures are mapped to XML schema complexType definitions.

Here is an example IDL file:

```
struct myStruct {
 char c;
 string str;
 octet o;
 short s;
 unsigned long long ull;
 float f;
 double d;
};
interface example {
 void myoperation(in myStruct input1);
};
```

Here is an example XML schema:

```
<xsd:complexType name="myStruct">
 <xsd:sequence>
  <xsd:element name="c" type="xsd:string" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="str" type="xsd:string" nillable="true" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="o" type="xsd:byte" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="s" type="xsd:short" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="ull" type="xsd:unsignedLong" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="f" type="xsd:float" maxOccurs="1" minOccurs="1"/>
  <xsd:element name="d" type="xsd:double" maxOccurs="1" minOccurs="1"/>
 </xsd:sequence>
</xsd:complexType>
```

Here is an XML example:

```
<example.myoperation>
 <input1>
  <c>c</c>
  <str>hello</str>
  <o>12</o>
  <s>10</s>
  <ull>110</ull>
  <f>12.0</f>
  <d>12.1</d>
 </input1>
</example.myoperation>
```

Modules

In CORBA, modules provide scope. If an interface is contained in a module in the IDL file, the interface name is qualified with the module name in the following format:

ModuleName.InterfaceName.OperationName

The following example shows a module in an IDL file.

```
Module one {
 Interface OneAInterface {
 };
};
```

The fully qualified name of the interface called OneAInterface is `one.OneAInterface`. In an IDL file, modules can be nested in other modules. In this case, the fully qualified name of the interface can include more than one module name, starting from the root module; for example:

ModuleNameA.ModuleNameB.InterfaceName.OperationName

An IDL file can contain more than one operation with the same name provided that the operations are in different modules.

CORBA naming service:

A CORBA naming service holds CORBA object references.

A CORBA server puts references to CORBA objects inside a naming service so that clients can query the naming service and obtain the object reference, then call operations on the CORBA objects. Typically, a client queries the naming service once, then caches the object reference.

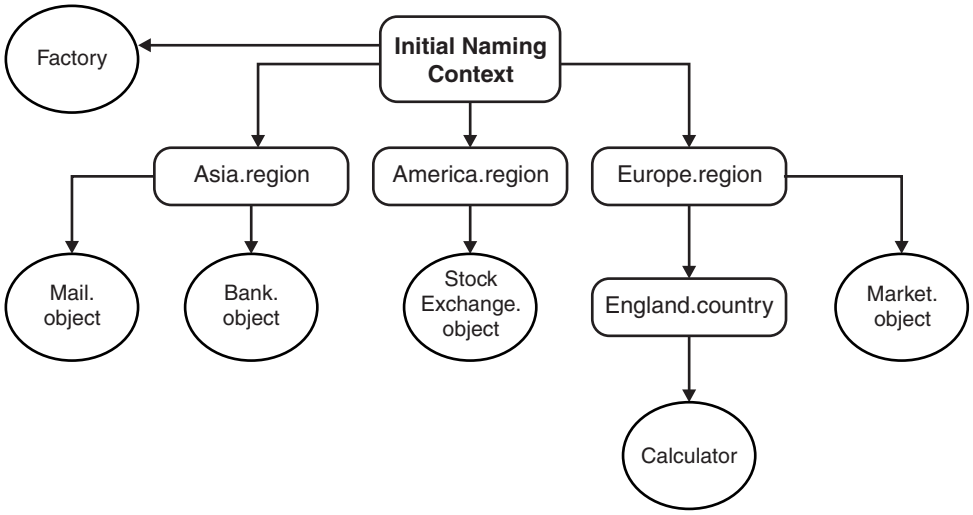
A CORBARequest node is a CORBA client; therefore, when it is deployed, the node contacts a naming service to obtain an object reference. If the object reference is not in the naming service at deployment time, or the naming service that is configured on the node is unavailable, the CORBARequest node issues a warning, and attempts to contact the naming service to get the object reference when it receives a message. If an object reference cannot be acquired from the naming service when the node receives a message, an error is issued. You can specify the location of an object reference by using the properties on the CORBARequest node, or by using the CORBA configurable service. For more information, see "CORBARequest node" on page 4349 and "Defining where the CORBARequest node gets the object reference" on page 734.

Identifying an object reference in a naming service

Each object in a naming service has a unique name. You must use this name when you configure the `Object reference name` property on the CORBARequest node.

Naming services are typically arranged in a hierarchy so that names can be given context or scope. The initial naming context is at the top of the hierarchy. Object references can be added to the initial naming context, and additional contexts can exist below it. The number of levels in the hierarchy is unlimited.

Object references and contexts can be assigned a *kind* to facilitate grouping. The kind is appended to the context in the format *context.kind*. If you are using WebSphere Message Broker to access an external CORBA application, you need to know the location of the naming service and the name of the object reference in the naming service. The following example shows how to determine the exact string representation of the name.



In the diagram, contexts are represented by squares, and object references are represented by circles.

- An object called Factory is directly attached to the initial naming context.
- Three contexts, with kind *region*, are also attached to the initial naming context.
- These three contexts each have one or more object references attached to them.
- The Europe context has an England context attached to it, of kind *country*, which has an object attached to it (*Calculator*).

The name that you specify when you configure the `Object reference name` property on the CORBARequest node reflects the position of the object in the hierarchy. The following table shows how to refer to the specific objects in the diagram.

Object	Object reference name
Factory	Factory
Bank	Asia.region/Bank.object
Mail	Asia.region/Mail.object
StockExchange	America.region/StrockExchange.object
Market	Europe.region/Market.object

Object	Object reference name
Calculator	Europe.region/England.country/Calculator

All objects in the naming service can be connected directly to the initial naming context; in which case, their names would be in the same format as the Factory object in this example.

Use the CORBARequest node to call an external CORBA application over Internet Inter-Orb Protocol (IIOP).

CORBA operation parameters:

CORBA operations can have parameters that can be modified by the server.

CORBA operations can have in, out, and inout parameters. In and inout parameters dictate the appearance of the tree under the DataObject domain when going into a CORBARequest node. The return type, inout and out parameters dictate the appearance of the tree when leaving a CORBARequest node.

The inbound message is contained in the element *interfaceName.operationName* and needs an element for every in or inout parameter. If the interface is contained in a module, the name is qualified with the name of the module. If the module is nested in other modules, all module names are stated; for example: *moduleNameA.moduleNameB.interfaceName.operationName*. Out parameters are not required because the client does not send a value for out parameters. These elements must be in the same order as the parameters in the IDL file.

The output message from the CORBARequest node is contained in the element *interfaceName.operationName*Response. If the interface is contained in a module, the name is qualified with the module name. The outbound message has an element for the return type, named *_return*, and an element for every inout and out parameter.

Here is an example of an IDL file:

```
interface exampleInterface {
 string outsideModuleOperation(in string one, out string two, inout string three);

};
```

The input message might look like the following example:

```
<exampleInterface.outsideModuleOperation>
 <one>something</one>
 <three>something</three>
</exampleInterface.outsideModuleOperation>
```

The output message might look like the following example:

```
<exampleInterface.outsideModuleOperationResponse>
 <_return>something</_return>
 <two>something</two>
 <three>something</three>
</exampleInterface.outsideModuleOperationResponse>
```

The input message requires all in and inout parameters, therefore one and three are specified. The output has the following elements:

- A *_return* element (because the operation has a return type of string)
- An element called *two* (because *two* is an out parameter)
- An element called *three* (because *three* is an inout parameter)

User-defined exceptions

Exceptions are propagated to the Error terminal under the DataObject domain; the structure of the message depends on the exception.

The following example shows how a user-defined exception is defined in an IDL file.

```
exception BadRecord {
    string why;
  };
```

```
interface SomeInterface {
  long bar(in float pi) raises (BadRecord);
};
```

The operation *bar* can issue the exception *BadRecord*. If this exception is issued, the following message is propagated to the Error terminal.

```
<BadRecord>
 <why>Reason text</why>
</BadRecord>
```

Edge cases

Two identified edge cases exist for reading a tree and producing a tree:

- No input parameters exist.
- A void function has no inout or out parameters

The following sample IDL file illustrates two examples.

```
interface exampleInterface {
 string exampleOne();
void exampleTwo(in string one);
};
```

- **Example 1 - no input parameters exist**

  Input message: The input message is irrelevant because the CORBARequest node does not look at the body of the message.

  Output message:

  ```
  <exampleInterface.exampleOneResponse>
   <_return>something</_return>
  </exampleInterface.exampleOneResponse>
  ```

- **Example 2 - A void function has no inout or out parameters**

  Input message:

  ```
  <exampleInterface.exampleTwo>
   <one>something</one>
  </exampleInterface.exampleTwo>
  ```

  Output message:

  ```
  <exampleInterface.exampleTwoResponse>
  </exampleInterface.exampleTwoResponse>
  ```

Connecting to an external CORBA application

Connecting to an external CORBA application involves importing an IDL file, creating a message flow, building a message, and processing the response from the CORBARequest node.

Before you begin

Before you start:

An IDL file is used to configure the CORBARequest node. Ensure that you have a valid IDL file that contains elements that are supported by WebSphere Message Broker. The CORBA IDL file must contain at least one interface that has one operation. For more information, see "CORBA support" on page 2149.

About this task

To connect to an external CORBA application, complete the following steps.

Procedure

1. Create a message flow project and a message set project.
2. Import an IDL file into the WebSphere Message Broker Toolkit, as described in "Importing an IDL file" on page 2952.
3. Develop a message flow that contains a CORBARequest node, as described in "Developing a message flow with a CORBARequest node" on page 2161.

4. Build a message to send to the CORBARequest node, as described in "Building a message for the CORBARequest node" on page 2164.
5. Process the response from the CORBARequest node, as described in "Processing responses from a CORBARequest node" on page 2167.

What to do next

After you have deployed a message flow that contains a CORBARequest node, you can change the location of the object reference by using a configurable service. For more information, see "Defining where the CORBARequest node gets the object reference" on page 734.

Related reference:

"CORBARequest node" on page 4349
Use the CORBARequest node to call an external CORBA application over Internet Inter-Orb Protocol (IIOP).

Developing a message flow with a CORBARequest node:

To connect to an external CORBA application, create a message flow that contains a CORBARequest node.

Before you begin

Before you start:

Ensure that you have created a message flow project and message set project, and that you have imported an IDL file, as described in "Connecting to an external CORBA application" on page 2159.

About this task

You can create and configure a message flow manually, or you can create a message flow by dragging an imported IDL file onto the canvas.

Creating a message flow from an imported IDL file:
Procedure

1. Drag an IDL file from the `CORBA IDLs` folder in the Broker Development view to an empty canvas. (If you have imported an IDL file that contains includes, drag the top-level IDL file onto the canvas.)

   A CORBARequest node is created. The `IDL file`, `Interface name`, and `Operation name` properties are set according to the IDL file.
2. If the IDL file contains more than one interface or operation, select an interface and operation from the dialog box.
3. Configure the following properties on the CORBARequest node:
   - `Naming service`: Specify the host name and port of the naming service.

     The format of this value is host:port, where port is optional; for example, localhost:2809. You can obtain this value from the administrator of the CORBA application that you are calling.
   - `Object reference name`: Specify the name of the object reference in the naming service.

     You can obtain this value from the CORBA server that you are calling. For more information about how to specify the object reference name, see "CORBA naming service" on page 2154.
4. Add to the message flow other nodes that build the incoming and outgoing messages.

   You can use an XML message for the CORBARequest node, or you can build a message by using a Compute, JavaCompute, or PHPCompute node. If the incoming message has a message model, you can use a Mapping node to build the message that is sent to the CORBARequest node.

   If the message that the CORBARequest node produces has a message model, you can use a Mapping node to build the outgoing message.
5. Build a message for the CORBARequest node by using the examples in "Building a message for the CORBARequest node" on page 2164.
6. Save the message flow.
7. Deploy the message flow. (If you have used an IDL file that contains includes, ensure that all the IDL files are deployed with the message flow.)

What to do next

You can also drag an IDL file onto an existing CORBARequest node. The existing `IDL file`, `Interface name`, and `Operation name` properties are replaced with values from the new IDL file, and the `Naming service` and `Object reference name` properties are cleared. If the IDL file contains more than one interface or operation, the `Interface name` property is set to the first interface in the IDL file, and the `Operation name` property is set to the first operation in that interface.

Creating a message flow manually:
Procedure

1. Create a message flow.
2. Add a CORBARequest node to the message flow.
3. Configure the following properties on the CORBARequest node:
   - `Naming service`: Specify the host name and port of the naming service.

     The format of this value is host:port, where port is optional; for example, localhost:2809. You can obtain this value from the administrator of the CORBA application that you are calling.

     You can also use a configurable service to specify a naming service; for more information, see "Defining where the CORBARequest node gets the object reference" on page 734.
   - `Object reference name`: Specify the name of the object reference in the naming service.

     You can obtain this value from the CORBA server that you are calling. For more information about how to specify the object reference name, see "CORBA naming service" on page 2154.

     You can also use a configurable service to specify an object reference name; for more information, see "Defining where the CORBARequest node gets the object reference" on page 734.
   - `IDL file`: Click **Browse** and select the IDL file from the message set project. If you have imported an IDL file that contains includes, select the top-level IDL file.
   - `Interface name`: Specify the name of the interface in the IDL file that the node calls.
   - `Operation name`: Specify the name of the operation from the interface that you select in the IDL file.

     You can override this property in the local environment by specifying a value in the following location:

     ```
     $LocalEnvironment/Destination/CORBA/Request/OperationName
     ```
4. Add to the message flow other nodes that build the incoming and outgoing messages.

   You can use an XML message for the CORBARequest node, or you can build a message by using a Compute, JavaCompute, or PHPCompute node. If the incoming message has a message model, you can use a Mapping node to build the message that is sent to the CORBARequest node.

   If the message that the CORBARequest node produces has a message model, you can use a Mapping node to build the outgoing message.
5. Build a message for the CORBARequest node by using the examples in "Building a message for the CORBARequest node" on page 2164.
6. Save the message flow.

7. Deploy the message flow. (If you have used an IDL file that contains includes, ensure that all the IDL files are deployed with the message flow.)

What to do next

Next: After you have deployed the message flow, learn how calls are processed by the CORBARequest node; see "Processing responses from a CORBARequest node" on page 2167.

"CORBARequest node" on page 4349
Use the CORBARequest node to call an external CORBA application over Internet Inter-Orb Protocol (IIOP).

Building a message for the CORBARequest node:

You can use an XML message for the CORBARequest node, or you can build a message by using another message flow node.

Before you begin

Before you start:

Ensure that you have created and configured a message flow with a CORBARequest node, as described in "Developing a message flow with a CORBARequest node" on page 2161.

About this task

The CORBARequest node requires an input message. The node can use an XML message from another node, or you can build a message by using a Compute, JavaCompute, or PHPCompute node. If the incoming message has a message model, you can use a Mapping node to build the message to send to the CORBARequest node. The incoming message tree must be in the DataObject domain, and the elements in the tree must match the IDL interface that you are calling. The physical representation of a message in the DataObject domain is XML; therefore, your application constructs message bodies like the following examples.

You can specify the location in the incoming message tree from which data is retrieved to form the request that is sent by the CORBARequest node. Specify this location by using the `Data location` property on the Request tab. The default value is `$Body`.

Procedure

1. Find out what data needs to be in the body of the message to send to the CORBARequest node.
2. Specify the top-level element (interface.operationName) for the message that you need to send to the CORBARequest node.
3. Specify a child for each in and inout parameter. You do not have to pass in a value for out parameters.

Example

The following examples show the XML and ESQL that could be received by a message flow.

A mixture of in inout and out parameters

Here is an example IDL file:

```
interface

ExampleOne {
 enum completion{YES, NO, MAYBE};
  typedef sequence<string> stringlist;
 struct stringobject {string member;};

 string exampleOneOperation(in string inparamA, inout string inoutparamA, out string outparamA);
 completion exampleOneOperationB(in stringlist inparamB, inout stringobject inoutparamB, out complet
}
```

This IDL file contains an interface with two operations, which have an in parameter, an inout parameter, and an out parameter.

For the first operation, *exampleOneOperationA*, you must pass in the parameters *inparamA* and *inoutparamA* under the top-level type *ExampleOne.exampleOneOperationA*. You do not need to pass in the *outparamA* parameter.

Here is an XML example:

```
<ExampleOne.exampleOneOperationA>
 <inparamA>your value</inparamA>
 <inoutparamA>your value</inoutparamA>
</ExampleOne.exampleOneOperationA>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationA".inparamA = 'yourvalue';

SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationA".inoutparamA = 'yourvalue';
```

For the second operation, *exampleOneOperationB*, you must pass in the parameters *inparamB* and *inoutparamB* under the top-level type *ExampleOne.exampleOneOperationB*. You do not need to pass in the *outparamB* parameter.

Here is an XML example:

```
<ExampleOne.exampleOneOperationB>
 <inparamB><item>your value</item></inparamB>
 <inoutparamB><member>your value</member></inoutparamB>
</ExampleOne.exampleOneOperationB>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationB".inparamB.item = 'your value';

SET
OutputRoot.DataObject."ExampleOne.exampleOneOperationB".inoutparamB.member = 'your value'
```

In and inout parameters only

Here is an example IDL file:

```
interface

ExampleTwo {
 enum completion{YES, NO, MAYBE};
 typedef sequence<string> stringlist;
 struct stringobject {string member;};

 string exampleTwoOperationA(in string inparamA, inout string inoutparamA);
 completion exampleTwoOperationB(in stringlist inparamB, inout stringobject inoutparamB);

}
```

This IDL file contains two operations with an in and inout parameter only. The removal of the out parameter and the existence of only in and inout parameters does not change the parameters that you need to pass in.

To call the first operation, *exampleTwoOperationA*, pass in *inparamA* and *inoutparamA* under the top-level type *ExampleTwo.exampleTwoOperationA*.

Here is an XML example:

```
<ExampleTwo.exampleTwoOperationA>
 <inparamA>your value</inparamA>
 <inoutparamA>your value</inoutparamA>
</ExampleTwo.exampleTwoOperationA>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationA".inparamA = 'yourvalue';

SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationA".inoutparamA = 'yourvalue';
```

To call the second operation, *exampleTwoOperationB*, pass in *inparamB* and *inoutparamB* under the top-level type *ExampleTwo.exampleTwoOperationB*.

Here is an XML example:

```
<ExampleTwo.exampleTwoOperationB>
 <inparamB><item>your value</item></inparamB>
 <inoutparamB><member>your value</member></inoutparamB>
</ExampleTwo.exampleTwoOperationB>
```

Here is an ESQL example:

```
SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationB".inparamB.item = 'your value';

SET
OutputRoot.DataObject."ExampleTwo.exampleTwoOperationB".inoutparamB.member = 'your value';
```

No parameters or out parameters only

If the operation contains no parameters, or out parameters only, you do not need to put anything in the body of the message. The CORBARequest node does not look at the incoming message.

What to do next

Next: Process the responses from the CORBARequest, as described in "Processing responses from a CORBARequest node" on page 2167.

"CORBARequest node" on page 4349
Use the CORBARequest node to call an external CORBA application over Internet Inter-Orb Protocol (IIOP).

Processing responses from a CORBARequest node:

Configure the CORBARequest node to define the location to which responses are sent.

Before you begin

Before you start:

Complete the tasks that are described in the following topics:

- "Developing a message flow with a CORBARequest node" on page 2161
- "Building a message for the CORBARequest node" on page 2164

About this task

The CORBARequest node has three output terminals:

- Out: For a successful invocation of the operation.
- Error: If a CORBA system exception or user-defined exception is issued.
- Failure: If a failure occurs in the node; for example, if the node cannot communicate with the naming service or it receives an incorrect message.

You can select the location to which to send the response by configuring the `Output data location` property on the **Result** tab. This property specifies the message tree location to which the CORBARequest node puts output. The output is put under the DataObject domain.

Procedure

- **Processing successful calls**

  When a call is successful, the resulting message is propagated to the Out terminal. Inside the tree is a top-level element named *InterfaceName.OperationName*Response. Under this type is the return type of the operation (named _return) and every inout or out parameter. In parameters are not propagated because they do not change.

  A mixture of in inout and out parameters

  Here is an example IDL file:

```
interface

ExampleOne {
   string exampleOneOperation(in string inparam, out string outparam, inout string inoutparam);

}
```

  You receive the parameters *outparam* and *inoutparam* under the top-level element `ExampleOne.exampleOneOperationResponse`.

  Here is an XML example:

```
<ExampleOne.exampleOneOperationResponse>
 <_return>The operation return value</_return>
 <outparam>value from corba app</outparam>
 </inoutparam>your value changed by the corba app<inoutparam>
</ExampleOne.exampleOneOperationResponse>
```

  Out and inout parameters

  Here is an example IDL file:

```
interface

ExampleTwo {
   string exampleTwoOperation(out string outparam, inout string inoutparam);

}
```

  The removal of the in parameter makes no difference to the message that is propagated from a CORBARequest node because in parameters are not propagated.

  Here is an XML example:

```
<ExampleTwo.exampleTwoOperationResponse>
 <_return>The operation return value</_return>
 <outparam>value from corba app</outparam>
 </inoutparam>your value changed by the corba app<inoutparam>
</ExampleTwo.exampleTwoOperationResponse>
```

  In parameters only or no parameters

  If the operation contains no parameters, or in parameters only, you receive the _return value under the top-level element.

  Here is an example IDL file:

```
interface

ExampleThree {
   string exampleThreeOperation(in string inparam);

}
```

  Here is an XML example:

```
<ExampleThree.exampleThreeOperationResponse>
 <_return>The operation return value</_return>
</ExampleThree.exampleThreeOperationResponse>
```

No return type (void) and no inout or out parameters

If the operation that you are calling has no return type (void) and no inout or out parameters, no values are returned from the CORBA application to put in the tree. In this case, only the top-level element is created.

Here is an example IDL file:

```
interface

ExampleFour {
   void exampleFourOperation(in string inparam);

}
```

Here is an XML example:

```
<ExampleFour.exampleFourOperationResponse>
</ExampleFour.exampleFourOperationResponse>
```

- **Processing user-defined exceptions and CORBA system exceptions**

  When a CORBA user-defined exception or a CORBA system exception occurs, a message is propagated to the Error terminal. CORBA system exceptions have a standard shape and look like this:

  In the IDL file:

```
exception SystemException { // descriptive of error

 unsigned long;      // more detail about error
 CompletionStatus;   // yes, no, maybe
}
```

  In the tree:

```
<SystemException>
 <minor>10</minor>
 <completed>maybe</completed>
</SystemException>
```

  The top-level element is the name of the CORBA system exception that is issued. The structure of a user-defined exception is based on the IDL for the exception. Here is an example:

  In the IDL file:

```
  exception BadRecord {
 string why;

};
```

  In the message:

```
<BadRecord>
 <why>reason text</why>
</BadRecord>
```

  As you can see from this example, the structure of the message is based on the exception, and is not qualified by the operation that was being called.

- **Handling failures in the node**

  Any failures are propagated to the Failure terminal. Possible failures include:

  – Inability to communicate with the CORBA server
  – Inability to communicate with the CORBA naming service
  – Invalid body (including the wrong top-level element or missing parameters)

Defining where the CORBARequest node gets the object reference:

You can specify an object reference name either on the CORBARequest node or by using a configurable service.

Before you begin

Before you start:

- Read "Common Object Request Broker Architecture (CORBA)" on page 2145 and "Configurable services" on page 1296 for background information.

About this task

By using configurable services, you can specify the location from which the CORBARequest node gets the object reference without the need to redeploy the message flow. You can also use the configurable service to specify this location for multiple CORBARequest nodes. To pick up new values when a configurable service is created or modified, you must reload the broker or execution group to which the message flow was deployed, by using the **mqsistop** and **mqsistart** commands, or the **mqsireload** command.

The properties of the CORBA configurable services are described in "Configurable services properties" on page 3766.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer (as described in "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644) or the **mqsicreateconfigurableservice** command shown in the following example.

  This example creates a CORBA configurable service called "myCORBAService" that connects to the CORBA host on the local host on port 2809, and looks for the object reference called "Europe.region/Market.object". (For more information about how to specify the object reference, see "CORBA naming service" on page 2154.)

  ```
  mqsicreateconfigurableservice MB7BROKER -c CORBA -o myCORBAService
  -n namingService,objectReferenceName -v localhost:2809,Europe.region/Market.object
  ```

  To pick up the new values in the configurable service, restart the execution group and message flow.
- To change a configurable service, use the WebSphere Message Broker Explorer or the **mqsichangeproperties** command shown in the following example.

  This example changes the location of the object reference.

  ```
  mqsichangeproperties MB7BROKER -c CORBA -o myCORBAService -n namingService,objectReferenceName
  ```

  To pick up the updated values in the configurable service, restart the execution group and message flow.
- To display all CORBA configurable services, use the WebSphere Message Broker Explorer or the **mqsireportproperties** command shown in the following example.

  ```
  mqsireportproperties MB7BROKER -c CORBA -o AllReportableEntityNames -r
  ```
- You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer or the **mqsideleteconfigurableservice** command shown in the following example.

  ```
  mqsideleteconfigurableservice MB7BROKER -c CORBA -o myCORBAService
  ```

  You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

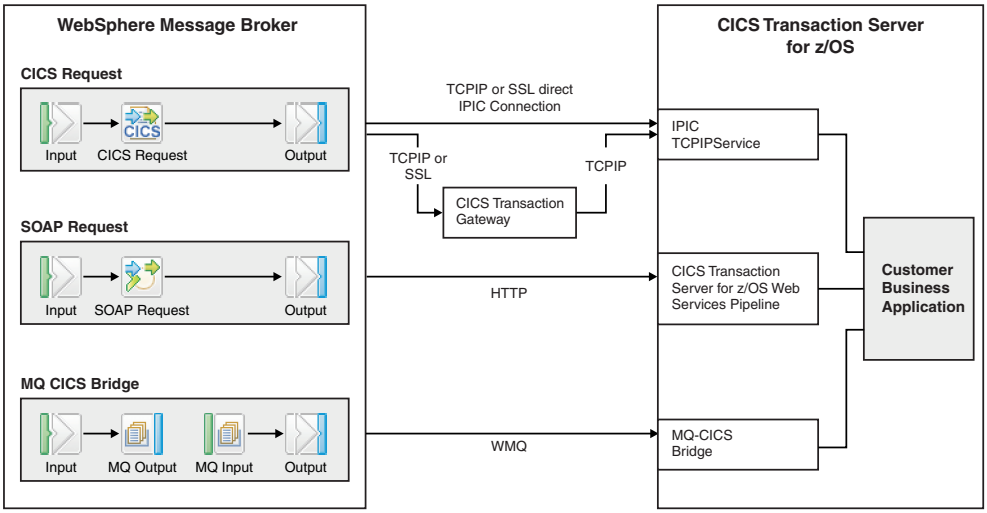
Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

CICS Transaction Server for z/OS overview

CICS Transaction Server for z/OS provides general-purpose transaction processing software for z/OS. CICS is a powerful application server that meets the transaction-processing needs of both large and small enterprises.

By using the CICS support that is provided in WebSphere Message Broker you can deploy CICS applications into a service-oriented architecture (SOA). This support keeps your business logic intact and requires little or no change to CICS and CICS applications.

The following diagram shows the layers of communication between WebSphere Message Broker and CICS.



You can use the following methods to connect to CICS:

- **CICSRequest node support**

  WebSphere Message Broker includes a CICSRequest node that supports connectivity to CICS by using the IP InterCommunications (IPIC) protocol, which is available in CICS Transaction Server for z/OS Version 3.2 and later.

  Support includes the following connection methods:

  – A direct connection to CICS (two-tier).
  – A connection to CICS through CICS Transaction Gateway for Multiplatforms (three-tier).

- **CICS Transaction Gateway for Multiplatforms**

  CICS Transaction Gateway for Multiplatforms is a high-performing, secure, and scalable solution that provides workload management and high-availability options for access to CICS. By using standards-based interfaces, CICS Transaction Gateway for Multiplatforms delivers access to new and existing CICS applications.

The CICSRequest node is non-transactional. For further information about the CICSRequest node, see "CICSRequest node" on page 4321.

- **CICS web services support**

  You can use the web services support in WebSphere Message Broker to connect to CICS applications. For further information about web Services, see "Processing Web service messages" on page 1601.

- **CICS-WebSphere MQ Integration**

  CICS has several components that support integration with WebSphere MQ. These components are:

  – The CICS-WebSphere MQ adapter, also known as the CICS-MQ attach (including the CKTI trigger monitor or task initiator). The term CICS-MQ adapter is used to refer to the CICS-WebSphere MQ adapter.

  – The CICS-WebSphere MQ bridge, also known as the CICS 3270 and DPL bridges. The term CICS-MQ bridge is used to refer to the CICS-WebSphere MQ bridge.

For further information about how to use the CICSRequest node to connect WebSphere Message Broker to CICS applications, see "CICS Transaction Server for z/OS connectivity."

For further information about CICS, see the CICS Library web page, which contains links to the CICS Information Center and associated IBM Redbooks publications.

"CICSRequest node" on page 4321
Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

CICS Library web page

CICS Transaction Server for z/OS connectivity:

Use the CICSRequest node to connect WebSphere Message Broker with CICS Transaction Server for z/OS applications.

The CICSRequest node that is available in WebSphere Message Broker provides connectivity to CICS applications by using IP InterCommunications (IPIC) protocol. IPIC is part of a CICS multi-version initiative to provide communications support over TCP/IP as an alternative to that provided over intersystem communication (ISC) and multiregion operation (MRO).

IPIC supports Distributed Program Link (DPL) requests over TCP/IP. The CICSRequest node communicates with CICS by sending Distributed Program Link

(DPL) requests over TCP/IP-based IPIC. IPIC provides a multiplexed single socket connection to CICS Transaction Server for z/OS Version 3.2 and later.

WebSphere Message Broker message flows can use the CICSRequest node to call programs that are running externally in a targeted CICS region. The CICSRequest node can be used by a message flow deployed to any broker platform. The CICSRequest node is non-transactional.

The CICSRequest node supports the following capabilities:

- Commareas.
- Channels and containers.
- Mirror transactions.
- A direct connection to CICS (two-tier).
- A connection to CICS through CICS Transaction Gateway for Multiplatforms (three-tier).
- Local environment overrides for some properties.
- Request timeout.
- A broker APPLID (client APPLID and qualifier) that can identify the application that is connecting to CICS, therefore identifying that WebSphere Message Broker is connected.
- CICSConnection configurable services.
- Secure Sockets Layer (SSL) protocol connection to CICS.
- Security identity.
- User name, or user name and password identity propagation.
- Resource statistics.

You can specify either a COMMAREA data structure or a channel data structure on the CICSRequest node to use as input for linking to CICS programs. The data structure that is specified as input returns the same data structure as output. Channels are an alternative for COMMAREAs, providing relief from the COMMAREA maximum size of `32766` bytes, and allowing greater flexibility in input/output data structures. For more information about using a COMMAREA or channel data structure, see “COMMAREA or channel data structures” on page 2183.

CICS channels hold a number of structures called containers. In WebSphere Message Broker, a CICS channel is represented as a message collection structure. A message collection can hold child messages, each treated as a container by the CICSRequest node. For information about using ESQL to create a message collection, see “Creating a message collection by using ESQL” on page 2758.

If a single container is required for input only, a message collection does not need to be constructed. Instead a regular message can be used, provided the 16-character maximum alphanumeric channel name and the single 16-character maximum alphanumeric container name are specified in the local environment. For more information about using single message mode, see “COMMAREA or channel data structures” on page 2183.

Because it is not possible to know how many containers are in the response, a message collection is always produced as output. However, the CICSRequest node `Result data location` property can be used to reduce the result tree down to a

single message folder, or down to a single field or subtree for output. For information about the `Result data location` property, see “CICSRequest node” on page 4321.

You can add name-value attributes to a message collection to create CICS containers. Name-value attributes in the message collection, apart from *`CollectionName`*, can be used in lieu of full message-folders for simple data. For example, a name-value string attribute can be set in the message collection and used directly by the CICSRequest node without needing to create a message set for the element. For more information about attributes, see “COMMAREA or channel data structures” on page 2183.

Name-value attributes can be produced from containers on output, as well as accepted for input. For information about creating an attribute instead of a message folder from a container, see “CICSRequest node” on page 4321.

You can specify a mirror transaction name on the CICSRequest node for CICS tasks and programs to run under. This grouping greatly assists stat collection, accounting, and aids decision making about task priority. For more information about mirror transactions, see “CICS Transaction Server for z/OS mirror transactions” on page 2189.

The CICSRequest node support in WebSphere Message Broker provides direct communication with CICS (two-tier connection) by sending Distributed Program Link (DPL) requests over TCP/IP-based IPIC, or communication with CICS through CICS Transaction Gateway for Multiplatforms (three-tier connection). For more information about the two-tier and three-tier connection models, see “CICS Transaction Server for z/OS overview” on page 2173 for a high-level overview, or “CICS Transaction Server for z/OS two-tier connectivity” on page 2177 and “CICS Transaction Server for z/OS three-tier connectivity” on page 2181 for detailed conceptual information.

For information about configuring the CICSRequest node to get connection details from a CICSConnection configurable service, see “Changing connection information for the CICSRequest node” on page 738.

You can configure the CICSRequest node or a CICSConnection configurable service to use SSL protocol. For more information, see “Securing the connection to CICS Transaction Server for z/OS by using SSL” on page 547.

You can use the **`mqsisetdbparms`** command to set a user ID and password for the CICSRequest node or CICSConnection configurable service. For detailed information about how to configure CICS security identity support, see “**`mqsisetdbparms`** command” on page 3954.

The CICSRequest node can use an identity that is present on an input message, and propagate it to CICS, by using the `Propagate` property on the security profile that is defined for the node. For more information, see “Propagating security credentials to CICS Transaction Server for z/OS” on page 2208 and “Identity and security token propagation” on page 426.

You can use the CICSRequest node to connect to a CICS application by using a synchronous style of message flow. For details about how to use this node in a message flow, see “CICSRequest node” on page 4321.

Use the **mqsisetdbparms** command to associate a specific user ID and password (or SSH identity file) with one or more resources that are accessed by the broker.

CICS Transaction Server for z/OS two-tier connectivity:

The CICSRequest node support in WebSphere Message Broker provides direct communication with CICS Transaction Server for z/OS (two-tier connection) by sending Distributed Program Link (DPL) requests over TCP/IP-based IP InterCommunications (IPIC) protocol.

The CICSRequest node also supports communication with CICS through CICS Transaction Gateway for Multiplatforms (three-tier connection). For more information about three-tier connections, see "CICS Transaction Server for z/OS three-tier connectivity" on page 2181.

A direct two-tier connection from WebSphere Message Broker to CICS can be made by using the CICSConnection configurable service or by setting the properties directly on the CICSRequest node.

CICSConnection configurable service connections:

A CICS connection from WebSphere Message Broker is made to a listening TCPIPSERVICE resource in CICS. When that connection is established, the active connection between WebSphere Message Broker and CICS is represented by an IPCONN resource.

Each CICSConnection configurable service results in a separate connection to CICS, so for every configurable service that is being used, there is an IPCONN resource in CICS. The properties of the IPCONN resource determine the properties of the link between WebSphere Message Broker and CICS.

The IPCONN resource that represents a WebSphere Message Broker to CICS connection can be created in two different ways; autoinstall or pre-defined.

Autoinstall:

Autoinstalling a connection means that when WebSphere Message Broker connects, the resource is created, and when WebSphere Message Broker disconnects, the resource is discarded. In this setup, the IPCONN is created from a template IPCONN that is named by a user-replaceable-module (URM), which is named in the TCPIPSERVICE resource. Properties of the IPCONN are based on that template resource.

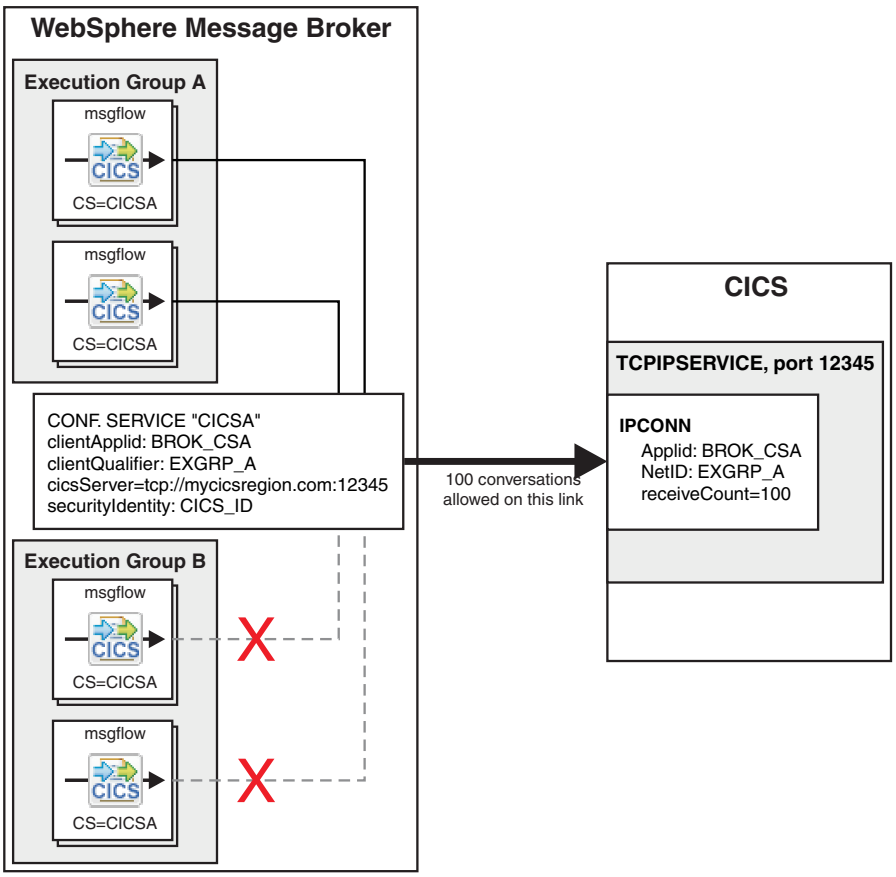
Pre-defined:

Alternatively, the IPCONN can be pre-defined by using standard CICS resource definition mechanisms, such as CICS Explorer, CEDA, or CICSPlex® Systems Manager (CICSPLEX SM). If the IPCONN definition is created in advance, it is matched to the incoming connection by using the IPCONN APPLID and Network ID properties, which correlate to the `clientApplid` and `clientQualifier` properties that can be set on a CICSConnection configurable service.

The advantage of pre-specifying the IPCONN is that you can tightly control the properties of incoming connections, including the security properties and the number of simultaneous requests. However the following rules apply:

- Do not configure different execution groups to use the same CICSConnection `clientApplid` and `clientQualifier` combination to connect to the same CICS region. An IPCONN is tied to WebSphere Message Broker through the CICSConnection configurable service properties `clientApplid` and `clientQualifier`. If this is attempted, only the first configurable service successfully connects.
- Do not specify a host name and port when defining the IPCONN resource in CICS. These fields are used for connections between CICS regions only, they must not be set for WebSphere Message Broker connections.

The following diagram shows how WebSphere Message Broker can directly connect to CICS by using a CICSConnection configurable service.



The two-tier direct CICS connection model is based on the following rules:

- Each configurable service name results in a separate connection to CICS.
- The CICSConnection configurable service must only be used from one execution group, because any further execution groups attempting to use the same configurable service thereafter fail to connect.
- The `clientApplid` and `clientQualifier` properties in the configurable service are used to find the IPCONN resource in CICS. A chosen `clientApplid` and `clientQualifier` combination must be unique to the CICS region. Only one IPCONN resource can exist with that combination.
- More than one message flow instance can use the CICS connection, however each request that goes through a CICSRequest node uses a conversation on the connection for the duration of the request.

When defining an IPCONN resource in CICS, consider the following properties:

- **CICS APPLID and Network ID**

  The CICS APPLID and Network ID properties must match the CICSConnection configurable service `clientApplid` and `clientQualifier` properties.
- **CICS host name and Port number**

  The CICS host name and port properties must be used for connections between CICS regions only, they must not be set for WebSphere Message Broker connections.

- **CICS TCPIPSERVICE**

  IPCONNs are owned by a parent TCPIPSERVICE resource in CICS.
- **CICS Receivecount**

  The CICS Receivecount property controls the number of simultaneous requests that can be performed over the connection. The number of simultaneous requests defaults to 100 for autoinstalled connections.
- **CICS Sendcount**

  The Sendcount property must be set to 0 because the Sendcount property is used for CICS connections only, and must not be used for WebSphere Message Broker connections.
- **CICS LINKAUTH**

  The CICS LINKAUTH property controls how the link security is managed. To use a resource in CICS, two security checks are performed; the "flowed" user, which checks the security credentials that are sent from WebSphere Message Broker, and the "link" user, which must also have permission for the resource. Both user IDs must have permission to use the resource before the request is granted. The link user ID is given low privileges, which means that even if the flowed user has many permissions, the link user ID can be used to cap the privilege of the connection. If LINKAUTH is set to SECUSER, the SECURITYNAME field is used to specify the link user ID. If set to CERTUSER, the link user is determined from an SSL client certificate that is mapped by RACF.
- **CICS USERAUTH**

  The CICS USERAUTH property determines how the flowed user security is configured. If USERAUTH is set to "LOCAL" or "DEFAULTUSER", no user ID or password is to be sent to CICS on a request. This means that all requests use the CICS region ID. If USERAUTH is set to "IDENTIFY", user IDs are flowed without a password. If USERAUTH is set to "VERIFY", user IDs and passwords are required.

Each CICSRequest node in a message flow acts as a request on one of the connections to CICS. Which connection is used is determined by the configurable service that is used.

For more information about configuring the CICSRequest node to get connection details from a CICSConnection configurable service, see “Changing connection information for the CICSRequest node” on page 738.

You can configure the CICSRequest node or a CICSConnection configurable service to use SSL protocol. For more information, see “Securing the connection to CICS Transaction Server for z/OS by using SSL” on page 547.

CICSRequest node connections:

If a CICSConnection configurable service is not specified on the CICSRequest node, and a host name is used directly in the `CICS server` property, the request shares a connection with other resources that have specified the same `CICS server` URL. The first CICSRequest node to be used opens the connection to CICS, regardless of whether a URL or a configurable service is specified in the `CICS server` property.

Related reference:

"CICSRequest node" on page 4321
Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

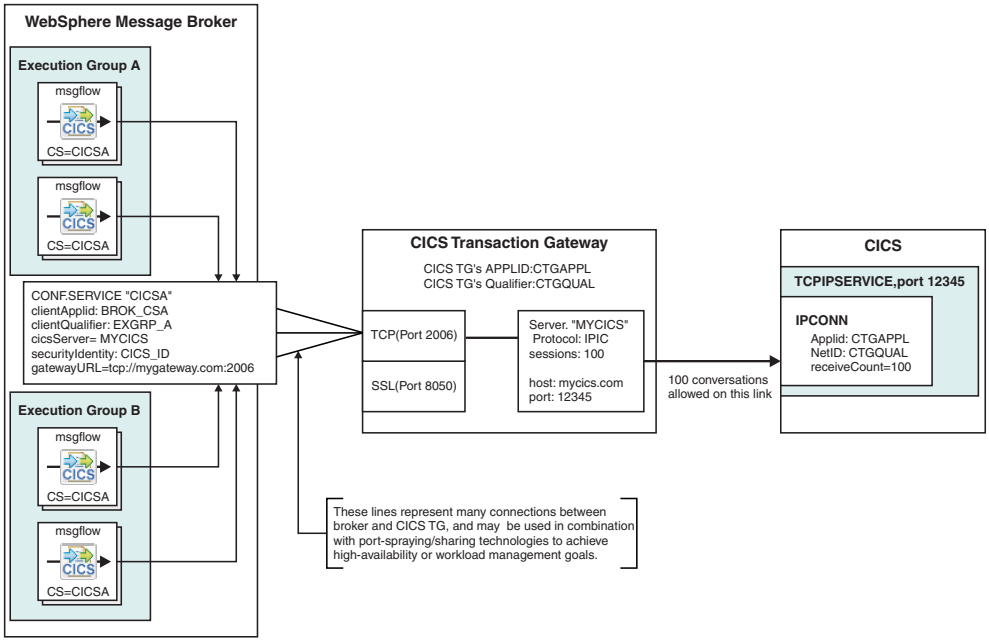
CICS Transaction Server for z/OS three-tier connectivity:

The CICSRequest node support in WebSphere Message Broker can provide communication with CICS Transaction Server for z/OS through CICS Transaction Gateway for Multiplatforms (three-tier connection).

The CICSRequest node also supports direct communication with CICS (two-tier connection) by sending Distributed Program Link (DPL) requests over TCP/IP-based IP InterCommunications (IPIC) protocol. For more information about two-tier connections, see "CICS Transaction Server for z/OS two-tier connectivity" on page 2177.

A three-tier connection from WebSphere Message Broker to CICS through CICS Transaction Gateway for Multiplatforms can be made by configuring the `cicsServer` and `gatewayURL` CICSConnection configurable service properties.

The following diagram shows how WebSphere Message Broker can make a connection to CICS through CICS Transaction Gateway for Multiplatforms by using the CICSConnection configurable service.



For more information about configuring the `cicsServer` and `gatewayURL` CICSConnection configurable service properties to make a three-tier connection, see "Configurable services properties" on page 3766.

The three-tier connection to CICS through CICS Transaction Gateway for Multiplatforms connection model is based on the following rules:

- The number of connections that can be made to CICS Transaction Gateway for Multiplatforms is determined by the maximum number of simultaneous CICS requests in progress. Ensure that the Connection Manager and Worker Thread resources in your CICS Transaction Gateway for Multiplatforms deployment have sufficient capacity to handle the number of required WebSphere Message Broker connections.
- The `clientApplid` and `clientQualifier` properties in the CICSConnection configurable service can be used to identify the broker connection within CICS Transaction Gateway for Multiplatforms. In addition, any CICS tasks that are started through the configurable service each contain point of origin information, including the specified client APPLID and qualifier, which you can find in the CICS task association data.
- Unlike two-tier connections, there is no restriction about sharing client APPLIDs between execution groups because the connection is made to CICS Transaction Gateway for Multiplatforms, and not to CICS directly.

For more information about configuring the CICSRequest node to get connection details from a CICSConnection configurable service, see "Changing connection information for the CICSRequest node" on page 738.

Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

COMMAREA or channel data structures:

CICS Transaction Server for z/OS programs can be linked to by using either a COMMAREA data structure or a channel data structure as input, which return the same data structure as output. The CICSRequest node supports interaction with CICS through COMMAREA or channel data structures.

Channels are a modern alternative for COMMAREAs, providing relief from the COMMAREA maximum size of `32766` bytes, and allowing greater flexibility in input/output data structures.

- "COMMAREAs"
- "Channels" on page 2184

COMMAREAs: If using a COMMAREA as the input data structure for communicating with CICS, the CICSRequest node takes a portion of the Input Body, as defined in the CICSRequest node Request properties, and sends it to CICS as the COMMAREA.

The returning COMMAREA is then put into the Output tree and replaces the existing Body at the location that is defined in the CICSRequest node Result properties. The COMMAREA can then be configured for parsing by using the CICSRequest node Response Message Parsing properties.

When defining a COMMAREA data structure as input, you must ensure that the CICSRequest node `Commarea length` property value is large enough to contain the input request data, or the output response data, but that it does not exceed the maximum value of `32767` bytes. If the `Commarea length` value is not large enough to be used for the response data, or the request data, a memory leak occurs in CICS. The size of the COMMAREA cannot be changed by the CICS program. If the

serialized request data is larger than the Commarea length, the data is truncated to the Commarea length. You can obtain the Commarea length value from the CICS administrator or developer.

The default value for the CICSRequest node data structure basic property is Commarea.

For more information about using a COMMAREA data structure as input, see "Defining a CICS Transaction Server for z/OS data structure" on page 2193, "Developing a message flow with a CICSRequest node" on page 2199, and "Building a message for the CICSRequest node" on page 2202.

Channels: CICS channels hold a number of structures called containers. Containers hold the business information that is accessed by the target CICS program. Each container can hold up to 2 GB of data, and channels can have as many containers within them as required, which provides flexibility in terms of the size and layout of data. Each container has a 16-character maximum alphanumeric container name, which is unique within the channel, and is used as the mechanism to retrieve the contents of the container from the channel.

There are two types of container; character or binary. The type of container can affect the data conversion between WebSphere Message Broker and CICS, however the container type does not have any impact on the format of the information that can be put into the container.

Character containers
Character containers are more likely to be individual strings or discrete data items, but can also be mapped structures, however it is important to remember that data conversion is applied to the data in the container. When a character container is constructed, the source coded character set ID (CCSID) information about the container is sent to CICS as metadata. The CICS program uses the GET CONTAINER application programming interface (API) call to convert the metadata to the default CCSID of the region, unless another CCSID is provided. The CICS program then places the container back into the channel, and the data is converted ready for the WebSphere Message Broker application to retrieve and use.

Binary containers
Binary containers can be mapped by using a COBOL copybook structure or they might be discrete values. Data conversion is not applied to the data in a binary container, therefore the data in a binary container is sent to CICS and retrieved from CICS in original form only.

Unlike COMMAREA structures, the size of the response channel does not need to resemble the request, whereas COMMAREAs must allow for the size of the response in the request.

Channels and containers in CICS

In the following example diagram, the CICS channel has two containers; CustomerName and Order.

Channel Name:		MyChannel		
CustomerName	CHAR	'Joe Bloggs'		
Order	BIN	100	Apples	0.39
...	...	...		

`CustomerName` is a character (CHAR) container that contains a single character string; `Joe Bloggs`. Because `CustomerName` is a character container, data conversion can be applied to the data in the container. `Order` is a binary (BIN) container that might be created by using a COBOL copybook structure or C header file, which you can then import to populate your message set with message definitions. The following example copybook describes the binary layout of the data that the CICS program expects to receive:

```
01 ORDER_STRUCTURE.
          03 QTY                 COMP-1.
          03 ITEM                PIC X(10).
          03 PRICE               PIC S9(9).
```

The target CICS program can retrieve both of these containers from the channel by providing the name of the container when using the `GET CONTAINER` API. When the data is provided to the CICS program, the program processes the data however it chooses. For example, the program can place other containers into the channel to provide a response to the called container by using the `PUT CONTAINER` API.

Channels and containers in WebSphere Message Broker

In WebSphere Message Broker, a CICS channel is represented as a message collection structure. A message collection can hold child messages, each treated as a container by the CICSRequest node. A message collection structure is used as both input and output to the CICSRequest node when using a channel data structure. For more information about message collections, see “Message collections” on page 2755, and for information about creating a message collection, see “Creating a message collection by using ESQL” on page 2758.

The message collection name is used to name the channel. The name of the child message in the message collection is used as the name of the container in the channel, and must be unique. If the child message name in the message collection is not unique, the request is rejected in CICS.

The following table shows the channel and container to message collection and child message mapping:

CICS	WebSphere Message Broker
Channel name	Message collection name
Container name (must be unique to the parent channel)	Child message name (must be unique to the message collection)

Name-value attributes

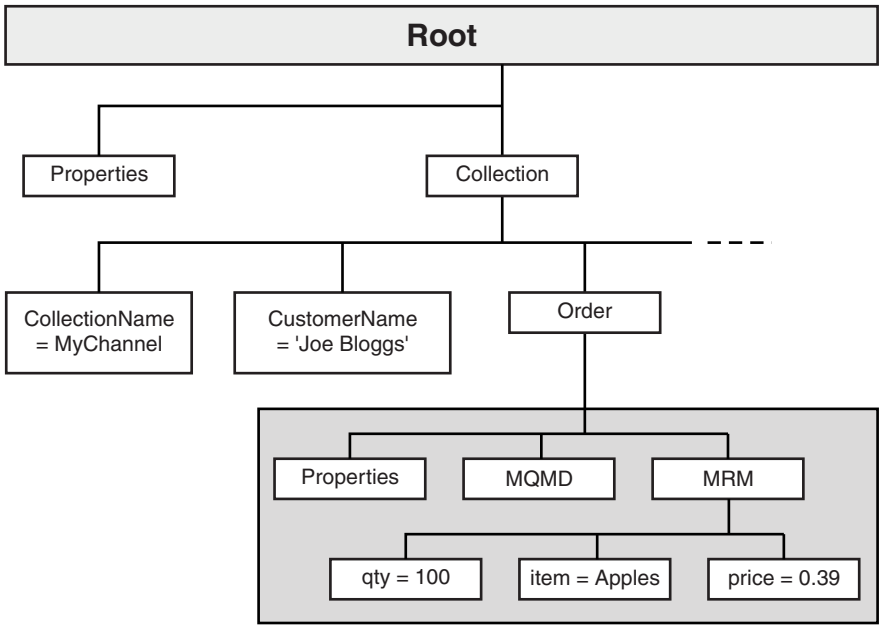
WebSphere Message Broker supports adding name-value attributes to a message collection to create a container. A message collection can have zero or more

attributes. The name of an attribute must be unique within a message collection. A standard attribute for the message collection is an attribute called *CollectionName*.

You can add name-value attributes to a message collection to create CICS containers. Name-value attributes in the message collection, apart from *CollectionName*, can be used in lieu of full message-folders for simple data. For example, a name-value string attribute can be set in the message collection and used directly by the CICSRequest node without needing to create a message set for the element.

Name-value attributes can be produced from containers on output, as well as accepted for input. For information about creating an attribute instead of a message folder from a container, see "CICSRequest node" on page 4321.

In the following example diagram, the CICS channel is represented by a message collection named `Collection`. `Collection` holds two containers that are represented by child messages named `CustomerName` and `Order`. *CollectionName* and `CustomerName` are both name-value attributes, however the *CollectionName* attribute is not treated as a container by the CICSRequest node, and is therefore not sent to CICS.



If the `CustomerName` attribute is to be treated as a character container by the CICSRequest node, the LocalEnvironment must reflect this.

LocalEnvironment

Each child message in a message collection is treated as having a default type of binary, which determines whether the data is converted to the CCSID in the CICS region. However, you can dynamically override this value to character, on a per message basis, in the local environment. For example, you can set the following value under `LocalEnvironment.Destination.CICS.RequestChannel.Containers`:

```
SET OutputLocalEnvironment.Destination.CICS.RequestChannel.Containers.<myContainerName> = CHARACTER;
```

When a message collection is emitted from the CICSRequest node following the request, the LocalEnvironment contains the returned type information for the containers. For example, when the response channel comes back from CICS, the LocalEnvironment shows the types of the containers that have come back in the following location:
`LocalEnvironment.CICS.ResponseChannel.Containers.<myContainerName> = CHARACTER`

The channel name, which has a 16-character alphanumeric limit, can be overridden as follows:

```
SET OutputLocalEnvironment.Destination.CICS.RequestChannel.ChannelName = <myNewChannelName>;
```

If a single container is required for input only, a message collection does not need to be constructed. Instead a regular message can be used, however, you must set the 16-character maximum alphanumeric `ChannelName` in the LocalEnvironment. The 16-character maximum alphanumeric `SingleMessageContainerName` that needs to be created must also be provided in the following location:

```
SET OutputLocalEnvironment.Destination.CICS.RequestChannel.SingleMessageContainerName = <mySingleM
```

Because a message collection allows each container in the channel to be modeled as a separate message, each message has its own structure and parsing options. For example, one container might be XML and another might be based on a copybook, which can be represented by using XMLNSC and MRM messages within a message collection.

Each child message in the message collection contains message domain, set, type, format, CCSID, and encoding information in the `Properties` folder that is associated with the child message, which is serialized into a byte stream and sent to CICS. Each child message folder within the message collection that is being sent to CICS is serialized at the level of the last child of the message property domain. Not all CICS containers require a message set to represent them.

In the previous example, the `Order` container can be represented as MRM, and a message set can be created from the copybook ORDER_STRUCTURE to represent it. The returning channel is converted into a message collection, where every child message in the message collection represents a container from the channel. Child messages in the message collection are mapped to a list of message domain, set, type, format, CCSID, and encoding information by using the child message name, however CCSID, and encoding information are ignored for character messages. If a mapping cannot be found in the message, a default mapping can be provided.

Because it is not possible to know how many containers are in the response, a message collection is always produced as output.

You can use the CICSRequest node Response Message Parsing properties to map a returning container to a message domain, set, type, format, CCSID, and encoding information. In particular, the `Result data location` property can be used to reduce the result tree down to a single message folder, or down to a single field or subtree for output. For information about the `Result data location` property, see "CICSRequest node" on page 4321.

The following details must be specified for the message to arrive at the CICSRequest node input terminal and be processed into a series of containers, and for those containers in the response channel to be placed back in the message as it leaves the node:

- The channel must be given a 16 character maximum alphanumeric name.

  Because the channel is represented by a message collection in WebSphere Message Broker, you can create the channel name by setting the message collection name. Message collection names are set by using the *CollectionName* attribute. For more information about creating a message collection and setting the message collection name, see "Creating a message collection by using ESQL" on page 2758.
- The following details must be specified for each container in the channel:
  - A 16 character maximum alphanumeric name.

    Because a container is represented by a child message in WebSphere Message Broker, you can create a container name by setting the child message name. For more information about creating a message collection and setting the child message name, see "Creating a message collection by using ESQL" on page 2758.
  - A container type; for example, `binary` or `character`.
  - A directory to use to place the response data into.

A sample is provided that demonstrates how to call a channel-based CICS program by creating and populating a message collection for the CICSRequest node, and how to process the collection after the call. For more information, see CICS Transaction Server for z/OS Channel Connectivity.

"CICSRequest node" on page 4321
Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

CICS Transaction Server for z/OS mirror transactions:

You can use a mirror transaction to group CICS Transaction Server for z/OS tasks and programs together. This grouping greatly assists stat collection, accounting, and aids decision making about task priority.

You can specify a mirror transaction name on the CICSRequest node for CICS tasks and programs to run under. For example, if each department in a business has a different mirror transaction name, work can be tracked back to the correct source, and decisions about task priority and quality of service (QoS) can be made in CICS. Potentially, different security privileges might be available depending on the transaction name chosen. Or the transaction name might be used as a way of indicating the origin of the task. Alternatively, a mirror transaction can be used to denote whether code page translation of the commarea data is required.

There are two ways that a mirror transaction can be specified:

Specifying a mirror transaction name that corresponds with a defined TRANSACTION resource in CICS:

You can specify a mirror transaction name by configuring the `Mirror transaction ID` property on the CICSRequest node Basic tab, however the `Mirror transaction ID` property value that you specify must correspond to a defined TRANSACTION resource in CICS. For example, if you have a defined TRANSACTION resource of `ATRN` in CICS, and you want tasks and programs to run under that transaction, you must configure `ATRN` as the `Mirror transaction ID` property value.

When the message flow containing the configured CICSRequest node is deployed, any CICS programs that are started thereafter appear in CICS as running under the specified mirror transaction.

Specifying a weaker form of mirror transaction that does not require a TRANSACTION resource to be defined in CICS:

You can use a weaker form of mirror transaction that does not change the TRANSACTION resource, but instead sets a variable called `EIBTRNID`, which is available to the called program. You can configure the `EIBTRNID` variable to tell the program what TRANSACTION resource it is running under, without the TRANSACTION resource being defined in CICS.

For example, you can specify this weaker form of mirror transaction by configuring the `Mirror transaction ID` property with the name of the required TRANSACTION resource; for example `ATRN`, and by selecting the `Set EIBTRNID only` property on the CICSRequest node Basic tab.

When the message flow containing the configured CICSRequest node is deployed, any CICS programs that are started thereafter appear in CICS as running under the specified mirror transaction.

If the value of the CICSRequest node `Mirror transaction ID` property is not set, the mirror transaction name defaults to `CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system.

The following table describes the mirror transaction handling that is applied depending on the configuration of the `Mirror transaction ID` and `Set EIBTRNID only` CICSRequest node properties. Where `ATRN` is an example of a user-defined transaction name:

Mirror transaction ID property value	**Set EIBTRNID only property value**	**Task and programs run under defined TRANSACTION resource:**	**EIBTRNID is:**
Blank	Cleared	`CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system	`CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system
`ATRN`	Cleared	`ATRN`	`ATRN`
`ATRN`	Selected	`CPMI` if called by a distributed platform, or `CSMI` if called by a z/OS system	`ATRN`

If you are considering whether to use a mirror transaction as a way of finding the point of origin of your data, using the CICS task association data might be a better alternative. All tasks that are initiated in CICS over IP InterCommunications (IPIC) protocol contain origin information, including source Internet Protocol (IP) and APPLID information.

The CICS mirror transaction properties can be changed by configuring the properties directly on the CICSRequest node, by using the **mqsiapplybaroverride** command, or by dynamically overriding these property values with elements in the message tree, on a per message basis, in the local environment. For more information about dynamically overriding CICSRequest node values, see "Local environment overrides for the CICSRequest node" on page 2191 and for information about the **mqsiapplybaroverride** command, see "Configurable properties" on page 3687.

"Configurable properties" on page 3687
Some properties of message flow nodes are configurable and can be changed by using the **mqsiapplybaroverride** command. The following table maps the message flow node properties to the corresponding properties of the **mqsiapplybaroverride** command.

Local environment overrides for the CICSRequest node:

When you use the CICSRequest node in a message flow, you can override some of its properties with elements in the message tree.

You can dynamically override values, on a per message basis, in the local environment. You can override the CICS Transaction Server for z/OS program that you are calling, the COMMAREA length, mirror transactions, and the processing of the response message.

You can set the following values under `LocalEnvironment.Destination.CICS`.

Setting	Description
CICSProgramName	Overrides the `Program name` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.CICSProgramName = 'progx';` You can override the location of this value by using a property on the CICSRequest node.
CICSCommareaLen	Overrides the `Commarea length` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.CICSCommareaLen = 100;`
mirrorTran	Overrides the `Mirror transaction ID` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.mirrorTran = 'ATRN';`
eibtrnidOnly	Overrides the `Set EIBTRNID only` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.eibtrnidOnly = 'TRUE';` Valid values are `TRUE`, `FALSE`, `YES`, or `NO`. Where `TRUE` or `YES` represents a selected check box for the `Set EIBTRNID only` property in the WebSphere Message Broker Toolkit. Where `FALSE` or `NO` represents a cleared check box in the WebSphere Message Broker Toolkit.

You can set the following values under `LocalEnvironment.Destination.CICS.Response`.

Setting	Description
messageDomain	Overrides the `Message domain` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageDomain = 'MRM';`
messageSet	Overrides the `Message set` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageSet = '{com.test}:MyMessageSet';`
messageType	Overrides the `Message type` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageType = 'messageA';`
messageFormat	Overrides the `Message format` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageFormat = 'XML1';`

Setting	Description
messageCCSID	Overrides the `Message coded character set ID` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageCCSID = 500;`
messageEncoding	Overrides the `Message encoding` property on the node; for example: `SET OutputLocalEnvironment.Destination.CICS.Response.messageEncoding = 785;`

You can also set LocalEnvironment values for CICS channels and containers. For more information, see "COMMAREA or channel data structures" on page 2183.

Connecting to a CICS Transaction Server for z/OS application

Connecting to a CICS Transaction Server for z/OS application involves creating a message flow, building a message, and processing the response from the CICSRequest node.

About this task

To connect to a CICS application, complete the following steps.

Procedure

1. Create a message flow project and a message set project. See "Creating a message flow project" on page 1425 and "Working with a message set project" on page 2838 for more information.
2. Define the COMMAREA data structure as a message set, as described in "Defining a CICS Transaction Server for z/OS data structure" on page 2193.
3. Configure IP InterCommunications (IPIC) protocol on CICS, as described in "Preparing the environment for the CICSRequest node" on page 736.
4. Optional: Configure the CICSRequest node to communicate with CICS Transaction Server for z/OS over the Secure Sockets Layer (SSL) protocol, as described in "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 547.

5. Develop a message flow that contains a CICSRequest node, as described in "Developing a message flow with a CICSRequest node" on page 2199.
6. Build a message to send to the CICSRequest node, as described in "Building a message for the CICSRequest node" on page 2202.
7. Process the response from the CICSRequest node, as described in "Processing responses from a CICSRequest node" on page 2204.

What to do next

You can change the connection details for the CICSRequest node by using the CICSConnection configurable service, as described in "Changing connection information for the CICSRequest node" on page 738.

The CICSRequest node can also use an identity that is present on an input message, and propagate it to CICS, by using the `Propagate` property on the security profile that is defined for the node. For more information, see "Propagating security credentials to CICS Transaction Server for z/OS" on page 2208

Defining a CICS Transaction Server for z/OS data structure:

Mapped data structures, such as COBOL copybooks or C structures, can be used to define an MRM message definition for a CICS Transaction Server for z/OS COMMAREA or a channel container.

Before you begin

Before you start:

- Create a message flow project and a message set project. See "Creating a message flow project" on page 1425 and "Working with a message set project" on page 2838 for more information.
- Optional: If you are using a COMMAREA data structure, read the COMMAREA concept information that is defined in the CICS Transaction Server for z/OS Version 4.1 Information Center online.

- Read the COMMAREA and channel concept information that is defined in "COMMAREA or channel data structures" on page 2183.
- Create a message definition file by using the New Message Definition File wizard in the WebSphere Message Broker Toolkit.
  - If you are using a C header file, see "Importing from C" on page 2934.
  - If you are using a COBOL data structure, see "Importing from COBOL copybooks" on page 2937.
  - For information about other data structures, see "Working with data structures" on page 2930.

About this task

After you have created the message definition, complete the following steps.

Procedure

1. Select the `Data structure` property value on the **Basic** tab of the CICSRequest node in accordance with the targeted CICS program. For example, if the target program is channel-based, select `Channel` as the data structure.
2. Ensure that the properties on the **Response Message Parsing** tab of the CICSRequest node specify the output COMMAREA or container structure.
3. Check that the upstream nodes are configured to provide the correct input structure.
4. Optional: If you are using a COMMAREA data structure, ensure that the CICSRequest node `Commarea length` property is large enough to hold the serialized input or output structures to avoid a memory leak in the CICS application.

What to do next

Next: If you are using a channel data structure, create a message collection to represent the channel data structure, as described in "Creating a message collection by using ESQL" on page 2758.

Read "CICS Transaction Server for z/OS connectivity" on page 2174 for background information.

About this task

The CICSRequest node can send IPIC requests over TCP/IP to CICS Transaction Server for z/OS Version 3.2 and later. Complete the following steps on CICS to perform this configuration:

Procedure

1. Set the System Initialization (SIT) parameter **TCPIP=YES**.
2. Define the TCP/IP address and host name for CICS. By default, they are defined in the PROFILE.TCPIP and TCPIP.DATA data sets.
3. Add a TCP/IP listener to CICS by using the following **CEDA** command to define a TCPIPSERVICE resource in a group:

   ```
   CEDA DEF TCPIPSERVICE(service-name) GROUP(group-name)
   ```

   Ensure that the group in which you define the service is in the GRPLIST system initialization parameter, so that the listener starts when CICS is started. Key fields are explained as follows:

   POrtnumber:
   The port on which the TCP/IP service listens.

   PROtocol:
   The protocol of the service is IPIC.

   TRansaction:
   The transaction that CICS runs to handle incoming IPIC requests. Set the field to CISS, which is the default.

   Backlog:
   The Backlog field is the number of TCP/IP connection requests are sent to CICS, which are placed in a TCP/IP queue to be assigned an IPCONN connection to CICS. The default value is 1. Do not use a value

of 0; a value of 0 indicates that no TCP/IP connection requests are to be assigned an IPCONN connection to CICS, which disables incoming connection requests.

Ipaddress:
The IP address, in dotted decimal form, on which the TCPIPSERVICE resource listens. For configurations with more than one IP stack, specify ANY to make the TCPIPSERVICE resource listen on all addresses.

SOcketclose:
Whether CICS waits before closing the socket after issuing a receive for incoming data on that socket. To ensure that the connection from the CICSRequest node always remains open, set SOcketclose to NO for IPIC connections.

SSl: Whether the CICS TCP/IP service is to use Secure Sockets Layer (SSL) protocol for encryption and authentication. Valid values are NO, YES, or CLIENTAUTH. Where:

- NO indicates that SSL is not to be used.
- YES indicates that the personal certificate of the CICS region must be trusted by WebSphere Message Broker.
- CLIENTAUTH indicates that the personal certificate of the CICS region must be trusted by WebSphere Message Broker, and the WebSphere Message Broker personal certificate must be trusted by CICS.

  The CICSRequest node does not support a separate truststore, so the keystore file must provide both personal and signer certificates. For more information, see "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 547.

4. Use the following command to install the TCPIPSERVICE definition:
   ```
   CEDA INS TCPIPSERVICE(service-name) GROUP(group-name)
   ```

Use the **mqsisetdbparms** command to associate a specific user ID and password (or SSH identity file) with one or more resources that are accessed by the broker.

Securing the connection to CICS Transaction Server for z/OS by using SSL:

Configure the CICSRequest node to communicate with CICS Transaction Server for z/OS over the Secure Sockets Layer (SSL) protocol by updating a CICSConnection configurable service or the CICSRequest node to use SSL.

Before you begin

Before you start:

Ensure that you have completed the following tasks:

1. The CICSRequest node does not support a separate truststore, so the keystore file must provide both personal and signer certificates. If client-authentication (CLIENTAUTH) is enabled in the TCPIPSERVICE in CICS, the broker keystore file must also contain a personal certificate that is trusted by CICS. To set up a public key infrastructure (PKI) at broker or execution group level, follow the instructions in "Setting up a public key infrastructure" on page 504.
2. Create a message flow project and message set project, as described in "Creating a message flow project" on page 1425 and "Working with a message set project" on page 2838.
3. Define the COMMAREA data structure as a message set, as described in "Defining a CICS Transaction Server for z/OS data structure" on page 2193.
4. Configure IP InterCommunications (IPIC) protocol on CICS, as described in "Preparing the environment for the CICSRequest node" on page 736.

About this task

To configure the CICSRequest node to use SSL, complete the following steps:

Procedure

1. For client-authenticated (CLIENTAUTH) SSL connections, CICS expects the SSL client certificate to be mapped to a RACF user ID. Therefore the SSL client certificate must be mapped to a RACF user ID before attempting to establish the SSL connection to CICS. If the client certificate is not mapped to a RACF user ID, the broker might display a `ECI_ERR_NO_CICS` response. You can map a client certificate to a RACF user ID by using the RACF command **RACDCERT**, which stores the client certificate in the RACF database and associates a user ID with it, or by using RACF certificate name filtering. Client certificates can be mapped one-to-one with a user ID, or a mapping from one to the other can be provided to allow a many-to-one mapping. You can achieve this mapping by using one of the following methods:
   - **Associating a client certificate with a RACF user ID**

a. Copy the certificate that you want to process into an MVS sequential file. The file must have variable length, blocked records (RECFM=VB), and be accessible from TSO.

b. Run the **RACDCERT** command in TSO by using the following syntax:

```
RACDCERT ADD('datasetname') TRUST [ ID(userid) ]
```

Where:

– *datasetname* is the name of the data set containing the client certificate.

– *userid* is the user ID to be associated with the certificate. This parameter is optional. If omitted, the certificate is associated with the user issuing the **RACDCERT** command.

When you issue the **RACDCERT** command, RACF creates a profile in the DIGTCERT class. This profile associates the certificate with the user ID. You can then use the profile to translate a certificate to a user ID without giving a password. For full details of RACF commands, see z/OS Security Server RACF Command Language Reference.

- **RACF certificate name filtering**

  With certificate name filtering, client certificates are not stored in the RACF database. The association between one or more certificates and a RACF user ID is achieved by defining a filter rule that matches the distinguished name of the certificate owner or issuer (CA). A sample filter rule might look like the following example:

```
RACDCERT ID(DEPT3USR) MAP SDNFILTER
(OU=DEPT1.OU=DEPT2.O=IBM.L=LOC.SP=NY.C=US)
```

  This sample filter rule would associate user ID DEPT3USR with all certificates when the distinguished name of the certificate owner contains the organizational unit DEPT1 and DEPT2, the organization IBM, the locality LOC, the state/province NY, and the country US.

2. Turn on SSL support in the broker by setting the `cicsServer` property on the CICSConnection configurable service, as shown in the following example. This example changes the CICSRequest node that is configured to use the *myCICSConnection* configurable service for the CICS instance that is running at `mycicsregion.com` port 56789. After you run this command, the CICSRequest node connects to CICS over SSL.

```
mqsichangeproperties MB7BROKER -c CICSConnection -o myCICSConnection -n
cicsServer -v ssl://mycicsregion.com:56789
```

   Alternatively you can configure the `CICS server` property directly on the CICSRequest node.

What to do next

Next: When you have configured the broker or the CICSRequest node to use SSL, develop a message flow that contains a CICSRequest node by following the steps in "Developing a message flow with a CICSRequest node" on page 2199.

Developing a message flow with a CICSRequest node:

To connect to a CICS Transaction Server for z/OS application, create a message flow that contains a CICSRequest node.

Before you begin

Before you start:

Ensure that you have completed the following tasks:

1. Create a message flow project and message set project, as described in "Creating a message flow project" on page 1425 and "Working with a message set project" on page 2838.
2. Define the COMMAREA or channel data structure, as described in "Defining a CICS Transaction Server for z/OS data structure" on page 2193.
3. Optional: If you are using a channel data structure, create a message collection to represent the channel data structure, as described in "Creating a message collection by using ESQL" on page 2758.

4. Configure IP InterCommunications (IPIC) protocol on CICS, as described in "Preparing the environment for the CICSRequest node" on page 736.
5. Optional: Configure the CICSRequest node to communicate with CICS Transaction Server for z/OS over the Secure Sockets Layer (SSL) protocol, as described in "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 547.

About this task

Complete the following steps to develop a message flow with a CICSRequest node.

Procedure

1. Create a message flow.
2. Add a CICSRequest node to the message flow.
3. Configure the following properties on the CICSRequest node.
   - `CICS server`: The `CICS server` property can be defined either as a configurable service name, for example *myCICSConnection*, or as a URL.

     You can either connect to CICS by using the two-tier connection model; for example, by making a direct connection from WebSphere Message Broker to CICS, or by using the three-tier connection model; for example, by connecting to CICS through CICS Transaction Gateway for Multiplatforms. For more information about the two-tier and three-tier connection models, see "CICS Transaction Server for z/OS overview" on page 2173 for a high-level overview, or "CICS Transaction Server for z/OS two-tier connectivity" on page 2177 and "CICS Transaction Server for z/OS three-tier connectivity" on page 2181 for detailed conceptual information.

     Using the two-tier connection model:
     If you are making a direct two-tier connection from WebSphere Message Broker to CICS, you can define the `CICS server` property either as a configurable service name, for example *myCICSConnection*, or as a URL.

     For more information about defining this property as a configurable service, see "Changing connection information for the CICSRequest node" on page 738.

     To define a URL, specify the protocol and the CICS host name and port number. The format of this value is *protocol*`://`*hostname*`:`*port*. Where:

     - *protocol* can be `tcp` or `ssl`.
     - *hostname* is the TCP/IP address of the CICS host.
     - *port* is the port number of the TCPIPSERVICE listener in CICS that is listening for IPIC requests over TCP/IP or SSL.

     For example: `tcp://mycicsregion.com:12345` or `ssl://mycicsregion.com:56789`. You can obtain the *hostname* and *port* values from the IPIC TCPIPSERVICE definition in the target CICS region.

     Using the three-tier connection model:
     If you are making a three-tier connection to CICS through CICS Transaction Gateway for Multiplatforms, the `CICS server` CICSRequest node property must be defined as a configurable service name, for example *myCICSConnection*.

For more information about defining this property as a configurable service, see "Changing connection information for the CICSRequest node" on page 738.

To make a three-tier connection to CICS through CICS Transaction Gateway for Multiplatforms, you must configure the `cicsServer` and `gatewayURL` CICSConnection configurable service properties. For more information about configuring the `cicsServer` and `gatewayURL` CICSConnection configurable service properties to make a three-tier connection, see "Configurable services properties" on page 3766.

- `Program name`: Specify the name of the program that you want to run in the target CICS region.

  You can override this property in the local environment by specifying a value in the following location:

  `$LocalEnvironment/Destination/CICS/CICSProgramName`

- `Data structure`: Specify whether to use a COMMAREA or a channel data structure. The default for this property is `Commarea`. The decision depends on the targeted CICS program, for example; whether the target program is channel-based or not.

- `Commarea length`:

  This property is not configurable if a value of `Channel` is selected for the `Data structure` property.

  The `Commarea length` property is the size, in bytes, of the COMMAREA that is used by the CICS program. The byte size value is sent to CICS, and before the program is started, an area of memory is created to match that number. For example, if you send a `Commarea length` value of `100`, 100 bytes are allocated. The program accesses this area as the `DFHCOMMAREA`.

  Ensure that the `Commarea length` property value is large enough to contain the input request data, or the output response data, but that it does not exceed the maximum value of `32767` bytes. If the `Commarea length` value is not large enough to be used for the response data, or the request data, a memory leak occurs in CICS.

  The size of the COMMAREA cannot be changed by the CICS program.

  If the serialized request data is larger than the `Commarea length`, the data is truncated to the `Commarea length`.

  You can obtain the `Commarea length` value from the CICS administrator or developer.

  You can override this property in the local environment by specifying a value in the following location:

  `$LocalEnvironment/Destination/CICS/CICSCommareaLen`

4. Save the message flow.
5. Deploy the message flow.

What to do next

Next: When you have created and configured the message flow, build a message by following the steps in "Building a message for the CICSRequest node" on page 2202.

Related concepts:

You can create a configurable service that the CICSRequest node or message flow refers to at run time for connection information, instead of defining the connection properties on the node or the message flow. The advantage being that you can change the host name and performance values without needing to redeploy your message flow.

Related reference:

"CICSRequest node" on page 4321
Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

Building a message for the CICSRequest node:

Create a message definition from a data structure and build a message by using another message flow node.

About this task

You can specify the location in the incoming message tree from which data is retrieved to form the request that is sent by the CICSRequest node. Specify this location by using the `Data location` Request property on the CICSRequest node.

Procedure

1. Find out what data needs to be in the body of the message to send to the CICSRequest node. The message body data must match the input structure that is required for your commarea, as defined in a message set definition based on the language structure. For example; COBOL or C copybook.
2. Ensure that the `Commarea length` Basic property value that is configured in the CICSRequest node is large enough to contain the input request data, or the output response data, but that it does not exceed the maximum value of `32767` bytes. If the `Commarea length` value is not large enough to be used for the response data, or the request data, a memory leak occurs in CICS. The size of the commarea cannot be changed by the CICS program. If the serialized request data is larger than the `Commarea length`, the data is truncated to the `Commarea length`. You can obtain the `Commarea length` value from the CICS administrator or developer.

Example

View the following sample to see how to use the CICSRequest node:

- CICS Transaction Server for z/OS Connectivity

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

The following example shows a message that has been modeled in the MRM domain, which can be received by a CICSRequest node and sent to CICS.

COBOL copybook

This example shows the structure of the data that CICS is expecting. The copybook describes the binary layout of the data that the CICS program expects to receive.

```
01 DFHAXCS-REQUEST.
   10 AXCS-COMMAND                  PIC S9(9) COMP.
   10 AXCS-FILE                    PIC X(8).
   10 AXCS-RIFLD                   PIC X(6) VALUE SPACES.
   10 AXCS-DATA.
      15 AXCS-STAT                 PIC X(1)  VALUE SPACES.
      15 AXCS-RECID                PIC X(6)  VALUE SPACES.
      15 AXCS-NAME                 PIC X(20) VALUE SPACES.
      15 AXCS-ADDRESS              PIC X(20) VALUE SPACES.
      15 AXCS-PHONE                PIC X(8)  VALUE SPACES.
      15 AXCS-DATE                 PIC X(8)  VALUE SPACES.
      15 AXCS-AMOUNT               PIC X(8)  VALUE SPACES.
      15 AXCS-COMMENT              PIC X(9)  VALUE SPACES.
```

The example copybook can be used to create a binary structure that requires 98 bytes of COMMAREA or memory space, as shown in the following example:

Table 22.

Name	**Type and Size**
AXCS-COMMAND	4 byte integer (fullword)
AXCS-FILE	8 byte character string
AXCS-RIFLD	6 byte character string
AXCS-STAT	1 byte character string
AXCS-RECID	6 byte character string
AXCS-NAME	20 byte character string
AXCS-ADDRESS	20 byte character string
AXCS-PHONE	8 byte character string
AXCS-DATE	8 byte character string
AXCS-AMOUNT	8 byte character string
AXCS-COMMENT	9 byte character string
Total	**98 bytes**

The COBOL copybook structure must be imported as a message definition, see “Importing from COBOL copybooks” on page 2937 for further information, and a message containing such a structure must be passed to the CICSRequest node. A second copybook might be required to map the returning COMMAREA.

What to do next

The advantage being that you can change the host name and performance values without needing to redeploy your message flow.

Related reference:

"CICSRequest node" on page 4321
Use the CICSRequest node to call CICS Transaction Server for z/OS programs over TCP/IP-based IP InterCommunications (IPIC) protocol.

Processing responses from a CICSRequest node:

The CICSRequest node can return different response messages that indicate the success or failure of the request sent to CICS Transaction Server for z/OS.

Before you begin

Before you start:

Ensure that you have built a message for the CICSRequest node, as described in "Building a message for the CICSRequest node" on page 2202.

About this task

The CICSRequest node has four output terminals:

- Out: The output terminal from which the message tree is propagated, including the data returned from CICS.
- Failure: The output terminal to which a message is routed if a CICSRequest node exception is detected, or a CICSRequest node to CICS connection failure occurs.
- Error: The output terminal to which a message is propagated if a CICS error (abend) occurs.
- Timeout: The output terminal to which the message is propagated if a per-request timeout occurs when an individual request is sent to CICS, but the request takes too long.

You can select the location to which to send the response by configuring the `Output data location` Result property on the CICSRequest node. This property specifies the location in the message tree to which the CICSRequest node places the output.

Procedure

- **Processing successful calls**

  When a CICSRequest node successfully calls a CICS application, the resulting message is propagated to the Out terminal.
- **Processing CICS abends**

  An abend in CICS causes a message to be propagated from the Error terminal. The input message is propagated with a CICS\AbendCode field in the LocalEnvironment. If the Error terminal is not connected, the abend is lost.
- **Processing request timeouts**

  If a CICSRequest node is configured with a `Request timeout` Basic property, and a particular message takes longer than the specified time in seconds to be processed, the request fails and the message is propagated from the Timeout terminal. The output message contains the input message body and a timeout exception in the ExceptionList. If the Timeout terminal is not connected and a timeout occurs, the request timeout exception is routed to the Failure terminal. If the Failure terminal is not connected, the broker throws an exception and returns control to the closest upstream node that can process it. The default behavior is that the message is returned to the input node.
- **Handling failures in the node**

  Any other failures are propagated to the Failure terminal. Possible failures include:

  – An inability to communicate with the target CICS region.
  – An internal CICSRequest node exception is detected.
  – An invalid message body. For example, a parsing error or input message is creating a structure that is larger than the `Commarea length` Basic property that is configured in the CICSRequest node. A similar situation for the returning COMMAREA cannot be detected. For example, if the returning data is larger than the value that is defined in the `Commarea length` property, a memory leak occurs in CICS. Therefore the `Commarea length` Basic property must be correctly configured.

Results

You can use the CICSConnection configurable service to change connection details for the CICSRequest node. See "Changing connection information for the CICSRequest node" on page 738 for details about creating, changing, reporting, and deleting the CICSConnection configurable service.

Changing connection information for the CICSRequest node:

You can create a configurable service that the CICSRequest node or message flow refers to at run time for connection information, instead of defining the connection properties on the node or the message flow. The advantage being that you can change the host name and performance values without needing to redeploy your message flow.

Before you begin

Before you start:

- Read "Configurable services" on page 1296 to find out more about configurable services.
- Read "CICS Transaction Server for z/OS overview" on page 2173 for background information.

About this task

Use the CICSConnection configurable service to change the CICS Transaction Server for z/OS connection information for the CICSRequest node. The advantage being that you can change the host name, performance, and security identity values without needing to redeploy your message flow. The properties of the CICSConnection configurable service are described in "Configurable services properties" on page 3766.

You can use the CICSConnection configurable service to configure the CICSRequest node to use Secure Sockets Layer (SSL) protocol. For more information, see "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 547.

Creating, changing, reporting, and deleting configurable services

Procedure

- To create a configurable service, use the WebSphere Message Broker Explorer; see "Using the WebSphere Message Broker Explorer to work with configurable services" on page 644 for more information, or the **mqsicreateconfigurableservice** command, as shown in the following example. This example creates a CICSConnection configurable service for the CICS instance that is running at `test.cics.ibm.com` port 12345. The broker is identified by APPLID *BRKApp* and qualifier *BRKQual*. The connection timeout is 10 seconds, the request timeout is 5 seconds, and the security identity is identified by *mySecurityIdentity* in this example:

  ```
  mqsicreateconfigurableservice MB7BROKER -c CICSConnection -o myCICSConnectionService
  -n cicsServer,clientApplid,clientQualifier,connectionTimeoutSecs,requestTimeoutSecs,
  securityIdentity
  -v tcp://test.cics.ibm.com:12345,BRKApp,BRKQual,10,5,mySecurityIdentity
  ```

- To change a configurable service, use the WebSphere Message Broker Explorer, or the **mqsichangeproperties** command, as shown in the following example. You must stop and start the execution group for the change of property value to take effect. This example changes the CICSRequest node that is configured to use the *myCICSConnectionService* configurable service. After you run this command, the CICSRequest node connects to the production system (`tcp://production.cics.ibm.com:12345`) instead of the test system (`tcp://test.cics.ibm.com:12345`).

  ```
  mqsichangeproperties MB7BROKER -c CICSConnection -o myCICSConnectionService
    -n cicsServer -v tcp://production.cics.ibm.com:12345
  ```

  See "Securing the connection to CICS Transaction Server for z/OS by using SSL" on page 547 for information about how to turn on SSL support in the broker by setting the `cicsServer` CICSConnection configurable service property.

- To display all CICSConnection configurable services, use the WebSphere Message Broker Explorer, or the **mqsireportproperties** command, as shown in the following example:

  ```
  mqsireportproperties MB7BROKER -c CICSConnection -o AllReportableEntityNames -r
  ```

- You can delete a configurable service that you have created by using the WebSphere Message Broker Explorer, or the **mqsideleteconfigurableservice** command, as shown in the following example:

  ```
  mqsideleteconfigurableservice MB7BROKER -c CICSConnection -o myCICSConnectionService
  ```

  You can delete only custom-named configurable services; you cannot delete IBM-defined configurable services.

Propagating security credentials to CICS Transaction Server for z/OS:

The CICSRequest node can use an identity that is present in the Properties folder of the message tree structure for the security credentials in a request, by using the `Propagate` property on the security profile that is defined on the node.

About this task

If a CICSRequest node is configured with a security profile, it extracts security tokens from the input message at run time, and propagates an identity to CICS.

Procedure

To propagate an identity to be used for the CICS request security credentials, complete the following steps.

1. Ensure that an appropriate security profile exists for the CICSRequest node, or create a security profile, by following the instructions in "Creating a security profile" on page 433.
2. Use the Broker Archive editor to select a security profile for the CICSRequest node that has identity propagation enabled. For detailed instructions, see "Configuring for identity propagation" on page 492.

Routing messages

Route messages through your message flow or the broker by using one or more of the techniques described in this section.

About this task

- "Using nodes for decision making"
- "Routing using publish/subscribe applications" on page 2215

Some nodes use fields in your messages to make routing decisions. You might need to define a model of your messages to enable access to the fields in the message for these nodes. For information about how to develop a message model, and why you might want to develop a message model, see "Constructing message models" on page 2838.

Related tasks:

Connect your client applications to the broker by using one or more of the supported protocols from other resources and software servers in your network.

"Processing events" on page 2717
Using event driven message processing you can control the flow of messages through your message flows.

"Transforming and enriching messages" on page 2227
Transform and enrich messages by using one or more of the techniques described in this section.

Using nodes for decision making

You can use several built-in nodes in different ways to control the path that a message takes through the message flow.

Before you begin

Before you start:

Read the concept topic about message flow nodes.

About this task

These nodes let you decide how messages are processed by specifying the route that each message takes through the message flow based on dynamic values such as message structure and content.

For more information, see the following topics:
- "Testing the message structure (Validate node)" on page 2211
- "Controlling the order of processing in a message flow" on page 2212
- "Using the destination list to route messages (RouteToLabel and Label nodes)" on page 2214

You can use one of the following nodes to determine the path taken by a message through the message flow based on its content:
- "Route node" on page 4669
- Filter node (ESQL)
- JavaCompute node
- PHPCompute node

Use the DatabaseRoute node to route messages using information from a database. For more information, see "DatabaseRoute node" on page 4373.

Related concepts:

"Local environment tree structure" on page 1056
The local environment tree is a part of the logical message tree in which you can store information while the message flow processes the message.

Related tasks:

"Designing a message flow" on page 1455
A message flow can perform a wide range of operations, depending on your business and operational requirements. For best performance and capability, you must design it to include the most appropriate nodes.

"Creating a message flow" on page 1431
Create a message flow to specify how to process messages in the broker. You can create one or more message flows and deploy them to one or more brokers.

"Defining message flow content" on page 1488
You can define message flow content by adding and configuring message flow nodes and connecting them to form flows.

Use the PHPCompute node to route and transform an incoming message, using the PHP scripting language.

"ResetContentDescriptor node" on page 4663
Use the ResetContentDescriptor node to request that the message is reparsed by a different parser.

"Route node" on page 4669
Use the Route node to direct messages that meet certain criteria down different paths of a message flow.

"RouteToLabel node" on page 4673
Use the RouteToLabel node in combination with one or more Label nodes to dynamically determine the route that a message takes through the message flow, based on its content.

"Validate node" on page 4959
Use the Validate node to check that the message that arrives on its input terminal is as expected. You can use this node to check that the message has the expected message template properties, and to check that the content of the message is correct by selecting message validation.

Testing the message structure (Validate node)

Use the Validate node to test the characteristics of the message structure.

About this task

If you set the Validate node properties appropriately, you can request that one or all of the message domain, message set, and message type are compared to a specific value. If the message matches those values for which you have requested the check, it is routed through the match terminal and is processed by the sequence of nodes that you have connected to that terminal.

If the message does not match any one of those values for which you have requested the check, it is routed through the failure terminal and is processed by the sequence of nodes that you have connected to that terminal.

For example, you might design a message flow that provides additional processing for all messages that are in the MRM domain. You can include a Validate node that tests just that characteristic of the message, and passes it to a sequence of nodes that provide the specialized processing. If the message is not in the MRM domain, the extra nodes are bypassed, and the failure terminal is wired up directly to the node that follows the sequence required for MRM messages only.

Controlling the order of processing in a message flow

Use the FlowOrder node to control the order of processing in a message flow.

About this task

When you connect message flow nodes together, the broker determines the way in which the different connections are processed. This includes the order in which they are processed. If you have connected more than one node or sequence of nodes to a single output terminal, you cannot predict whether one sequence is processed before another for a message.

If the order of processing is important in your message flow, use the FlowOrder node to force a prescribed order of processing of the messages that are propagated by this node.

The FlowOrder node has two output terminals that you can connect to control the order in which subsequent nodes process the message. The output terminals, named First and Second, are always processed in that order.

When you connect a node or sequence of nodes to the First terminal, the input message is passed to the next node, and all processing defined by all subsequent nodes in this sequence is completed before control returns to the FlowOrder node.

The input message is then propagated to the next node in the sequence of nodes connected to the Second terminal.

The message passed to both sequences of nodes, from the First terminal and the Second terminal, is identical. It is always the message that the FlowOrder node receives as input. The message that the FlowOrder node propagates to the Second terminal is in no way affected by the processing of the message that has been performed by the sequence of nodes connected to the First terminal.

The FlowOrder node provides no other processing on the input message; it is used only for imposing order on subsequent processing.

Related concepts:

Related reference:

"FlowOrder node" on page 4458
Use the FlowOrder node to control the order in which a message is processed by a message flow.

Testing the message content (Filter node)

You can use the Filter node to determine the path taken by a message through the message flow based on its content.

About this task

You can customize the Filter node by using ESQL statements to determine if the message content meets some condition. The condition tested must yield a Boolean result, that is it must be true or false (or unknown). You can create the test to reference information from a database, if applicable.

You can connect nodes following the Filter node to the corresponding terminals of the Filter node, and process the message according to its content.

Look at the following samples to see how to use the Filter node:
- Airline Reservations
- Error Handler

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Using the destination list to route messages (RouteToLabel and Label nodes)

You can determine the path that a message takes through the message flow by using the RouteToLabel and Label nodes.

About this task

These nodes provide a more flexible way to process messages than the Filter node, which depends on the Boolean result of an ESQL expression for its logic.

When you use RouteToLabel and Label nodes, you must include a Compute node that determines, by using some combination of message content, database content, and ESQL logic, how messages are to be processed next. Configure the Compute node to create a destination list (in the DestinationList folder in the local environment subtree) that contains the destination for each message, specified as the LabelName of a Label node. The Compute node passes the message to the RouteToLabel node, which reads the destination list and propagates the message to either the first or last item on the destination list, according to the value that is specified for the RouteToLabel node's `Mode` property. Although there is no limit to the number of destinations that the Compute node writes in the destination list, the RouteToLabel node propagates the message only to a single label node. This use of the destination list is in contrast to its use to define the final recipients of the output messages. For more information about the procedure for creating a destination list, see "Creating destination lists" on page 1477.

If you intend to derive destination values from the message itself, or from a database, you might also need to cast values from one type to another. For more information about the local environment, see "Local environment tree structure" on page 1056. For more information about casting, see "Supported casts" on page 5273.

Look at the following sample to see how to use these nodes:
- Airline Reservations

The XML_PassengerQuery message flow in the previous sample demonstrates how you can use the destination list in the local environment to route messages based on the information in the message itself.

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Routing using publish/subscribe applications

You can route your messages to applications using the publish/subscribe method of messaging.

There are two situations where you can use publish/subscribe in WebSphere Message Broker. These situations are where you want to:

- Provide additional transformation or routing function, or both, at publication time.
- Filter messages based on the content of the body of the message.

Developing publish/subscribe applications

For background information about the publish/subscribe method of messaging, see the following topics:

- "Publish/Subscribe"
- "Publishers" on page 2218
- "Publications" on page 2219
- "Subscribers" on page 2220
- "Filters" on page 2221
- "Subscription points" on page 2222

Publish/Subscribe in WebSphere Message Broker Version 7.0

In WebSphere Message Broker Version 7.0, publish/subscribe uses the function available in WebSphere MQ Version 7.0.

Publish/Subscribe

Publish/subscribe is a style of messaging application in which the providers of information (publishers) are decoupled from the consumers of that information (subscribers).

In a publish/subscribe system, a publisher does not need to know who uses the information (publication) that it provides, and a subscriber does not need to know who provides the information that it receives as the result of a subscription.

Compare this with a point-to-point style of messaging application, in which the application that sends messages needs to know the destinations of the messages that it sends.

Queue managers make sure that messages arrive at the correct destinations, and are transformed to the format required at each destination.

A typical publish/subscribe system has more than one publisher and more than one subscriber, and often more than one queue manager. An application can be both a publisher and a subscriber.

The publisher generates a message that it wants to publish and defines the topic of the message.

A subscriber registers a request for a publication by specifying one of the following items:

- The topic, or topics, of the published messages that it is interested in.
- The subscription point from which it wants to receive publications.
- The content filter that should be applied to the published message.
- The name of the queue (known as the subscriber queue) on which publications that match the criteria selected are placed. This queue can be a cluster queue, so that publications can be distributed to clustered subscribers.

Related concepts:

"Publishers" on page 2218
A *publisher* is an application that makes information about a specified topic available to a queue manager in a publish/subscribe system.

Changes to nodes in WebSphere Message Broker Version 7.0:

There are changes to the nodes provided in this version of the product. These changes include removal of the SCADA and RealTime nodes.

The Publication node has two additional terminals, Out and No Match; see "Publication node" on page 4643 for further information.

WebSphere MQ Telemetry Transport is supported from WebSphere MQ; see the WebSphere MQ Telemetry Transport documentation for further information.

WebSphere MQ Real-time Transport and WebSphere MQ Telemetry Transport are no longer supported. As a result of this change, the following nodes have been removed:

Real-timeInput node
Flows containing Real-timeInput nodes that have been migrated to WebSphere Message Broker Version 7.0 will not start until these nodes have been removed from the flow and the flow has been redeployed.

Real-timeOptimizedFlow node
Flows containing Real-timeOptimizedFlow nodes that have been migrated to WebSphere Message Broker Version 7.0 will not start until these nodes have been removed from the flow and the flow has been redeployed.

If your message flows contain only a Real-timeOptimizedFlow node, no WebSphere Message Broker flow is required after you have migrated to WebSphere Message Broker Version 7.0.

SCADAInput node
Flows containing SCADAInput nodes that have been migrated to WebSphere Message Broker Version 7.0 will not start until these nodes have been removed from the flow and the flow has been redeployed.

SCADAOutput node
Flows containing SCADAOutput nodes that have been migrated to WebSphere Message Broker Version 7.0 will fail if processing reaches the node and you receive a `BIP` warning message.

MQeInput
The MQeInput node has been removed. This node was deprecated in an earlier version of the product.

MQeOutput
The MQeOutput node has been removed. This node was deprecated in an earlier version of the product.

Contact your account representative for more information about support for WebSphere MQ Real-time Transport and WebSphere MQ Telemetry Transport.

Additionally, although the MQOptimizedFlow node still works, this node is redundant.

The SCADAOutput node, available in earlier versions of WebSphere Message Broker, is not supported in WebSphere Message Broker Version 7.0. See for information about migrating your message flows from WebSphere Message Broker to WebSphere Message Broker Version 7.0.

Publishers:

A *publisher* is an application that makes information about a specified topic available to a queue manager in a publish/subscribe system.

In a publish/subscribe system, an application, known as the publisher, can send a message to a message queue or port that is associated with an input node in a message flow that contains a Publication node.

Another application, known as the subscriber, can send a subscription request to the queue manager, which then sends relevant publication messages to the message queue or port of the subscriber.

A published message can be requested by more than one subscriber, and a subscriber can request messages, on the same or different topics, from more than one publisher.

Related concepts:

Publications:

A *publication* is a piece of information about a specified topic that is available to a queue manager in a publish/subscribe system.

Typically, a queue manager distributes a publication that it receives to all applications that are connected to it and that have registered a subscription for the publication. The queue manager also distributes the publication to all other queue managers connected to it, either directly or through a network of queue managers that have subscribers for the publication.

Local publications: Publishers can restrict access to their publications to only those subscribers that are registered to the same queue manager as the publisher. This publication is known as a *local publication*. Local publications are not forwarded to other queue managers.

Global publications: A publication whose distribution is not restricted to only those subscribers that are registered to the same queue manager as the publisher is known as *global publication*. A global publication is forwarded to all queue managers, connected either directly or through a network of queue managers, that have one or more subscribers for the publication.

Retained publications: Typically, a queue manager discards a publication after it has been sent. However, a publisher can specify (in the case of the *Publish* message, by specifying the *RetainPub* option) that it wants the queue manager to keep a copy of the publication, which is then called a *retained publication*.

If a retained publication has been published, new subscribers to that publication receive the publication without having to wait for it to be published again.

For example, a subscriber that registers a subscription for a stock price receives the latest published stock price immediately, and does not have to wait for the stock price to be republished.

A queue manager retains only one publication for each combination of topic and subscription point.

State and event information: Information being published can be categorized either as *state* information or as *event* information.

State information is information about the current state of something. The current price of stock or the current score in a soccer match are both examples of state information.

Event information is information about an individual event that occurs. A change in the price of stock or the scoring of a particular goal in a soccer match are both examples of event information.

When an event occurs, the current state information is no longer required and is superseded by new state information.

If a publication contains state information, it is often published as a retained publication. A new subscriber typically wants the current information immediately; the subscriber does not want to wait for an event that causes the information to be republished.

Related concepts:

"Subscription points" on page 2222
A *subscription point* is the name that a subscriber uses to request publications from a particular set of Publication nodes. It is the property of a Publication node that differentiates that Publication node from other Publication nodes in the same message flow.

Subscribers:

A *subscriber* is an application that requests information about a specified topic from a publish/subscribe queue manager.

The subscribing application might be a WebSphere MQ or WebSphere Message Broker application.

The subscriber sends a subscription request to a queue manager, specifying which publications it wants to receive. The request defines the topic, the filter, and the subscription point of each publication.

Messages that are published by a publisher can be received by more than one subscriber, and a subscriber can receive messages, on the same or different topics, from more than one publisher.

Related concepts:

"Publish/Subscribe" on page 2215
Publish/subscribe is a style of messaging application in which the providers of information (publishers) are decoupled from the consumers of that information (subscribers).

"Publishers" on page 2218
A *publisher* is an application that makes information about a specified topic available to a queue manager in a publish/subscribe system.

"Publications" on page 2219
A *publication* is a piece of information about a specified topic that is available to a queue manager in a publish/subscribe system.

"Filters"
A *filter* is an expression, which might include wildcard characters, that is applied to the content of a publication message to determine whether it matches a subscription.

"Subscription points" on page 2222
A *subscription point* is the name that a subscriber uses to request publications from a particular set of Publication nodes. It is the property of a Publication node that differentiates that Publication node from other Publication nodes in the same message flow.

Filters:

A *filter* is an expression, which might include wildcard characters, that is applied to the content of a publication message to determine whether it matches a subscription.

When you register a subscription, in addition to specifying a topic and subscription point, you can specify a filter to select publications according to their contents. WebSphere Message Broker must know how to parse the contents of the message correctly, which can be achieved in a number of ways:

- The message is a self-defining XML message.
- The message template is defined in the MQRFH2 header.

  If the message has an MQRFH header, the message set and type are taken from that header. Otherwise, the message is assumed to be as defined in the properties (domain, set, type, and format) of the input node.

The filter itself is entered as an ESQL expression; for example:

```
Body.Name LIKE 'Smit%'
```

This example means that the contents of a field called Name in the body of a publication message are extracted and compared with the string given in the expression. If the string in the message starts with the characters "Smit", the expression evaluates to TRUE and the publication is sent to the subscriber.

If you want to select publications using filters only, without specifying a topic, you can register a subscription with the required filter and a topic of "#" (all topics). You then receive publications on only those topics for which you have access authority.

This subscription results in all publications from all connected brokers being sent to the broker that is local to the subscriber. Therefore, for performance reasons, if you have set up a network of brokers, you are advised to not use this technique.

Related concepts:

"Content based filtering using ESQL" on page 2223
WebSphere MQ supports message selection based on `Root.MQMD` and message properties; WebSphere Message Broker Version 7.0 provides extra options.

Related reference:

“ESQL reference” on page 5019
SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

Subscription points:

A *subscription point* is the name that a subscriber uses to request publications from a particular set of Publication nodes. It is the property of a Publication node that differentiates that Publication node from other Publication nodes in the same message flow.

A subscriber that registers a subscription without specifying a subscription point receives publications from any unnamed Publication node in the message flow, if there is a match with the topic and filter specified by the subscriber.

This behavior applies to all message flows running in all brokers connected in the same network, unless the local has been specified when registering the subscription.

Using subscription points: If you have more than one Publication node in a message flow, you can differentiate between them by specifying subscription points. Choose values that indicate the type of message that is routed to each Publication node.

Example: Consider an application that publishes stock prices. The prices that are available from the first Publication node in the message flow are in dollars. This Publication node uses the default subscription point.

You can define a second path through the message flow that takes the price in dollars, and converts this using a defined conversion value, to produce the same message but with the stock price in pounds. These messages are published at a second Publication node that has its subscription point property set to "Pounds".

You might have another message flow, in the same broker or a connected broker, that publishes stock prices in pounds on the same topic. Make sure that it uses the "Pounds" subscription point, and that all other message flows that publish their stock prices in dollars use the default subscription point.

Subscribers specifying the relevant topic (for example, "stock") can then choose whether to receive the information in dollars or in pounds, by using the default subscription point or the "Pounds" subscription point when they subscribe.

Content based filtering using ESQL

WebSphere MQ supports message selection based on `Root.MQMD` and message properties; WebSphere Message Broker Version 7.0 provides extra options.

Content based filters in WebSphere Message Broker Version 7.0 extend WebSphere MQ message selectors to allow the use of ESQL expressions to filter on the entire message.

You can use the following:

Correlation names
: In content based filters, the message can be accessed using the `Root`, `Body`, and `Properties` correlation names.

  Any other correlation name is interpreted as a WebSphere MQ message property, apart from the following list of excluded reserved names:

  - `Database`
  - `DestinationList`
  - `Environment`
  - `LocalEnvironment`
  - `ExceptionList`
  - `LocalEnvironment`

  Any other top level identifier is assumed to be a WebSphere MQ message property, and is accepted.

Trees
: The content based filtering engine does not update the message tree. It accesses the message tree as read-only. Any statements that attempt to modify the tree are rejected.

  By supporting ESQL, content based filtering in WebSphere Message Broker Version 7.0 supports fully-qualified Namespaces, as documented in "ESQL reference" on page 5019.

ESQL expressions
: Content based filtering accepts any ESQL expression, with the exclusion of database access, that returns a Boolean value.

Related concepts:

"Content based filtering" on page 6409
Content based filtering allows a subscriber to filter messages based on their content.

Related tasks:

"Enabling content-based filtering with publish/subscribe"
It is possible to subscribe to messages, based on a selection of message payload content, in WebSphere Message Broker Version 7.0. You must enable content based filtering explicitly.

You can configure content based filtering using the WebSphere Message Broker Explorer.

Related reference:

"ESQL reference" on page 5019
SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

Enabling content-based filtering with publish/subscribe:

It is possible to subscribe to messages, based on a selection of message payload content, in WebSphere Message Broker Version 7.0. You must enable content based filtering explicitly.

Before you begin

Before you start

- Read about Selectors on WebSphere MQ.
- Read the following overview of how WebSphere MQ selects content of messages.

  When an application publishes on a topic string, where one or more subscribers have a selection string selecting on the content of the message, WebSphere MQ requests that the extended message selection provider parse the publication and inform WebSphere MQ whether the publication matches the selection criteria specified by each subscriber with a content filter.

  If the extended message selection provider determines that the publication matches the subscriber's selection string, the message continues to be delivered to the subscriber.

  If the extended message selection provider determines that the publication does not match, the message is not delivered to the subscriber. This might cause the WebSphere MQ MQPUT or MQPUT1 call to fail with reason code MQRC_PUBLICATION_FAILURE. If the extended message selection provider is unable to parse the publication, reason code MQRC_CONTENT_ERROR is returned and the MQPUT or MQPUT1 call fails.

  If the extended message selection provider is unavailable or is unable to determine whether the subscriber should receive the publication, reason code MQRC_SELECTION_NOT_AVAILABLE is returned and theWebSphere MQ MQPUT or MQPUT1 call fails.

  When a subscription is being created with a content filter and the extended message selection provider is not available, the WebSphere MQ MQSUB call fails with reason code MQRC_SELECTION_NOT_AVAILABLE. If a subscription with a content filter is being resumed and the extended message selection provider is not available, the WebSphere MQ MQSUB call returns a warning of MQRC_SELECTION_NOT_AVAILABLE, but the subscription is allowed to be resumed.

- z/OS For z/OS systems, verify that the message broker started task ID has `UPDATE` access permission to profile `<MQ_QMNAME>.BATCH` of class `MQCONN`.

- Linux UNIX Windows On Linux, UNIX and Windows systems, grant authorization for the system to the queue manager: `setmqaut -t <qmgr> +system -p <brokerUserId>`

About this task

WebSphere Message Broker extends the message selection support provided by WebSphere MQ. WebSphere Message Broker does this by allowing ESQL statements rather than SQL92 statements, and filtering based on message content. See "Content based filtering using ESQL" on page 2223 for details of the scope and exclusions of supported ESQL.

The main external differences in the current implementation of content-based filtering are:

- Content based filtering is no longer limited to WebSphere MQ MQRFH2 subscribers. WebSphere Message Broker Version 7.0 provides content filtering services for the following WebSphere MQ subscribers:

  MQRFH2

  MQSUB

  If you are performing content filtering based on the *NameValueData* field, within an MQRFH2 header, on z/OS, the data can be present either in the first or second MQRFH2 header. For example, the filter:

  ```
  Root.MQRFH2.mcd.Msd='XML'
  ```

  might not work as you expect on z/OS. Use the following syntax to search all MQRFH2 headers:

  ```
  FOR ANY Root.MQRFH2[] AS I (I.mcd.Msd='XML')
  ```
- WebSphere MQ message properties are supported as part of the filter expression.
- If the publication does not contain an `mcd` folder, the payload is assumed to be XMLNSC.

Read the following steps to see how to enable content-based filtering on WebSphere Message Broker Version 7.0.

Procedure

1. Set the `cbfEnabled` property of the `ContentBasedFiltering` object for the execution group in which you want content-based filtering to run.

   You set the `cbfEnabled` property from the command line using either the:

   - **`mqsichangeproperties`** command; see "Content based filtering component parameter values" on page 3805 for more information, or
   - WebSphere Message Broker Explorer; see "Setting content-based filtering options using the WebSphere Message Broker Explorer" on page 2226 for more information.

   Note that you must explicitly enable the `cbfEnabled` property for content based filtering to work; the default setting is for content based filtering to be off.
2. Restart the execution group for the change to take effect.

   If you enable content based filtering in multiple execution groups on z/OS, content based filtering is active in only one execution group at any time. Subsequent execution groups for which content based filtering is enabled,

propagate the following messages to the syslog on start up (for each content based filtering thread) and then every 30 minutes, as they fail to connect to the queue manager:

```
BIP2111E MQ04BRK jheg1 15 MESSAGE BROKER INTERNAL ERROR: DIAGNOSTIC INFORMATION
 'Error occurred in Content Based Filtering Thread'. : ImbCbfWorker(909)
BIP2624E MQ04BRK jheg1 14 UNABLE TO CONNECT TO QUEUE MANAGER 'MQ04': MQCC=2;
 MQRC=2002; MESSAGE FLOW NODE 'ContentBasedFiltering'. : ImbCbfWorker(214)
```

If you stop the execution group that is currently providing content based filtering services, another execution group for which content based filtering is enabled connects to the queue manager and provides content based filtering services.

Both the `evaluationThreads` and `validationThreads` properties default to one if content-based filtering is enabled.

Evaluation threads are used to validate content filters against a given publication at publication time. A network with a high number of publications might require the `evaluationThreads` property to be increased (up to a maximum of 32) to handle the workload at publication time.

Validation threads are used to validate syntax of content filters at subscription time. A publish/subscribe network with a high number of subscribers, especially if dynamic subscribers, might require the `validationThreads` property to be increased (up to a maximum of 32) to handle the high throughput of subscription requests.

It is possible to enable this function in multiple execution groups, but you must ensure that any message sets required to parse any published message (and referenced in the `mcd` folder of that message) are deployed to all the execution groups that have been enabled for content-based filtering.

Any errors encountered parsing the message within the evaluation thread cause WebSphere MQ to return MQRC_CONTENT_ERROR to the publishing application. The parsing error appears as well in the event log as a WebSphere Message Broker exception.

Example of a subscription `<psc>` folder processing ESQL and message properties in the filter:

```
<psc>
 <Command>RegSub</Command><Topic>topic</Topic>
   <Filter>
   SUBSTRING(Root.XMLNSC.Name.FirstName FROM 1 FOR 1) = 'J' and usr.flag = 'yes'
   </Filter>
</psc>
```

Setting content-based filtering options using the WebSphere Message Broker Explorer:

You can configure content based filtering using the WebSphere Message Broker Explorer.

About this task

To configure content based filtering:

Procedure

1. Open the WebSphere Message Broker Explorer.
2. Right-click the execution group to select the Properties dialog.
3. Select the ContentBasedFiltering tab.
4. Select **Enabled** from the drop down list to enable content based filtering.
5. Select the number of Validation (Subscription) Threads and Evaluation (Publication) Threads you require. Valid values for each of these options is a number in the range 1 - 32.

   Entering any other value causes an error to appear in the Properties dialog.

   If you have not enabled content based filtering, the fields controlling the thread values are grayed out.
6. Restart the execution group for the changes to take effect.

Results

You have configured content based filtering.

Transforming and enriching messages

Transform and enrich messages by using one or more of the techniques described in this section.

About this task

Use one or more of following five options for transforming and enriching the messages in your message flows:

- Mappings
- ESQL
- Java
- XSL style sheets
- PHP

For more information about these options, and why you might choose one in preference to another, see "Client application programming interfaces" on page 1038. To use some of these options for transforming and enriching messages you might need to create a model of the messages that you want to transform. For information about how to develop a message model, and why you might want to develop a message model, see "Constructing message models" on page 2838.

For details of the tasks associated with these options, use the instructions provided in the following sections:
- "Using message mappings"
- "Developing ESQL" on page 2370
- "Developing Java" on page 2628
- "Using XSL Transform" on page 2669
- "Using PHP" on page 2670

Using message mappings

Message mappings define the blueprint for creating a message.

Message mapping overview

Message mappings define the blueprint for creating a message, where the created message is known as the target message.

Input and output objects are defined by reference to message models, which provide a definition of the message structure and type through the following components:

- Simple elements and attributes, which define the type, range, and default values
- Complex elements, which build the structure of the message
- Repeating simple or complex elements
- Other (embedded) messages

Messages can contain protocol-specific headers, which might have to be manipulated by WebSphere Message Broker. Dynamic setting of a message destination (routing) within the WebSphere Message Broker might also be required.

Values for target message elements can be derived from:

- Input message elements (the input message is also known as the source message)
- Database tables
- Constant values
- WebSphere MQ constants
- Functions supplied by the Mapping node
- User-defined functions

The logic to derive values can be simple or complex; conditional statements might be needed, as might loops, summations, and other functions. All of the mappings shown earlier can be achieved using a Mapping node.

You can also create a reusable form of map known as a submap. Submaps allow you to use a set of mapping functions in multiple maps to transform a common set of elements in the input object to the output object.

The Mapping node supports the following message domains:

MRM
XMLNSC
XMLNS
MIME
SOAP
DataObject
JMSMap
JMSStream
XML
BLOB
IDOC

The Mapping node does not support the JSON message domain, because no JSON message modeling is supported.

Related concepts:

Use the Mapping node to construct one or more new messages and populate them with various types of information.

Advanced schema structures:

You can use several advanced schema structures in mappings.

This section contains information about the following subjects:

- "Substitution groups"
- "Wildcards"
- "Derived types"
- "List types" on page 2231
- "Union types" on page 2231

Substitution groups: A substitution group is an XML Schema feature that provides a means of substituting one element for another in an XML message. The element that can be substituted is called the *head* element, and the substitution group is the list of elements that can be used in its place.

The head element and any mapped substitutions are shown by default in the Source and Target panes of the Message Mapping editor. The mapped substitutions are listed beneath the head element. You can show and hide the substituting elements displayed in the Source and Target panes by selecting **Show Substituting Elements**. You create mappings to or from members of substitution groups in the same way as you would map other elements.

An abstract head element of a substitution group is not displayed and when substitution is blocked, the substitution group folder is not displayed.

Wildcards: A mapping that you perform to or from a wildcard results in a submap call. Specify the wildcard replacement when you choose the parameter of a submap call.

A wildcard element or attribute can be instantiated only with another element or attribute. The Message Mapping editor allows only a global element or attribute as a wildcard replacement.

Derived types: For an element of a given type, the base type and the mapped derived types are shown by default in the Source and Target panes of the Message

Mapping editor. All attributes and elements of the base and derived types are listed under each type respectively. You can show and hide the derived types displayed in the Source and Target panes by selecting **Show Derived Types**.

You create mappings to or from a derived type and its contents in the same way that you would map any type or type content. When you map a derived type element, the Message Mapping editor generates ESQL code with the appropriate xsi:type attribute.

List types: A list type is a way of rendering a repeating simple value. The notation is more compact than the notation for a repeating element and provides a way to have multi-valued attributes.

You map list type attributes or elements in the same way that you would map any other simple type attribute or element. Mapping between two list type elements is the same as mapping between any two simple type elements.

To transform between a list type and a non-list type, such as a repeating element, write an ESQL function, then package the function as a map. The Message Mapping editor automatically selects this submap as the default transformation for the list type.

Union types: A union type is the same as a union of two or more other simple types and it allows a value to conform to any one of several different simple types.

Use the Message Mapping editor to create mappings to or from union type attributes or elements in the same way as you would map atomic simple type attributes or elements, as shown in the following diagram:

```
<xsd:simpleType name="zipUnion">
 <xsd:union memberTypes="USState listOfMyIntType"/>
</xsd:simpleType>
<xsd:element name=zip type=zipUnion/>
```

Creating a message map file in the Broker Development view:

Before you begin

You can create a message map file for use in your message flows in the Broker Development view. If you want to add a database to your message map file, you must have created a database definition for the database.

About this task

To create a message map (.msgmap) file in the Broker Development view:

Procedure

1. From the Broker Application Development perspective, click **File** > **New** > **Message Map**.

   Alternatively, in the Broker Development view, right-click the message flow project that you want to create the message map in and click **New** > **Message Map**.

   The New Message Map wizard opens.
2. Specify the Project, Name and Schema for the message map. The project list is filtered to show only projects in the active working set. Click **Next**.
3. Follow the on-screen instructions to complete the New Message Map wizard:
   a. On the **Select map kind and its source and target** pane, select the type of map you want to create.
      - If you select the option **Message map called by a message flow node**, a message map is created that can be accessed from a node. Properties are associated with any source or target messages, and you can select to include message headers and the LocalEnvironment with the message body.
      - If you select the option **Submap called by another map**, a message map is created that can be referenced from another message map. This is known as a submap and can contain components of a message body such as global elements, global attributes, and global types. A submap does not contain Properties, message headers, or the LocalEnvironment.

   b. Expand the Messages, Message Components, and Data Sources folders and their children, to display all the available options. Select the Messages, Message Components, Database Selects, Stored Procedures, and User Defined Functions that you want to use for your map from **Select Map Sources**. The stored procedure list, if any, shows the stored procedure signature, such as the procedure name, its parameter mode (IN/OUT/INOUT), parameter name, and the data type.

c. Expand the Messages and Data Targets folders and their children, to display all the available options. Select the Messages, Table Inserts, Table Updates and Table Deletes that you want to use as targets for your map from **Select Map Targets**.

The information contained inside a square bracket is the data source name, schema name, and the database project which contains the database definition.

Messages, data sources and data targets are filtered to show only resources from the active working set. If you cannot find the Messages, Message Components, Data Sources or Data Targets that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.

4. Select **Finish** to create the new message map. The "Message Mapping editor" on page 4981 opens with the selected sources and targets.

What to do next

After you have created a message map file, configure the message mappings. You must also configure the **Mapping routine** property on your mapping node to match the name of your new mapping file.

Analyzing the impact of changes to message maps:

Use impact analysis to analyze the effect of renaming or moving message maps.

Before you begin

Before you start:

You must have completed the following tasks:

- "Creating a message flow project" on page 1425
- "Creating a message map file in the Broker Development view" on page 2233
- "Enabling and disabling indexing" on page 1454

About this task

This information covers the following tasks:

- "Renaming message maps"
- "Moving a message map"

Renaming message maps:
Procedure

1. In the Broker Development view, right-click the object that you want to rename, then click **Impact Analysis** > **Rename**.
2. In the Impact Analysis - Rename Artifact window, type the new name of the object, then click **Analyze Impact**.

   The Rename Artifact dialog box shows the results of impact analysis, listing primary and secondary impacts.

   You can view the results of impact analysis in the Impact Analysis dialog box, or the Impact Analysis view of the WebSphere Message Broker Toolkit. For more information about how to view information about selected resources, mark changes as complete, copy results to an external application, and view previous results, see "Impact Analysis view" on page 6801.

Moving a message map:
Procedure

1. In the Broker Development view, right-click the file, then click **Impact Analysis** > **Move**.
2. In the bottom panel, select the new folder for the object, then click **Analyze Impact**.

   The Impact Analysis - Move Artifact dialog box shows the results of impact analysis, listing primary and secondary impacts.

   You can view the results of impact analysis in the Impact Analysis dialog box, or the Impact Analysis view of the WebSphere Message Broker Toolkit. For more information about how to view information about selected resources, mark changes as complete, copy results to an external application, and view previous results, see "Impact Analysis view" on page 6801.

Creating a message mapping file from a Mapping node:

You can use a Mapping node to create a message map with messages and databases as both sources and targets.

Before you begin

Before you create a mapping file, ensure that you complete the following tasks:

1. "Creating a message flow project" on page 1425.
2. "Creating a message flow" on page 1431.
3. Define message flow content that includes a Mapping node; for more information, see "Defining message flow content" on page 1488.

About this task

To create a message map (`.msgmap`) file from a Mapping node:

Procedure

1. Open your message flow from the Broker Application Development perspective.
2. Double-click the Mapping node, or right-click the Mapping node and click **Open Map**. The New Message Map wizard opens.
3. Select the combination of Messages, Data Sources, or both, that you want to use as sources for your map from Select map sources. Select the combination of Messages, Data Targets, or both, that you want to use as targets for your map from Select map targets.

   If you cannot find the Messages, Data Sources or Data Targets that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.
4. Click **OK** to create the new message map. The Message Mapping editor opens with the selected sources and targets, for more information see "Message Mapping editor" on page 4981.

What to do next

After you have created a message map file, you can configure the message mappings, see "Configuring message mappings" on page 2237.

Related concepts:

"Message Mapping editor" on page 4981

"DataDelete node" on page 4382
Use the DataDelete node to interact with a database in the specified ODBC data source.

Configuring message mappings:

Use the Message Mapping editor to configure a message mapping.

About this task

When you have created a map, you can edit it using the Message Mapping editor.

The editor provides the ability to set values for:

- Message destination
- Message content
- Message headers

See the "Mapping node" on page 4571 topic for more information about how to set the properties of a Mapping node.

Wizards and dialog boxes are provided for tasks such as adding mappable elements and working with submaps. Mappings that are created with the Message Mapping editor are validated and compiled automatically, ready to be added to a broker archive (BAR) file, and for subsequent deployment to WebSphere Message Broker.

Use the Message Mapping editor to perform the following tasks:

Common tasks:

- "Mapping from source: by selection" on page 2240
- "Mapping from source: by name" on page 2241
- "Mapping a target element from source message elements" on page 2254
- "Mapping a target element from database tables" on page 2288
- "Mapping a target element from database stored procedures" on page 2290
- "Mapping a target element from database user-defined functions" on page 2292
- "Setting the value of a target element to a constant" on page 2257
- "Setting the value of a target element to a WebSphere MQ constant" on page 2258
- "Setting the value of a target element to an ESQL constant" on page 2260
- "Setting the value of a target element using an expression or function" on page 2261

- “Configuring conditional mappings” on page 2265
- “Configuring mappings for repeating elements” on page 2266

Message destination tasks: You might map a destination so that the destination can be set dynamically, by setting values in LocalEnvironment.Destination. You can also retrieve information after a message has been sent, by accessing information in LocalEnvironment.WrittenDestination.

- “Configuring the LocalEnvironment” on page 2271
- “Mapping headers and folders” on page 2271

Message content tasks:

- “Adding messages or message components to the source or target” on page 2273
- “Adding a database as a source or target” on page 2274
- “Showing or hiding substituting elements in the Message Mapping editor”
- “Showing or hiding derived types in the Message Mapping editor” on page 2239

Message header tasks:

- “Configuring message headers” on page 2271
- “Mapping headers and folders” on page 2271

Related concepts:

Showing or hiding substituting elements in the Message Mapping editor:

You can use the **Show Substituting Elements** dialog box to show and hide substituting elements in the Message Mapping editor.

About this task

The head element and any mapped substitutions are shown by default in the Mapping editor. You can use the **Show Substituting Elements** dialog to show and hide the substituting elements in the Mapping editor:

Procedure

1. In either the Source or the Target pane, right-click the element that you want to show or hide the substituted elements for. If an element has substituted elements, it is displayed as a substitutions folder in the Source or the Target pane.
2. Click **Show Substituting Elements** on the pop-up menu. The Show Substituting Elements dialog box is displayed.

3. In the Show Substituting Elements dialog box, select elements to show them in the Message Mapping editor, or clear them to hide them in the Message Mapping editor. You cannot hide any element that is already used in a mapping.
4. Click **OK**.

Results

The elements that you have chosen to show or to hide are stored as preferences in your workspace.

Showing or hiding derived types in the Message Mapping editor:

You can use the **Show Derived Types** dialog box to show and hide derived types in the Message Mapping editor.

About this task

For an element of a given type, only the base type and any mapped derived types are shown in the Message Mapping editor. You can use the **Show Derived Types** dialog to show and hide derived types:

Procedure

1. In either the Source or the Target pane, right-click the element that you want to show or hide the derived types for. If an element has derived types it is displayed as a specializations folder in the Source or the Target pane.
2. Click **Show Derived Types** on the pop-up menu. The Show Derived Types dialog box is displayed.
3. In the Show Derived Types dialog box, select elements to show them in the Message Mapping editor, or clear them to hide them in the Message Mapping editor. You cannot hide any element that is already used in a mapping.
4. Click **OK**.

Results

The elements that you have chosen to show or to hide are stored as preferences in your workspace.

Mapping from source: by selection:

You can map from source fields by using Map from Source, or by using the drag-and-drop method.

About this task

Using Map from Source

Procedure

1. Select the source and target elements that you want to map by clicking them. (Ctrl+click to select multiple source or target elements.)
2. Click **Map** > **Map from Source**.

   There are four possible scenarios that result in mapping by selection using Map from Source.

   - If more than one mappable source element is selected, the selected sources are mapped to the selected target.
   - If more than one mappable target element is selected, the selected source is mapped to the selected targets.
   - If one mappable source and one mappable target are selected, and neither element has any children, the selected source is mapped to the selected target.
   - If one mappable source and one mappable target are selected, where both the elements have children and the same type definition, the selected source is mapped to the selected target.
   - If one mappable source and one mappable target are selected, and one of them is an element with mixed content and the other does not have any children, the mixed content is mapped with the other selected item.

What to do next

Using the drag-and-drop method

Drag the appropriate source element or elements onto the target element or elements (Ctrl+click to select multiple source or target elements.)

When you use the drag-and-drop method to map from source, mapping by selection is always performed. You can use the drag-and-drop method in the following scenarios:

- More than one mappable source element is selected. In this case, the selected sources are mapped to the selected target.
- More than one mappable target element is selected. In this case, the selected source is mapped to the selected targets.
- One mappable source and one mappable target are selected, and neither element has any children. In this case, the selected source is mapped to the selected target.
- One mappable source and one mappable target are selected, and one of them is an element with mixed content and the other does not have any children. In this case, the selected mixed content is mapped to the other selected item.
- The selected source and target elements have the same type definition, or the source type is derived from the target type. In this case the entire structure below the element is copied.

In other scenarios, when a mapping by selection is not possible, the Map by Name wizard opens to enable a Map by Name mapping to be performed instead.

Use an Oracle database user-defined function as a source in a Mapping node.

Mapping from source: by name:

The Map by Name wizard is used to map complex types by examining the names of source elements and target elements to create mappings.

About this task

The Map by Name wizard can also be used to map database columns. The following steps describe how to map from source using the Map by Name wizard.

Using the Map by Name wizard

Procedure

1. Click the source and target complex elements, database, schema, table, database stored procedure, or database user-defined function that you want to map.
2. Click **Map** > **Map by Name**. The Map by Name wizard opens to allow you to perform mapping by name.
3. Choose the appropriate option from the Select how to map from source to target wizard:
   - **Map leaves of the selected nodes**. This option maps the leaves of the source element to the leaves of the target element, that match each other; this option is selected by default.
   - **Map immediate children of the selected nodes**. This option maps only the immediate children of the source element to the immediate children of the target element that match each other. This option is available only when the selected source and target elements have immediate children that are mappable.
4. After selecting the **Map leaves of the selected nodes** or **Map immediate children of the selected nodes** option, specify how names are matched.
   - **Case sensitive**. This option enables you to select whether you want to match the case sensitivity of the name; this option is not selected by default.
   - **Alphanumeric characters (Letters and digits only)**. This option excludes special characters (for example & and -) from the name; this option is selected by default.

   The preceding two options are independent of one another, and you can select their values separately.
5. Specify the Mapping Criteria between the sources and targets.

   If the source and target names that you are using satisfy more than one of the following options, the order in which names are matched is:

   a. Same
   b. Synonym
   c. Similar

   Any target that is matched during an earlier step is excluded from name matching in a later step.

   - **Create mappings between sources and targets with the same name**. This option matches items of the same name, and is selected by default.

     Whether the two names are considered to be the same, depends on your selections for **Case sensitive** and **Alphanumeric characters (Letters and digits only)**.

     For example, if you have used the default options for **Case sensitive** and **Alphanumeric characters (Letters and digits only)**, GIVEN_NAME and GivenName are considered to be a match.

     However, if you have selected **Case sensitive** as well as **Alphanumeric characters (Letters and digits only)**, the two names are considered to be identical only if they contain the same alphanumeric characters in the same order, and the characters are of the same case.

See “Mapping by Same Name” on page 2245 for further information.

- **Create mappings when source and target names are more similar than**. This option allows you to specify how similar two words have to be to create a mapping between them by varying the result from zero to 100 percent. The result is displayed and the default value is 60; see “Sample similarity values” on page 2245 for some examples of how similar words are matched to one another.
- **Create mappings between source and target names defined as synonyms in file**. This option allows you to create mappings for word pairs that are defined in a synonym file. A synonym file is a flat text file with file extension `.txt` or `.csv`. See “Creating and using a synonym file” on page 2251 for further information about how you create a synonym file from a spreadsheet written in Microsoft Excel.

  See “Format of the synonym file” on page 2247 for further information about the synonym file itself, and “Algorithm used to match synonyms” on page 2252 for further information about the methods that are used to match synonyms in a synonym file.

6. Click **Finish** to complete the process, or **Next** to obtain further options.

What to do next

The Map by Name wizard opens automatically when you use the drag-and-drop method to map from source where the source and target are complex types with different type definitions, or where the source type is not derived from the target type.

The way in which synonyms are matched by the `Map by Name` function, to create mappings between specific sources and targets, follows a particular set of rules.

"Sample similarity values" on page 2245
The following table lists words that are similar to one another, together with their similarity value in percent.

Selecting matches:

Use the Map by Name wizard to select the mappings that you want to create.

About this task

When you have specified how you require the names to be matched on the initial panel of the Map by Name wizard, and have selected **Next**, you see a panel that displays all the matches found.

You can now select the options that you require:

Procedure

1. Select a row in the **Selectable Mapping Targets** column that you want to change. Selecting a folder tree node results in the entire tree branch being selected or not selected.
2. Click **Edit** to start the **Select Mapping Source** dialog.
3. To select a mapping target, select the appropriate tree node check box. Conversely, to remove a mapping target, clear the appropriate tree node check box.
4. Ensure that you have selected only the number of matches that you require. The third column displays the number of sources selected for each mapping target. The cell has a value greater than one when the source of a map contains several elements of certain names under various containers, and the source names match to the same target name.
5. Click **Finish** to complete the mapping process, or click **Back** to change the matches that you have set up. When you click **Finish**, you obtain a warning message if either, or both, of the following conditions apply:
   a. More than a few sources to map to the same target.
   b. Many targets for which you want to create mappings.

"Selecting matches" on page 2244
Use the Map by Name wizard to select the mappings that you want to create.

Mapping by Same Name:

Options are available when you select **Create mappings between sources and targets with the same name** or a similar name.

About this task

When you select **Create mappings between sources and targets with the same name**, the following rules apply:

1. Any target field that has a fixed value is excluded in name matching. Any target that is already mapped, or under a container that is already mapped, is excluded from name matching.
2. If a source and a target have the same name, it is a match, regardless of the kind of, and XSD type of, the source and target. An element, an attribute, and a database column can all form a match if their names are the same.
3. XML namespaces are excluded from name matching. Therefore, `abc:something` and `xyz:something` are considered the same, as are `{http://www.abc.com}:something` and `{http://www.xyz.com}:something`.
4. When multiple sources have the `same` name as one target, one mapping is created. However, when multiple targets have the `same` name as one source, multiple mappings are created, each for one source and one target.
5. When performing `Map from Source` for a selected source and a selected target, the WebSphere Message Broker Toolkit might insert some `for` and `if` statements based on the repeatability (maximum occurrences) of the selected source and target, and their containers.

   The same process occurs for `Map by Name`, based on the repeatability of the selected sources and targets, and their containers.

   However, there are not any `for` or `if` statements inserted on descendants of the selected source and target.
6. When you select the **Map leaves of the selected nodes** option, the following steps are taken to match names:

   a. Compare the relative path and item name of the selected source or target

   b. Compare the item name without relative path

   For example, if you invoke the action **Create mappings between sources and targets with the same name** and have a:

   - Source path for `partNum` of `$source/po:purchaseOrder/`**`items`**`/item/partNum`, where **items** is the selection that you made in the source.
   - Target path for `partNum` of `$target/`**`po:purchaseOrder`**`/items/item/partNum`, where **po:purchaseOrder** is the selection that you made in the target.

   During step a) the source and target path names involved in the same-name test are `/items/item/partNum` and `item/partNum`.

   During step b) the source and target item names that are involved in same-name test are `partNum` and `partNum`; that is, name matches are done using short names without their paths.

   Note that sources and targets matched in a previous step do not participate in a later step.

Mapping by similar name

1. Fixed value targets and mapped targetstargets and mapped targets are excluded in name matching; see Point 1 in the preceding section.
2. The *similarity* test is done using the name of an element, an attribute, or a database column regardless of its type; see Point 2 in the preceding section.
3. The *similarity* test applies in the same way to case sensitivity and alphanumeric characters as for **Mapping by same name**.
4. Namespace or namespace prefixes do not participate in the *similarity* test; see Point 3 in the preceding section.
5. The behavior for the situation when multiple sources are similar to one target, and when multiple targets are similar to one source, is the same as Point 4 in the preceding section.

6. The repeatability (maximum occurrences) of containers and descendants of the selected source and target are handled in the same way as in Point 5 in the preceding section.
7. When you select the option **Create mappings when source and target names are more similar than**, you must also select **Create mappings between sources and targets with the same name**.
8. When you select **Map leaves of the selected nodes**, the following steps are taken to match names.

   Sources and targets matched in a previous step are ignored in later steps:
   - The path names starting after the selected source and target are the same.
   - The item names excluding the path are the same.
   - The item names excluding the path are similar.
9. You can select the similarity threshold for two words to be considered similar.
10. You cannot use any other similarity algorithm.

You can create a synonym file manually, or by generating a synonym file from the information that is contained in a Microsoft Excel spreadsheet, using the following set of instructions.

"Using message mappings" on page 2228
Message mappings define the blueprint for creating a message.

Related reference:

"Algorithm used to match synonyms" on page 2252
The way in which synonyms are matched by the `Map by Name` function, to create mappings between specific sources and targets, follows a particular set of rules.

"Format of the synonym file"
`Map by Name` allows you to create mappings between specific sources and targets by putting the names of the sources and targets in a file called the synonym file.

Format of the synonym file:

`Map by Name` allows you to create mappings between specific sources and targets by putting the names of the sources and targets in a file called the synonym file.

Synonyms, in the context of the synonym file, are groups of words that represent mappings that you want to create.

File type:
A synonym file can reside anywhere in your file system, only if the encoding used in the synonym file is the same as that used by the Eclipse Toolkit system.

However, if the synonym file uses a specific encoding that is, or might be, different from the encoding of the Eclipse Toolkit, the file must reside in a project in the WebSphere Message Broker Toolkit.

If the synonym file is created outside the WebSphere Message Broker Toolkit, and uses a specific encoding, save the file under a WebSphere Message Broker Toolkit project and click **Refresh** to make the file visible in the navigator.

The synonym file uses Tab-separated or comma-separated files only. If you have written your mapping requirement in any external application, for example, Microsoft Word or Microsoft Excel, you must export the relevant data in a format that the synonym file supports.

Item names in the file:
A synonym file contains the names of items to be mapped, without the path to the item or the namespace of the item.

For example, if you want to map `partNum` to `partNumber` in the following XML, you must put `partNum` in the synonym file, not `item/partNum`, `items/item/partNum`, or `purchaseOrder/items/item/partNum`.

```
<po:purchaseOrder xmlns:po="http://www.ibm.com">
 <items>
    <item>

```

Synonyms in the file can:

- Be case sensitive or not case sensitive
- Contain the entire mapping item name
- Have non alphanumeric characters removed

Rows in the synonym file:
In the synonym file, each row represents one group of names to be mapped between each other and each row must contain at least two names. Names within a row are separated by commas in `.csv` files, and by Tab characters in `.txt` files.

A synonym file can contain an optional special row at the top. This top row contains key words **Source**, **Target**, or **Source_Target**, separated by the same delimiter used in the remainder of the file. The top row is used to indicate whether the synonyms are to be used to match names in mapping the source or the target:

- If the first word in the top row is **Target**, the first name only, in each subsequent row is searched in the mapping target for name matching.
- If the second word in the top row is **Source**, the second name only, in each subsequent row is searched in the mapping source for name matching.

- If the third word in the top row is **Source_Target**, the third name only, in each subsequent row is searched in both the mapping source and mapping target for name matching.

The top row must not contain fewer key words than the maximum number of names in any row in the file.

If the top row contains any word other than **Source**, **Target**, or **Source_Target**, the top row is ignored and it is assumed that the top row is missing. If you omit the optional top row, every name in the synonym file is considered to be **Source_Target**; that is, any name found either in the mapping source or in the mapping target is matched.

If a synonym file contains two rows:

car	*automobile*
automobile	*vehicle*

car and *vehicle* are not considered to be synonyms.

In order to make all three words synonyms, your synonym file can have either:

- One row with all three words -

car	*automobile*	*vehicle*

or

- Three rows -

car	*automobile*
automobile	*vehicle*
car	*vehicle*

Special characters:
You can write synonym files manually, or export them from another application; for example, Microsoft Excel. Item names in synonym files reflect the application domain and do not have to match exactly the names in the XML schema or the relational database column.

For example, a synonym file might contain the row:

```
summer      l'été
```

As `l'été` does not conform to the XML NCName format, you could name the element `l_été`. As long as all the alphanumeric characters in the synonym file match those in the schema, you can use the file with the option **Letters and digits only, ignore non-alphanumeric characters**.

Many mapping requirements are written in Microsoft Excel, and cells in a Microsoft Excel file might contain specific characters like double quotation marks, space, new line, comma, and so on. When such a Microsoft Excel file is saved as a Tab-separated or comma-separated file, they contain additional double quotation marks.

Two groups of synonyms in a synonym file are delimited either by a Line Feed (LF) character, or Line Feed followed by a Carriage Return (LFCR). A Carriage Return (CR) character by itself does not end a group of synonyms.

Leading and trailing space characters adjacent to the delimiter (comma or Tab character) are ignored. Blank rows, or rows that contain only space characters, are permitted and ignored in a synonym file.

Different editors might inject different space characters into a synonym file; spaces are not used to delimit synonyms, and spaces are ignored unless they are inside double quotation marks.

If a synonym contains a comma, a double quotation mark, a carriage return, or a leading or trailing space that is significant, the synonym must be enclosed in double quotation marks. A double quotation mark within a synonym is escaped with another double quotation mark. For example:

```
"comma,separated"
"double""quote"
  "with<CR>
   newline"
  "  spaces   "
```

When the synonym file is read by the WebSphere Message Broker Toolkit, the double quotation marks at the beginning and end of the synonym are removed and the WebSphere Message Broker Toolkit stores the following in the synonym table:

```
comma,separated
double"quote
  with<CR>newline
    spaces
```

The WebSphere Message Broker Toolkit reads a synonym file containing these special characters correctly, and you should select the **Letters and digits only, ignore non-alphanumeric characters** option when using the synonym file.

Creating and using a synonym file:

You can create a synonym file manually, or by generating a synonym file from the information that is contained in a Microsoft Excel spreadsheet, using the following set of instructions.

About this task

The following set of instructions describes how to create a synonym file where the original mapping requirement is written in Microsoft Excel. If your original requirement is written in a table in Microsoft Word you must copy and paste the table into Microsoft Excel before you begin.

Amend the process to allow for extra facilities that your enterprise uses.

Procedure

1. Select the section of the Microsoft Excel spreadsheet that you require. For example, if you have a Product that you want to map to a Part number, select that section of the spreadsheet.
2. Remove all columns from the spreadsheet, except the ones containing the source field name and the target field name.

   You might have to edit some of the cells. For example, if your mapping instruction includes the phrase `based on`, remove this phrase.
3. If the source or target fields contain paths, remove the paths to leave only the short names of the item.

   However, it is helpful to sort the column before removing the paths. Sorted path names can indicate which is the best source or target to select when invoking the action.

   If all the interested sources (or targets) start with the same path prefix, you might consider selecting the lowest source (or target) node in the tree which has that common path prefix.
4. Remove all rows that do not have a source field name and a target field name. For example, if you have an obsolete product that no longer has a part number and you have put `n/a` in the source, remove that row.
5. Select the **Save As** function in Microsoft Excel to save the spreadsheet into a format acceptable by our WebSphere Message Broker Toolkit.

   You can use either a Tab delimited `.txt` file or a comma delimited `.csv` file.

   A comma delimited file can be opened using Microsoft Excel and it looks like the original Microsoft Excel file; the file can also be viewed using a text editor.
6. Create the mappings using the synonym file.

   Select the options in the **Map by Name** wizard that match your requirements; for example, select the default options of **Map leaves of the selected nodes** and **Alphanumeric characters (Letters and digits only)**.

   When you have chosen these options, select **Create mappings between source and target names defined as synonyms in file**.

   If you need to map same-name sources to targets, and the synonym file does not contain rows with those names (for example a row with **car,car**), select the

Create mappings between sources and targets with the same name option, in addition to **Create mappings between source and target names defined as synonyms in file**.

You can select both **Create mappings between sources and targets with the same name** and **Create mappings when source and target names are more similar than**, in addition to **Create mappings between source and target names defined as synonyms in file**, if your synonym file does not contain a row **color,colour** and you want to map between them.

7. Click **Finish**.
8. Edit mapping expressions based on what is required.

   For example, if you have the following value:

   ```
   PRODUCT  $SOURCE/Batch/Detail/Replace/PartNumber
   ```

   edit the mapping expression to:

   ```
   xs:boolean($source/Batch/Detail/Replace/PartNumber = 1)
   ```

9. Create all the mappings that the Map by Synonym process has not generated. Use the drag-and-drop method, **Map from Source**, or the **Enter Expression** process.

`Map by Name` allows you to create mappings between specific sources and targets by putting the names of the sources and targets in a file called the synonym file.

"Algorithm used to match synonyms"
The way in which synonyms are matched by the `Map by Name` function, to create mappings between specific sources and targets, follows a particular set of rules.

Algorithm used to match synonyms:

The way in which synonyms are matched by the `Map by Name` function, to create mappings between specific sources and targets, follows a particular set of rules.

1. Fixed value targets and mapped targets are excluded in name matching; see point 1 in “Mapping by Same Name” on page 2245.
2. The synonym matching is done by using the name of an element, an attribute, or a database column regardless of its type; see point 2 in “Mapping by Same Name” on page 2245.
3. The synonym matching of alphanumeric characters is not case-sensitive, and is identical to that used in “Mapping from source: by name” on page 2241.
4. Namespace or namespace prefixes do not participate in synonym matching; see point 3 in “Mapping by Same Name” on page 2245.
5. The behavior for the situation when multiple sources are synonyms of one target, and when multiple targets are synonyms of one source, is the same as point 4 in “Mapping by Same Name” on page 2245.
6. The repeatability (maximum occurrences) of containers and descendants of the selected source and target are handled in the same way as in point 5 in “Mapping by Same Name” on page 2245.
7. If a source and a target have the `same` name, they are not considered a match under the option for synonyms. If you require a mapping for same-name sources and targets, you must also select the **same name** option.
8. In addition to mapping synonyms, you might want to create mappings for some, but not all, same-name sources and targets. In this case, you have two options:
   - Clear **Create mappings between sources and targets with the same name**, and include the same-name sources and targets in the synonym file
   - Select **Create mappings between sources and targets with the same name**, and clear the unwanted mappings on the second page of the wizard.
9. When you select **Map leaves of the selected nodes** together with both same name and synonym mapping options, the following steps are taken to match names.

   Sources and targets matched in a previous step do not participate in a later step:
   - The path names starting after the selected the source and target are the same
   - The item names excluding the path are the same
   - The item names excluding the path are synonyms
10. When you select **Map leaves of the selected nodes**, and you require synonyms to be mapped without mapping same names, only the item names are checked for synonyms; paths are ignored.

`Map by Name` allows you to create mappings between specific sources and targets by putting the names of the sources and targets in a file called the synonym file.

Mapping a target element from source message elements:
About this task

You can map the following objects:

- Simple source elements to simple target elements
- Source structures to target structures (where the source and target are of the same type)
- Source structures to target structures (where the source and target are of a different type)
- Simple source elements to target structures (where the target structure is a complex type element with mixed content)
- Source structures to simple target elements (where the source structure is a complex type element with mixed content)
- Multiple simple source elements to a simple target element

The following sections describe how to perform mapping for these particular scenarios using the Message Mapping editor.

Mapping simple source elements to simple target elements

In the following example, the source element called Name does not contain the same children as the target element called Name:

Source	Target
Name Title First_name Middle_name Last_name	Name Title First_names Last_name

To map one of the child elements, drag the element from the Source pane onto the corresponding element in the Target pane; for example, drag the Last_name source element onto the Last_name target element.

The mapping is represented by a line between the source element and the target element and an entry for the mapping in Xpath format appears in the Spreadsheet pane. A triangular icon indicates which elements in the Source and Target panes have been mapped.

Mapping source structures to target structures (where the source and target are of the same type)

In the following example, the source element called Name has the same structure as the target element called Name:

Source	Target
Name Title First_name Middle_name Last_name	Name Title First_name Middle_name Last_name

To map the entire source structure to the target structure, drag the parent element (Name) from the Source pane onto the corresponding element (Name) in the Target pane. All the child elements are mapped.

Mapping source structures to target structures (where the source and target are of a different type)

In the following example, the source element called Name has a different structure to the target element called DifferentName:

Source	Target
Name Title First_name Middle_name Last_name	DifferentName Title FirstName LastName

To map the entire source structure to the target structure, drag the parent element (Name) from the Source pane onto the corresponding element (DifferentName) in the Target pane. The Map By Name wizards opens. Select **Map leaves** and **Map items of same and similar names** to map all child elements in the target. The source element Middle_name will not be mapped, as there is no target element with the same or a similar name.

Mapping simple source elements to target structures

In the following example, source element *Name1* contains three simple elements to be mapped: *Title*, *FirstName*, and *LastName*. The target element *Name2* contains two attributes, *Title* and *GivenName*, and uses mixed content to carry *Surname*.

Source	Target
Name1 Title FirstName LastName	Name2 (mixed) @Title @GivenName

The following mappings can be created using **Map from Source** or drag and drop:

```
Title <- -> @Title
FirstName <- -> @GivenName
LastName <- -> Name2
```

If the following source XML document is used:

```
<Name1>
 <Title>Mr.</Title>
 <FirstName>John</FirstName>
 <LastName>Doe</LastName>
</Name1>
```

the following target XML document will be produced from the mappings:

```
<Name2 GivenName="John" Title="Mr.">Doe</Name2>
```

Mapping source structures to simple target elements

In the following example, the source element *Name1* contains two attributes, *Title* and *GivenName*, and uses mixed content to carry *Surname*. The target element *Name2* contains three simple elements to be mapped to.

Source	Target
Name1 (mixed) @Title @GivenName	Name2 Title FirstName LastName

The following mappings can be created using **Map from Source** or drag and drop:

```
@Title <- -> Title
@GivenName <- -> FirstName
Name1 <- -> LastName
```

If the following source XML document is used:

```
<Name1 GivenName="John" Titile="Mr.">Doe</Name1>
```

the following target XML document will be produced from the mappings:

```
<Name2>
 <Title>Mr.</Title>
 <FirstName>John</FirstName>
 <LastName>Doe</LastName>
</Name2>
```

Mapping multiple source elements to a simple target element

In the following example, you want to concatenate the *First_name* and *Middle_name* source elements to form a single target element called *First_names*:

Source	Target
Name Title First_name Middle_name Last_name	Name Title First_names Last_name

To map multiple source elements to a simple target element, Ctrl+click the appropriate source elements (First_name and Middle_name) and the target element (First_names), then click **Map** > **Map from Source**. A concatenate function appears in the Spreadsheet pane; you can edit this function to define how the concatenated target element looks, for example, by adding a white space between the two source elements.

Results

To customize the target element (for example, to make the target value equal to the source value plus one), see "Setting the value of a target element using an expression or function" on page 2261. You cannot map a simple element if one of its ancestors also has a mapping. For example, you cannot map Properties from source to target, then map Properties/MessageFormat.

Setting the value of a target element to a constant:

Use the Message Mapping editor to set the value of a target element to a constant.

About this task

Procedure

1. In the Target pane, right-click the target element or attribute and click **Enter Expression**. If the target element or attribute has a default value, this value is added to the Edit pane.
2. Enter the required constant in the Edit pane and click **Enter**. When entering the constant, observe the following rules:
   - Enclose string element values in single quotation marks.
   - Enter numeric element values without quotation marks.
   - For boolean element values enter `0` for false or `1` for true, without quotation marks. Alternatively, you can enter the `fn:false()` function for false, or the `fn:true()` function for true.

The Spreadsheet pane is updated with the value that you have defined.

Results

You cannot set a value for a simple element if one of its ancestors also has a mapping. For example, you cannot map Properties from source to target, then set a value for `Properties/MessageFormat`.

Example

You can also set a target element to a WebSphere MQ constant or an ESQL constant.

Setting the value of a target element to a WebSphere MQ constant:

There are two ways to set the value of a target element to a WebSphere MQ constant, depending on whether the target element has an entry in the Map Script column of the Message Mapping editor Spreadsheet pane.

About this task

Procedure

- If the target element has an entry in the Map Script column:
  1. In the Spreadsheet pane, select the target element.
  2. Enter `$mq:` followed by the WebSphere MQ constant in the Edit pane.
  3. Press **Enter**.

  The Spreadsheet pane is updated with the expression for a WebSphere MQ constant.
- If the target element does not have an entry in the Map Script column:
  1. In the Target pane, right-click the target element and click **Enter Expression**.
  2. Enter `$mq:` followed by the WebSphere MQ constant in the Edit pane.
  3. Press **Enter**.

  The Spreadsheet pane is updated with the expression for a WebSphere MQ constant.

Example

The following examples demonstrate how to enter a WebSphere MQ constant in the Edit pane:

```
$mq:MQ_MSG_HEADER_LENGTH
$mq:MQMD_CURRENT_VERSION
```

When the map is saved a warning message is displayed if the expression entered for the WebSphere MQ constant is incorrect, for example, if the constant is not recognized. This is an example of the warning message: `The target "$target/purchaseOrder/comment" is not referencing a valid variable`.

Content Assist (**Edit** > **Content Assist**) provides a list of the WebSphere MQ constants available.

1. Select `$mq: ( MQ constants )`
2. Select **Edit** > **Content Assist** again to display a list of the available constants.

WebSphere MQ constants that can be used as values for target elements, grouped by the parameter or field to which they relate, can be found in the *WebSphere MQ Constants* book.

Setting the value of a target element to an ESQL constant:

There are two ways to set the value of a target element to an ESQL constant, depending on whether the target element has an entry in the Map Script column of the Message Mapping editor Spreadsheet pane.

About this task

Procedure

- If the target element has an entry in the Map Script column:
  1. In the Spreadsheet pane, select the target element.
  2. Enter `$esql:` followed by the ESQL constant in the Edit pane.
  3. Press **Enter**.

  The Spreadsheet pane is updated with the expression for a WebSphere MQ constant.
- If the target element does not have an entry in the Map Script column:
  1. In the Target pane, right-click the target element and click **Enter Expression**.
  2. Enter `$esql:` followed by the ESQL constant in the Edit pane.
  3. Press **Enter**.

  The Spreadsheet pane is updated with the expression for a WebSphere MQ constant.

Example

The following examples demonstrate how to enter an ESQL constant in the Edit pane:

```
$esql:ValidateLocalError
$esql:ParseComplete
```

When the map is saved a warning message is displayed if the expression entered for the ESQL constant is incorrect, for example, if the constant is not recognized. This is an example of the warning message: `The target "$target/purchaseOrder/comment" is not referencing a valid variable`.

Content Assist (**Edit** > **Content Assist**) provides a list of the WebSphere MQ constants available.

1. Select `$esql: ( ESQL Constants )`
2. Select **Edit** > **Content Assist** again to display a list of the available constants.

Setting the value of a target element using an expression or function:

About this task

There are two ways to set the value of a target element to an expression, depending on whether the target element has an entry in the Map Script column of the Message Mapping editor Spreadsheet pane:

Procedure

- If the target element has an entry in the Map Script column:
  1. In the Spreadsheet pane, select the target element.
  2. Enter the required expression in the Edit pane.
  3. Press **Enter**.

  The Spreadsheet pane is updated with the value or expression.
- If the target element does not have an entry in the Map Script column:
  1. In the Target pane, right-click the target element and click **Enter Expression**. If the target element has a default value, this value is added to the Edit pane.
  2. Enter the required expression in the Edit pane.
  3. Press **Enter**.

  The Spreadsheet pane is updated with the value or expression.

Example

The following examples demonstrate techniques for entering mapping expressions in the Edit pane.

- If the target element is derived from a source element, drag the source element or elements onto the Edit pane; for example:

  ```
  $source/Properties/MessageSet
  ```

- Use arithmetic expressions, such as:
  ```
  $source/Properties/Priority + 1
  ```
- Use mapping, Xpath or ESQL function names. Content Assist (**Edit** > **Content Assist**) provides a list of available functions. For example:
  ```
  esql:upper($source/Properties/ReplyIdentifier)
  ```
- You can perform casting in the Edit pane; for example:
  ```
  xs:string($source/Properties/CodedCharSetId)
  ```

You cannot enter an expression for a simple element if one of its ancestors also has a mapping. For example, you cannot map Properties from source to target, then set a value of Properties/MessageFormat.

There are two ways to set the value of a target element to a WebSphere MQ constant, depending on whether the target element has an entry in the Map Script column of the Message Mapping editor Spreadsheet pane.

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Creating a BLOB output message using a message map:

Use the Message Mapping editor to create a bit stream from a message source, and create it as a BLOB output message.

Before you begin

Before you start:

Create a mapping that includes a BLOB message as a target; see "Creating a message mapping file from a Mapping node" on page 2236.

About this task

Take the following steps:

Procedure

1. Right-click the BLOB message that you want to map in the Target pane, and select **Enter Expression** from the menu.
2. In the Edit pane, type `esql:asbitstream()`.
3. Drag the source field to the Edit pane, placing it between the parentheses, for example:
   ```
   esql:asbitstream($source/po:purchaseOrder)
   ```

Alternatively, you can use content assist to select the `esql:asbitstream` function. In the Edit pane press Ctrl+Space to display a list of available functions and associated parameters. The `asbitstream` function is an ESQL Field function. The function can take other parameters; see "ESQL mapping functions" on page 4998.

When you move the cursor out of the Edit pane, or press Enter, the mapping is displayed between the fields in the Source and Target panes.

Related tasks:

"Storing a BLOB message in a database table using a message map" on page 2297
Use the Message Mapping editor to create a bit stream from a BLOB message, and store it in a database table.

Mapping from a BLOB message to an output message:

Use the Message Mapping editor to parse a BLOB message.

Before you begin

Before you start:

Create a mapping; see "Creating a message mapping file from a Mapping node" on page 2236.

About this task

Take the following steps:

Procedure

1. Right-click the element in the target pane, and select **Enter Expression** from the menu.
2. In the Edit pane, type `msgmap:element-from-bitstream()`.
3. Drag the BLOB to the Edit pane, placing it between the parentheses, for example:

   ```
   msgmap:element-from-bitstream($source/BLOB)
   ```

   Alternatively, you can use content assist to select the `msgmap:element-from-bitstream` function. In the Edit pane press Ctrl+Space to display a list of available functions and associated parameters. The function can take other parameters; see "Predefined mapping functions" on page 5007. When you move the cursor out of the Edit pane, or press Enter, the mapping is displayed between the fields in the Source and Target panes.

Deleting a source or target element:
About this task

The following steps describe how to delete source and target elements using the "Message Mapping editor" on page 4981:

Procedure

- To delete a source path, modify the expression so that it no longer uses the source value to compute the target.

  If this is the last use of the source path, the line linking the source and target is removed. If the expression no longer has any value, the target becomes unmapped.
- To delete a target from the Edit pane, click the target and click **Delete**.

  The target structure is preserved if possible.
  - If you delete a "for" row, clicking **Delete** removes the single row.
  - If you have an `if`, an `elseif`, or an `else` statement, clicking **Delete**:
    1. On an `elseif` statement deletes the `elseif` statement and the contents of the statement.
    2. On an `else` statement deletes the `else` statement and the contents of the statement.
    3. On an `if` statement with a subsequent `elseif` statement, deletes the `if` statement and the contents of the statement, and causes the subsequent `elseif` statement to become an `if` statement.
    4. On an `if` statement with only a subsequent `else` statement, deletes everything except the contents of the `else` statement.
    5. On an `if` statement with no subsequent statements, deletes everything except the contents of the `if` statement.
- To delete a database source, click the SELECT statement then remove all references to the source manually. Alternatively, delete the SELECT source in the Source pane then remove all references to the source manually.
- To delete a database target, delete the INSERT, UPDATE or DELETE statement. Alternatively, update or delete the statement in the Target pane.

Edit and configure message maps using the Message Mapping editor.

Configuring conditional mappings:

How to set the value of a target element conditionally in a Mapping node.

Procedure

1. In the Spreadsheet pane of the Message Mapping editor, select the target element and click **Map** > **If**.

   One row is added to the Spreadsheet pane, above the target element:

   - In ths row, Map Script is set to "if".

     Its value is an expression that is evaluated to see whether it is true. If true, the target element is set to the value specified in its "Value" column. Initially, its "Value" column is set to ‘fn:true()’, which means that the condition is always met, and the target element is always set to the "Value" column.

2. Change the expression in the if row’s "Value" column by selecting the cell, or the if row, in the Spreadsheet pane, and setting the value in the Edit pane.

   Amend the expression in the Edit pane to specify the correct condition statement by performing the following steps:

   a. Select any database columns that are pertinent to the condition statement, and drag them from the Source pane into the Edit pane.
   b. Select any source message elements with values that are pertinent to the condition statement, and drag them from the Source pane into the Edit pane.
   c. Open Content Assist by clicking **Edit** > **Content Assist** and select the functions to be applied to the condition.

3. Add further condition statements by selecting the if row in the Spreadsheet pane, and clicking **Map** > **Else If**.

   Two rows are added to Spreadsheet pane, below the target element:

   - In the first row, Map Script is set to `elseif`. Process this as described in Step 2.
   - In the second row, Map Script is set to the target element. Its `Value` cell is initially blank. Set this value as described in “Setting the value of a target element to a constant” on page 2257, and “Setting the value of a target element using an expression or function” on page 2261.

4. To set the value of a target element when the `if` statement is not true, select the `if` statement for the target element in the Spreadsheet pane, and click **Map** > **Else**.

   Two rows are added to Spreadsheet pane, below the target element:

   - In the first row, Map Script is set to `else`. You cannot enter anything in the Value column of this row.

- In the second row, Map Script is set to the target element; its value is initially blank. Set this value as described in “Setting the value of a target element to a constant” on page 2257, and “Setting the value of a target element using an expression or function” on page 2261.

Configuring mappings for repeating elements:
About this task

To configure the Mapping node to process repeating elements, use the ‘For’ option in the Message Mapping editor Spreadsheet pane. The following combinations of repeating elements are possible:

Procedure

- repeating source and non-repeating target
- non-repeating source and repeating target
- repeating source and repeating target

Results

By default, if the source is a database, it is processed as a repeating source.

Related tasks:

“Configuring a repeating source and a non-repeating target”

Related reference:

“Message mappings” on page 4981
Edit and configure message maps using the Message Mapping editor.

Configuring a repeating source and a non-repeating target:

To map a repeating source element to a non-repeating target element, drag elements between the Message Mapping editor Source and Target panes.

About this task

The following items appear in the Spreadsheet pane:

- A "for" row with Value set to the repeating source element.
- An "if" row with Value set to `msgmap:occurrence($source/...) = 1`.
- A row with Map Script set to the target field and Value set to the source field.

The first occurrence of the source field is mapped to the target field. The "for"' row specifies that a loop is to be iterated for the specified repeating element. The if row restricts the logic to a single occurrence of the repeating element. See “Configuring conditional mappings” on page 2265 for more information on conditional logic in a mapping node.

Procedure

1. To map an occurrence other than the first, change the expression in the if row to `msgmap:occurrence($source/...) = n`, where *n* is the occurrence that you want to map.

   If the repeating source field is within one or more repeating structures, a hierarchy of `for` and `if` rows is placed in the Spreadsheet pane, one for each level of repetition.
2. If the source field contains a numeric data type, mapping all occurrences of a repeating source field to a non-repeating target results in the sum of all the source elements. Perform this mapping by selecting the source element and target element and clicking **Map** > **Accumulate**.

   This action sets the following value in the Spreadsheet pane for the target element:

   ```
   fn:sum($source/...)
   ```

   The result of the accumulate action is a numeric value. If your target has a different data type, you must cast the result to the appropriate type for the selected target. For example, if your target is xs:string type, you must alter the results of the accumulate action from `fn:sum($source/x/y/z)` to `xs:string(fn:sum($source/x/y/z))`, in order to cast the result to the correct data type for your target.

   You cannot map different occurrences of a repeating source element to different non-repeating target elements.

Configuring a non-repeating source and a repeating target:

To map a non-repeating source element to a repeating target element, drag elements between the Message Mapping editor Source and Target panes.

About this task

The first occurrence of the target element is set to the value of the source element.

To map to an occurrence other than the first, complete the following steps:

Procedure

1. If the target element is not shown in the Spreadsheet pane, right-click its lowest ancestor row, then click **Insert Children**. Repeat this action until the target element is shown.
2. Right-click the target element and click **Insert Sibling After** or **Insert Sibling Before** to select the location to insert the repeating target elements. The **Insert Sibling After** or **Insert Sibling Before** options are not enabled if there is nothing valid to be inserted at the selected location. Selecting either of these opens the Insert Sibling Statement wizard.
3. Select the element to insert from the list of valid items.
4. Enter the number of instances to be added and click **OK**. The number of instances to be added must be less than or equal to the maximum occurrence specified for the selected element.

Results

The specified number of instances of the repeating target element are added to the Spreadsheet pane. The inserted statements do not have a mapping expression and any children are not displayed. Right-click each element, then click **Insert Children** to display any child elements.

What to do next

By repeating the **Insert Sibling After** and **Insert Sibling Before** action, it is possible to insert more repeating elements in the target than the maximum occurrence specifies. Verify that the number of repeating elements is valid, and delete any unwanted entries.

Configuring a repeating source and a repeating target:
About this task

To map a repeating source element to a repeating target element drag elements between the Message Mapping editor Source and Target panes. The following items appear in the Spreadsheet pane:

Procedure

- A 'for' row with Value set to the repeating source element.
- A row with Map Script set to the target field and Value set to the source field.

Results

All occurrences of the source element are mapped to the respective occurrences of the target element. You can map repeating source structures to repeating target structures if the source and target are of the same complex type.

Populating a message map:

Use the Insert Children wizard to add elements from the Target pane to the Spreadsheet pane. The Insert Children wizard creates child structures for the selected parent structure.

About this task

When you add a message target to a message map, $target in the Spreadsheet pane is populated by default with Properties and the message body root. The Properties fields MessageSet, MessageType and MessageFormat, are added together with their default values, unless the selected message is in the BLOB domain. Other message elements and their children can be added to the Spreadsheet pane without creating

mappings by using the Insert Children wizard. The following steps show how to populate the Spreadsheet pane with other message elements using the Insert Children wizard:

Using the Insert Children wizard

Procedure

1. Right-click a parent element in the Spreadsheet pane and click **Insert Children**. The Insert Children wizard is displayed.
2. Select the items you want to create mappings for. Items required in the target message are selected by default. The selected items are added to the Spreadsheet pane.
3. Repeat **Insert Children** to add further child elements to the Spreadsheet pane.

Results

If any target elements are missing warning messages are displayed in the Message Mapping Editor. These warning messages indicate the name and expected position of the missing elements. You can used the Insert Children wizard to add the missing elements.

What to do next

You can also use the Insert Children wizard to add target elements to the Spreadsheet pane when there are existing mappings. Any existing mappings are not altered by the wizard.

If the target map is a submap the Spreadsheet pane is populated by default with the selected element or attribute root. You can use the Insert Children wizard in the submap to add any child elements to the Spreadsheet pane in the same way.

Configuring the LocalEnvironment:
About this task

You can set values in the LocalEnvironment in the same way as setting values in other elements of a message. Add the LocalEnvironment to your message map using the **Add or Remove Headers and Folders** dialog as described in "Mapping headers and folders." If you set any values in the target LocalEnvironment, set the mapping mode property for the Mapping node to a value that contains LocalEnvironment. To do this, select the mapping node in your message flow and click **Properties** > **Basic** > **Mapping Mode**.

You cannot map Local Environment objects that are not listed.

Related concepts:

"Local environment tree structure" on page 1056
The local environment tree is a part of the logical message tree in which you can store information while the message flow processes the message.

Configuring message headers:

You can set values for headers in the same way as setting values in other elements of a message.

About this task

Add the appropriate headers to your message map using the **Add or Remove Headers and Folders** dialog box as described in "Mapping headers and folders." If you set any values in the target LocalEnvironment, set the Mapping mode property for the Mapping node to a value that contains LocalEnvironment. To do this, select the mapping node in your message flow and click **Properties** > **Basic** > **Mapping Mode**.

You cannot map headers that are not listed.

Related tasks:

"Mapping headers and folders"
Include message headers and folders for source and target messages in a message map.

Mapping headers and folders:

Include message headers and folders for source and target messages in a message map.

Before you begin

Before mapping headers and folders, ensure that you do the following tasks:

1. Create a message flow project
2. Create a message flow
3. Define message flow content
4. Create a message map file from the navigator or create a message map from a node.

About this task

The following types of message headers and folders can be included for source and target messages in a message map (note that a submap does not include message headers):

- LocalEnvironment
- Properties
- MQ Headers
- HTTP Headers
- JMS Transport Header
- Email Headers

If you choose not to map message headers or the LocalEnvironment explicitly in your message map, the output message is produced with the same message headers as the input message. When you Populate the message map, the Properties folder for the source and target are displayed in the message map, with MessageSet and MessageType initially set based on the target message.

MessageFormat is set to the default wire format of the message set if the parser domain is MRM. The other properties are blank initially, and the message headers are copied from the input message.

Alternatively, if you choose to map any message headers or the LocalEnvironment in your message map, no message headers are copied from the input message. You must add mappings for these headers to ensure that the target message contains appropriate headers to make a valid output message.

If your target message contains an MQRFH2 header, you must select from either the MQRFH2 or MQRFH2C parser in the Add or Remove Headers and Folders dialog. For more information about the MQRFH2 and MQRFH2C parsers, see "The MQRFH2 and MQRFH2C parsers" on page 4253.

To add message headers or other folders to a message map:

Procedure

1. Right-click your message map in the Broker Development view and select **Open** or right-click your mapping node and select **Open Map** to open the Message Mapping editor.
2. Right-click `$source` in the Source pane and select **Add or Remove Headers and Folders** to add message headers or other folders to the source message. The Add or Remove Headers and Folders dialog box opens.
3. Ensure that **Selected headers and other folders** is selected. If **No folders (map body element only)** is selected your map is a submap, and cannot have

headers associated with it. You can change the submap to a message map by selecting **Selected headers and other folders**.

4. Select the headers that you want to map from the list. If you want to map MQ Headers or HTTP Headers, you must select individual headers by expanding the list. If you are using MQ Headers you must include the MQMD, and so this is automatically selected for you.
5. Click **OK** to add the selected message headers or folders to the message map.
6. Right-click `$target` in the Target pane and select **Add or Remove Headers and Folders** to add message headers or other folders to the output message.
7. Repeat steps 3 to 5 to add the headers and folders that you require to the target message.
8. Configure the message header and folder mappings in the same way as other mappings.

What to do next

You can use **Add or Remove Headers and Folders** to remove message headers or the LocalEnvironment folder. Right-click on either the `$source` or the `$target` to open the Select Message Headers dialog box. Clear the headers or other folders to remove them from the message map. Removing a message header or other folder from the message map removes any associated mappings that you have created. You can remove the Properties folder from the message map, but all built-in parsers require some values in the Properties folder for the output message.

You can map multiple instances of a header by right-clicking on the header in the Message Mapping editor Spreadsheet pane and selecting **Insert Sibling Before** or **Insert Sibling After**. Select the header from the Insert Sibling Statement dialog.

Adding messages or message components to the source or target:
About this task

You can add additional messages or message components as sources or targets in your message map. To add a message or message component to a source or target:

Procedure

1. From the Message Mapping editor, click **Map** > **Add Sources and Targets**
   The Add Map Sources and Targets wizard opens.

Alternatively, right-click in the Source pane and click **Add Sources** or right-click in the Target pane and click **Add Targets**.

2. Select messages or message components from the message sets that are in your WebSphere Message Broker Toolkit workspace.

   If you cannot find the messages or message components that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.

   If one does not already exist, a project reference is created from your message flow project to the message set project that contains the selected messages or message components.

Results

You can also add sources and targets by dragging the resources from the Broker Development view in the Broker Application Development perspective onto the source or target pane of your message map. Select resources under Messages or Elements and Attributes or Types from your Message Definitions and drag them onto the source or target pane. If you add a message to the message map, Properties are also added. If you add an element, attribute or type to the to the message map a global element for a submap is created. Your message map must use messages, global elements or global types, but not a combination of more than one type.

What to do next

A Mapping node can have only one source message, but can have several target messages. Therefore, you cannot add a source message if one already exists.

Adding a database as a source or target:

Add a database as a source, and database tables as targets, to message maps that support database mappings.

Before you begin

You must create a database definition for your database before you can add it, or the associated tables, to a message map.

About this task

You can add database sources and targets in a number of different ways:

Procedure

- In an existing message map, click **Select Data Source** to add a database as a source.
  1. In the Spreadsheet pane, select the location to add a database table source to your mapping. For example, select `$target`.
  2. Click **Map** > **Select Data Source**. Alternatively, right-click in the Spreadsheet pane and click **Select Data Source**. The Select Database As Mapping Source wizard opens.
  3. Select your database from the list. If you cannot find the Data Sources or Data Targets that you expect, clear **Apply working set filtering to artifact selection(s) on the page** to view additional options.
  4. When you select a database source during map file creation, the database source is placed in the map script as a sibling (as opposed to a container) of the one or more message targets in the map. When you create a mapping from an item in the database source, the mapper moves the database source in the map script structure to the lowest container of all mappings that use the database source. You can move the database source in the map script by using drag-and-drop or copy-paste actions.
- You can specify the databases and database tables that you want to use in the New Message Map wizard when you create a message map.
  1. Create a message map file by using **File** > **New** > **Message Map**, or by right-clicking your mapping node and selecting **Open Map**.
  2. From **Select map sources**, select the Database Sources for your message map.
  3. From **Select map targets**, select the database tables to use as targets in your message map. If you are not creating a message map from a DataDelete, DataInsert, or DataUpdate node, expand the relevant database operation and select from the list of tables. You can select from the following database operations:
     - **Table Inserts**
     - **Table Updates**
     - **Table Deletes**

     If you cannot find the Data Sources or Data Targets that you expect, clear **Apply working set filtering to artifact selection(s) on the page** to view additional options.
  4. When you select a database source during map file creation, the database source is placed in the map script as a sibling (as opposed to a container) of the one or more message targets in the map. When you create a mapping from an item in the database source, the mapper moves the database source in the map script structure to the lowest container of all mappings that use the database source. You can move the database source in the map script by using drag-and-drop or copy-paste actions.
- In an existing message map, click **Add Sources and Targets** to add a database as a source and database tables as a target.
  1. From the Message Mapping editor, click **Map** > **Add Sources and Targets**. Alternatively, right-click in the Source pane and click **Add Sources**, or right-click in the Target pane and click **Add Targets**.
  2. From **Select map sources**, select the Database Sources for your message map.

3. From Data Targets, in **Select map targets**, select the database tables to use as targets in your message map. If you are not creating a message map from a DataDelete, DataInsert, or DataUpdate node, expand the relevant database operation, and select from the list of tables. You can select from the following database operations:
   - **Table Inserts**
   - **Table Updates**
   - **Table Deletes**

   If you cannot find the Data Sources or Data Targets that you expect, clear **Apply working set filtering to artifact selection(s) on the page** to view additional options.

   You can map to an element within a View, the name of which is annotated with `(read-only view)`.

   You cannot select View in the Add Maps dialog for **Insert**, **Update**, or **Delete**, because View is read only.
4. When you add a database source using the **Add Sources** action, the database source is placed in the map script as a sibling (as opposed to a container) of the one or more message targets in the map. When you create a mapping from an item in the database source, the mapper moves the database source in the map script structure to the lowest container of all mappings that use the database source. You can move the database source in the map script by using drag-and-drop or copy-paste actions.

Results

When you have added the database as a source:

- The Source pane contains a $db:select entry.
- The Spreadsheet pane contains a $db:select entry.

When you have added the database table as a target:

- The Target pane and Spreadsheet pane contain one of the following entries:
  - a $db:insert entry
  - a $db:update entry
  - a $db:delete entry

  You can change the database operation on a selected table by using the **Change Database Operation** dialog.

What to do next

You cannot add a database as a source or a target to an Extract node.

Adding database definitions to the WebSphere Message Broker Toolkit:

Use the New Database Definition File wizard to add database definitions to the WebSphere Message Broker Toolkit.

About this task

You must have a database definition defined in the WebSphere Message Broker Toolkit to create database mappings. You can also use database definitions in other nodes, such as the Compute node, to validate references to database sources and tables. Database definitions are stored in a data design project. You must associate the data design project with all message flow projects that you want to use the database definitions with.

Complete the following steps to add a database definition to the WebSphere Message Broker Toolkit:

Procedure

1. Click **File** > **New** > **Database Definition**. The New Database Definition File wizard is displayed.
2. Select an existing data design project, or click **New** to create a new data design project.
3. Select the database type and version that you want to connect to from the **Database and Version** list. Ensure that you select a database from the list that is supported by WebSphere Message Broker; you can use this wizard in a shell-share environment with other Rational products that support other databases or versions.

   For a list of databases supported by the broker, see "Supported databases" on page 3591.
4. Click **Next**.
5. Either select to create a new database connection or select a connection to use from the list of existing connections. If you select to use an existing connection, the existing database definition is overwritten.
6. Click **Next**.
7. If you selected to create a new connection:
   a. Optional: You can enter a custom value for the Connection Name if you clear **Use default naming convention**.
   b. Enter values for the Connection to the database, for example, Database name, Host name and Port number.
   c. Enter values for the User ID and Password to connect to the database. Click **Test Connection** to verify the settings you have selected for your database. The default Port number for a DB2 database is 50000. If the connection fails, enter other values such as 50001, 50002 and so on, for the Port number, and test the connection again.
   d. Click **Next**. An error is generated if any of the connection details are wrong. If you specify a Database that already has a database definition in the data design project, click **Yes** in the Confirm file overwrite window to overwrite the existing database definition.
8. Alternatively, if you selected to use an existing connection:

a. Click **Yes** in the Confirm file overwrite window to overwrite the existing database definition.
b. Enter values for the User ID and Password to connect to the database, and click **Next**.

9. Select one or more database schemas from the list and click **Next**.
10. Select the elements that you require on the Database Elements page. You can select any option, in addition to **Tables**, on the Database Elements page.
    a. Select **Views** to see all the database views in the Data Project Explorer
    b. Select **Routines** to add stored procedures and user defined functions to the database definition file.

    If you select other additional options, the database definition files that you create contain more information than the Compute, Database, or Mapping nodes require.
11. Click **Finish**.
12. Add the data design project as a reference to the message flow project:
    a. Right-click the message flow project, and click **Properties**.
    b. Click **Project References**, and select the data design project from the list to add as a referenced project.
    c. Click **OK**.

Results

A new database definition file is added to your data design project. The database definition file name has the following format:`<database>.dbm`. Database definition files are associated with the Data Project Explorer view and the Data Source Explorer view. Tools are available in these views for working with your databases.

What to do next

Database definition files in the WebSphere Message Broker Toolkit are not automatically updated. If you make a change to your database, you must re-create the database definition files.

Importing large databases to the WebSphere Message Broker Toolkit:

Use the Data Source Explorer view of the WebSphere Message Broker Toolkit to select which options you require when you import large databases.

About this task

You must have a database definition defined in the WebSphere Message Broker Toolkit to create database mappings. The following steps tell you how to import specific element definitions into your database definition.

Complete the following steps to import specific database definitions to the WebSphere Message Broker Toolkit:

Procedure

1. Open the Data perspective of the WebSphere Message Broker Toolkit.
2. In the Data Source Explorer view select **Connections**, and right-click to start the New Connection wizard.
3. To create a connection:
   a. Optional: You can enter a custom value for the Connection Name if you clear **Use default naming convention**.
   b. Enter values for the Connection to the database, for example, Database name, Host name, and Port number.
   c. Enter values for the user ID and password to connect to the database. Click **Test Connection** to verify that the settings you have selected for your database. The default Port number for a DB2 database is 50000. If the connection fails, enter other values such as 50001, 50002, and so on, for the Port number, and test the connection again.
   d. Click **Next**. An error is generated if any of the connection details are wrong.
4. On the Filter panel, enable the filter and select the schemas that you require.
5. Click **Finish** to complete the creation of a database connection.
6. In the Data Source Explorer view, expand the folders of the new Database Connection to locate the database elements for which you need definitions.
7. Select the folder that contains the elements you require, right-click, and select **Filter**.
8. On the Filter panel, enable filtering and select the elements that you require.
9. Click **Finish**. The Data Source Explorer view now shows only the elements that you selected.
10. Switch to the Broker Application Development perspective.

11. Click **File** > **New** > **Database Definition**. The New Database Definition File wizard is displayed.
12. Select an existing data design project, or click **New** to create a data design project.
13. Select the database type and version that you want to connect to from the **Database and Version** list. Ensure that you select a database from the list that is supported by WebSphere Message Broker; you can use this wizard in a shell-share environment with other Rational products that support other databases or versions.

    For a list of databases supported by the broker, see "Supported databases" on page 3591.
14. Click **Next**.
15. On the Select Connection panel, select **Use an existing connection**. This connection is the one that you created in steps 1 on page 2280 to 9 on page 2280 earlier.
16. Click **Next**.
17. Enter values for the user ID and password to connect to the database, and click **Next**.
18. Select one or more database schemas from the list and click **Next**.
19. Select the elements that you require on the Database Elements page. You can select any option, in addition to **Tables**, on the Database Elements page.
    a. Select **Views** to see all the database views in the Data Project Explorer
    b. Select **Routines** to add stored procedures and user-defined functions to the database definition file.
20. Click **Finish**.
21. Add the data design project as a reference to the message flow project:
    a. Right-click the message flow project, and click **Properties**.
    b. Click **Project References**, and select the data design project you created, from the list, to add as a referenced project.
    c. Click **OK**.
22. Carry out the following procedure, to ensure that only the elements you selected appear in a map:
    a. Drag a Mapping node node onto a flow editor.
    b. Double-click the Mapping node node to bring up the map creation dialog.
    c. Follow the prompts to create the map, selecting the data source that references your new database definition as either a source or target.

What to do next

Database definition files in the WebSphere Message Broker Toolkit are not automatically updated. If you change your database, you must re-create the database definition files.

Creating a message map file from a DataInsert node:

You can use a DataInsert node to create mappings to insert new data into a database from a message, another database or both.

Before you begin

Before creating a message map file, ensure you do the following:

1. Create a message flow project
2. Create a message flow
3. Define message flow content that includes a DataInsert node
4. Create a database definition

About this task

To create a message map (.msgmap) file from a DataInsert node:

Procedure

1. From the Broker Application Development perspective, open your message flow, right-click your DataInsert node, and click **Open Map**. The New Message Map for Data Insert Node wizard opens.
2. Select the combination of Messages, Data Sources or both that you want to use as sources for your map from Select map sources.

   If you cannot find the Messages or Data Sources that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.

3. From the Select map targets pane, select the tables under Table Inserts into which you want to insert new data. The tables that you select are added to the new message map as targets.
4. Select **OK** to create the new message map. The "Message Mapping editor" on page 4981 opens with the selected sources and targets.

What to do next

After you have created a message map file, you can now configure the message mappings.

Related concepts:

"Message Mapping editor" on page 4981

Creating a message map file from a DataUpdate node:

You can use a DataUpdate node to create mappings to update existing data in a database from a message, another database or both.

Before you begin

Before creating a message map file, ensure you do the following:

1. Create a message flow project
2. Create a message flow
3. Define message flow content that includes a DataUpdate node
4. Create a database definition

About this task

To create a message map (.msgmap) file from a DataUpdate node:

Procedure

1. From the Broker Application Development perspective, open your message flow, right-click your DataUpdate node, and click **Open Map**. The New Message Map for Data Update Node wizard opens.
2. Select the combination of Messages, Data Sources or both that you want to use as sources for your map from Select map sources.

   If you cannot find the Messages or Data Sources that you expect, select the **Show all resources in workspace** check box.
3. From the Select map targets pane, select the tables under Table Updates in which you want to update data. The tables that you select are added to the new message map as targets.
4. Select **OK** to create the new message map. The "Message Mapping editor" on page 4981 opens with the selected sources and targets.

What to do next

After you have created a message map file, you can now configure the message mappings.

Creating a message map file from a DataDelete node:

You can use a DataDelete node to create mappings to delete data from a database based on information from an input message, another database or both.

Before you begin

Before creating a message map file, ensure you do the following:

1. Create a message flow project
2. Create a message flow
3. Define message flow content that includes a DataDelete node

4. Create a database definition

About this task

To create a message map (.msgmap) file from a DataDelete node:

Procedure

1. From the Broker Application Development perspective, open your message flow, right-click your DataDelete node, and click **Open Map**. The New Message Map for Data Delete Node wizard opens.
2. Select the combination of Messages, Data Sources or both that you want to use as sources for your map from Select map sources.

   If you cannot find the Messages or Data Sources that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.
3. From the Select map targets pane, select the tables under Table Deletes from which you want to delete data. The tables that you select are added to the new message map as targets.
4. Select **OK** to create the new message map. The "Message Mapping editor" on page 4981 opens with the selected sources and targets.

What to do next

After you have created a message map file, you can now configure the message mappings.

Change database operation of a message map:

If you have created a message map that performs a database operation such as data insert, data update or data delete on a database table you might want to change the database operation that the map performs.

About this task

You might also have created a database mapping by dragging a table from the Broker Development view onto a message map and want to change the default insert operation to another database operation.

To change the database operation of a database table in your message map:

Procedure

1. From the Broker Application Development perspective, open your message map.
2. Right-click on the target database table in the target pane and click **Change Database Operation**. The Select Database Operation dialog is displayed.
3. Select the database operation you want to perform on the selected table:
   - Insert
   - Update
   - Delete
4. Click **OK** to change the database operation on the selected table.

What to do next

If you change the database operation of your message map to or from data delete you must re-create any mappings to your target database columns.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Mapping from a message and database:

You can create a message map that uses both a message and a database as a source.

Before you begin

Before creating a message map file, ensure you complete the following steps:

1. Create a message flow project
2. Create a message flow
3. Define message flow content
4. Create database definitions

About this task

The following instructions describe how to specify a message and a database as the data source.

Procedure

1. Right-click a node that supports mapping, such as the Mapping node, and click **Open Map**.
2. Follow the on-screen instructions to complete the New Message Map wizard:
   a. Select the combination of Messages and Data Sources that you want to use as sources for your message map from Select map sources.
   b. Select the combination of Messages, Data Targets or both that you want to use as targets for your map from Select map targets.
3. Perform mapping as usual from the source message.
4. Follow the guidance in "Mapping a target element from database tables" on page 2288 to create the mappings from a source database to the target message or database table.
5. Follow the guidance in "Mapping a target element from database stored procedures" on page 2290 to create the mappings from a database stored procedure to the target message or database table.
6. Follow the guidance in "Mapping a target element from database user-defined functions" on page 2292 to create the mappings from a database user-defined function to the target message or database table.

"Mapping a target element from database user-defined functions" on page 2292
Use an Oracle database user-defined function as a source in a Mapping node.
"Creating a database to database mapping" on page 2295
You can create a message map that uses a database as both the source and target. The contents of the source database can be used to interact with the same or a different database table. The message map can also include a message as a source, but a message is not required. You can, for example, use a timer node to schedule regular updates to a database.

Mapping a target element from database tables:

To map a target element from a database table, set up the Mapping node to retrieve the relevant rows from the database and populate the message target elements with values from database.

About this task

You can add a database as a source for a mapping in several ways, as described in "Adding a database as a source or target" on page 2274. After you have added a database to the mapping, the Spreadsheet pane contains a $db:select entry in the Map Script column. By default, its value is fn:true(), which means that all rows are retrieved from the database table. In database SQL, you can restrict the number of rows by adding a WHERE clause to a database call. In the Mapping node, the equivalent method of restricting the number of selected rows is to use a $db:select expression.

Complete the following steps to restrict the number of rows that are selected in a Mapping node:

Procedure

1. In the Spreadsheet pane, click the $db:select row. fn:true() is entered in the Edit pane.
2. Edit the expression in the Edit pane to specify the correct condition for the database call. To help you achieve this condition, you can:
   a. Select all database columns that are relevant to the rows that are retrieved, and drag them from the Source pane to the Edit pane. These database column names are used in an SQL WHERE clause.
   b. Select all source message elements with values that are relevant to the rows that are retrieved, and drag them from the Source pane into the Edit pane. These values can be matched against the selected database columns.
   c. Click **Edit** > **Content Assist** to open Content Assist.
   d. From Content Assist, select the functions to apply to message elements in the database call.

Results

The following example of a $db:select entry shows a database column that is matched against a constant or a field from an input message:

```
$db:select_1.BROKER50.JDOE.RESOLVEASSESSOR.ASSESSORTYPE = 'WBI' or $db:select_1.BROKER50.JDOE.
RESOLVEASSESSOR.ASSESSORTYPE = $source/tns:msg_tagIA81CONF/AssessorType
```

A $db:select entry retrieves all qualifying rows, therefore more than one row might be retrieved. By default, the selection is treated as repeating, which is indicated by the 'for' row below $db:select in the Spreadsheet pane.

After you have configured the $db:select, populate the target message from the database by dragging the database column from the Source Pane to the message element in the Target pane. The mapping is indicated by a line between the database column in the Source pane and the element in the Target pane. An entry for this map in XPath format also appears in the Spreadsheet pane. Triangular icons are displayed in the Source and Target panes next to objects that have been mapped.

You can map to an element within a View, the name of which is annotated with `(read-only view)`.

What to do next

Using database selects

By default, a $db:select entry is accompanied by a 'for' row that iterates over the select result set. Ensure that your 'for' row is in the correct position for your mapping. The behavior of the map is determined by the position of the 'for' row in the Spreadsheet pane. For example, if the results of the $db:select statement matched five rows in the database, and the 'for' row is the parent of the $target entry in the Spreadsheet pane, five complete messages are generated by the mapping node. If the 'for' row is positioned within the message body, one message is generated with five repeating elements in the message body.

A mapping can contain multiple 'for' rows, associated with a $db:select entry, that perform a single database select and iterate over the results multiple times. For example, multiple 'for' rows can be used in conditional mappings, where an individual 'for' row is used with a 'condition' or an 'else'.

A 'for' row is not always required and can be deleted in the following circumstances:

- If the database select returns only one row.
- If you use an aggregate XPath function on the select results.

  For example: fn:sum or fn:count.

All $db:select expressions must be within the scope of the $db:select entry in the Spreadsheet pane, meaning that each one must be a descendant of the select statement. If a $db:select expression is out of scope, the Message Mapping editor moves the $db:select entry to a position where the $db:select expression is in scope. Ensure that the position of the $db:select entry is correct for your message mapping.

Database table join

Database table join is supported for tables within the same database. For example, consider the following two tables where PRODUCT_ID and PART_NUMBER match.

```
Table    Column        Row 1    Row 2    Row 3      Row 4
ORDER    PRODUCT_ID    456      456      345        123
         QUANTITY      100      200      300        400

PRODUCT  PART_NUMBER   123      456      789        012
         PART_NAME     pen      pencil   paperclip  glue
         PRICE         0.25     0.15     0.02       0.99
```

A $db:select expression with the following syntax joins the tables:

```
$db:select.MY_DB.SCHEMA1.ORDER.PRODUCT_ID=$db:select.MY_DB.SCHEMA2.PRODUCRT.PART_NUMBER
```

The $db:select expression in the example generates the following result set.

```
                Row 1    Row 2    Row 3
PRODUCT_ID      456      456      123
QUANTITY        100      200      400
PART_NUMBER     456      456      123
PART_NAME       pencil   pencil   pen
PRICE           0.15     0.15     0.25
```

You can then use the 'for' row to iterate through the results set in the same way as results from a single table.

Mapping a target element from database stored procedures:

Use a DB2 or Oracle database stored procedure as a source in a Mapping node.

Before you begin

Before you start:

You must include the database stored procedure in your database definition. See "Adding database definitions to the WebSphere Message Broker Toolkit" on page 2278. Only DB2 and Oracle databases are supported for this task.

About this task

To map a target element from a database stored procedure, set up the Mapping node to:

- run the stored procedure to retrieve the relevant rows from the database
- populate the message target elements with values from the database

Complete these steps to map a target element from a stored procedure:

Procedure

1. Add a stored procedure as a source for the mapping, as described in "Adding a database as a source or target" on page 2274. After you have added a stored procedure to the mapping, the Source pane and the Spreadsheet pane contain $db:proc entries. These $db:proc entries contain details of the parameters used by the stored procedure. For each parameter it shows its name, its mode (either IN, INOUT, or OUT), and its data type.

   The $db:proc entry in the Spreadsheet pane also contains a 'for' row. By default, the position of the 'for' row in the $db:proc entry indicates that when there is more than one record in the result set, the output message body contains repeating elements. If you want a separate message to be output for each record in a result set, move the $target element in the Spreadsheet pane below the 'for' row.

   If you are using a DB2 stored procedure which specifies a maximum number of result sets, the Source pane also includes a list of result sets. If you are using an Oracle stored procedure which specifies ref cursor parameters of mode INOUT or OUT, the Mapping node treats them as named result sets rather than parameters. The Mapping node does not support ref cursor parameters of mode IN.
2. If your stored procedure has parameters of mode IN or INOUT provide values for each of them:
   a. Type an expression in the **Value** field next to the parameter in the Spreadsheet pane.
   b. Select the parameter in the Spreadsheet pane, drag an element from the source message to the Edit pane, and press Enter.
3. If your stored procedure sets a return value, right-click on the $db:proc entry in the Source pane and select **Toggle Add/Remove Stored Procedure Return Value**. An element called ReturnValue of type INTEGER is added to the Source pane.

   DB2 on distributed systems returns SQLCODE if the stored procedure does not set a return value.

   DB2 on z/OS and Oracle stored procedures do not set a return value.
4. For each result set that your stored procedure returns, define the columns it contains:
   a. Right-click on the result set entry in the Source pane and select **Add or Remove Result Set Columns**. The Add or Remove Result Set Columns window opens.
   b. (Optional) Select an item from the **Restore previous settings from** list. The **Result set columns** list is replaced.
   c. (Optional) Select columns in the **Available database table columns** list, and add them to the **Result set columns** list.

d. (Optional) Type a column name in the **New column** field, and add it to the **Result set columns** list. Use this method to add calculated columns that are named in the stored procedure.

e. (Optional) Change the name in the **Save current settings to** field that is used to save the columns shown in the **Result set columns** when you click **Finish**. The settings are saved in the `\.metadata` directory. You can retrieve these settings in another message map, as described in step 4a. If you do not change the default name the settings are automatically retrieved when the stored procedure is used in another message map.

Mapping a target element from database user-defined functions:

Use an Oracle database user-defined function as a source in a Mapping node.

Before you begin

Before you start:

You must include the database user-defined function in your database definition. See "Adding database definitions to the WebSphere Message Broker Toolkit" on page 2278. Only Oracle databases are supported for this task.

About this task

To map a target element from a database user-defined function, set up the Mapping node to:

- run the user-defined function to retrieve the relevant rows from the database
- populate the message target elements with values from the database

Complete these steps to map a target element from a user-defined function:

Procedure

1. Add a user-defined function as a source for the mapping, as described in "Adding a database as a source or target" on page 2274. After you have added a user-defined function to the mapping, the Source pane and the Spreadsheet pane contain $db:func entries. These $db:func entries contain details of the parameters used by the user-defined function. For each parameter it shows its name, its mode (either IN, INOUT, or OUT), and its data type.

   The $db:func entry in the Spreadsheet pane also contains a 'for' row. By default, the position of the 'for' row in the $db:func entry indicates that when there is more than one record in the result set, the output message body contains repeating elements. If you want a separate message to be written for each record in a result set, move the $target element in the Spreadsheet pane below the 'for' row.

   If you are using an Oracle user-defined function which specifies ref cursor parameters of mode INOUT or OUT, the Mapping node treats them as named result sets rather than parameters. The Mapping node does not support ref cursor parameters of mode IN.

   If you are using an Oracle user-defined function which returns a value of ref cursor data type, the Mapping node treats it as a named result set.
2. If your user-defined function has parameters of mode IN or INOUT provide values for each of them:
   a. Type an expression in the **Value** field next to the parameter in the Spreadsheet pane.
   b. Select the parameter in the Spreadsheet pane, drag an element from the source message to the Edit pane, and press Enter.
3. For each result set that your user-defined function returns, define the columns it contains:
   a. Right-click on the result set entry in the Source pane and select **Add or Remove Result Set Columns**. The Add or Remove Result Set Columns window opens.
   b. (Optional) Select an item from the **Restore previous settings from** list. The **Result set columns** list is replaced.
   c. (Optional) Select columns in the **Available database table columns** list, and add them to the **Result set columns** list.
   d. (Optional) Type a column name in the **New column** field, and add it to the **Result set columns** list. Use this method to add calculated columns that are named in the user-defined function.
   e. (Optional) Change the name in the **Save current settings to** field that is used to save the columns shown in the **Result set columns** when you click **Finish**. The settings are saved in the`\.metadata` directory. You can retrieve these settings in another message map, as described in step 3a. If you do not change the default name the settings are automatically retrieved when the user-defined function is used in another message map.

Deleting data from a database with a mapping node:

You can use a DataDelete or Mapping node to delete data from a database, based on information from an input message, another database or both.

Before you begin

You must do the following before you can delete data from a database using a mapping node:

1. Create a message flow project
2. Create a message flow
3. Define message flow content that includes a DataDelete or a Mapping node
4. Create a message map file from a DataDelete node or Create a message map file from a Mapping node

About this task

You cannot create mappings to delete data from a database by dragging from the source to the target. Instead, you select rows to delete based on the content of the source. You can use an expression to match the content of the source to the target field, for example, use the following instructions to delete all rows in the database that match the content of a field from the input message:

Procedure

1. Right-click your DataDelete or Mapping node, and click **Open Map**. The "Message Mapping editor" on page 4981 opens with your selected sources and targets.
2. Select `$db:delete` in the Spreadsheet pane.
3. Drag the appropriate source element from the message in the Source pane to the Edit pane. For example, `$source/shipTo/accNum`.
4. Drag the appropriate target database field from the Target pane to the Edit pane. For example, `$db:delete.SAMPLE.MYSCHEMA.CUSTOMER.CONTACT_ID`.
5. Change the expression in the Edit pane to set the target field to be equal to the source element. For example, `$source/shipTo/accNum = $db:delete.SAMPLE.MYSCHEMA.CUSTOMER.CONTACT_ID`.

What to do next

You can use conditional mappings such as If statements to create more complex mappings that define which data to delete from a database. You can also use conditional statements in a Mapping node to perform different database operations depending on the content of the input message. For example, you can add a Table Inserts target, a Table Updates target and a Table Deletes target to a message map, then use conditional statements to define which of the operations to perform.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

"DataDelete node" on page 4382
Use the DataDelete node to interact with a database in the specified ODBC data source.

Creating a database to database mapping:

You can create a message map that uses a database as both the source and target. The contents of the source database can be used to interact with the same or a different database table. The message map can also include a message as a source, but a message is not required. You can, for example, use a timer node to schedule regular updates to a database.

Before you begin

Before creating a message map file with a database to database mapping, ensure you do the following:

1. Create a message flow project

2. Create a message flow
3. Define message flow content
4. Create database definitions

About this task

To create a database to database mapping:

Procedure

1. Right-click a node that supports database mapping in your flow, such as the Mapping node, and click **Open Map**. The New Message Map wizard opens for your node.
2. Select the Data Sources and any Messages that you want to use as sources for your map from **Select map sources**.

   If you cannot find the Messages or Data Sources that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.
3. From Select map targets expand the database operation that you want to perform. You can select from the following database operations:
   - Table Inserts
   - Table Updates
   - Table Deletes
4. Select the database tables that you want to map.

   You can create a message map that performs a combination of database inserts, updates or deletes by selecting database tables from different database operations. For example, if you want to create a conditional mapping that updates data in a database if it already exists, but inserts the data if it does not already exist in the database, you can select the same database table under Table Inserts and Table Updates.
5. Select **OK** to create the new message map. The "Message Mapping editor" on page 4981 opens with the selected sources and targets.

What to do next

After you have created a message map file, you can now configure the message mappings.

Storing a BLOB message in a database table using a message map:

Use the Message Mapping editor to create a bit stream from a BLOB message, and store it in a database table.

Before you begin

Before you start:

Create a mapping; see "Creating a message mapping file from a Mapping node" on page 2236.

About this task

Take the following steps:

Procedure

1. In the Target pane, right-click the column that will store the bitstream, and select **Enter Expression** from the menu.
2. In the Edit pane, type `esql:asbitstream()`. You can use content assist; `asbitstream` is a *Field function*.
3. Drag the source field, for example `$source/po:purchaseOrder`, to the Edit pane, placing it between the parentheses. The entry in the Edit pane looks like this:

   ```
   esql:asbitstream($source/po:purchaseOrder, 'purchaseOrder',
   'PurchaseOrder', 'XML1', 0, 0, $esql:FolderBitStream)
   ```

   Alternatively, you can use content assist to select the `esql:asbitstream` function. In the Edit pane press Ctrl+Space to display a list of available functions and associated parameters. The `asbitstream` function is an ESQL Field function. The function can take other parameters; see "ESQL mapping functions" on page 4998.

   When you move the cursor out of the Edit pane, or press Enter, the mapping is displayed between the fields in the Source and Target panes.

Related tasks:

Some predefined ESQL functions are available for use with message maps.

Mapping from a BLOB field in a database table to an output message:

Use the Message Mapping editor to parse a bit stream from a field in a database table into a folder in a target message.

Before you begin

Before you start:

Create a mapping; see "Creating a message mapping file from a Mapping node" on page 2236.

About this task

Take the following steps:

Procedure

1. Right-click the element in the target pane, and select **Enter Expression** from the menu.
2. In the Edit pane, type `msgmap:element-from-bitstream()`.
3. Drag the field from the database table to the Edit pane, placing it between the parentheses, for example:

   ```
   msgmap:element-from-bitstream($db:select.RESERVDB.USER.XMLFLIGHTTB.FLIGHTDATE)
   ```

   Alternatively, you can use content assist to select the `msgmap:element-from-bitstream` function. In the Edit pane press Ctrl+Space to display a list of available functions and associated parameters. The function can take other parameters; see "Predefined mapping functions" on page 5007. For example:

   ```
   msgmap:element-from-bitstream($db:select.RESERVDB.USER.XMLFLIGHTTB.FLIGHTDATE,
   'ReserveMessageSet', 'FlightMessage', 'XML1', 0, 0, $esql:FolderBitStream)
   ```

   When you move the cursor out of the Edit pane, or press Enter, the mapping is displayed between the fields in the Source and Target panes.

Creating and calling submaps and subroutines:

Use submaps, ESQL subroutines, or both, to map source elements to target elements.

About this task

The following topics describe how to work with submaps and ESQL subroutines:

Procedure

- "Creating a new submap"
- "Creating a new submap for a wildcard source" on page 2300
- "Creating a submap to modify a database" on page 2301
- "Converting a message map to a submap" on page 2302
- "Converting an inline mapping to a submap" on page 2304
- "Calling a submap" on page 2305
- "Calling a map from ESQL" on page 2306
- "Calling an ESQL routine" on page 2308
- "Creating and calling your own user-defined ESQL routine" on page 2308

Related concepts:

"Message mapping overview" on page 2229
Message mappings define the blueprint for creating a message, where the created message is known as the target message.

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Creating a new submap:
About this task

This topic describes how to create a new submap. There are three ways to create a new submap:

Procedure

- **Using File > New > Message Map**
  1. From the Broker Application Development perspective, click **File** > **New** > **Message Map**. The New Message Map wizard opens.
  2. Specify the project name and the name for the new submap.
  3. Specify that the new map is a submap by selecting the option: **Submap called by another map**.
  4. Select the combination of Message Components or Data Sources that you want to use as sources for your map from **Select map sources** and select the combination of Message Components or Data Targets that you want to use as targets for your map from **Select map targets**.

     If you cannot find the Message Components, Data Sources or Data Targets that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.
  5. Click **Finish**.

  The new submap opens in the Message Mapping editor.
- **Using Create new submap**
  1. From the Broker Application Development perspective, open the message map for the required node.
  2. In the Source pane, expand the tree and select the source.
  3. In the Target pane, expand the tree and select the target.
  4. Right-click either the source or target, then click **Create New Submap**.

The new submap opens in the Message Mapping editor. If the original map file was called `simple_mapping.msgmap`, the new submap is called `simple_mapping_submap0.msgmap`.

- **Using Convert to submap**
  1. From the Broker Application Development perspective, open the message map.
  2. Select one of the following types of submap to create a new submap from an inline mapping:
     - Element statement that maps a global element or an element of global type
     - Attribute statement that maps either a global attribute or an attribute of a global type
     - Database insert statement
     - Database update statement
     - Database delete statement
  3. Right-click the mapping statement that you want to convert to a submap or database submap in the Script pane, and click **Convert to submap**. A new submap is created and a statement is added to the original message map to call the new submap.

  The new submap opens in the Message Mapping editor. If the original map file was called `simple_mapping.msgmap`, the new submap is called `simple_mapping_submap0.msgmap`.

Use submaps, ESQL subroutines, or both, to map source elements to target elements.

Creating a new submap for a wildcard source:

You can map a wildcard value in the source to a wildcard value in the target.

About this task

You might expect a wildcard in a Mapping node for example, when you are using a SOAP message (where the Body element contains a wildcard). This type of wildcard represents the payload of the message, where the payload is a message that is defined elsewhere in the message set. The submap can involve from 0 to n source wildcards and 0 or 1 target wildcards.

The "Message Mapping editor" on page 4981 shows three kinds of wildcard, all of which allow you to create a submap:

Mapper construct	Message model construct	Choose concrete item for submap
Wildcard element	Wildcard element	Global element
Wildcard attribute	Wildcard attribute	Global attribute
Message with Wildcard Message child	Group with `Composition` of Message and `Content Validation` of Open or Open Defined	Message

Procedure

1. Switch to the Broker Application Development perspective.
2. Open the message map for the required node.
3. In the Source pane, expand the tree and select the source wildcard.
4. In the Target pane, expand the tree and select the target wildcard.
5. Right-click either the source or the target wildcard, and click **Create new submap**. The Wildcard Specification wizard opens.
6. From the Wildcard Specification wizard, select the concrete item that will replace the source wildcard, according to the values shown in the table at the beginning of this topic.
7. Click **Next**.
8. From the Wildcard Specification wizard, select the concrete item that will replace the target wildcard, according to the values shown in the table at the beginning of this topic.
9. Click **Finish**.
10. Click **OK**. The submap opens in the Message Mapping editor.
11. From the submap, map the source message elements to the target message elements as required.
12. Click **OK**.

Related concepts:

"Mapping node" on page 4994
The Mapping node has one or more mappings that are stored in message map files (with a `.msgmap` file extension). These files are configured using the Message Mapping editor.

Use submaps, ESQL subroutines, or both, to map source elements to target elements.

Creating a submap to modify a database:

About this task

Use the Create New Database Submap wizard to create a submap to modify a database.

You must have an existing message map from which to call the submap. The following steps describe how to create a submap to modify a database:

Procedure

1. In the Broker Application Development perspective, open the calling message map.
2. In the Source pane, right-click the message component containing the fields to be used to modify the database and click **Create New Database Submap**. The source can be a wildcard, an element, or an attribute. The Create New Database Submap wizard opens.
3. If the selected source is a wildcard, select a message or message component for the source wildcard from **Select a defined item to replace the source wildcard** pane. If you cannot find the message components that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.
4. From **Select database submap targets** expand the database operation that you want to perform. You can select from the following database operations:
   - **Table Inserts**
   - **Table Updates**
   - **Table Deletes**
5. Select the database tables that you want to map. If you cannot find the Data Targets that you expect, select the **Show all resources in workspace** check box.
6. Click **OK**. A new submap is created with the selected message or message component in the Source pane, and the database table in the Target pane. In the calling message map `$db:call` is added to the Target pane.

What to do next

After you have created the submap file, configure the message mappings for the database table.

The Mapping node has one or more mappings that are stored in message map files (with a `.msgmap` file extension). These files are configured using the Message Mapping editor.

The Broker Application Development perspective is the default perspective that is displayed when you start the WebSphere Message Broker Toolkit.

Converting a message map to a submap:

About this task

You can convert between a message map and a submap in order to change the usage of the map. You might convert a message map to a submap because you want to reuse the same mappings for multiple nodes. Use the following instructions to convert a message map to a submap for each message in the message map.

Procedure

1. From the Broker Application Development perspective right-click your message map and click **Open**.
2. Right-click `$source` in the Source pane and select **Add or Remove Headers and Folders**. The Add or Remove Headers and Folders dialog opens.
3. Select **No folders (map body element only)**. Any previously selected headers or folders are cleared.
4. Click **OK** to remove the headers and folders.
5. Repeat steps 2 to 4 to select to map body element only from your target message under `$target` in the Target pane.
6. Delete target map statements for existing mappings to properties, message headers or other folders such as LocalEnvironment. These mappings are flagged with warning messages after the headers are removed.
7. Remove the reference to the new submap from any mapping nodes. If a reference to the submap exists in the Mapping Routine property of a mapping node an error message is displayed on the message flow.
8. Save the submap, and check for any broken references as indicated by errors or warnings in the Problems view.

Results

The submap is now ready to be used. See calling a submap for more information.

Example

To convert a submap to a message map, click **Add or Remove Headers and Folders** for the source and target messages, and select to map **Selected headers**. You must ensure that no other maps call the changed map, check for errors in the Problems view to indicate this problem. See mapping headers and folders for more information about mapping headers, Properties and the LocalEnvironment.

Converting an inline mapping to a submap:

To change the usage of a map, you can convert between inline mappings in a message map and a submap.

About this task

You might convert parts of an existing message map to a submap because you want to reuse the same mappings for multiple nodes. You can convert inline mappings to submaps from messages or databases. You must select one of the following types of statement to create a submap or a database submap:

- Element statement that maps a global element or an element of global type
- Attribute statement that maps either a global attribute or an attribute of a global type
- Database insert statement
- Database update statement
- Database delete statement

The target that is added to the new submap is the global element, attribute, type, or database insert, update, or delete that you select. The source that is added to the new submap is the appropriate global element or type from the source from the selected mappings that are included in the submap. If mappings included in the selected statement do not reference any source, only a target is added to the submap. If the source contains a database select that is not referenced by any other part of the original message map, a database select is added as a source to the submap, and removed from the original message map. However, if the source contains a database select that is referenced by any other part of the original message map, the original message map retains the select, and the submap performs a separate select. If you do not want to perform two database select operations, do not use a database submap under these conditions.

Use the following instructions to convert inline mappings in a message map to a submap or database submap:

Procedure

1. From the Broker Application Development perspective right-click your message map and click **Open**.
2. Right-click the mapping statement that you want to convert to a submap or database submap in the Script pane, and click **Convert to submap**. A new submap is created and a statement is added to the original message map to call the new submap.

Results

The submap is now ready to be used.

Calling a submap:
About this task

Use the Call Existing Submap wizard to call a submap. The submap must already be in the workspace.

If a submap does not exist, use the **Create New Submap** menu option to create a submap that you can call. This action creates the new submap in the same folder as the calling map. It also allocates a default map operation name to the new submap. If the source or target in the calling map is a wildcard, a wizard allows you to choose a replacement element.

You can also map from a wildcard to a wildcard.

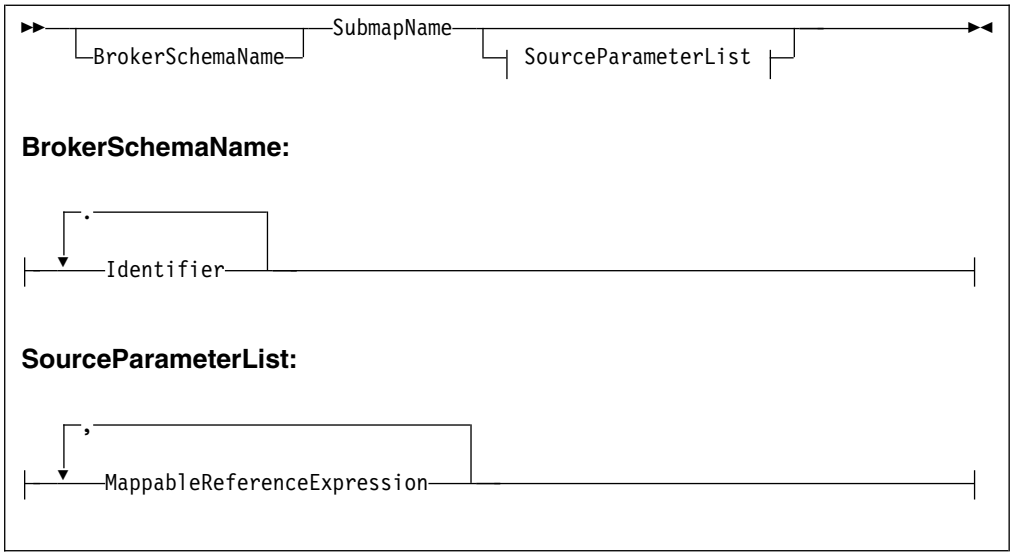
The following steps describe how to call a submap:

Procedure

1. In the Broker Application Development perspective, open the calling map.
2. In the Source and Target panes, select one or more sources and one target. Any of the sources or the target can be a wildcard, an element, or an attribute.
3. Click **Map** > **Call Existing Submap**. The Call Existing Submap wizard opens.
4. Complete the wizard, following the on-screen instructions.

Results

The call to the submap takes the following format:



Only source parameters appear in the call and only message parameters appear in the list.

Calling a map from ESQL:

You can use the Message Mapping editor to perform mappings to a certain level of complexity. To create even more complex mappings, use ESQL. ESQL is particularly suitable for interacting with databases.

Before you begin

If a map does not already exist, create one.

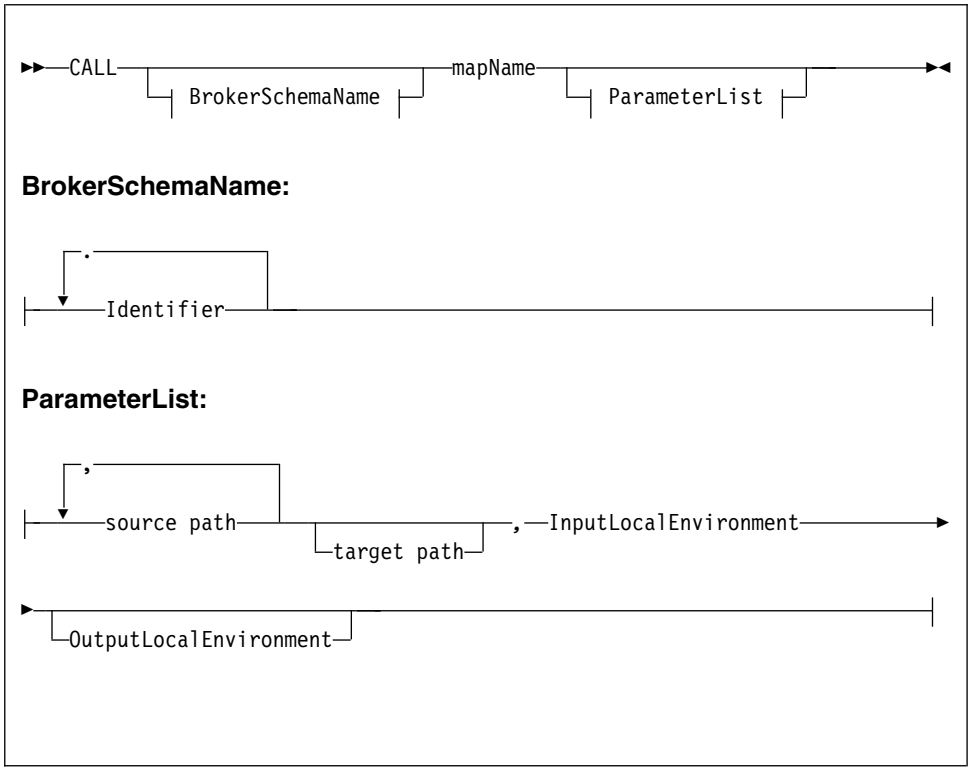
About this task

The following steps describe how to call a map (which can be a submap) from ESQL. Calling a map from ESQL uses different parameters to when you call a submap from another map due to this extra level of complexity (when calling a map from ESQL, the two local environment parameters are added at the end of the CALL statement).

Procedure

1. Right-click a node that supports ESQL and click **Open ESQL**. The ESQL file opens for that node.
2. Add a CALL statement to call a map. Alternatively, press Ctrl+Space to access ESQL content assist, which provides a drop-down list that includes the map name and expected parameters.

   The following syntax diagram demonstrates the CALL statement:



Results

Notes:

1. Only source parameters appear in the call and only message parameters appear in the list.
2. If the map builds a message target, include the `target path` and `OutputLocalEnvironment` parameters. If the map does not build a message target (for example, if the map interacts with a database), these two parameters do not appear.

Calling an ESQL routine:

About this task

To call an existing ESQL routine from a mapping, select the routine from the Call Existing ESQL Routine wizard. The ESQL routine must already exist in the workspace.

Procedure

1. Switch to the Broker Application Development perspective.
2. Open the required mapping.
3. In the Source pane, select the required source.
4. In the Target pane, select the required target.
5. Right-click either the Source or Target pane and click **Call ESQL Routine**. The Call ESQL routine wizard opens.
6. Select the routine where the parameters and return types match the source and target selection.
7. Click **OK**.

Creating and calling your own user-defined ESQL routine:

For complex mappings, you can create user-defined ESQL functions that can be called from the Message Mapping editor.

About this task

This topic describes how to create a user-defined ESQL function, and how to use it in an existing message map.

Procedure

1. Create a new ESQL file, or open an existing ESQL file.
2. Enter your ESQL function in the ESQL file. Ensure that you do not enter the ESQL in any existing modules.
3. Save the ESQL file.
4. Right-click your Mapping node node, and click **Open Map** to open your message map in the Message Mapping editor.
5. Select the target that you want to generate using your ESQL function from the appropriate target message or target database table.
6. In the Edit pane, enter the expression to call the ESQL function and any parameters to pass to the function. For example:

   ```
   esql:concatValues($source/Pager/Text, ' Powered by IBM.')
   ```

   Where `concatValues` is the name of the user-defined ESQL function and the following parameters:

   - `$source/Pager/Text` is a field in the source message
   - `' Powered by IBM.'` is text

   The following code is the ESQL used for the user-defined ESQL function in the preceding example:

   ```
   CREATE FUNCTION concatValues(IN val INTEGER, IN str CHAR) RETURNS CHAR
    BEGIN
     return str || ' plus int val ' || CAST(val AS CHAR);
    END;
   ```

   You can also use **Edit** > **Content Assist** to select user-defined ESQL functions. The user-defined ESQL functions are located at the end of the list of ESQL functions.
7. Save the message map file by clicking **File** > **Save**.

Calling a Java method:

To call an existing Java method from a mapping node, select the method from the Call Existing Java Method wizard, or enter an XPath expression in the Edit pane.

Before you begin

See "Message mapping tips and restrictions" on page 2314 for information about the types of methods that are available through the wizard, and through content assist.

Using the wizard:
About this task

To use the Call Existing Java Method wizard, take the following steps:

Procedure

1. Switch to the Broker Application Development perspective.
2. Open the required message map.
3. If the method requires input parameters, select one or more fields in the Source pane. Your choice determines which methods are subsequently displayed in the wizard. If you select no source fields, the wizard shows only methods that take no parameter. If you select two fields, the wizard displays only methods that take two parameters, and so on.
4. In the Target pane, select the required target field to be mapped to the return value of the Java method. The target field must be a simple, non-wildcard type.
5. Right-click either the Source or Target pane and click **Call Java Method**. The Call Existing Java Method wizard opens.
6. Select the method, then click **OK**.

Entering an XPath expression:
About this task

You can enter the expression directly, without using content assist. Enter a function call expression, with the following syntax:

```
java:package_name.class_name.method_name (parameters)
```

You can omit the package name if there is no package, or if you are using a default package.

To use content assist, take the following steps:

Procedure

1. Switch to the Broker Application Development perspective.
2. Open the required message map.
3. In the Edit pane, click **Edit** > **Content Assist**.
4. Select **java: (Java Methods)**, then click **Edit** > **Content Assist**. All qualifying Java methods are displayed.
5. Select the method.

6. If the method requires input parameters, drag the appropriate source fields to the method's parameter area. The number of source fields included must match the number of input parameters that the method takes.

Example

This is an example of a method that takes one input parameter:

```
java:mypackage1.MyClass1.myMethod1($source/po:purchaseOrder/po:comment)
```

Separate parameters by a comma:

```
java:mypackage1.MyClass1.myMethod1($source/po:purchaseOrder/name,
  $source/po:purchaseOrder/phone)
```

Transforming a SOAP request message:
About this task

SOAP is an XML-based language defined by the W3C for sending data between applications. A SOAP message comprises an envelope containing:

- An optional header (containing one or more header blocks)
- A mandatory body.

For common envelope message formats, such as SOAP, where both the envelope and the messages that can appear within that envelope have to be modeled, use the Message Mapping editor to select from available messages at points in the model that are defined with **Composition="message"** and **Content validation="open"** or **"open defined"**.

Define the mappings by selecting from the allowed constituent messages. For example, in the case of SOAP, the outer level message is called Envelope and has one mandatory child element called Body, which is modeled with **Composition="message"**. If the permitted content of Body is modeled by separate messages Msg1 ... MsgN, define mappings for each separate message (Envelope.Body.Msg1 to Envelope.Body.MsgN).

For complex type elements with type composition message, the Message Mapping editor follows these rules:

Content validation	Messages offered
Closed	Messages available in any message sets in the workspace
Open defined	Any message defined within the current message set
Open	The Message Mapping editor does not support open or open defined content when the type composition is NOT message

Mapping an embedded message

When you are working with type composition message, with content open or open-defined (and no children defined), map the embedded message using a submap:

Procedure

1. In the main map, expand the levels (both source and target) of Envelope and Body until you find the wildcard message, and select this on both the source and target sides.
2. Right-click either the source or target and click **Create New Submap**.
3. From the dialog box, select a source (for example `reqmess`) and a target (for example `rspmess`).
4. With the submap open in the Message Mapping editor, make the appropriate mappings between the source (`reqmess`) and target (`rspmess`).

Editing a default-generated map manually:

A map that is generated by the Message Mapping editor might not do everything that you want; you can change maps manually to enhance its operation.

About this task

You can edit the structure directly by inserting, moving, copying, pasting, and deleting rows. The pop-up menu provides a list of available editing actions with their keyboard equivalents. Here are some specific operations that you might want to perform:

Procedure

- "Creating message headers"
- "Creating conditional mappings"

Creating message headers:
About this task

When you create a map from a Mapping node, or if you select the option **Message map called by a message flow node** from the New Message Map wizard, the map that is created allows additional elements including WebSphere MQ, HTTP, and JMS headers to be mapped.

If you use a Mapping node for a database to message mapping without specifying a source message, the Message Mapping editor cannot generate an output header for the map file that is created. To ensure that an output header is created, perform one of the following steps:

Procedure

- When you create the message map, add message headers to the target message and ensure that all mandatory fields in the header are set.
- Add an additional source message to the map. The source message must be the same message as the intended target message. You do not need to create any mappings from the source message because the headers from the source message are automatically copied to the output message tree.

Creating conditional mappings:
About this task

When a mapping involves one of the following items:

- Schema choice group
- Derived type element
- Substitution group member
- Wildcard character
- Repeating element

the default mapping that is generated by the Message Mapping editor might be placed under an `if` statement. If the `if` statement is not what you had expected, edit the statements; here are the changes that you can make:

Procedure

- Move statements in or out of an `if/elseif/else` block.
- Reorder `if` and `elseif` statements.
- Create new `elseif` statements.
- Create new `if` statements.

What to do next

See the "Configuring conditional mappings" on page 2265 topic for more information about conditional mappings.

Message mapping tips and restrictions:

Information to help you use message mapping.

These tips assume that you have created a Mapping node within the message flow, opened the Message Mapping editor, and selected both a source and a target message:

- "Mapping a message when the source is a list and the target is a list from source, but with a new entry at the top of the list"
- "Changing the target message domain" on page 2315
- "Overriding the database schema name" on page 2315
- "Mapping batch messages" on page 2316
- "Mapping restrictions" on page 2316
- "Requirements for calling a Java method" on page 2316

Mapping a message when the source is a list and the target is a list from source, but with a new entry at the top of the list

1. Expand the target to display the element for which you want to create a new first instance. This might be a structure or a simple element.
2. Right-click the element and click **If**. An `if` line appears and wraps around the element.
3. Right-click the `if` line and click **Else If**. There are now two entries in the spreadsheet for your element.
4. Set the first of these entries to values of your choice.
5. Right-click the second entry and click **For**. A `for` line appears in the spreadsheet.
6. Set the second entry to the value or values mapped from the source.
7. Set the `for` entry to the looping condition.
8. Click **For**, then drag the source field that represents the loop condition to the Expression editor.

Changing the target message domain

When you first create a mapping, you nominate a message set for the target message. The parser that is associated with the output message is determined by the Message Domain property of the message set. For example, when a message set is first created, the default message domain is MRM. Therefore, the Mapping node generates ESQL with the following format:

```
SET OutputRoot.MRM.Fielda...
```

If you change the runtime parser to XMLNSC, for example, the Mapping node generates ESQL with the following format:

```
SET OutputRoot.XMLNSC.MessageA.FieldA...
```

The parser of the source message is determined by the contents of the MQRFH2 header or by the properties of the input node. The Mapping node generates a target message with a parser that matches the message domain of the message set. The Mapping node supports the following message domains:

MRM
XMLNSC
XMLNS
MIME
SOAP
DataObject
JMSMap
JMSStream
XML
BLOB
IDOC

To change the message domain property of your message set:

1. Open the message set file `messageset.mset`.
2. Change the Message Domain property to a supported domain.
3. Save your message set, and save any message flows and message maps that reference your message set, if they have not already been saved. Saving these files generates updated ESQL for mapping the changed message set.

   If you have made no updates to your flows or message maps after changing the message domain of your message set, you must clean the related message flow projects so that updated ESQL code can be generated:

   a. Select a project and click **Project** > **Clean Project**.
   b. Select **Clean all projects** or **Clean selected projects**.
   c. Click **OK**.
4. Deploy the changed message set.
5. Deploy the message flow that contains the mappings, and test your ESQL in a Compute node and in other nodes to ensure that the message flow still functions as expected.

Overriding the database schema name

To change the database schema name that is generated in ESQL, use the Override Database Schema wizard in the Specify Runtime Schema dialog box. The default name is the schema name of the database definitions that are imported into the

WebSphere Message Broker Toolkit. Use the Specify Runtime Schema dialog box to change the value.

Mapping batch messages

You can configure a message mapping that sorts, orders, and splits the components of a multipart message into a series of batch messages. These components can be messages or objects, and they can have different formats; in this case, each component is converted and the message is reassembled before being forwarded.

1. Use a "RouteToLabel node" on page 4673 in the message flow to receive multipart messages as input.

   The RouteToLabel node is the next node in sequence after the "Mapping node" on page 4571, and causes the flow to jump automatically to the specified label. You can specify a single RouteToLabel value in a splitting map for all maps that output a message assembly. You can also use conditions to set the RouteToLabel value, depending on the values in the source message.
2. Use the "Message Mapping editor" on page 4981 to build maps that transform and propagate batch messages using a single node, without having to define an intermediate data structure.

Multipart messages can also contain repeating embedded messages, where each repeated instance of a message is propagated separately. Embedded messages must be from the same message set as the parent message.

Mapping restrictions

Unless stated explicitly, you can achieve the required functionality by calling an ESQL function or procedure. The following restrictions apply:

- Exceptions cannot be thrown directly in Mapping nodes.
- Self-defined elements cannot be manipulated in Mapping nodes (support for wildcard symbols is limited if the wildcard symbols represent embedded messages).
- The Environment tree cannot be manipulated in the Mapping node.
- User variables cannot be defined or set.
- CASE expressions cannot be emulated; you must use IF ... ELSE.
- Trees cannot be copied from input to output in order to modify elements within the copied tree. For example, the following ESQL cannot be modeled in a Mapping node:

  ```
  SET OutputRoot.MQMD = InputRoot.MQMD; SET OutputRoot.MQMD.ReplyToQ = 'NEW.QUEUE';
  ```

  You must set each field in the structure individually if you intend to modify one or more sibling fields.

Requirements for calling a Java method

All of the following conditions must be satisfied for the method to be shown in the Call Existing Java Method wizard, or in content assist:

- The method must be public static, in a Java project.
- The method must be in a Java project accessible from the project map.
- If the method is inside a JAR file, the JAR file must be in the Java build path. To add a JAR file to the build path:
  1. Right-click the project folder for the project on which you are working, and click **Properties**.

2. Click **Java Build Path** in the left pane.
3. Click the **Libraries** tab.
4. Complete one of the following steps:
   - To add an internal dependency, click **Add JARs**, select the JAR file that you want to add, then click **OK**.
   - To add an external dependency, click **Add External JARs**, select the JAR file that you want to add, then click **Open**. Copy the JAR file to the `shared-classes` directory required. For more details of the `shared-classes` directories available and the effects of each, see "Java shared classloader" on page 2637. If you do not copy the JAR file to a valid `shared-classes` directory, `ClassNotFoundException` exceptions are generated at run time.

- The default scope of the search is all methods in .java source files in the workspace, excluding application libraries and application JAR files in the Java build path, and all the JRE system libraries. To change the scope, change the preferences in the Toolkit:
  1. Click **Window** > **Preferences**.
  2. Expand the **Broker Development** node, then click **Message Map Editor**.
  3. Select and clear the check boxes as appropriate.
- The method must have a return value.
- Return values and Java parameters must be one of the following data types:

Data types	Equivalent XML schema type for mapping	Comments
java.lang.Long	byte, unsignedShort, long, unsignedByte, short, int, unsignedInt	
java.lang.Double	float, double	
java.math.BigDecimal	nonNegativeInteger, negativeInteger, integer, nonPositiveInteger, positiveInteger, unsignedLong, decimal	
java.lang.String	NCName, Name, IDREF, normalizedString, string, anyURI, NOTATION, token, NMTOKEN, language, ID, ENTITIES, QName, ENTITY	
byte[]	base64Binary, hexBinary	
com.ibm.broker.plugin.MbDate	date, gYear, gMonth, gDay, gYearMonth, gMonthDay	
com.ibm.broker.plugin.MbTime	time	
com.ibm.broker.plugin.MbTimestamp	dateTime	
java.lang.Boolean	boolean	
com.ibm.broker.plugin.MbElement	A complex type	Valid only for input parameters, not return values.

- The method must not have a `throws` clause.
- The number of source fields selected must match the number of input parameters that the method takes.
- If you are using a working set, only the methods in the current working set are displayed. Clear the check box **Apply working set filtering to artifact selection(s) on the page** to display all the methods in the workspace. If you are

not using a working set, all the methods in the entire workspace are displayed. Content assist shows all methods in the workspace, whether you are using a working set or not.

When you create the BAR file you must select the Java project or JAR file that contains the method that you are calling.

Message mapping scenarios

About this task

This section contains some message mapping scenarios that demonstrate how to make the most of the message mapping functions:

Procedure

- "Scenario A: Mapping an airline message" on page 2319
- "Scenario B: Simple message enrichment" on page 2330
- "Scenario C: Using a broker as auditor" on page 2338
- "Scenario D: Complex message enrichment" on page 2345
- "Scenario E: Resolving a choice with alternative message data" on page 2368
- "Scenario F: Updating the value of a message element" on page 2369

Related tasks:

"Using message mappings" on page 2228
Message mappings define the blueprint for creating a message.

Scenario A: Mapping an airline message:

This scenario demonstrates how to create, configure, and deploy a new message mapping.

About this task

The message flow that is used in this example reads an XML input message (an airline message), then uses a Mapping node to achieve the following transformations:

- Convert the input message from XML to COBOL
- Modify an element in the input message from the results that are obtained by a database lookup
- Concatenate two elements in the input message to form a single element in the output message

Follow these steps to complete this scenario:

Procedure

1. "Example names and values"
2. "Connect to the database and obtain the definition files" on page 2321
3. "Create the message flow" on page 2323
4. "Create the mapping file" on page 2324
5. "Configure the mapping file" on page 2325
6. "Deployment of the mapping" on page 2329

What to do next

Next: Go to "Example names and values."

Related tasks:

"Using message mappings" on page 2228

Edit and configure message maps using the Message Mapping editor.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Example names and values:

View the resources that are created for the airline message scenario.

About this task

The following table describes the names and definitions of the resources that are created.

Resource	Name	Definition
Alias name	AIRLINEDBALIAS	The same as connection name and database name in this case
Broker archive (BAR) file name	AIRLINE	Contains the message flow and message set projects, and the mapping file, and is deployed to the default execution group for the run time
COBOL copybook	AirlineRequest.cbl	Controls the structure of the COBOL output message
Connection name	AIRLINECONN	The same as alias name and connection name in this case
Database	AIRLINEDB	Contains the table XREF and is the same as the connection name and the alias name in this case
Database table (table tree)	XREF	Contains lookup information (in this case the two-code airline city code abbreviations STATE=Illinois, ABBREV=IL)
Default project	AIRLINE_MFP	The default message flow project. You copy the database definitions to this project.
Default queue manager	WBRK6_DEFAULT_QUEUE_MANAGER	The default queue manager that controls the message queue
ESQL select operation	`$db:select.AIRLINEDB.AIRLINE_SCHEMTREE. XREF.ABBERV`	The ESQL select operation that performs a qualified database select operation
Input (XML) message	`c:\airline\data\AirlineRequest.xml`	The input message (in this case an XML message)
Input message source fields	FirstName,LastName	The source elements in the input message that are concatenated
Input queue name property	AIRLINE_Mapping_IN	The input queue
Mapping node rename	XML_TO_COBOL	The name of the node in the message flow that performs the mapping (the node was renamed from its default name)
Message mapping file name	AIRLINE.msgmap	The file that contains the mapping configuration used by the Mapping node
Message Set property	AIRLINE_MSP2	The message set project name
Message Type property	msg_AIRLINEREQUEST	The message type
Message Format	Binary1	The custom wire format (CWF) for COBOL output message
Message flow name	AIRLINE_Mapping	The name of the message flow
Message flow project	AIRLINE_MFP	The name of the message flow project
Message set projects	AIRLINE_MSP1,AIRLINE_MSP2	The names of the message set projects

Resource	Name	Definition
Msg Domain node property	MRM	The message domain node property
Msg Set Name node property	AIRLINE_MSP1	The message set name node property
Msg Type property	AirlineRequest	The message type property
Msg Format node property	XML1	The input message format
Output message target field	NAME	The result of concatenating FirstName and LastName in the input message. NAME is the element that is created in the output message.
Output queue name property	AIRLINE_Mapping_OUT	The output queue name
Resource folder	airline\resources	The folder where the mapping resources are stored
Schema tree	AIRLINE_SCHEMTREE	The name of the schema tree
Source	ABBREV	The source
Source tree	$source/AirlineRequest	The source tree
Source message	AirlineRequest	The source message
Target	STATE	The target
Target message	AIRLINEREQUEST	The target message
Target tree	$target/AIRLINEREQUEST	The target tree
XPath concatenation function	`fn:concat(fn:concat($source/ AirlineRequest/Purchase/ Customer/FirstName,' '), $source/AirlineRequest/ Purchase/Customer/LastName)`	The W3C XPath 1.0 Specification function that concatenates FirstName and LastName

What to do next

Now go to "Connect to the database and obtain the definition files."

Related tasks:

"Using message mappings" on page 2228
Message mappings define the blueprint for creating a message.

"Message mapping scenarios" on page 2318

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Connect to the database and obtain the definition files:

Demonstrate how to define a database connection to enable a message flow to access a database table. You must define the database to the WebSphere Message Broker Toolkit.

Before you begin

Before you start:

Create a message flow project.

About this task

The Database Definition wizard uses the JDBC interface to communicate with the database server; therefore, you must ensure that the database client JAR file on your local or WebSphere Message Broker Toolkit host is at a compatible level to allow communication with the database server. If necessary, consult your database vendor for further advice.

Procedure

1. Switch to the Broker Application Development perspective.
2. Select the message flow project that you want to create the database definition files in, and click **File** > **New** > **Database Definition**. The New Database Definition File wizard opens.
3. Select an existing data design project, or click **New** to create a new data design project.
4. Select the database type and version that you want to connect to from the **Database and Version** list. Ensure that you select a database from the list that is supported by WebSphere Message Broker; you can use this wizard in a shell-share environment with other Rational products that support other databases or versions.

   For a list of databases supported by the broker, see "Supported databases" on page 3591.
5. Click **Next**.
6. Select **To create a new database connection**, and click **Next**.
7. Clear **Use default naming convention**, and enter a connection name; for example, AIRLINEDBALIAS.
8. Enter values for the Connection to the database; for example, Database name, Host name, and Port number.
9. Enter values for the User ID and Password to connect to the database. Click **Test Connection** to verify the settings that you have selected for your database. The default Port number for a DB2 database is 50000. If the connection fails, enter other values such as 50001, 50002 and so on, for the Port number, and test the connection again.
10. Click **Next**.
11. Select one or more database schemas from the list, and click **Next**.
12. Click **Finish**.
13. Add the data design project as a reference to the message flow project:
    a. Right-click the message flow project, and click **Properties**.
    b. Click **Project References**, and select the data design project from the list to add as a referenced project.
    c. Click **OK**.

Results

The database definition is added to a new Data design project. You have now defined the database to the mapping tools.

What to do next

Now go to "Create the message flow."

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

"Supported databases" on page 3591
You can optionally configure databases to contain data that is accessed by your message flows. Databases from IBM and other suppliers are supported at specific versions on supported operating systems.

Create the message flow:

Before you begin

Before you start:

1. Create a message flow project.
2. "Connect to the database and obtain the definition files" on page 2321.
3. Create a message flow by adding an MQInput node, and renaming the node (for example, to AIRLINE_Mapping_IN).
4. Set the queue name property (for example, to AIRLINE_Mapping_IN).
5. Add an MQOutput node to the message flow, and rename the node (for example, to AIRLINE_Mapping_OUT).

About this task

This topic demonstrates how to specify a message flow project, add a Mapping node, wire the nodes, and set the node properties.

Procedure

1. Switch to the Broker Application Development perspective.
2. Open the message flow (for example, AIRLINE_Mapping) within the message flow project (for example, AIRLINE_MFP). This message flow forms the starting point for the mapping task.
3. Open the palette of nodes and add a Mapping node to the message flow. You might need to scroll down to find the Mapping node.
4. Rename the Mapping node (for example, to XML_TO_COBOL) by right-clicking the node and clicking **Rename**.
5. Wire the node terminals (for example, AIRLINE_Mapping_IN> XML_TO_COBOL> AIRLINE_Mapping_OUT).
6. Modify the properties of the MQInput node (for example, AIRLINE_Mapping_IN) by right-clicking the node and clicking **Properties**.
7. Click **OK**.
8. Modify the properties of the Mapping node (for example, XML_TO_COBOL).
9. Set the data source as the database name (for example, AIRLINEDBALIAS)
10. Click **OK**.

Results

You have now created the required message flow, wired the nodes, and set the node properties.

What to do next

Now go to "Create the mapping file."

Related reference:

"Message Flow editor" on page 6810
The Message Flow editor is the default editor provided by the Broker Application Development perspective for defining a graphical representation of a message flow in the WebSphere Message Broker Toolkit, and for setting properties for individual message flow nodes.

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Create the mapping file:
Before you begin

Before you start:

Follow the instructions in these topics:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323

About this task

This topic demonstrates how to create a new mapping file, specify how it will be used, and specify the source and target mappable elements.

Procedure

1. Switch to the Broker Application Development perspective.
2. From the message flow, right-click the mapping node (for example XML_TO_COBOL) and click **Open Map**. The New Message Map wizard opens.
3. Select the combination of Messages, Data Sources or both that you want to use as sources for your map from **Select map sources** (for example, AirlineRequest) from the first message set project (for example, AIRLINE_MSP1). If you cannot find the Messages, Data Sources or Data Targets that you expect, clear the **Apply working set filtering to artifact selection(s) on the page** check box.
4. Select the combination of Messages, Data Targets or both that you want to use as targets for your map from **Select map targets** (for example, AIRLINEREQUEST) from the second message set project (for example, AIRLINE_MSP2).
5. Click **Finish**.

Results

You have now created the mapping file, defined its usage, and specified the source and target mappable elements.

What to do next

Now go to "Configure the mapping file" on page 2325.

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Configure the mapping file:
Before you begin

Before you start:

Follow the instructions in these topics:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323
3. "Create the mapping file" on page 2324

About this task

This set of topics demonstrates how to configure the mapping file by:

Procedure

1. Specifying a data source
2. Mapping the message properties
3. Writing an XPath function that concatenates the elements in the input message
4. Specifying an ESQL select command

What to do next

Now go to "Specify the data source."

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Specify the data source:
Before you begin

Before you start:

Follow the instructions in these topics:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323
3. "Create the mapping file" on page 2324

About this task

This topic demonstrates how to specify the database to use as the source for the mapping.

Procedure

1. From the Message Mapping editor Spreadsheet pane, select an item. The item that you select determines the scope of the $db:select entry that is created by the action. For example, you can select $target, an element, an attribute, a For condition, or another $db:select entry. The Select database as mapping source dialog box opens.
2. Right-click and click **Select data source**.

3. From the Select Database as mapping source page, select a database (for example, AIRLINEDB) and click **Finish**. The Message Mapping editor adds the sources of the database table (for example, the XREF table) to the tree in the Message Mapping editor Source pane.

Results

You have now added the data source to the Message Mapping editor Source pane.

What to do next

Now go to "Map the message properties."

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Map the message properties:

This topic demonstrates how to map the message set, message type and message format properties.

Before you begin

Before you map the message properties, ensure you do the following:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323
3. "Create the mapping file" on page 2324
4. "Specify the data source" on page 2325

About this task

To map the message properties:

Procedure

1. From the Message Mapping editor Spreadsheet pane, expand the entries by clicking **+** to reveal the message properties.
2. Right-click $target and click **Insert Children**.
3. Right-click Properties and click **Insert Children**. The MessageSet, MessageType and MessageFormat properties contain default values for the target message.
4. To change the format of the output message, change the MessageFormat property to the appropriate value. You must use quotation marks around the value of MessageFormat, because the values are string literals and without quotation marks, the values will be interpreted as XPath locations.
5. From the Message Mapping editor Source pane, expand the properties for the $source tree, and for each remaining property, map the source element to its corresponding target element by dragging from source to target. Alternatively, select Properties in both the source and the target panes and use **Map by Name** to map all of the properties.
6. Save the map by clicking **File** > **Save**.

Results

You have now mapped message set, message type and message format properties.

What to do next

Now go to "Add the XPath concatenate function."

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Add the XPath concatenate function:
Before you begin

Before you start:

Follow the instructions in these topics:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323
3. "Create the mapping file" on page 2324
4. "Specify the data source" on page 2325
5. "Map the message properties" on page 2326

About this task

This topic demonstrates how to write an XPath function that concatenates the FirstName and LastName from the input message, and adds a white space separator in the target NAME element. When you add the XPath expression and save the map, link lines are automatically generated between the source and target to indicate that these elements are mapped.

Procedure

1. From the Message Mapping editor Source pane, select the first source to concatenate (for example, FirstName), Ctrl+click to select the second source to concatenate (for example, LastName), and drag both elements onto the target (for example, NAME) in the Target pane.
2. From the Message Mapping editor Spreadsheet pane, select the target (for example, NAME).
3. From the Edit pane, enter the XPath function (for example, `fn:concat($source/AirlineRequest/Purchase/Customer/FirstName, ' ', $source/AirlineRequest/Purchase/Customer/LastName)`
4. Save the map by clicking **File** > **Save**.

Results

You have now added an XPath function that concatenates the two source elements in the input message into a single target element in the output message.

What to do next

Now go to "Add the database Select operation."

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Add the database Select operation:

Before you begin

Before you start:

Follow the instructions in these topics:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323
3. "Create the mapping file" on page 2324
4. "Specify the data source" on page 2325
5. "Map the message properties" on page 2326
6. "Add the XPath concatenate function" on page 2327

About this task

This topic provides instructions on how to add a database select operation that makes a qualified selection from a data source. In the spreadsheet pane the `$db:select` statement has the default value `fn:true()`, which returns all entries in the table. You must therefore replace this value with one that qualifies the selection, for example:

```
$db:select.LAB13STA.ARGOSTR.XREF.STATE=$source/AirlineRequest/Purchase/Customer/State
```

The XPath in this example selects only the records from the database where the value in the STATE column for each record matches the value of the State field from the input message. In the spreadsheet pane the `$db:select` statement is associated with a `For` entry which is used to iterate over the mappings for the target message. For each row in the database matching the `$db:select` statement a separate target message is created with the mappings beneath `$target`.

The following steps describe how to create message mappings to generate a target message based on records in a database matching the contents of an input message:

Procedure

1. In the spreadsheet pane replace the existing value `fn:true()` with the value to match in the database (for example a field in the input message as shown in the preceding example).
2. Create mappings from the database fields in the Source pane to include in the target message, by dragging them from the source pane onto the target elements. A `$db:select` statement is added to the value column in the spreadsheet pane (for example, `$db:select.AIRLINEDB.AIRLINE_SCHEMTREE.XREF.ABBREV`).
3. Create any mappings you require from the source message to the target message.
4. Save the mapping by clicking **File** > **Save**.
5. Save the message flow.
6. Check for any errors in the Problems view.

Results

You have now made a qualified selection from the database.

What to do next

Now go to "Deployment of the mapping."

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Deployment of the mapping:

How to map to the run time, creating a broker archive (BAR) file for deployment in the default execution group.

Before you begin

Before you start:

Follow the instructions in these topics:

1. "Connect to the database and obtain the definition files" on page 2321
2. "Create the message flow" on page 2323
3. "Create the mapping file" on page 2324
4. "Configure the mapping file" on page 2325

About this task

Create a broker archive (BAR) file, which contains the message flow, message set projects and the mapping file, for deployment to the run time and the default execution group.

Procedure

1. From the Broker Application Development perspective, right-click the project under the Broker Archives heading.
2. Click **New** > **Message Broker Archive**.
3. Name the BAR file (for example, AIRLINE).
4. Click **Add to**. The Add to broker archive page is displayed.
5. Select the message flow project and message set projects that are used by this flow (for example, AIRLINE_MFP,AIRLINE_MSP1, AIRLINE_MSP2) and click **OK**. The projects are added to the BAR file. A status indicator and message panel show when the process has completed.
6. Check to ensure that the required projects have been included in the BAR file.
7. Save the BAR file by clicking **File** > **Save**.
8. For deployment of the BAR file, right-click the BAR file and click **Deploy File**. The Deploy a BAR file page is displayed.
9. Select the default execution group, and click **OK**. A message in the Broker Administration message dialog box indicates successful deployment, and the deployed message flow project and message set projects are displayed in the Navigator view. A message in the Deployment log also indicates successful deployment.

Results

You have completed this scenario.

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

Scenario B: Simple message enrichment:

This scenario demonstrates simple message enrichment. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

The scenario also involves creating a broker, and inputting instance messages that can contain MQRFH2 headers.

This scenario uses repeating instances and requires the following mapping functions:

- MRM in, MRM out (non-namespace)
- Map a simple and complex element source - target
- Map the same element source - target
- Map a different element source - target
- Map an attribute source - target
- Map a one-sided element (edit mapping)
- Map a one-sided attribute (edit mapping)
- Perform arithmetic on numeric field mapping
- Map a repeating simple element - single instance
- Map all instances of a repeating simple element
- No MQRFH2 header

The names and values used for message flows, message sets, elements and attributes, and the expressions and code samples are for illustrative purposes only.

Follow these steps to complete this scenario:

1. "Develop a message flow and message model for simple and complex element mapping" on page 2331
2. "Develop a message flow and message model for a target-only element" on page 2333
3. "Develop a message flow and message model for dealing with repeating elements" on page 2334
4. "Develop a message flow and message model for a simple message without an MQRFH2 header" on page 2336

Related tasks:

Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow and message model for simple and complex element mapping:
About this task

This is the first stage of the scenario to perform simple message enrichment. This topic demonstrates how to develop a message flow and message model for simple and complex element mapping, where there is the same source and target, a different source and target, or an attribute source and target. This task also involves changing field values and creating an instance document.

Procedure

1. From the Broker Application Development perspective, create the following resources:
   a. a message set project (for more details, see "Creating a message set" on page 2842).
   b. a message set called MAPPING3_SIMPLE_messages. Ensure that the message set is namespace enabled with XML wire format.
   c. a message definition file (no target namespace) called SIMPLE.
2. Create a message called addev1 that has the following structure:

```
addev1
        ssat          (xsd:string) local attribute
        ssel          (xsd:string) local element
        dsel1        (xsd:string) local element
        atel           local complex element
             latt       (xsd:string) attribute
        cel1          local complex element
             intel      (xsd:int) local element
             strel      (xsd:string) local element
        dsel2         (xsd:string) global element
        cel2           (cel2ct) global complex type
            intel        (xsd:int) local element
            fltel         (xsd:float) local element
```

3. Create a message flow project called MAPPING3_SIMPLE_flows.
4. Create a message flow called addev1 that contains the following mapping: MQInput -> Mapping -> MQOutput.
5. Open the map in the Message Mapping editor and select message addev1 as both source and target
6. Expand all levels of both messages and wire the elements as shown:

```
ssat --- ssat
ssel --- ssel
dsel1 -- dsel2
latt ---- latt
cel1 --- cel1
dsel2 -- dsel1
(cel2)
   intel ---- fltel
   fltel ---- intel
```

7. In the Spreadsheet pane, set the following expression:

```
dsel1  |  esql:upper($source/addev1/dsel2)
@latt  |   esql:upper($source/addev1/atel/@latt)
(cel2)
    intel   |  $source/addev1/cel2/fltel + 10
    fltel    |  $source/addev1/cel2/intel div 10
```

8. Create an instance document with the appropriate RFH2 header and the following data:

```
<addev1 ssatt="hello">
<ssel>this</ssel>
<dsel1>first</dsel1>
```

```
<atel latt="attrib"/>
<cel1>
<intel>2</intel>
<strel>lcomp</strel>
</cel1>
<dsel2>second</dsel2>
<cel2>
<intel>252</intel>
<fltel>3.89E+1</fltel>
</cel2>
</addev1>
```

Results

You have created the following resources:

- message set MAPPING3_SIMPLE_messages, which you have populated with message addev1
- message flow addev1 in project MAPPING3_SIMPLE_flows, which contains the mapping addev1_Mapping.msgmap
- a file that contains an instance message

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This is the second stage of the scenario to perform simple message enrichment. This topic demonstrates how to deploy the message set and message flow and run the data through the broker.

Procedure

1. Create a broker archive (BAR) file called addev1.
2. Add the message set MAPPING3_SIMPLE_messages and the message flow addev1 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance document on the input queue.

Results

The output message looks like this:

```
<addev1 ssat="hello">
<ssel>this</ssel>
<dsel1>SECOND</dsel1>
<atel latt="ATTRIB"/>
<cel1>
<intel>2</intel>
<strel>lcomp</strel>
</cel1>
<dsel2>first</dsel2>
<cel2>
<intel>48</intel>
<fltel>2.5E+1</fltel>
</cel2>
</addev1>
```

What to do next

Now go to "Develop a message flow and message model for a target-only element."

Develop a message flow and message model for a target-only element:
Before you begin

Before you start

Perform the steps in the following topic:

1. "Develop a message flow and message model for simple and complex element mapping" on page 2331

About this task

This is the third stage of the scenario to perform simple message enrichment. This topic demonstrates how to develop a message flow and message model for a target-only element. It also involves attributing a mapping and creating an instance document.

Procedure

1. Create a message called addev2, which has the following structure:

```
addev2
    matt             (xsd:string) local attribute
    ssel              (xsd:string)  local element
    csel              local complex element
        elatt          (xsd:string)  local attribute
```

2. Create a second message called trigger, which has the following structure:

```
trigger
   start               (xsd:string) local element
```

3. Create a message flow called addev2, which contains the following mapping: MQInput -> Mapping -> MQOutput.
4. Open the map and select trigger as the source and addev2 as the target.
5. In the Spreadsheet pane, expand the target message fully and set the target fields as shown:

```
matt    |   'first attribute'
ssel     |   'string element'
elatt     |   'second attribute'
```

6. Expand the Properties folder in the Spreadsheet pane and set the following value:

```
MessageType   |   'addev2'
```

7. Create an instance document with the appropriate RFH2 header and the following data:

```
<trigger>
<start>yes</start>
</trigger>
```

Results

You have created the following resources:

- two messages called addev2 and trigger
- a message flow called addev2, which contains the mapping addev2_Mapping.msgmap

- a file that contains an instance message

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This is the fourth stage of the scenario to perform simple message enrichment. This topic demonstrates how to deploy the message set and message flow and run the data through the broker.

Procedure

1. Create a broker archive (BAR) file called addev2.
2. Add the message set MAPPING3_SIMPLE_messages and the message flow addev2 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance document on the input queue.

Results

The output message looks like this:

```
<addev2 matt="first attribute">
<ssel>string element</ssel>
<csel elatt="second attribute"></csel>
</addev2>
```

What to do next

Now go to "Develop a message flow and message model for dealing with repeating elements."

Develop a message flow and message model for dealing with repeating elements:
Before you begin

Before you start

Perform the steps in the following topics:

1. "Develop a message flow and message model for simple and complex element mapping" on page 2331
2. "Develop a message flow and message model for a target-only element" on page 2333

About this task

This is the fifth stage of the scenario to perform simple message enrichment. This topic demonstrates how to develop a message flow and message model for dealing with repeating elements, a single instance and all instances.

Procedure

1. Create a message called addev3, which has the following structure:

```
addev3
    frepstr        (xsd:string) local element, minOcc=3, maxOcc=3
    vrepstr       (xsd:string) local element, minOcc=1, maxOcc=4
    urepstr       (xsd:string)  local element, minOcc=1, maxOcc=-1
```

2. Create a message flow called addev3, which contains the following mapping: MQInput -> Mapping -> MQOutput.
3. Open the map and select addev3 as both source and target
4. In the upper pane, map each source to the corresponding target, as illustrated in this example:

```
frepstr --- frepstr
vrepstr --- vrepstr
urepstr --- urepstr
```

5. In the Spreadsheet pane, expand fully the target addev3.
6. Highlight and delete the For item above the vrepstr entry.
7. Create an instance message with the appropriate RFH2 header and the following data:

```
<addev3>
<frepstr>this</frepstr>
<frepstr>that</frepstr>
<frepstr>other</frepstr>
<vrepstr>only one</vrepstr>
<vrepstr>extra</vrepstr>
<urepstr>first</urepstr>
<urepstr>second</urepstr>
<urepstr>third</urepstr>
<urepstr>fourth</urepstr>
<urepstr>fifth</urepstr>
</addev3>
```

Results

You have created the following resources:

- a message called addev3
- a message flow called addev3, which contains the mapping addev3_Mapping.msgmap
- a file that contains an instance message

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This is the sixth stage of the scenario to perform simple message enrichment. This topic demonstrates how to deploy the message set and message flow and run the data through the broker.

Procedure

1. Create a broker archive (BAR) file called addev3.
2. Add the message set MAPPING3_SIMPLE_messages and the message flow addev3 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance document on the input queue.

Results

The output message looks like this:

```
<addev3>
<frepstr>this</frepstr>
<frepstr>that</frepstr>
<frepstr>other</frepstr>
<vrepstr>only one</vrepstr>
<urepstr>first</urepstr>
<urepstr>second</urepstr>
<urepstr>third</urepstr>
<urepstr>fourth</urepstr>
<urepstr>fifth</urepstr>
</addev3>
```

What to do next

Now go to "Develop a message flow and message model for a simple message without an MQRFH2 header."

Develop a message flow and message model for a simple message without an MQRFH2 header:

Before you begin

Before you start

You must complete the following tasks:

1. "Develop a message flow and message model for simple and complex element mapping" on page 2331
2. "Develop a message flow and message model for a target-only element" on page 2333
3. "Develop a message flow and message model for dealing with repeating elements" on page 2334

About this task

This is the seventh stage of the scenario to perform simple message enrichment. This topic demonstrates how to develop a message flow and message model for a simple message without an MQRFH2 header.

Procedure

1. Create a message set called MAPPING3_SIMPLE_xml. A message set project is also automatically created; this message set project has the same name as the message set that you created.
2. On the message set parameters page, set the *Message Domain* property to XML.
3. Create a message definition file called SIMPLE.
4. Create a message called addev4 that has the following structure:

```
addev4
   str1                  (xsd:string)  local element
   cel                    local complex element
       int1               (xsd:int) local element
       bool1             (xsd:boolean) local element
```

5. Create a message flow called addev4 that contains the following connected nodes: MQInput -> Mapping -> MQOutput.
6. Select the Input Message Parsing properties tab of the MQInput node, and set the *Message Domain* property to XML.

7. Open the map and select addev4 as both source and target.
8. Map the inputs to the corresponding outputs, as shown in this example:

```
str1 --- str1
int1 --- int1
bool1 --- bool1
```

9. Create an instance message that has no MQRFH2 header, but contains the following data:

```
<addev4>
<str1>this</str1>
<cel>
<int1>452</int1>
<bool1>0</bool1>
</cel>
</addev4>
```

Results

You have created the following resources:

- A message set called MAPPING3_SIMPLE_xml that contains the message addev4
- A message flow called addev4 that contains the mapping addev4_Mapping.msgmap
- A file that contains an instance message

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This is the final stage of the scenario to perform simple message enrichment. This section describes how to deploy the message set and message flow, and how to the run the data through the broker.

Procedure

1. Create a broker archive (BAR) file called addev4.
2. Add the message flow called addev4 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance document on the input queue.

Results

The output message has the following content:

```
<addev4>
<str1>this</str1>
<cel>
<int1>452</int1>
<bool1>0</bool1>
</cel>
</addev4>
```

You have completed the scenario.

Related concepts:

"Message sets overview" on page 1162
A message set is a container for grouping messages and associated message resources (elements, types, groups).

"Broker archive" on page 3216
The unit of deployment to the broker is the *broker archive* or *BAR* file.

"MQInput node" on page 4594
Use the MQInput node to receive messages from clients that connect to the broker by using the WebSphere MQ Enterprise Transport, and that use the MQI and AMI application programming interfaces.

Scenario C: Using a broker as auditor:

This scenario demonstrates how to use a broker as an auditor. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

It also involves creating a broker, and sending instance messages that can contain MQRFH2 headers.

The scenario uses database updates that have been defined by using mappings. The broker receives a confirmation for a provisional booking, the message flow inserts a row into a database table representing the confirmation, updates a counter in another table representing the key of the confirmation, and deletes the provisional booking from a third table.

This scenario uses the DataDelete, DataInsert and DataUpdate nodes in the message flow, and requires the following mapping functions:

- Mapping in DataInsert node
- Combine input data into single insert
- Mapping in DataUpdate node
- Mapping in DataDelete node
- BAR file to override data source

The names and values used for message flows, message sets, elements and attributes, and the expressions and code samples are for illustrative purposes only.

Follow these steps to complete this scenario:

1. "Develop a message flow" on page 2339
2. "Deploy the message set and message flow" on page 2341
3. "Override the data source of one of the nodes" on page 2343
4. "Create a BAR file, edit the configuration, and deploy" on page 2344

"DataUpdate node" on page 4390
Use the DataUpdate node to interact with a database in the specified ODBC data source.

Develop a message flow:

Create a message flow to use in mapping scenario C, which shows how to use your broker as an auditor.

About this task

This step is the first task in creating "Scenario C: Using a broker as auditor" on page 2338. Develop a message flow to map several fields of input data into a single insert record for a database. See also how to update another table, delete a third table, and develop corresponding message models and instance messages.

Procedure

1. Create a database called MAPDB, and a table called CONFIRMATION, which contains the following columns:

   ```
   RESID                INTEGER
   ```

2. Populate the CONFIRMATION table with the value shown:

   ```
   9052
   ```

3. Create another table called RESERVATION, which contains the following columns:

   ```
   RESID           INTEGER
   NAME            VARCHAR(20)
   PARTY           INTEGER
   PAYMENT         DECIMAL(8,2)
   ```

4. Populate the RESERVATION table with the values shown:

   ```
   8214,'ARCHIBALD',2,0.0
   2618,'HENRY', 4, 120.0
   9052,'THAW', 3, 85.0
   ```

5. Create another table called PROVISIONAL, which contains the following columns:

   ```
   RESID                   INTEGER
   ```

6. Populate the PROVISIONAL table with the values shown:

   ```
    8214 2618
   ```

7. Create a Windows ODBC Data Source Name for the database, then create a definition for the database in the workbench by clicking **File** > **New** > **Database Definition File**. For information about how to complete this step,

including how to choose a supported database and version, follow the instructions provided in "Adding database definitions to the WebSphere Message Broker Toolkit" on page 2278.

8. Create a message set project and a message set called MAPPING3_AUDIT_messages (ensuring that the message set is namespace enabled, with XML wire format) and create a message definition file called AUDIT.
9. Create a message called addev1, which has the structure:

```
addev1
   id                (xsd:int) local element
   status            (xsd:string) local element
   name              (xsd:string) local element
   size              (xsd:int) local element
   payment           (xsd:decimal) local element
```

10. Create a message flow project called MAPPING3_AUDIT_flows.
11. Create a message flow called addev1, which contains the following structure: MQInput ->DataInsert -> DataUpdate -> DataDelete -> MQOutput.
12. For the DataDelete node, set the Data Source property to MAPDB.
13. Open the mapping for the DataInsert node and select MAPPING3_AUDIT_messages addev1 as the source, and MAPDB.SCHEMA.CONFIRMATION as the target.
14. Wire the source to the target as shown:

```
addev1             MAPDB
       id -------------- RESID
```

15. For the DataUpdate node, set the Data Source property to MAPDB.
16. Open the mapping for the DataUpdate node and select MAPPING3_AUDIT_messages addev1 as the source, and MAPDB.SCHEMA.RESERVATION as the target.
17. Wire the source to the target as shown:

```
addev1             MAPDB
       id -------------- RESID
       name ---------- NAME
       size ------------ PARTY
       payment ------- PAYMENT
```

18. In the Message Mapping editor Spreadsheet pane, select $db:update and change fn:true() to $db:update.MAPDB.MQSI.RESERVATION.RESID = $source/addev1/id and $source/addev1/status = 'CONFIRM'.
19. For the DataDelete node, set the Data Source property to MAPDB.
20. Open the mapping for the DataDelete node and select MAPPING3_AUDIT_messages addev1 as the source, and MAPDB.SCHEMA.PROVISIONAL as the target.
21. In the Message Mapping editor Spreadsheet pane, select $db:delete and change fn:false() to $db:delete.MAPDB.MQSI.PROVISIONAL.RESID = $source/addev1/id.
22. Create the following instance message with appropriate MQRFH2 headers:

```
<addev1>
<id>8214</id>
<status>CONFIRM</status>
<name>ARCHIBALD</name>
<size>2</size>
<payment>1038.0</payment>
</addev1>
```

Results

You have created the following resources:

- A message set called MAPPING3_AUDIT_messages, which is populated with the message addev1
- A message flow called addev1 in project MAPPING3_AUDIT_flows, which contains the mapping files `addev1_DataInsert.msgmap`, `addev1_DataUpdate.msgmap`, and `addev1_DataDelete.msgmap`
- The database MAPDB with populated tables CONFIRMATION, RESERVATION, and PROVISIONAL
- A file that contains an instance message for test.

What to do next

Next: Continue with the next step, "Deploy the message set and message flow."

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Related tasks:

"Adding database definitions to the WebSphere Message Broker Toolkit" on page 2278
Use the New Database Definition File wizard to add database definitions to the WebSphere Message Broker Toolkit.

Related reference:

"Scenario C: Using a broker as auditor" on page 2338
This scenario demonstrates how to use a broker as an auditor. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Supported databases" on page 3591
You can optionally configure databases to contain data that is accessed by your message flows. Databases from IBM and other suppliers are supported at specific versions on supported operating systems.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Deploy the message set and message flow:

Deploy the message flow that you have created to support mapping scenario C, which shows how to use your broker as an auditor.

Before you begin

Before you start

Perform the first step for this scenario, described in "Develop a message flow" on page 2339.

About this task

This step is the second task in creating "Scenario C: Using a broker as auditor" on page 2338. Deploy the message set and message flow, and run the instance messages through the broker.

Procedure

1. Create a BAR file called `addev1`.
2. Add the message set MAPPING3_AUDIT_messages, and the message flow addev1, to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance document on the input queue.

Results

The output messages are the same as the input messages. The database table has the following content:

```
CONFIRMATION
RESID
-----------
       9052
       8214

RESERVATION
RESID       NAME                 PARTY       PAYMENT
----------- -------------------- ----------- ----------
       8214 ARCHIBALD                      2    1038.00
       2618 HENRY                          4     120.00
       9052 THAW                           3      85.00

PROVISIONAL
RESID
-----------
       2618
```

What to do next

Next: Continue with the next step, "Override the data source of one of the nodes" on page 2343.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Override the data source of one of the nodes:

Override the data source property for a node in the message flow that you have created to support mapping scenario C, which shows how to use your broker as an auditor.

Before you begin

Before you start

Complete the first two steps for this scenario:

1. "Develop a message flow" on page 2339
2. "Deploy the message set and message flow" on page 2341

About this task

This step is the third task in creating "Scenario C: Using a broker as auditor" on page 2338. Override the data source of one of the nodes by changing the configuration of its broker archive (BAR) file.

Procedure

1. Create a database called ALTDB, and a table called CONFIRMATION, which contains the following columns:

   ```
   RESID                INTEGER
   ```

2. Create a Windows ODBC Data Source Name for the database, then register the database in the WebSphere Message Broker Toolkit by clicking **File** > **New** > **Database Definition File**. For information about how to complete this step, including how to choose a supported database and version, follow the instructions provided in "Adding database definitions to the WebSphere Message Broker Toolkit" on page 2278.

Results

You have created a database called ALTDB with a table called CONFIRMATION.

What to do next

Next: Continue with the next step, "Create a BAR file, edit the configuration, and deploy" on page 2344.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Create a BAR file, edit the configuration, and deploy:

Create a broker archive file and deploy the message flow for mapping scenario C, which shows how to use your broker as an auditor.

Before you begin

Before you start

Perform the first three steps for this scenario:

1. "Develop a message flow" on page 2339
2. "Deploy the message set and message flow" on page 2341
3. "Override the data source of one of the nodes" on page 2343

About this task

This step is the fourth and last task in creating "Scenario C: Using a broker as auditor" on page 2338. Learn how to create a broker archive (BAR) file, edit the configuration, and deploy.

Procedure

1. Add the message flow addev1 to the BAR file again.
2. Select the Manage and Configure tab of the BAR file editor.
3. Expand the message flow, and click the DataInsert icon.
4. In the Properties view, change the Data Source field from MAPDB to ALTDB, and save the BAR file.
5. Deploy the BAR file to the broker.
6. Put the instance document on the input queue.

Results

The output message is the same as the input. In the ALTDB database, the table has the following content:

```
CONFIRMATION
RESID
-----------
       8214
```

What to do next

Next: You have now completed scenario C. If you want more information about how to use maps, return to "Message mapping scenarios" on page 2318, and explore another scenario.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Related tasks:

"Message mapping scenarios" on page 2318

Related reference:

"Scenario C: Using a broker as auditor" on page 2338

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Scenario D: Complex message enrichment:

This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

The scenario also involves creating a broker, and putting instance messages that can contain MQRFH2 headers to input queues.

This scenario requires the following mapping functions:

- MRM in, MRM out (namespace)
- Other nodes required to complete message
- Conditional mapping
- CASE mapping (both syntax formats)
- If/condition
- Combining multiple source fields into a single target field (inter namespace)
- Nested repeating complex and simple elements
- Target data derived from database
- String, numeric, datetime functions
- User-defined ESQL procedures and functions
- User-defined Java routines

The names and values used for message flows, message sets, elements, and attributes, and the expressions and code samples, are for illustrative purposes only.

Follow these steps to complete this scenario:

1. "Develop a message flow that contains other nodes" on page 2346
2. "Develop a message flow to map target fields from multiple other fields" on page 2349
3. "Develop a message flow and message model for mapping a complex nested, repeating message" on page 2352
4. "Develop a message flow for populating a target from a database" on page 2358
5. "Develop a message flow using a user-defined ESQL function" on page 2361
6. "Develop a message flow using a user-defined Java procedure" on page 2364

Related tasks:

"Using message mappings" on page 2228
Message mappings define the blueprint for creating a message.

"Transforming and enriching messages" on page 2227
Transform and enrich messages by using one or more of the techniques described in this section.

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow that contains other nodes:

Create a message flow to use in mapping scenario D, which describes complex message enrichment.

About this task

This step is the first task in creating "Scenario D: Complex message enrichment" on page 2345. Learn how to complete the following procedures:

- Develop a message flow that contains other nodes (for example, a Filter node)
- Create mappings that use conditions
- Develop corresponding message models, which use all main data types, and instance messages

Procedure

1. Switch to the Broker Application Development perspective
2. Create the following resources:
   - A message set project and a message set called MAPPING3_COMPLEX_messages, ensuring that the message set is namespace enabled with XML wire format
   - A message definition file called COMPLEX, which has a target namespace www.complex.net, with prefix comp
3. Create messages addev1, addev1s and addev1n with the following structures:

```
addev1
   bool      (xsd:boolean) local element
   bin        (xsd:hexBinary) local element
   dat        (xsd:dateTime) local element
   dec       (xsd:decimal) local element
   dur        (xsd:duration) local element
   flt          (xsd:float) local element
   int         (xsd:int) local element
   str         (xsd:string) local element
addev1s
   bin        (xsd:hexBinary) local element
   dat        (xsd:dateTime) local element
   dur        (xsd:duration) local element
   str         (xsd:string) local element
addev1n
   dec       (xsd:decimal) local element
   flt          (xsd:float) local element
   int         (xsd:int) local element
```

4. Create a message flow project called MAPPING3_COMPLEX_flows.
5. Create a message flow called addev1 which contains the following structure:

```
MQInput -> Filter -> Mapping -> Compute
                  \                       \ --> RCD -> MQOutput
                   \-> Mapping1-----------/
```

6. In the Filter node, set the following ESQL:

```
IF Body.bool THEN
            RETURN TRUE;
        ELSE
            RETURN FALSE;
        END IF;
```

7. In the Mapping node that is connected to the Filter node true terminal (Mapping1), open the map and select addev1 as source and addev1s as target.
8. Wire the source to target as shown:

```
bin --- bin
dat --- dat
dur --- dur
str --- str
```

9. In the Message Mapping editor Spreadsheet pane, expand Properties and set the following values:

```
MessageType   |     'addev1s'
```

10. Right-click the target dat and click **If**.
11. Replace the condition fn:true() with `$source/comp:addev1/str = 'dat'`.
12. Set the value for dat to `$source/comp:addev1/dat + xs:duration("P3M")`.
13. Right-click the condition and click **Else**.
14. Right-click the target dur and click **If**.
15. Replace the condition fn:true() with `$source/comp:addev1/str = 'dur'`.
16. Set the value for dur to `$source/comp:addev1/dur + xs:duration("P1Y")`.
17. Right-click the condition and click **Else**.
18. Open the map for the node that is connected to the false terminal (Mapping) of the Filter node and select addev1 as source and addev1n as target.
19. Wire the source to target as shown:

```
dec --- dec
flt --- flt
int --- int
```

20. In the Message Mapping editor Spreadsheet pane, expand Properties and set the following values:

```
MessageType     |     'addev1n'
```

21. Set the ESQL in the Compute node to:

```
CALL CopyMessageHeaders();
        SET OutputRoot.MRM.dec = InputBody.dec * 10;
        SET OutputRoot.MRM.flt = InputBody.flt * 10;
        SET OutputRoot.MRM.int = InputBody.int * 10;
```

22. In the ResetContentDescriptor node, set the Message Domain to XMLNS and select **Reset Message Domain**.
23. Create three instance messages with the appropriate MQRFH2 headers:

```
<comp:addev1 xmlns:comp="http://www.complex.net">
<bool>1</bool>
<bin><![CDATA[010203]]></bin>
<dat>2005-05-06T00:00:00+00:00</dat>
<dec>19.34</dec>
<dur>P2Y4M</dur>
<flt>3.245E+2</flt>
<int>2104</int>
<str>dat</str>
</comp:addev1>
```

```
<comp:addev1 xmlns:comp="http://www.complex.net">
<bool>1</bool>
<bin><![CDATA[010203]]></bin>
<dat>2005-05-06T00:00:00+00:00</dat>
<dec>19.34</dec>
<dur>P2Y4M</dur>
<flt>3.245E+2</flt>
<int>2104</int>
<str>dur</str>
</comp:addev1>
```

```
<comp:addev1 xmlns:comp="http://www.complex.net">
<bool>0</bool>
<bin><![CDATA[010203]]></bin>
<dat>2005-05-06T00:00:00+00:00</dat>
<dec>19.34</dec>
<dur>P2Y4M</dur>
<flt>3.245E+2</flt>
<int>2104</int>
<str>dat</str>
</comp:addev1>
```

Results

You have created the following resources:

- A message set called MAPPING3_COMPLEX_messages, which is populated with the messages addev1, addev1s and addev1n
- A message flow called addev1 in the project MAPPING3_COMPLEX_flows, which contains the mapping files `addev1_Mapping.msgmap` and `addev1._Mapping1.msgmap`
- Files that contain instance messages for test

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This step is the second task in creating "Scenario D: Complex message enrichment" on page 2345. Deploy the message set and message flow and run the instance messages through the broker.

Procedure

1. Create a BAR file called addev1.
2. Add the message set MAPPING3_COMPLEX_messages and the message flow addev1 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance documents on the input queue.

Results

The output messages have the following content:

```
<comp:addev1s xmlns:comp="http://www.complex.net">
<bin><![CDATA[010203]]></bin>
<dat>2005-08-06T00:00:00-01:00</dat>
<dur>P2Y4M</dur>
<str>dat</str>
</comp:addev1s>
```

What to do next

Edit and configure message maps using the Message Mapping editor.

"Scenario D: Complex message enrichment" on page 2345
This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow to map target fields from multiple other fields:

Develop a message flow to map target fields from multiple other fields, and develop corresponding message models and instance documents to use in mapping scenario D, which describes complex message enrichment.

Before you begin

Before you start

Perform the first two tasks for this scenario, described in step "Develop a message flow that contains other nodes" on page 2346.

About this task

This step is the third task in creating "Scenario D: Complex message enrichment" on page 2345.

Procedure

1. In the COMPLEX message definition, in namespace www.complex.net, create a message called addev2, which has the following structure:

```
addev2
   firstname            (xsd:string) local element
   lastname             (xsd:string) local element
   branch                (xsd:string) local element
   accountno           (xsd:string) local element
   balance               (xsd:decimal) local element
   transvalue            local complex element, base type xsd:decimal
      transdir            (xsd:string) local attribute
```

2. In the message set MAPPING3_COMPLEX_messages, create a new message definition file called COMP2, which has the target namespace www.comp2.net, with prefix c2.

3. In the COMP2 message definition, create a message called addev2out, which has the structure:

```
addev2out
    accountdetails      (xsd:string) local element
    transvalue            (xsd:decimal) local element
    balance               (xsd:decimal) local element
```

4. Create a message flow called addev2, which contains the following structure: MQInput -> Mapping -> MQOutput.
5. Open the map for the Mapping node, and select addev2 as the source and addev2out as the target.
6. Wire the source to target as shown:

```
accountno --- accountdetails
balance --- balance
transvalue --- transvalue
```

7. In the Message Mapping editor Spreadsheet pane, expand Properties and set the following values:

```
MessageType   |     'addev2out'
```

8. Set the accountdetails target to `fn:concat($source/comp:addev2/accountno, $source/comp:addev2/branch, $source/comp:addev2/lastname, $source/comp:addev2/firstname)`.
9. Right-click the target transvalue and click **If**.
10. Change the value of the `if` statement from fn:true() to `$source/comp:addev2/transvalue/@transdir = 'DEBIT'`.
11. Select transvalue and set its value to `$source/comp:addev2/transvalue * (-1)`.
12. Right-click the `if` statement and click **Else**.
13. Right-click the target balance and click **If**.
14. Change the value of the `if` statement from fn:true() to `$source/comp:addev2/transvalue/@transdir = 'DEBIT'`.
15. Select balance and set its value to `$source/comp:addev2/balance - $source/comp:addev2/transvalue`.
16. Right-click the `if` statement and click **Else If**.
17. Change the value of the `elseif` statement from fn:true() to `$source/comp:addev2/transvalue/@transdir = 'CREDIT'`.
18. Select balance following the second condition statement and set its Value to `$source/comp:addev2/balance + $source/comp:addev2/transvalue`.
19. Create two instance messages with the appropriate MQRFH2 headers:

```
<comp:addev2 xmlns:comp="http://www.complex.net">
<firstname>Brian</firstname>
<lastname>Benn</lastname>
<branch>52-84-02</branch>
<accountno>567432876543</accountno>
<balance>1543.56</balance>
<transvalue transdir="DEBIT">25.28</transvalue>
</comp:addev2>
```

```
<comp:addev2 xmlns:comp="http://www.complex.net">
<firstname>Brian</firstname>
<lastname>Benn</lastname>
<branch>52-84-02</branch>
<accountno>567432876543</accountno>
<balance>1543.56</balance>
<transvalue transdir="CREDIT">25.28</transvalue>
</comp:addev2>
```

Results

You have created the following resources:

- A message called addev2 in the message definition called COMPLEX
- A message called addev2out in the message definition called COMP2
- A message flow called addev2, which contains the mapping file `addev2_Mapping.msgmap`
- Files that contain instance messages for test

What to do next

Now deploy the message set and message flow

Deploy the message set and message flow:
About this task

This step is the fourth task in creating "Scenario D: Complex message enrichment" on page 2345. Deploy the message set and message flow and run the instance messages through the broker.

Procedure

1. Create a BAR file called addev2.
2. Add the message set MAPPING3_COMPLEX_messages and the message flow addev2 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance documents on the input queue.

Results

The output messages have the following content:

```
<c2:addev2out xmlns:c2="http://www.comp2.net"  xmlns:comp="http://www.complex.net">
<accountdetails>567432876543 52-84-02 Benn Brian</accountdetails>
<transvalue>-25.28</transvalue>
<balance>1518.28</balance>
</c2:addev2out>
```

What to do next

Next: Continue with the next step, "Develop a message flow and message model for mapping a complex nested, repeating message" on page 2352.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Related tasks:

"Message mapping scenarios" on page 2318

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

"Scenario D: Complex message enrichment" on page 2345
This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow and message model for mapping a complex nested, repeating message:

Develop a message flow and message model for mapping a complex nested, repeating message, and develop corresponding instance documents, to use in mapping scenario D, which describes complex message enrichment.

Before you begin

Before you start

Perform the previous tasks for this scenario, described in the following steps:

1. "Develop a message flow that contains other nodes" on page 2346
2. "Develop a message flow to map target fields from multiple other fields" on page 2349

About this task

This step is the fifth task in creating "Scenario D: Complex message enrichment" on page 2345.

Procedure

1. In the COMPLEX message definition, in namespace www.complex.net, create a message called addev3, which has the following structure:

```
addev3
 choice
    sstr                    (xsd:string) local element
    intrep                 (xsd:int) local element, minOcc=2, maxOcc=6
    dur                     (xsd:duration) local element
 choice
    comp1               local complex element
       dat1                (xsd:date) local element
       sval                (xsd:string) local element
    comp2               local complex element
       bool1              (xsd:boolean) local element
       dat2                (xsd:date) local element
    comprep            local complex element, minOcc=1, maxOcc=4
       int1                (xsd:int) local element
       dec1               (xsd:decimal) local element
 binel                     (xsd:hexBinary) local element
 lelem                     local complex element, base type xsd:string
    latt                    (xsd:int) local attribute
 lcomp                    local complex element
    head                    (xsd:string) local element
    incomp                local complex element
       count                (xsd:int) local element
       comp:gcompel   global complex element, minOcc=0, maxOcc=-1
          fstr                (xsd:string) local element
          multel             local complex element
             in1              (xsd:boolean) local element
             in2              (xsd:string) local element
             in3              (xsd:float) local element
    footer                  (xsd:string) local element
 repstr                     (xsd:string) local element, minOcc=1, maxOcc=-1
```

2. Create a message flow called addev3, which contains the following structure: MQInput -> Mapping -> MQOutput.

3. Open the map for the Mapping node, and select addev3 as the source and target.
4. Map each source element to its corresponding target element:

```
sstr --- sstr
intrep --- intrep
dur --- dur
dat1 --- dat1
sval --- sval
bool1 --- bool1
dat2 --- dat2
int1 --- int1
dec1 --- dec1
binel --- binel
lelem --- lelem
latt --- latt
head --- head
count --- count
fstr --- fstr
multel --- multel
footer --- footer
repstr --- repstr
```

5. In the Message Mapping editor Spreadsheet pane, for the `if` statement, change fn:true() to `fn:exists($source/comp:addev3/sstr)`.
6. For the `elseif` statement, change fn:true() to `fn:exists($source/comp:addev3/intrep)`.
7. For the second `elseif` statement, change fn:true() to `fn:exists($source/comp:addev3/dur)`.
8. For the first complex choice `if` statement, change fn:true() to `fn:exists($source/comp:addev3/comp1)`.
9. For the second complex choice `elseif` statement, change fn:true() to `fn:exists($source/comp:addev3/comp2)`.
10. For the third complex choice `elseif` statement, change fn:true() to `fn:exists($source/comp:addev3/comprep)`.
11. Create the following instance messages, with appropriate MQRFH2 headers:

```
<comp:addev3 xmlns:comp="http://www.complex.net">
<sstr>first</sstr>
<comp1>
<dat1>2005-06-24</dat1>
<sval>date value</sval>
</comp1>
<binel><![CDATA[3132333435]]></binel>

</comp:addev3>
```

Results

You have created the following resources:

- A message called addev3 in the message definition COMPLEX
- A message flow called addev3, which contains the mapping file `addev3_Mapping.msgmap`
- Files that contain instance messages for test

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This step is the sixth task in creating "Scenario D: Complex message enrichment" on page 2345. Learn how to deploy the message set and message flow and run the instance messages through the broker.

Procedure

1. Create a BAR file called addev3.

2. Add the message set MAPPING3_COMPLEX_messages and the message flow addev3 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance documents on the input queue.

Results

The output messages look like this:

```
<comp:addev3 xmlns:comp="http://www.complex.net">
<sstr>first</sstr>
<comp1>
<dat1>2005-06-24</dat1>
<sval>date value</sval>

This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow for populating a target from a database:

Develop a message flow that updates a message from a database for mapping scenario D, complex message enrichment.

Before you begin

Before you start

Perform the previous tasks for this scenario, described in the following steps:

1. "Develop a message flow that contains other nodes" on page 2346
2. "Develop a message flow to map target fields from multiple other fields" on page 2349
3. "Develop a message flow and message model for mapping a complex nested, repeating message" on page 2352

About this task

This step is the seventh task in creating "Scenario D: Complex message enrichment" on page 2345. Develop a message flow for populating a target from a database, and create a corresponding message model and instance documents.

Procedure

1. Create a database called MAPDB and create a table called TRANSACTION, which has the following columns:

```
ACCOUNT        VARCHAR(12)
TDATE               DATE
VALUE              DECIMAL(8,2)
```

2. Populate the database with the values shown:

```
'12345678901', '2005-04-25', -14.25
'12345678901', '2005-04-25', 100.00
'12345678901','2005-05-15', 2891.30
'12345678901','2005-06-11', -215.28
```

3. Create a Windows ODBC Data Source Name for the database.
4. Add a definition for the database to the workbench by clicking **File** > **New** > **Database Definition File**. For information about how to complete this step, including how to choose a supported database and version, follow the instructions provided in "Adding database definitions to the WebSphere Message Broker Toolkit" on page 2278.
5. In the COMPLEX message definition, in namespace www.complex.net, create a message called addev4in, which has the following structure:

```
addev4in
   account             (xsd:string) local element
   tdate                 (xsd:date) local element
```

6. In the COMP2 message definition, in namespace www.comp2.net, create a message called addev4out, which has the following structure:

```
addev4out
   account             (xsd:string) local element
   tdate                 (xsd:date) local element
   value                 (xsd:decimal) local element, minOcc=0, maxOcc=-1
```

7. Create a message flow called addev4, which contains the following structure: MQInput -> Mapping -> MQOutput.
8. Open the map for the Mapping node, and select addev4in as the source and addev4out as the target.
9. Map the input to outputs as shown:

```
account --- account
tdate --- tdate
```

10. In the Message Mapping editor Spreadsheet pane, right-click the target value, and click **Select Data Source**.
11. Select MAPDB, and click **Finish**.
12. In the top pane, expand the MAPDB tree and wire the values as shown:

```
VALUE  --- value
```

13. In the Spreadsheet pane, select the target $db:select and change fn:true() to: `$db:select.MAPDB.SCHEMA.TRANSACTION.ACCOUNT=$source/comp:addev4in/account` and `$db:select.MAPDB.SCHEMA.TRANSACTION.TDATE=$source/comp:addev4in/tdate`
14. Expand the Properties tree and set the following values:

```
MessageType     |    'addev4out'
```

15. Set the data source property for the Mapping node to MAPDB.
16. Create the following instance messages with appropriate MQRFH2 headers:

```
<comp:addev4in xmlns:comp="http://www.complex.net">
<account>12345678901</account>
<tdate>2005-05-15</tdate>
</comp:addev4in>
```

```
<comp:addev4in xmlns:comp="http://www.complex.net">
<account>12345678901</account>
<tdate>2005-04-25</tdate>
</comp:addev4in>
```

Results

You have created the following resources:

- A message called addev4in in a message definition called COMPLEX
- A message called addev4out in a message definition called COMP
- A message flow called addev4, which contains the mapping file `addev4_Mapping.msgmap`
- Files that contain instance messages

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This step is the eighth task in creating "Scenario D: Complex message enrichment" on page 2345. Deploy the message set and message flow and run the instance messages through the broker.

Procedure

1. Create a BAR file called addev4.
2. Add the message set MAPPING3_COMPLEX_messages and the message flow addev4 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance documents on the input queue.

Results

The output messages have the following content:

```
<c2:addev4out xmlns:c2="http://www.comp2.net" xmlns:comp="http://www.complex.net" >
<account>12345678901</account>
<tdate>2005-05-15</tdate>
<value>2891.3</value>
</c2:addev4out>
```

What to do next

Next: Continue with the next step, "Develop a message flow using a user-defined ESQL function" on page 2361.

Edit and configure message maps using the Message Mapping editor.

"Scenario D: Complex message enrichment" on page 2345
This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Supported databases" on page 3591
You can optionally configure databases to contain data that is accessed by your message flows. Databases from IBM and other suppliers are supported at specific versions on supported operating systems.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow using a user-defined ESQL function:

Develop a message flow that calls an ESQL function for mapping scenario D, complex message enrichment.

Before you begin

Before you start

Perform the previous tasks for this scenario, described in the following steps:

1. "Develop a message flow that contains other nodes" on page 2346
2. "Develop a message flow to map target fields from multiple other fields" on page 2349
3. "Develop a message flow and message model for mapping a complex nested, repeating message" on page 2352
4. "Develop a message flow for populating a target from a database" on page 2358

About this task

This step is the ninth task in creating "Scenario D: Complex message enrichment" on page 2345. Develop a message flow that uses a user-defined ESQL function, and create corresponding message models and instance documents.

Procedure

1. In the COMPLEX message definition, in namespace www.complex.net, create messages called addev5in and addev5out, which have the following structures:

```
addev5in
   value1                  (xsd:decimal) local element
   operator               (xsd:string) local element
   value2                  (xsd:decimal) local element
   rate                      (xsd:decimal) local element

addev5out
   grossvalue             (xsd:decimal) local element
   netvalue                 (xsd:decimal) local element
```

2. Create a message flow called addev5, which contains the following structure: MQInput -> Mapping -> MQOutput.

3. Open the map for the Mapping node, and select addev5in as the source and addev5out as the target.
4. In the MAPPING3_COMPLEX_flows project, create an ESQL file called addev5, and code the following functions:

```
CREATE FUNCTION calcGrossvalue(IN value1 DECIMAL, IN operator CHAR,
 IN value2 DECIMAL) RETURNS DECIMAL
          BEGIN
              DECLARE outval DECIMAL;
              CASE operator
              WHEN 'PLUS' THEN
                  SET outval = value1 + value2;
              WHEN 'MINUS' THEN
                  SET outval = value1 - value2;
              WHEN 'MULTIPLY' THEN
                  SET outval = value1 * value2;
              WHEN 'DIVIDE' THEN
                  SET outval = value1 / value2;
              ELSE
                  THROW USER EXCEPTION MESSAGE 2949 VALUES('Invalid Operator', operator);
                  SET outval = -999999;
              END CASE;
            RETURN outval;
          END;
```

```
CREATE FUNCTION calcNetvalue(IN value1 DECIMAL, IN operator CHAR, IN value2 DECIMAL,
 IN rate DECIMAL) RETURNS DECIMAL
    BEGIN
        DECLARE grossvalue DECIMAL;
        SET grossvalue=calcGrossvalue(value1, operator, value2);
        RETURN (grossvalue * rate );
    END;
```

5. In the Message Mapping editor Spreadsheet pane, expand the message and select grossvalue.
6. In the Expression pane, enter the expression:

```
esql:calcGrossvalue($source/comp:addev5in/value1,
$source/comp:addev5in/operator,
$source/comp:addev5in/value2)
```

7. Select the target netvalue, and in the Expression pane, enter the following expression:

```
esql:calcNetvalue($source/comp:addev5in/value1,
$source/comp:addev5in/operator,
$source/comp:addev5in/value2,
$source/comp:addev5in/rate)
```

8. Expand the Properties tree and set the following values:

```
MessageType      |       'addev5out'
```

9. Create the following instance messages, with appropriate MQRFH2 headers:

```
<comp:addev5in xmlns:comp="http://www.complex.net">
<value1>125.32</value1>
<operator>PLUS</operator>
<value2>25.86</value2>
<rate>0.60</rate>
</comp:addev5in>
```

```
<comp:addev5in xmlns:comp="http://www.complex.net">
<value1>118.00</value1>
<operator>MINUS</operator>
<value2>245.01</value2>
<rate>0.30</rate>
</comp:addev5in>
```

```
<comp:addev5in xmlns:comp="http://www.complex.net">
<value1>254.02</value1>
<operator>MULTIPLY</operator>
<value2>3.21</value2>
<rate>0.75</rate>
</comp:addev5in>

<comp:addev5in xmlns:comp="http://www.complex.net">
<value1>1456.33</value1>
<operator>DIVIDE</operator>
<value2>18.58</value2>
<rate>0.92</rate>
</comp:addev5in>

<comp:addev5in xmlns:comp="http://www.complex.net">
<value1>254.02</value1>
<operator>MOD</operator>
<value2>3.21</value2>
<rate>0.75</rate>
</comp:addev5in>
```

Results

You have created the following resources:

- Messages called addev5in and addev5out in a message definition called COMPLEX
- A message flow called addev5, which contains the mapping file `addev5_Mapping.msgmap` and ESQL file `addev5.esql`
- Files that contain instance messages

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This step is the tenth task in creating "Scenario D: Complex message enrichment" on page 2345. Deploy the message set and message flow, and run the instance messages through the broker.

Procedure

1. Create a BAR file called addev5.
2. Add the message set MAPPING3_COMPLEX_messages and the message flow addev5 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance documents on the input queue.

Results

The output messages have the following content:

```
<comp:addev5out xmlns:comp="http://www.complex.net">
<grossvalue>151.18</grossvalue>
<netvalue>90.708</netvalue>
</comp:addev5out>

<comp:addev5out xmlns:comp="http://www.complex.net">
<grossvalue>-127.01</grossvalue>
<netvalue>-38.103</netvalue>
</comp:addev5out>
```

```
<comp:addev5out xmlns:comp="http://www.complex.net">
<grossvalue>815.4042</grossvalue>
<netvalue>611.55315</netvalue>
</comp:addev5out>
```

```
<comp:addev5out xmlns:comp="http://www.complex.net">
<grossvalue>78.381593110871905274488697524219 59</grossvalue>
<netvalue>72.111065662002152852529601722282 02</netvalue>
</comp:addev5out>
```

If you do not see any message output, look for an entry in the Deployment Log with content similar to the following entry:

```
BIP2949 ( BRK.default ) A user generated ESQL exception has been thrown. The additional
information provided with this exception is: ''Invalid Operator'' ''MOD''
'addev5.Mapping.ComIbmCompute' '%5' '%6' '%7' '%8' '%9' '%10' '%11'
```

This exception was thrown by a THROW EXCEPTION statement, and shows the normal behavior of the THROW statement; this exception is user-generated, so the user action is determined by the message flow and the type of exception that is thrown.

What to do next

Next: Continue with the next step, "Develop a message flow using a user-defined Java procedure."

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Related tasks:

"Message mapping scenarios" on page 2318

Edit and configure message maps using the Message Mapping editor.

"Scenario D: Complex message enrichment" on page 2345
This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Develop a message flow using a user-defined Java procedure:

Develop a message flow that calls a Java procedure for mapping scenario D, complex message enrichment.

Before you begin

Before you start

Perform the previous tasks for this scenario, described in the following steps:

1. "Develop a message flow that contains other nodes" on page 2346
2. "Develop a message flow to map target fields from multiple other fields" on page 2349

3. "Develop a message flow and message model for mapping a complex nested, repeating message" on page 2352
4. "Develop a message flow for populating a target from a database" on page 2358
5. "Develop a message flow using a user-defined ESQL function" on page 2361

About this task

This step is the eleventh task in creating "Scenario D: Complex message enrichment" on page 2345. Develop a message flow using a user-defined Java procedure, and create corresponding message models and instance documents.

Procedure

1. In the COMPLEX message definition, in namespace www.complex.net, create messages called addev6in and addev6out, which have the following structures:

```
addev6in
    hexdata               (xsd:hexBinary) local element
addev6out
    decval                 (xsd:decimal) local element
    fltval                    (xsd:float) local element
    intval                  (xsd:int) local element
```

2. Create a message flow called addev6, which contains the following structure: MQInput -> Mapping -> MQOutput.
3. Open the map for the Mapping node, and select addev6in as the source and addev6out as the target.
4. In the MAPPING3_COMPLEX_flows project, create an ESQL file called `addev6` and put these functions in it:

```
CREATE PROCEDURE decFromBinary( IN hexval BLOB )
 RETURNS DECIMAL
 LANGUAGE JAVA
 EXTERNAL NAME "addev6.decFromBinary";
CREATE PROCEDURE fltFromBinary( IN hexval BLOB )
 RETURNS DECIMAL
 LANGUAGE JAVA
 EXTERNAL NAME "addev6.fltFromBinary";
CREATE PROCEDURE intFromBinary( IN hexval BLOB )
 RETURNS DECIMAL
 LANGUAGE JAVA
 EXTERNAL NAME "addev6.intFromBinary";
```

5. Create a Java source file called `addev6.java`, which has the following contents:

```
import java.lang.*;
import java.math.*;

public class addev6 {
    //
    // Return decimal element from binary string
    //
    public static BigDecimal decFromBinary( byte[] hexval) {
    // Look for element named decval
    String search = "decval";
    String snval = findElement(hexval ,search );
    // Convert the value to decimal type
    BigDecimal numval = new BigDecimal(snval);
    return numval;
    }
    //
    // Return float element from binary string
```

```
    //
    public static Double fltFromBinary( byte[] hexval) {
    // Look for element named fltval
    String search = "fltval";
    String snval = findElement(hexval ,search );
    // Convert the value to float type
    Double numval = new Double(snval);
    return numval;
    }
    //
    // Return integer element from binary string
    //
    public static Long intFromBinary( byte[] hexval) {
    // Look for element named intval
    String search = "intval";
    String snval = findElement(hexval ,search );
    // Convert the value to integer type
    Long numval = new Long(snval);
    return numval;
    }
    //
    // Locate the named element and its value in the binary data
    //
    private static String findElement( byte[] hexval, String search ) {
    // Convert bytes to string
    String hexstr = new String(hexval);
    // Fixed length label/value pairs (length=14)
    int nvals = hexstr.length() / 14;
    String numval = "";
    String[] label = new String[nvals];
    String[] value = new String[nvals];
    // Loop over number of label/value pairs
    for ( int i=0; i < nvals; i ++ ) {
        // get start position
        int st = i * 14;
        // label is length 6
        int endl = st + 6;
        // value is length 8
        int endv = endl + 8;
        // extract label and value from string
        label[i] = hexstr.substring( st, endl);
        value[i] = hexstr.substring( (endl+1), endv);
        // Check whether the current pair has the label requested
        if ( label[i].compareTo( search) == 0 ) {
        // trim padding from the value
        numval = value[i].trim();
        }
    }
    return numval;
    }
}
```

6. Compile the Java code, and add the location of the class file to the system classpath. You might have to restart Windows if you edit the CLASSPATH.
7. In the Message Mapping editor Spreadsheet pane, expand the target message and set the target decval to the value `esql:decFromBinary($source/comp:addev6in/bval)`.
8. Set the target fltval to `esql:fltFromBinary($source/comp:addev6in/bval)`.
9. Set the target intval to `esql:intFromBinary($source/comp:addev6in/bval)`.
10. Expand the Properties target and set the values shown:

    ```
    MessageType     |     'addev6out
    ```

11. Create the following instance message, with appropriate MQRFH2 headers:

```
<comp:addev6in xmlns:comp="http://www.complex.net">
<bval>
<![CDATA[64656376616c20202031342e3238666c7476616c
2020312e34452b32696e7476616c2020202020313230]]>
</bval>
</comp:addev6in>
```

Results

You have created the following resources:

- Messages called addev6in and addev6out in a message definition called COMPLEX
- A message flow called addev6, which contains the mapping file `addev6_Mapping.msgmap` and ESQL file `addev6.esql`
- A Java source file called `addev6.java` and a compiled class file called `addev6.class` in a place where the system CLASSPATH can find it
- Files that contain instance messages

What to do next

Now deploy the message set and message flow.

Deploy the message set and message flow:
About this task

This step is the final task in creating "Scenario D: Complex message enrichment" on page 2345. Deploy the message set and message flow, and run the instance message through the broker.

Procedure

1. Create a BAR file called addev6.
2. Add the message set MAPPING3_COMPLEX_messages and the message flow addev6 to the BAR file.
3. Deploy the BAR file to the broker.
4. Put the instance documents on the input queue.

Results

The output message has the following content:

```
<comp:addev6out xmlns:comp="http://www.complex.net">
<decval>14.28</decval>
<fltval>1.4E+2</fltval>
<intval>120</intval>
</comp:addev6out>
```

What to do next

Next: You have now completed scenario D. If you want more information about how to use maps, return to "Message mapping scenarios" on page 2318, and explore another scenario.

Related concepts:

"Message Mapping editor" on page 4981
You use the Message Mapping editor to create and edit message mappings.

Related tasks:

"Message mapping scenarios" on page 2318

Related reference:

"Message mappings" on page 4981
Edit and configure message maps using the Message Mapping editor.

"Scenario D: Complex message enrichment" on page 2345
This scenario demonstrates complex message enrichment and uses complex message manipulation. Use the WebSphere Message Broker Toolkit to create message flows and message sets, and to create and deploy broker archive (BAR) files.

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Scenario E: Resolving a choice with alternative message data:

This scenario demonstrates how to resolve a choice with alternative message data.

Before you begin

Before you start:

1. Create the appropriate message model, either by using the tooling or by importing the message structure files (for example, C header or XML Schema Definition files).
2. Create a message flow that has the following structure:

   ```
   MQInput > Mapping > MQOutput
   ```

About this task

The following message model is used in this example:

```
chsmess  (message)
 head   (xsd:string)
 choice  (group)
  str1  (xsd:string)
  int1  (xsd:int)
  dur1  (xsd:duration)
 footer  (xsd:string)
```

Procedure

1. Right-click the Mapping node and click **Open Map**.
2. Accept the default project and name, and click **Next**.
3. Accept the default usage and click **Next**.
4. Clear **Based on records in a database** and click **Next**.
5. Select `chsmess` as the source message and the target message, and click **OK**.
6. In the Connection pane, open the source and target trees by clicking the addition (+) icons.
7. Open the `chsmess` tree in the Source and Target panes in the same way.
8. In both Source and Target panes, click the addition (+) icon next to the `choice` group.
9. Click `head` in the Message Mapping editor Source pane and drag it onto `head` in the Target pane. A line joins them.
10. Repeat Step 10 for each corresponding element (`str1`, `int1`, `dur1`, and `footer`.)
11. In the Map Script | Value table, open the tree by clicking the `$target +` box.

12. Open the chsmess tree. A set of if-elseif elements appears.
13. Open each if or elseif element. One if or elseif statement exists for each choice; each if or elseif statement has the condition 1=1.
14. Click the first function (for example, for str1) and change it in the Edit pane so that it has the content $source/chsmess/head='str1. If the input element head has a value str1, the assignment str1 <- $source/chsmess/str1 takes place.
15. Click the second function (for example, for int1) and change it in the Expression editor so that it has the content $source/chsmess/head='int1'. If the input element head has a value int1, the assignment int1 <- $source/chsmess/int1 takes place.
16. Click the third function (for example, for dur1) and change it in the Expression editor so that it has the content $source/chsmess/head='dur1'. If the input element head has a value dur1, the assignment dur1 <- $source/chsmess/dur1 takes place.
17. Save the mapping by clicking **File** > **Save**.

Results

You have completed this scenario. The message model contains a choice that has been resolved by using other data in the instance message.

Scenario F: Updating the value of a message element:

This scenario demonstrates how to update the value of a message element.

Before you begin

Before you start:

1. Create the appropriate message model, either by using the WebSphere Message Broker Toolkit, or by importing the message structure files (for example, C header or XML Schema Definition files).
2. Create a message flow that has the following structure:
   ```
   MQInput > Mapping > MQOutput
   ```

About this task

The message model used in this example has the following structure:

```
simple  (message)
  int (xsd:int)
  str (xsd:str)
```

Procedure

1. Right-click the Mapping node and click **Open Map**.
2. Select `simple` as the source message and the target message and click **OK**.
3. In the connection pane, open the source and target trees by clicking the addition (+) icons.
4. Open the `simple` trees on both sides in the same way.
5. Select `int` in the Message Mapping editor Source pane, and drag it onto `int` in the Target pane. A line joins them.
6. Select `str` in the Message Mapping editor Source pane and drag it onto `str` in the Target pane. A line joins them.
7. In the Map Script | Value table, open the tree by clicking the `$target +` box
8. Open the `simple` tree in the same way; both `int` and `str` have values (for example, `int $source/simple/int` and `str $source/simple/str`).
9. Select the value for `int`. The value appears in the Expression Editing pane.
10. Edit the value so that it has the content `$source/simple/int + 1` and press Enter. The value in the table is updated (the input value is incremented).
11. Select the value for `str` and edit it so that it has the content `esql:upper($source/simple/str)`, and press Enter. The value in the table is updated (the input value to is changed to uppercase).
12. Save the mapping by clicking **File** > **Save**.

Results

You have completed this scenario. The input and output messages have the same structure and format, but the element values have been modified.

Developing ESQL

Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

About this task

You must create, for each node, an ESQL module in which you code the ESQL statements and functions to tailor the behavior of the node. You can access message content, or database content, or both, to achieve the results that you require. ESQL modules are maintained in ESQL files, managed through the Broker Application Development perspective.

This section provides the following information:

- "ESQL overview"
- "Managing ESQL files" on page 2390
- "Writing ESQL" on page 2413

You can use the ESQL debugger, which is part of the flow debugger, to debug the code that you write. The debugger steps through ESQL code statement by statement, so that you can view and check the results of every line of code that is run.

ESQL overview

Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

This section contains introductory information about ESQL.

- For descriptions of ESQL user tasks, see "Writing ESQL" on page 2413.
- For reference information about ESQL, see "ESQL reference" on page 5019.

Read the following information before you proceed:

- An overview of message flows in "Message flows overview" on page 1022.
- An overview of message trees in "The message tree" on page 1041, and the topics within this container, paying special attention to "Logical tree structure" on page 1042.

ESQL is based on Structured Query Language (SQL) which is in common usage with relational databases such as DB2. ESQL extends the constructs of the SQL language to provide support for you to work with message and database content to define the behavior of nodes in a message flow.

The ESQL code that you create to customize nodes within a message flow is defined in an ESQL file, typically named `<message_flow_name>.esql`, which is associated with the message flow project. You can use ESQL in the following built-in nodes:

- "Compute node" on page 4340
- "Database node" on page 4354
- "DatabaseInput node" on page 4360
- "Filter node" on page 4452

You can also use ESQL to create functions and procedures that you can use in the following built-in nodes:

- "DataDelete node" on page 4382
- "DataInsert node" on page 4386
- "DataUpdate node" on page 4390
- "Extract node" on page 4412
- "Mapping node" on page 4571
- "Warehouse node" on page 4963

To use ESQL correctly and efficiently in your message flows, you must also understand the following concepts:

- Data types
- Variables
- Field references
- Operators
- Statements
- Functions
- Procedures
- Modules

Use the ESQL debugger, which is part of the flow debugger, to debug the code that you write. The debugger steps through ESQL code statement by statement, so that you can view and check the results of every line of code that is run.

"ESQL reference" on page 5019
SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

ESQL data types:

A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

Within a broker, the fields of a message contain data that has a definite data type. It is also possible to use intermediate variables to help process a message. You must declare all such variables with a data type before use. A variable's data type is fixed; If you try to assign values of a different type you get either an implicit cast or an exception. Message fields do not have a fixed data type, and you can assign values of a different type. The field adopts the new value and type.

It is not always possible to predict the data type that results from evaluating an expression. This is because expressions are compiled without reference to any kind of message schema, and so some type errors are not caught until run time.

ESQL defines the following categories of data. Each category contains one or more data types.

- Boolean
- Datetime
- Null
- Numeric
- Reference
- String

A message flow is a sequence of processing steps that run in the broker when an input message is received.

"Correlation names" on page 1069
A correlation name is a field reference that identifies a well-defined starting point in the logical message tree and is used in field references to describe a standard part of the tree format.

"Message mapping overview" on page 2229
Message mappings define the blueprint for creating a message, where the created message is known as the target message.

"Representation of ESQL datetime data types" on page 5030
When your application sends a message to a broker, the way in which the message data is interpreted depends on the content of the message itself and the configuration of the message flow. If your application sends a message to be interpreted either by the generic XML parser, or the MRM parser, that is tailored by an XML physical format, the application can include date or time data that is represented by any of the XML Schema primitive datetime data types.

"CAST function" on page 5245

"Supported casts" on page 5273

ESQL variables:

An ESQL variable is a data field that is used to help process a message.

You must declare a variable and state its type before you can use it. The data type of a variable is fixed; if you code ESQL that assigns a value of a different type, either an implicit cast to the data type of the target is implemented or an exception is raised (if the implicit cast is not supported).

To define a variable and give it a name, use the DECLARE statement.

The names of ESQL variables are case-sensitive; therefore, make sure that you use the correct case in all places. The simplest way to guarantee that you are using the correct case is always to define variables using uppercase names.

The WebSphere Message Broker Toolkit marks variables that have not been defined. Remove all these warnings before deploying a message flow.

You can assign an initial value to the variable on the DECLARE statement. If an initial value is not specified, scalar variables are initialized with the special value NULL, and ROW variables are initialized to an empty state. Then, you can change the value of a variable by using the SET statement.

ESQL Variables declared at Module level 'belong' to a single node. However, variables declared at the Schema level are also given to each node that references that schema. So although variables at schema level are only declared once, each ESQL node has its own copy, which is not shared with any other node (unless the variable is marked `SHARED`).

Three types of built-in node can contain ESQL code and therefore support the use of ESQL variables:
- "Compute node" on page 4340
- "Database node" on page 4354
- "DatabaseInput node" on page 4360
- "Filter node" on page 4452

Scope, lifetime, and sharing characteristics of variables

The scope, lifetime, and sharing characteristics of variables describe how widespread and for how long a particular ESQL variable is available:

Scope Is a measure of the range over which a variable is visible. In the broker environment, the scope of variables is typically limited to the individual node.

Lifetime
Is a measure of the time for which a variable retains its value. In the broker environment, the lifetime of variables varies but is typically restricted to the life of a thread within a node.

Sharing characteristics
Indicate whether each thread has its own copy of a variable or whether one variable is shared between many threads. In the broker environment, variables are typically not shared.

Types of variable

External
External variables (defined with the EXTERNAL keyword) are also known as *user-defined properties*, see "User-defined properties in ESQL" on page 2376. They exist for the entire lifetime of a message flow and are visible to all messages passing through the flow. You can define external variables only at the module and schema level. You can modify the initial values of external variables (optionally set by the DECLARE statement) at design time, by using the Message Flow editor, or at deployment time, by using the Broker Archive editor. You can query and set the values of user-defined properties at run time by using the Administration API for WebSphere Message Broker (also known as the CMP API). For more information, see "Setting message flow user-defined properties at run time in a CMP application" on page 985.

Normal
Normal variables have a lifetime of just one message passing through a node. They are visible to that message only. To define normal variables, omit both the EXTERNAL and SHARED keywords.

Shared
Shared variables can be used to implement an in-memory cache in the message flow, see "Optimizing message flow response times" on page 3264. Shared variables have a long lifetime and are visible to multiple messages passing through a flow, see "Long-lived variables" on page 2378. Shared variables exist for the lifetime of the execution group process, the lifetime of the flow or node, or the lifetime of the node SQL that declares the variable (whichever is the shortest). Shared variables are initialized when the first message passes through the flow or node after each broker startup.

See also the ATOMIC option of the “BEGIN ... END statement” on page 5070. The BEGIN ATOMIC construct is useful when a number of changes must be made to a shared variable and it is important to prevent other instances seeing the intermediate states of the data.

Use the Filter node to route a message according to message content.

“DECLARE statement” on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

“BEGIN ... END statement” on page 5070
The BEGIN ... END statement gives the statements defined within the BEGIN and END keywords the status of a single statement.

User-defined properties in ESQL:

Access user-defined properties (UDPs) as variables in your ESQL program by specifying the EXTERNAL keyword on a DECLARE statement. For example, the ESQL statement `DECLARE today EXTERNAL CHARACTER 'monday'` defines a user-defined property called today with an initial value monday.

Before you can use a user-defined property, you must define the property in the Message Flow editor when you construct a message flow that uses it. When you define a UDP in the Message Flow editor, you must define a value and the property type. The value can be a default value, which varies according to the type of the UDP. The value that is assigned to the UDP in the Message Flow editor takes precedence over a value that you have assigned to the UDP in your ESQL program.

You can also define a UDP for a subflow. A UDP has global scope and is not specific to a particular subflow. If you reuse a subflow in a message flow, and those subflows have identical UDPs, you cannot set the UDPs to different values.

Before you deploy the message flow that uses the UDP, you can change the value of the UDP in the Broker Archive editor. If you try to deploy a message flow that contains a UDP that has had no value assigned to it, a deployment failure occurs. For more information, see "Configuring a message flow at deployment time with user-defined properties" on page 2626.

You can use UDPs to set configuration data, and use them like typical properties. No external calls to user-written plug-ins or parsing of environment trees are involved, and parsing costs of reading data out of trees are removed. The value of the UDP is finalized in the variable at deployment time.

You can declare UDPs only in modules or schemas. You can query, discover, and set UDPs at run time, to dynamically change the behavior of a message flow. For more information, see "User-defined properties" on page 1147.

You can access UDPs from the following built-in nodes that use ESQL:
- Compute
- Database
- DatabaseInput
- Filter

For a description of how to access a UDP from a JavaCompute node, see "Accessing message flow user-defined properties from a JavaCompute node" on page 2659.

"Broker Archive editor" on page 6794
Use the Broker Archive editor to create and manage broker archive (BAR) files.

Long-lived variables:

You can use appropriate long-lived ESQL data types to cache data in memory.

Sometimes data has to be stored beyond the lifetime of a single message passing through a flow. One way to store this data is to store the data in a database. Using a database is good for long-term persistence and transactionality, but access (particularly write access) is slow.

Alternatively, you can use appropriate long-lived ESQL data types to provide an in-memory cache of the data for a certain period of time. Using long-lived ESQL data types makes access faster than from a database, although this speed is at the expense of shorter persistence and no transactionality.

You create long-lifetime variables by using the SHARED keyword on the DECLARE statement. For further information, see "DECLARE statement" on page 5117.

The following sample demonstrates how to define shared variables using the DECLARE statement. The sample demonstrates how to store routing information in a database table and use shared variables to store the database table in memory in the message flow to improve performance.

- Message Routing

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Long-lived data types have an extended lifetime beyond that of a single message passing through a node. Long-lived data types are shared between threads and exist for the life of a message flow (the time between configuration changes to a message flow), as described in the following tables.

Table 23. Short lifetime variables

	Scope	**Life**	**Shared**
Schema & Module	Node	Thread within node	Not at all
Routine Local	Node	Thread within routine	Not at all
Block Local	Node	Thread within block	Not at all

Table 24. Long lifetime variables

	Scope	**Life**	**Shared**
Node Shared	Node	Life of node	All threads of flow
Flow Shared	Flow	Life of flow	All threads of flow

Features of long-lived ESQL data types include:

- The ability to handle large amounts of long-lifetime data.
- The joining of data to messages fast.
- On multiple processor machines, multiple threads can access the same data simultaneously.
- Subsequent messages can access the data left by a previous message.
- Long lifetime read-write data can be shared between threads, because there is no long-term association between threads and messages.
- In contrast to data stored in database tables in the environment, this type of data is stored privately; that is, within the broker.
- ROW variables can be used to create a modifiable copy of the input message; see "ESQL ROW data type" on page 5038.
- It is possible to create shared constants.

A typical use of these data types might be in a flow in which data tables are 'read-only' as far as the flow is concerned. Although the table data is not actually static, the flow does not change it, and thousands of messages pass through the flow before there is any change to the table data.

Examples include:

- A table which contains a day's credit card transactions. The table is created each day and that day's messages are run against it. Then the flow is stopped, the table updated and the next day's messages run. These flows might perform better if they cache the table data rather than read it from a database for each message.
- The accumulation and integration of data from multiple messages.

Related concepts:

"ESQL variables" on page 2374
An ESQL variable is a data field that is used to help process a message.

"User-defined properties in ESQL" on page 2376
Access user-defined properties (UDPs) as variables in your ESQL program by specifying the EXTERNAL keyword on a DECLARE statement. For example, the ESQL statement `DECLARE today EXTERNAL CHARACTER 'monday'` defines a user-defined property called today with an initial value monday.

Related reference:

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable

and, optionally, its initial value.

"ESQL ROW data type" on page 5038
The ROW data type holds a *tree structure*. A row in a database is a particular type of tree structure, but the ROW data type is not restricted to holding data from database rows.

Broker properties:

For each broker, WebSphere Message Broker maintains a set of properties. You can access some of these properties from your ESQL programs. A subset of the properties is also accessible from Java programs. It can be useful, at run time, to have real-time access to details of a specific node, flow, or broker.

Broker properties are divided into four categories:

- Properties that relate to a specific node
- Properties that relate to nodes in general
- Properties that relate to a message flow
- Properties that relate to the execution group

For a description of the broker, flow, and node properties that are accessible from ESQL and Java, see "Broker properties that are accessible from ESQL and Java" on page 5302.

Broker properties have the following characteristics.

- They are grouped by broker, execution group, flow, and node.
- They are case-sensitive. Their names always start with an uppercase letter.
- They return NULL if they do not contain a value.

All nodes for which user programs can edit ESQL support access to broker properties. These nodes are:

- Compute nodes
- Database nodes
- DatabaseInput nodes
- Filter nodes
- All derivatives of these nodes

User-defined properties can be queried, discovered, and set at run time to dynamically change the behavior of a message flow. You can use the Administration API for WebSphere Message Broker(CMP API) to manipulate these properties, which can be used by a systems monitoring tool to perform automated actions in response to situations that it detects in the monitored systems. For more information, see "User-defined properties" on page 1147.

A *complex property* is a property to which you can assign multiple values. Complex properties are displayed in a table in the Properties view, where you can add, edit, and delete values, and change the order of the values in the table. You cannot promote complex properties; therefore, they are not shown in the Promote properties dialog box. Nor can you configure complex properties; therefore, they are not supported in the Broker Archive editor. For an example of a complex property, see the `Query elements` property of the DatabaseRoute node.

For more information about editing the properties of a node, see "Configuring a message flow node" on page 1503.

Related concepts:

Use the DatabaseRoute node to route messages using information from a database in conjunction with XPath expressions.

ESQL field references:

An ESQL field reference is a sequence of period-separated values that identify a specific field (which might be a structure) within a message tree or a database table.

The path from the root of the information to the specific field is traced using the parent-child relationships.

A field reference is used in an ESQL statement to identify the field that is to be referenced, updated, or created within the message or database table. For example, you might use the following identifier as a message field reference:

```
Body.Invoice.Payment
```

You can use an ESQL variable of type REFERENCE to set up a dynamic pointer to contain a field reference. This might be useful in creating a fixed reference to a commonly-referenced point within a message; for example the start of a particular structure that contains repeating fields.

A field reference can also specify element types, XML namespace identifications, indexes and a type constraint; see "ESQL field reference overview" on page 5049 for further details.

The first name in a field reference is sometimes known as a *Correlation name*.

Related concepts:

“ESQL field reference overview” on page 5049
You can use ESQL field references to form paths to message body elements.

ESQL operators:

An ESQL operator is a character or symbol that you can use in expressions to specify relationships between fields or values.

ESQL supports the following groups of operators:

- Comparison operators, to compare one value to another value (for example, "less than"). Refer to “ESQL simple comparison operators” on page 5057 and “ESQL complex comparison operators” on page 5058 for details of the supported operators and their use.
- Logical operators, to perform logical operations on one or two terms (for example, AND). Refer to “ESQL logical operators” on page 5062 for details of the supported operators and their use.
- Numeric operators, to indicate operations on numeric data (for example, +). Refer to “ESQL numeric operators” on page 5064 for details of the supported operators and their use.

There are some restrictions on the application of some operators to data types; not all lead to a meaningful operation. These are documented where they apply to each operator.

Operators that return a Boolean value (TRUE or FALSE), for example the "greater than" operator, are also known as *predicates*.

“ESQL operators” on page 5056
A list of the various groups of operators that ESQL supports.

ESQL statements:

An ESQL statement is an instruction that represents a step in a sequence of actions or a set of declarations.

ESQL provides a large number of different statements that perform different types of operation. All ESQL statements start with a keyword that identifies the type of statement and end with a semicolon. An ESQL program consists of a number of statements that are processed in the order they are written.

As an example, consider the following ESQL program:

```
DECLARE x INTEGER;
SET x = 42;
```

This program consists of two statements. The first starts with the keyword DECLARE and ends at the first semicolon. The second statement starts with the keyword SET and ends at the second semicolon. These two statements are written on separate lines and it is conventional (but not required) that they be so. You will notice that the language keywords are written in capital letters. This is also the convention but is not required; mixed case and lowercase are acceptable.

The first statement declares a variable called x of type INTEGER, that is, it reserves a space in the computer's memory large enough to hold an integer value and allows this space to be subsequently referred to in the program by the name x. The second statement sets the value of the variable x to 42. A number appearing in an ESQL program without decimal point and not within quotation marks is known as an integer literal.

ESQL has a number of data types and each has its own way of writing literal values. These are described in “ESQL data types” on page 2373.

For a full description of all the ESQL statements, see “ESQL statements” on page 5067.

Related concepts:

“Message flows overview” on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

"Message mapping overview" on page 2229
Message mappings define the blueprint for creating a message, where the created message is known as the target message.

"ESQL data types" on page 2373
A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

ESQL nested statements:

An ESQL nested statement is a statement that is contained within another statement.

Consider the following ESQL program fragment:

```
IF Size> 100.00 THEN
  SET X = 0;
  SET Y = 0;
  SET REVERSE = FALSE;
ELSE
  SET X = 639;
  SET Y = 479;
  SET REVERSE = TRUE;
END IF;
```

In this example, you can see a single IF statement containing the optional ELSE clause. Both the IF and ELSE portions contain three nested statements. Those within the IF clause are processed if the operator > (greater than) returns the value TRUE (that is, if Size has a value greater than 100.00); otherwise, those within the ELSE clause are processed.

Many statements can have expressions nested within them, but only a few can have statements nested within them. The key difference between an expression and a statement is that an expression calculates a value to be used, whereas a statement performs an action (usually changing the state of the program) but does not produce a value.

SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

ESQL functions:

A function is an ESQL construct that calculates a value from a number of given input values.

A function usually has input parameters and can, but does not usually have, output parameters. It returns a value calculated by the algorithm described by its statement. This statement is usually a compound statement, such as BEGIN... END, because this allows an unlimited number of nested statements to be used to implement the algorithm.

ESQL provides a number of predefined, or "built-in", functions which you can use freely within expressions. You can also use the CREATE FUNCTION statement to define your own functions.

When you define a function, you must give it a unique name. The name is handled in a non-case sensitive way (that is, use of the name with any combination of uppercase and lowercase letters matches the declaration). This is in contrast to the names that you declare for schemas, constants, variables, and labels, which are handled in a case sensitive way, and which you must specify exactly as you declared them.

Consider the following ESQL program fragment:

```
SET Diameter = SQRT(Area / 3.142) * 2;
```

In this example, the function SQRT (square root) is given the value inside the brackets (itself the result of an expression, a divide operation) and its result is used in a further expression, a multiply operation. Its return value is assigned to the variable Diameter. See "Calling ESQL functions" on page 5168 for information about all the built-in ESQL functions.

In addition, an ESQL expression can refer to a function in another broker schema (that is, a function defined by a CREATE FUNCTION statement in an ESQL file in the same or in a different dependent project). To resolve the name of the called function, you must do one of the following:

- Specify the fully-qualified name (<SchemaName>.<FunctionName>) of the called function.
- Include a PATH statement to make all functions from the named schema visible. Note that this technique only works if the schemas do not contain identically-named functions. The PATH statement must be coded in the same ESQL file, but not within any MODULE.

Note that you cannot define a function within an EVAL statement or an EVAL function.

SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

"Calling ESQL functions" on page 5168
Most ESQL functions belong to a schema called SQL and this is particularly useful if you have functions with the same name.

"CREATE FUNCTION statement" on page 5091
The CREATE FUNCTION statement defines a callable function or procedure.

"CREATE MODULE statement" on page 5101
The CREATE MODULE statement creates a module, which is a named container associated with a node.

"CREATE PROCEDURE statement" on page 5103
The CREATE PROCEDURE statement defines a callable function or procedure.

ESQL procedures:

An ESQL procedure is a subroutine that has no return value. It can accept input parameters from, and return output parameters to, the caller.

Procedures are very similar to functions. The main difference between them is that, unlike functions, procedures have no return value. Thus they cannot form part of an expression and are invoked by using the CALL statement. Procedures commonly have output parameters

You can implement a procedure in ESQL (an internal procedure) or as a database stored procedure (an external procedure). The ESQL procedure must be a single

ESQL statement, although that statement can be a compound statement such as BEGIN END. You cannot define a procedure within an EVAL statement or an EVAL function.

When you define a procedure, give it a name. The name is handled in a non-case sensitive way (that is, use of the name with any combination of uppercase and lowercase letters matches the declaration). That is in contrast to the names that you declare for schemas, constants, variables, and labels, which are handled in a case sensitive way, and which you must specify exactly as you declared them.

An ESQL expression can include a reference to a procedure in another broker schema (defined in an ESQL file in the same or a different dependent project). If you want to use this technique, either fully qualify the procedure, or include a PATH statement that sets the qualifier. The PATH statement must be coded in the same ESQL file, but not within a MODULE.

An external database procedure is indicated by the keyword EXTERNAL and the external procedure name. This procedure must be defined in the database and in the broker, and the name specified with the EXTERNAL keyword and the name of the stored database procedure must be the same, although parameter names do not have to match. The ESQL procedure name can be different from the external name it defines.

Overloaded procedures are not supported to any database. (An overloaded procedure is one that has the same name as another procedure in the same database schema which has a different number of parameters, or parameters with different types.) If the broker detects that a procedure has been overloaded, it raises an exception.

Dynamic schema name resolution for stored procedures is supported; when you define the procedure you must specify a wildcard for the schema that is resolved before invocation of the procedure by ESQL. This is explained further in “Invoking stored procedures” on page 2503.

"CREATE MODULE statement" on page 5101
The CREATE MODULE statement creates a module, which is a named container associated with a node.

"CREATE PROCEDURE statement" on page 5103
The CREATE PROCEDURE statement defines a callable function or procedure.

ESQL modules:

A module is a sequence of declarations that define variables and their initialization, and a sequence of subroutine (function and procedure) declarations that define a specific behavior for a message flow node.

A module must begin with the `CREATE` *`node_type`* `MODULE` statement and end with an `END MODULE` statement. The *node_type* must be one of COMPUTE, DATABASE, DATABASEEVENT, or FILTER. For DatabaseInput nodes, the required *node_type* is DATABASEEVENT. For Compute, Database, and Filter nodes the required *node_type* is the same as the node. For example, you must use the COMPUTE *node_type* in ESQL modules for Compute nodes. For Compute, Database and Filter nodes, the entry point of the ESQL code is the function named MAIN, which has MODULE scope. ESQL modules for DatabaseInput nodes do not contain the MAIN function, but contain three procedures named READEVENTS, BUILDMESSAGE, and ENDEVENT. For more information about these three procedures, see "Configuring a DatabaseInput node" on page 2120.

Each module is identified by a name which follows `CREATE` *`node_type`* `MODULE`. The name might be created for you with a default value, which you can modify, or you can create it yourself. The name is handled in a non-case-sensitive way (that is, use of the name with any combination of uppercase and lowercase letters matches the declaration). This is in contrast to the names that you declare for schemas, constants, variables, and labels, which are handled in a case-sensitive way, and which you must specify exactly as you declared them.

You must create the code for a module in an ESQL file which has a suffix of `.esql`. You must create this file in the same broker schema as the node that references it. There must be one module of the correct type for each corresponding node, and it is specific to that node and cannot be used by any other node.

When you create an ESQL file (or complete a task that creates one), you indicate the message flow project and broker schema with which the file is associated and specify a name for the file.

Within the ESQL file, the name of each module is determined by the value of the corresponding property of the message flow node. For example, the property *`ESQL Module`* for the Compute node specifies the name of the module in the ESQL file for that node. The default value for this property is the name of the node. You can

specify a different name, but you must ensure that the value of the property and the name of the module that provides the required function are the same.

For Compute, Database, and Filter nodes, the module must contain the function MAIN, which is the entry point for the module. This function is included automatically if the module is created for you. Within MAIN, you can code ESQL to configure the behavior of the node. If you include ESQL within the module that declares variables, constants, functions, and procedures, these are of local scope only and can be used within this single module.

For DatabaseInput nodes, the module must contain the three procedures READEVENTS, BUILDMESSAGE, and ENDEVENT. These procedures are included automatically, together with comments to describe the procedure, if the module is created for you. Within the three procedures, you can code ESQL to configure the behavior of the node, see "Configuring a DatabaseInput node" on page 2120. If you include ESQL within the module that declares variables, constants, functions, and procedures, these are of local scope only and can be used within this single module.

If you want to reuse ESQL constants, functions, or procedures, you must declare them at broker schema level. You can then refer to these constants, functions or procedures from any resource within that broker schema, in the same or another project. If you want to use this technique, either fully qualify the procedure, or include a PATH statement that sets the qualifier. The PATH statement must be coded in the same ESQL file, but not within any MODULE.

Managing ESQL files

In a message flow project, manage ESQL files that contain the ESQL code that you provide to modify or customize the behavior of Compute, Database, DatabaseInput, and Filter nodes.

About this task

The ESQL code for a node is contained in a module that is associated with the node. Each module must be created in an ESQL file (file extension `.esql`) . You can change the name of the module in the ESQL file from its default value of *`MessageFlow_NodeName`*, where *MessageFlow* is the name of the message flow and *NodeName* is the name of the node. The name of the module in the ESQL file must match the name specified for the module in the `ESQL Module` property of the corresponding node.

The following topics describe how to manage ESQL files.

- "Creating an ESQL file" on page 2391
- "Opening an existing ESQL file" on page 2393
- "Creating ESQL for a node" on page 2394

"ESQL reference" on page 5019
SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

Creating an ESQL file:

When you include a node in your message flow that requires ESQL to customize its function (the Compute, Database, DatabaseInput, and Filter nodes), you must code the ESQL statements that provide the customization in an ESQL module in an ESQL file. You can use the same ESQL file for more than one module.

Before you begin

Before you start:

For background information, see "ESQL overview" on page 2371.

To complete this task, you must have created a message flow project to contain your ESQL file.

About this task

ESQL files are stored in a file system or in a shared repository. If you are using a file system, you can use the local file system or a shared drive. If you store files in a repository, you can use any of the available repositories that are supported by Eclipse, for example CVS.

To create an ESQL file, complete the following steps.

Procedure

1. Click **File** > **New** > **Message Flow ESQL File**.

   You can also press Ctrl+N. A dialog box opens, in which you can select the wizard to create a new object. Click Message Brokers; a list of objects that you can create for WebSphere Message Broker is shown. Click **Message Flow ESQL File**, then click **Next**. The New Message Flow ESQL File wizard opens.
2. Enter the name of the message flow project in which to create the ESQL file.

   You must enter the name of an existing message flow project. The dialog box opens with the current project name entered in the project name field. You can accept this value or change it to specify a different project. You can also click **Browse** to view a list of valid projects (projects that are defined and shown in the Navigator view), and select the appropriate value from that list. The list is filtered to only show projects in the active working set.

   If you type in the name of a project that does not exist, the error message `The specified project does not exist` is shown in the dialog box and you cannot continue until you specify a valid project name.
3. If you want the ESQL file to be defined in a specific broker schema, enter the name of the broker schema in the appropriate entry field, or click **Browse** to

select the broker schema from the list of valid broker schema for this project. (If the default broker schema is the only one that is defined in this project, **Browse** is disabled.)

4. Enter a name for the new ESQL file. If you enter a name that is already in use for an ESQL file in this project, the error message `The resource <name>.esql already exists` is shown and you must specify a different name.

   When creating ESQL files, the overall file path length must not exceed 256 characters, due to a Windows file system limitation. If you try to add a message flow to a broker archive file with ESQL or mapping files with a path length that exceeds 256 characters, the compiled message flow is not generated and cannot be deployed. Therefore, make sure that the names of your ESQL files, mapping files, projects, and broker schema are as short as possible.
5. Click **Finish**.

Results

The ESQL file opens in the editor, where you can edit the file, then save it.

An ESQL file can also be created automatically for you. You can right-click a Compute, Database, DatabaseInput, or Filter node, then click **Open ESQL**. If the module identified by the appropriate property does not already exist in the broker schema, a module is created automatically. This module is created in the file `<message_flow_name>.esql` in the same broker schema in the same project as the `<message_flow_name>.msgflow` file. If that ESQL file does not already exist, that is also created for you.

The contents of a single ESQL file do not have any specific relationship with message flows and nodes. It is your decision which modules are created in which files (unless the specified module, identified by the appropriate property, is created by default in the file `<message_flow_name>.esql` as described above). Monitor the size and complexity of the ESQL in each file, and split the file if it becomes difficult to view or manage.

If you create reusable subroutines (at broker schema level) in an ESQL file, you might want to refer to these routines from ESQL modules in another project. To refer to the routines, specify that the project that runs the subroutines depends on the project in which the ESQL file containing them is defined. You can specify this behavior when you create the second project, or you can update project dependencies by selecting the project, clicking **Properties**, and updating the dependencies in the Project Reference page of the Properties dialog box.

SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

Opening an existing ESQL file:

You can add to and modify ESQL code that you have created in an ESQL file.

Before you begin

Before you start:

To complete this task, you must have created an ESQL file, as described in "Creating an ESQL file" on page 2391.

About this task

To open an existing ESQL file, complete the following steps.

Procedure

1. In the Broker Development view, double-click the ESQL file that you want to open. The file is opened in the editor view.
2. Edit the contents of file to make your changes. The file can contain modules that relate to specific nodes in a message flow, PATH statements, and declarations at broker schema level, such as reusable constants and procedures. You can select the content that you want to work with by selecting its name in the Outline view. The code for the selected resource is highlighted.
3. Save and close the ESQL file.

Results

You can also open an ESQL file when you have a message flow open in the editor view by right-clicking an appropriate node (a Compute, Database, DatabaseInput, or Filter node), then clicking **Open ESQL**. In this case, the ESQL file that contains
