     – DataObject
     – JSON
     – BLOB
     – MIME

- MRM
- JMSMap
- JMSStream
- XMLNS

You can also specify a user-defined parser, if appropriate.

- If you are using the MRM or IDOC parser, or the XMLNSC parser in validating mode, select the `Message set` that you want to use. This list is populated with available message sets when you select MRM, XMLNSC, or IDOC as the domain.
- If you are using the MRM parser, select the correct message type from the list in `Message type`. This list is populated with available message types when you select the MRM parser.
- If you are using the MRM or IDOC parser, select the correct message format from the list in `Message format`. This list is populated with available message formats when you select the MRM or IDOC parser.
- Specify the message coded character set ID in `Message coded character set ID`.
- Select the message encoding from the list in `Message encoding` or specify a numeric encoding value. For more information about encoding, see "Data conversion" on page 1151.

7. On the **Parser Options** subtab:
   - `Parse timing` is, by default, set to `On Demand`, which causes parsing of the message to be delayed. To cause the message to be parsed immediately, see "Parsing on demand" on page 4173.
   - If you are using the XMLNSC parser, set values for the properties that determine how the XMLNSC parser operates. For more information, see "Manipulating messages in the XMLNSC domain" on page 2546.
8. Use the **Records and Elements** tab to specify how the data is interpreted as records. Only one record is retrieved each time the TCPIPServerReceive node is started; therefore, if the TCP/IP stream contains multiple logical messages, you must start the node multiple times to receive all the messages.
   - Use the `Record detection` property to determine how the data is split into records, each of which generates a single message. Choose from the following options:
     - `Connection closed` specifies that all of the data sent during a connection is a single record.
     - `Fixed Length` specifies that each record is a fixed number of bytes in length. Each record contains the number of bytes specified in the `Length` property, except possibly a shorter final record in the file.
     - Select `Delimited` if the records that you are processing are separated, or terminated, by a DOS or UNIX line end or by a sequence of user-defined delimiter bytes. Specify the delimiter and delimiter type in the `Delimiter` and `Delimiter type` properties.
     - Select `Parsed Record Sequence` if the data contains a sequence of one or more records that are serially recognized by the parser that is specified in `Message domain`. The node propagates each recognized record as a separate message. If you select this `Record detection` option, the parser specified in `Message domain` must be either XMLNSC or MRM (either CWF or TDS physical format).
   - If you set `Record detection` to `Fixed Length`, use `Length` to specify the required length of the output record. This value must be between 1 byte and 100 MB. The default is `80` bytes.

If you set Record detection to Connection closed, Fixed Length, or Delimited, a limit of 100 MB applies to the length of the records. If you set Record detection to Parsed Record Sequence, the TCPIPServerReceive node does not determine or limit the length of a record. Nodes that are downstream in the message flow might try to determine the record length or process a long record. If you intend to process large records in this way, ensure that your broker has sufficient memory. You might have to apply message flow techniques described in the Large Messaging sample to make the best use of the available memory.

- If you set Record detection to Delimited, use Delimiter to specify the delimiter to be used. Choose from the following options:
  - DOS or UNIX Line End, on UNIX systems, specifies the line feed character (<LF>, X'0A'), and, on Windows systems, specifies a carriage return character followed by a line feed character (<CR><LF>, X'0D0A'). The node treats both of these strings as delimiters, irrespective of the system on which the broker is running. If both strings can be seen in the same record, the node recognizes both as delimiters. The node does not recognize X'15' which, on z/OS systems, is the 'newline' byte; set this property to Custom Delimiter and set Custom delimiter to 15 if your input file is coded using EBCDIC new lines.
  - Custom Delimiter (hexadecimal), permits a sequence of bytes to be specified in Custom delimiter (hexadecimal)
- In Custom delimiter (hexadecimal), specify the delimiter byte or bytes to be used when Delimiter is set to Custom delimiter (hexadecimal). Specify this value as an even-numbered string of hexadecimal digits. The default is X'0A' and the maximum length of the string is 16 bytes (represented by 32 hexadecimal digits).
- If you set Record detection to Delimited, use Delimiter type to specify the type of delimiter. Permitted values are:
  - Infix. If you select this value, each delimiter separates records. If the data ends with a delimiter, the (zero length) data following the final delimiter is still propagated, although it contains no data.
  - Postfix. If you specify this value, each delimiter terminates records. If the data ends with a delimiter, no empty record is propagated after the delimiter. If the data does not end with a delimiter, it is processed as if a delimiter follows the final bytes of the data. Postfix is the default value.
- The TCPIPServerReceive node considers each occurrence of the delimiter in the input as either separating (infix) or terminating (postfix) each record. If the data begins with a delimiter, the node treats the (zero length) contents preceding that delimiter as a record and propagates an empty record to the flow. The delimiter is never included in the propagated message.

9. Use the **Validation** tab to provide validation based on the message set for predefined messages. For more information about validation, see "Validating messages" on page 1478. For information about how to complete this tab, see "Validation tab properties" on page 4169.

Terminals and properties:
The terminals of the TCPIPServerReceive node are described in the following table.

Terminal	Description
In	The input terminal that accepts a message for processing by the node.

Terminal	Description
Out	The output terminal to which the message is routed if it is successfully retrieved from an external resource. If no errors occur within the input node, a message received from an external resource is always sent to the Out terminal first.
Timeout	The terminal to which a message is sent when the time specified in the `Timeout waiting for a data record` property has been exceeded. The message text is `Timeout value is exceeded`.
Failure	The output terminal to which the message is routed if an error occurs. These errors include failures caused by retry processing. Even if the Validation property is set, messages propagated to this terminal are not validated.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Description properties of the TCPIPServerReceive node are described in the following table.

Property	M	C	Default	Description
Node name	No	No	TCPIPServerReceive	The name of the node.
Short description	No	No		A brief description of the node.
Long description	No	No		Text that describes the purpose of the node in the message flow.

The Basic properties of the TCPIPServerReceive node determine how the TCP/IP connection is controlled, and are described in the following table.

Property	M	C	Default	Description	**mqsiapplybaroverride command property**
Connection details	Yes	Yes		A string containing the port number to be used, or the name of a configurable service. The following formats are supported: • `Configurable service name`. This value is used to look up the port and host name in configurable services. For example, `TCPIPProfile1`. • `<Port>`. This value is the port number; for example, `1111`. • `<Port>`. This value is the port number. In this case, the host name is assumed to be `localhost`.	connectionDetails
Timeout waiting for a data record (seconds)	Yes	Yes	`60`	Specifies how long the node listens on a connection for more data after the first byte of data has arrived. You can specify any length of time in seconds. The default is `60` seconds. When the specified time has been exceeded, all available data is sent to the Failure terminal.	timeoutWaitingForData

The Advanced properties of the TCPIPServerReceive node determine how the data stream is controlled, and are described in the following table.

Property	M	C	Default	Description
Close connection	Yes	No	No	Controls when the connection is closed, or if it remains open. Valid options are: • Select No to leave the connection open. This value is the default. • Select After timeout to close the connection when a timeout occurs. • Select After data has been received to close the connection when the end of the record is found.
Close input stream after a record has been received	Yes	No	Cleared	Specifies whether to close the input stream as soon as the data has been retrieved. When the connection input stream is reserved, no other node can use it without knowing the ID. By default this property is not selected.
Input Stream Modification	No	No	Leave unchanged	Specifies whether to reserve the input stream for use only by input and receive nodes that specify the connection ID, or to release the input stream at the end of the flow. Valid options are: • Select Leave unchanged to leave the input stream as it was when it entered the node. This value is selected by default. • Select Release input stream to specify that this input stream is returned to the pool and is available for use by any input or receive node. • Select Reserve input stream (for use by future TCPIP input and receive nodes) to specify that this input stream can be used only by this node and by other input or receive nodes that request it by specifying the connection ID. When the connection input stream is reserved, no other nodes can use it without specifying the correct connection ID. • Select Reserve input stream (for use by future TCPIP input and receive nodes) then release after propagate to specify that this input stream can be used only by this node and receive nodes that request it by specifying the correct connection ID. After the message has been propagated, this input stream is returned to the pool and becomes available for use by any input or receive node.
Output Stream Modification	No	No	Leave unchanged	Specifies whether to reserve this output stream or release it and return it to the pool for use by any output node. These options are available only if you have not selected the Close output stream after a record has been sent property. • Select Leave unchanged to leave the output stream as it was when it entered the node. This value is selected by default. • Select Release output stream to specify that this output stream is returned to the pool and is available for use by any output node. • Select Reserve output stream (for use by future TCPIP output nodes) to specify that this output stream can be used only by this node and by other output nodes that request it by specifying the connection ID. When the connection input stream is reserved, no other nodes can use it without specifying the correct connection ID. • Select Reserve output stream (for use by future TCPIP output nodes) then release after propagate to specify that this output stream can be used only by this node and output nodes that request it by specifying the correct connection ID. After the message has been propagated, this output stream is returned to the pool and becomes available for use by any output node.

The Request properties of the TCPIPServerReceive node specify the location of the data to be written. You can specify the properties on this tab as XPath or ESQL expressions. Content Assist is available in the Properties view and also in the XPath Expression Builder, which you can run by clicking **Edit** to the right of each property. The Request properties are described in the following table:

Property	M	C	Default	Description
Port location	Yes	No	`$LocalEnvironment/TCPIP/Receive/Port`	The message element location that contains the Port. Specify the location of the value to override the `Port` that is set in the `Connection details` property of the **Basic** tab. If you do not specify a location, the default value is `$LocalEnvironment/TCPIP/Receive/Port`.
ID location	Yes	No	`$LocalEnvironment/TCPIP/Receive/Id`	The message element location that contains the ID. Specify the location of the `Id` of the socket that is being used. This internal identifier is used by WebSphere Message Broker to uniquely identify a connection. If you do not specify a location, the default value is `$LocalEnvironment/TCPIP/Receive/Id`.
Reply ID location	Yes	No	`$LocalEnvironment/TCPIP/Receive/ReplyId`	The message element location that contains the Reply ID. Specify the location of the Reply ID that is stored on the connection being used. The Reply ID can be used when data is returned in an input node. If you do not specify a location, the default value is `$LocalEnvironment/TCPIP/Receive/ReplyId`.
Record length location	No	No	`$LocalEnvironment/TCPIP/Receive/Length`	The message element location that contains the record length to be read. Specify the location of the value to override the `Length (bytes)` property on the **Records and elements** tab. If you do not specify a location, the default value is `$LocalEnvironment/TCPIP/Receive/Length`.

The Result properties of the TCPIPServerReceive node determine where the reply is to be stored, and are described in the following table:

Property	M	C	Default	Description
Output data location	No	No	`$OutputRoot`	The start location in the output message tree where the parsed elements from the bit string of the message are stored.

Property	M	C	Default	Description
Copy local environment	No	No	Selected	Specifies whether the local environment is copied to the output message. • If `Copy local environment` is selected, a new copy of the local environment is created in the tree, and it is populated with the contents of the local environment from the preceding node. Therefore, that if a node changes the local environment, the upstream nodes are not affected by those changes because they have their own copies. This value is the default. • If `Copy local environment` is not selected, the node does not generate its own copy of the local environment, but uses the local environment that is passed to it by the preceding node. Therefore, if a node changes the local environment, the changes are reflected by the upstream nodes.

The Input Message Parsing properties of the TCPIPServerReceive node determine how to parse the incoming message.

If the incoming message has an MQRFH2 header, you do not have to set values for the Input Message Parsing properties because the values are derived from the `<mcd>` folder in the MQRFH2 header; for example:

```
<mcd><Msd>MRM</Msd><Set>DHM4UO906S001</Set><Type>receiptmsg1</Type>
<Fmt>XML</Fmt></mcd>
```

If you set values, and if they differ from the values in the MQRFH2 header, the values in the MQRFH2 header take precedence.

The TCPIPServerReceive node Input Message Parsing properties are described in the following table.

Property	M	C	Default	Description	**mqsiapplybaroverride command property**
Message domain	No	No	`BLOB`	The domain that is used to parse the incoming message. The default is `BLOB`. You can choose from the following options: • XMLNSC • DataObject • JSON • BLOB • MIME • MRM • JMSMap • JMSStream • XMLNS You can also specify a user-defined parser, if appropriate.	

Property	M	C	Default	Description	mqsiapplybaroverride command property
Message set	No	No		If you are using the MRM or IDOC parser, or the XMLNSC parser in validating mode, select the `Message set` in which the incoming message is defined. The list contains the message sets that are available when you select MRM, XMLNSC, or IDOC as the domain. If you set this property, then later update the project dependencies to remove this message set reference, a warning is issued. Either update the `Message Set` property, or restore the reference to this message set project.	
Message type	No	No		The name of the incoming message. If you are using the MRM parser, select the correct message type from the list in `Message type`. This list is populated with available message types when you select the MRM parser.	
Message format	No	No		The name of the physical format of the incoming message. If you are using the MRM or IDOC parser, select the correct message format from the list in `Message format`. This list is populated with available message formats when you select the MRM or IDOC parser.	
Message coded character set ID	Yes	No	`Broker System Default`	The ID of the coded character set used to interpret the data being read.	messageCodedCharSetIdProperty
Message encoding	Yes	No	`Broker System Determined`	The encoding scheme for numbers and large characters used to interpret the data being read. Valid values are `Broker System Determined` or a numeric encoding value. For more information about encoding, see "Data conversion" on page 1151.	messageEncodingProperty

The Parser Options properties of the TCPIPServerReceive node are described in the following table.

Property	M	C	Default	Description
Parse timing	No	No	`On Demand`	This property controls when an input message is parsed. Valid values are: • `On Demand` • `Immediate` • `Complete` `Parse timing` is, by default, set to `On Demand`, which causes parsing of the message to be delayed. To cause the message to be parsed immediately, see "Parsing on demand" on page 4173.
Build tree using XML schema data types	No	No	Cleared	This property controls whether the syntax elements in the message tree have data types taken from the XML Schema.

Property	M	C	Default	Description
Use XMLNSC compact parser for XMLNS domain	No	No	Cleared	This property controls whether the XMLNSC Compact Parser is used for messages in the XMLNS Domain. If you set this property, the message data is displayed under XMLNSC in nodes that are connected to the output terminal when the input MQRFH2 header or Input Message Parsing property, `Message Domain`, is XMLNS.
Retain mixed content	No	No	Cleared	This property controls whether the XMLNSC parser creates elements in the message tree when it encounters mixed text in an input message. If you select the check box, elements are created for mixed text. If you clear the check box, mixed text is ignored and no elements are created.
Retain comments	No	No	Cleared	This property controls whether the XMLNSC parser creates elements in the message tree when it encounters comments in an input message. If you select the check box, elements are created for comments. If you clear the check box, comments are ignored and no elements are created.
Retain processing instructions	No	No	Cleared	This property controls whether the XMLNSC parser creates elements in the message tree when it encounters processing instructions in an input message. If you select the check box, elements are created for processing instructions. If you clear the check box, processing instructions are ignored and no elements are created.
Opaque elements	No	No	Blank	This property is used to specify a list of elements in the input message that are to be opaquely parsed by the XMLNSC parser.

The Records and Elements properties of the TCPIPServerReceive node specify how the data is interpreted as records, and are described in the following table:

Property	M	C	Default	Description
Record detection	Yes	No	`Connection closed`	The mechanism used to identify records in the input data. • `Connection closed` specifies that all of the data sent during a connection is a single record. • `Fixed Length` specifies that each record is a fixed number of bytes in length. Each record contains the number of bytes specified in the `Length` property, except possibly a shorter final record in the file. • Select `Delimited` if the records you are processing are separated, or ended, by a DOS or UNIX line end or by a sequence of user-defined delimiter bytes. Specify the delimiter and delimiter type in the `Delimiter` and `Delimiter type` properties. • Select `Parsed Record Sequence` if the data contains a sequence of one or more records that are serially recognized by the parser specified in `Message domain`. The node propagates each recognized record as a separate message. If you select this `Record detection` option, the parser specified in `Message domain` must be either XMLNSC or MRM (either CWF or TDS physical format).

Property	M	C	Default	Description
Length (bytes)	Yes	No	0	If you set Record detection to Fixed Length, use Length to specify the required length of the output record in bytes. This value must be in the range 1 byte through 100 MB. The default is 80 bytes. If you set Record detection to Connection closed, Fixed Length, or Delimited, a limit of 100 MB applies to the length of the records. If you set Record detection to Parsed Record Sequence, the TCPIPServerReceive node does not determine or limit the length of a record. Nodes that are downstream in the message flow might try to determine the record length or process a long record. If you intend to process large records in this way, ensure that your broker has sufficient memory. You might have to apply message flow techniques described in the Large Messaging sample to make the best use of the available memory.
Delimiter	Yes	No	DOS or UNIX Line End	If you set Record detection to Delimited, use Delimiter to specify the delimiter to be used. Choose from the following options: • DOS or UNIX Line End, on UNIX systems, specifies the line feed character (<LF>, X'0A'), and, on Windows systems, specifies a carriage return character followed by a line feed character (<CR><LF>, X'0D0A'). The node treats both of these strings as delimiters, irrespective of the system on which the broker is running. If both strings are displayed in the same record, the node recognizes both as delimiters. The node does not recognize X'15' which, on z/OS systems, is the 'newline' byte; set this property to Custom Delimiter and set Custom delimiter to 15 if your input file is coded using EBCDIC new lines, such as EBCDIC files from a z/OS system. • Custom Delimiter (hexadecimal), permits a sequence of bytes to be specified in Custom delimiter (hexadecimal)
Custom delimiter (hexadecimal)	No	No		The delimiter byte or bytes to be used when Delimited record detection and Custom Delimiter (Hexadecimal) are selected. This property is mandatory only if the Delimiter property is set to Custom Delimiter (Hexadecimal). Specify this value as an even-numbered string of hexadecimal digits. The default is X'0A' and the maximum length of the string is 16 bytes (represented by 32 hexadecimal digits).
Delimiter type	Yes	No	Postfix	The location of the delimiter when Delimited record detection and Custom Delimiter (Hexadecimal) are selected. Valid options are: • Infix. If you select this value, each delimiter separates records. If the data ends with a delimiter, the (zero length) data following the final delimiter is still propagated, although it contains no data. • Postfix. If you specify this value, each delimiter ends records. If the data ends with a delimiter, no empty record is propagated after the delimiter. If the data does not end with a delimiter, it is processed as if a delimiter follows the final bytes of the data. Postfix is the default value. The TCPIPServerReceive node considers each occurrence of the delimiter in the input as either separating (infix) or terminating (postfix) each record. If the data begins with a delimiter, the node treats the (zero length) contents preceding that delimiter as a record and propagates an empty record to the flow. The delimiter is never included in the propagated message. This property is ignored unless the Delimiter property is set to Custom Delimiter (Hexadecimal).

The Validation properties of the TCPIPServerReceive node are described in the following table.

For a full description of these properties, see "Validation properties" on page 4169.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Validate	No	Yes	None	This property controls whether validation takes place. Valid values are • None • Content and Value • Content • Inherit	validateMaster
Failure action	No	No	Exception	This property controls what happens if validation fails. You can set this property only if you set Validate to Content or Content and Value. Valid values are: • User Trace • Local Error Log • Exception • Exception List	

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

Use the TCPIPServerInput node to create a server connection to a raw TCPIP socket, and to receive data over that connection.

"TCPIPServerOutput node" on page 4903
Use the TCPIPServerOutput node to create a server connection to a raw TCP/IP socket, and to send data over the connection to an external application.

"TCPIPClientReceive node" on page 4877
Use the TCPIPClientReceive node to receive data over a client TCP/IP connection.

Throw node

Use the Throw node to throw an exception in a message flow.

This topic contains the following sections:

Purpose:

An exception can be caught and processed by:

- A preceding TryCatch node
- The message flow input node (the built-in nodes, for example HTTPInput and MQInput, have Catch terminals)
- A preceding AggregateReply node

Include a Throw node to force an error path through the message flow if the content of the message contains unexpected data. For example, to back out a message that does not contain a particular field, you can check (using a Filter node) that the field exists; if the field does not exist, the message can be passed to a Throw node that records details about the exception in the exception list subtree in the message.

The Throw node is contained in the **Construction** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:

Look at the following samples to see how to use this node:

- Airline Reservations
- Error Handler
- Large Messaging

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Include a Throw node with a TryCatch node in your message flow to alert the systems administrator of a potential error situation; for example, if you have a Compute node that calculates a number, test the result of this calculation and

throw an exception if the result exceeds a certain amount. The TryCatch node catches this exception and propagates the message to a sequence of nodes that process the error.

Terminals and properties:
When you have put an instance of the Throw node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The Throw node terminal is described in the following table.

Terminal	Description
In	The input terminal that accepts a message for processing by the node.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Throw node Description properties are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type: Throw	The name of the node.
Short Description	No	No		A brief description of the node.
Long Description	No	No		Text that describes the purpose of the node in the message flow.

The Throw node Basic properties are described in the following table.

Property	M	C	Default	Description
Message Catalog	No	No		The name of the message catalog from which the error text for the error number of the exception is extracted. Enter the fully-qualified path and file name of the message catalog that contains the message source. This file can be your own message catalog, or the default message catalog that is supplied with WebSphere Message Broker. To use the default supplied catalog, leave this property blank.
Message Number	No	No	`3001`	The error number of the exception that is being thrown. • If you have created your own message catalog, enter the number for the message in the catalog that you want to use when this exception is thrown. • If you are using the default message catalog, specify a number between 3001 (the default) and 3049. These numbers are reserved in the default catalog for your use. The text of each of these messages in the default message catalog is identical, but you can use a different number in this range for each situation in which you throw an exception; use the number to identify the exact cause of the error.

Property	M	C	Default	Description
Message Text	No	No		Additional text that explains the cause of the error. Enter any additional free format text that contains information that you want to include with the message when it is written to the local error log; for example, if you have checked for the existence of a particular field in a message and thrown an exception when that field is not found, you might include the text: `The message did not contain the required field: Branch number` If you are using the default message catalog, this text is inserted as `&1` in the message text.

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

Use the Trace node to generate trace records that you can use to monitor the behavior of a message flow.

"TryCatch node" on page 4949
Use the TryCatch node to provide a special handler for exception processing.

TimeoutControl node

Use the TimeoutControl node to process an input message that contains a timeout request.

This topic contains the following sections:
- "Purpose"
- "Using this node in a message flow"
- "Terminals and properties" on page 4933

Purpose:
The TimeoutControl node validates the timeout request message, stores the message, and propagates the message (unchanged) to the next node in the message flow. For more information, see "Sending timeout request messages" on page 2810.

The TimeoutControl node is contained in the **Timer** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:
Use a TimeoutControl node and a TimeoutNotification node together in a message flow for an application that requires events to occur at particular times, or at regular intervals.

Examples of when you can use the timeout nodes in a message flow include:
- You need to run a batch job every day at midnight.
- You want information about currency exchange rates to be sent to banks at hourly intervals.
- You want to confirm that important transactions are processed within a certain time period and perform some other specified actions to warn when a transaction has not been processed in that time period.

You can use more than one TimeoutControl node with a TimeoutNotification node. Timeout requests that are initiated by those TimeoutControl nodes are all processed by the same TimeoutNotification node if the same `Unique identifier` is used for the TimeoutNotification node and each of the TimeoutControl nodes.

You can use TimeoutControl nodes with a TimeoutNotification node that is in a separate message flow only if the following conditions are met:
- The same `Unique identifier` is used for your TimeoutNotification node and each of your TimeoutControl nodes

- The message flow that contains your TimeoutControl nodes and the message flow that contains your TimeoutNotification node are deployed to the same execution group

Look at the following sample for more details about how to use the timeout processing nodes:

- Timeout Processing

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Terminals and properties:
When you have put an instance of the TimeoutControl node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The TimeoutControl node terminals are described in the following table.

Terminal	Description
In	The input terminal that accepts a message tree for processing (which includes validating the timeout request specified in the message tree at `Request location`) and adds it to the control queue.
Failure	The output terminal to which the input message is propagated if a failure is detected during processing in this node. If this terminal is not connected to another node, error information is passed back to the previous node in the message flow.
Out	The output terminal to which incoming messages are propagated, unchanged, after successful timeout request processing. If this terminal is not connected to another node, no propagation occurs. If propagation of the message fails, the message is propagated to the Failure terminal.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Description properties of the TimeoutControl node are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type, TimeoutControl	The name of the node.
Short description	No	No		A brief description of the node.
Long description	No	No		Text that describes the purpose of the node in the message flow.

The Basic properties of the TimeoutControl node are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Unique identifier	Yes	Yes	None	This is the only mandatory property for the node. Its value must be unique within the broker. The equivalent property of the TimeoutNotification node with which it is paired must have the same value. The maximum length of this identifier is 12 characters. This name is also used to identify a Timer configurable service (if one exists) to be used by the node.	uniqueIdentifier
Request location	No	No	None	This property describes where to find the timeout request information in the incoming message. This value can be any valid location in the input message tree and is validated at run time. If you do not specify a request location, InputLocalEnvironment.TimeoutRequest is assumed. For more information about the timeout request message, see "Sending timeout request messages" on page 2810.	
Request persistence	No	No	Automatic	This property controls whether an incoming timeout request survives a restart of either the broker or the message flow that contains the TimeoutNotification node that is paired with this TimeoutControl node. Select `Yes` if you want the incoming request to persist; select `No` if you do not. If you select `Automatic` (the default), the Persistence setting in the Properties folder of the incoming message is used.	

The Message properties of the TimeoutControl node are described in the following table.

The TimeoutControl node Message properties are described in the following table.

Property	M	C	Default	Description
Stored message location	No	No	None	This property identifies the location of the part of the request message that you want to store for propagation by the TimeoutNotification node with which this node is paired. If you do not specify a value, the entire message is stored. You can specify any valid location in the message tree. If you choose to store the entire message, you do not need to specify any values in `Message domain`, `Message set`, `Message type`, or `Message format`.

Property	M	C	Default	Description
Message domain	No	No	BLOB	The domain that is used to parse the stored timeout request message by the TimeoutNotification node. If you do not specify a value and the message location is stored, the default value is BLOB. Select the name of the parser that you are using. This value, and the three corresponding values in Message set, Message type, and Message format, are used by the TimeoutNotification node with which it is paired when it rebuilds the stored message for propagation. If you have stored the entire request message (by leaving Stored message location blank), do not specify any values here. If you choose to store part of the request message, specify values here that reflect the stored request message fragment as if it were the entire message, which is the case when it is processed by the TimeoutNotification node. Choose from the following parsers: • XMLNSC • JSON • BLOB • MRM • XMLNS You can also specify a user-defined parser, if appropriate.
Message set	No	No	None	The name or identifier of the message set in which the stored timeout request message is defined. If you are using the MRM parser, or the XMLNSC parser in validating mode, select the Message set that you want to use from the list. If you set this property, then later update the project dependencies to remove this message set reference, a warning is issued. Either update the Message set property, or restore the reference to this message set project.
Message type	No	No	None	The name of the stored timeout request message. If you are using the MRM parser, select the correct message from the list in Message type. This list is populated with messages that are defined in the Message set that you have selected.
Message format	No	No	None	The name of the physical format of the stored timeout request message. If you are using the MRM parser, select the format of the message from the list in Message format. This list includes all the physical formats that you have defined for this Message set.

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

The supplied configurable services, and the configurable services that you create, are defined by their names and properties. You can use the supplied services.

TimeoutNotification node

Use the TimeoutNotification node to manage timeout-dependent message flows.

This topic contains the following sections:
- "Purpose"
- "Using this node in a message flow"
- "Terminals and properties" on page 4937

Purpose:
The TimeoutNotification node is an input node that you can use in two ways:

- A TimeoutNotification node can be paired with one or more TimeoutControl nodes.

  The TimeoutNotification node processes timeout request messages that are sent by the TimeoutControl nodes with which it is paired, and propagates copies of the messages (or selected fragments of the messages) to the next node in the message flow.
- A TimeoutNotification node can be used as a stand-alone node.

  Generated messages are propagated to the next node in the message flow at time intervals that are specified in the configuration of this node.

The TimeoutNotification node is contained in the **Timer** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:

Use a TimeoutControl node and a TimeoutNotification node together in a message flow for an application that requires events to occur at a particular time, or at regular intervals; for example, when you want a batch job to run every day at midnight, or you want information about currency exchange rates to be sent to banks at hourly intervals.

You can use more than one TimeoutControl node with a TimeoutNotification node. Timeout requests that are initiated by those TimeoutControl nodes are all processed by the same TimeoutNotification node if the same `Unique identifier` is used for the TimeoutNotification node and each of the TimeoutControl nodes. However, do not use the same `Unique identifier` for more than one TimeoutNotification node.

You can use TimeoutControl nodes with a TimeoutNotification node that is in a separate message flow only if the following conditions are met:

- The same `Unique identifier` is used for your TimeoutNotification node and each of your TimeoutControl nodes
- The message flow that contains your TimeoutControl nodes and the message flow that contains your TimeoutNotification node are deployed to the same execution group

Timeout request messages are stored for processing on a queue used by the TimeoutNotification node. By default, this queue is the SYSTEM.BROKER.TIMEOUT.QUEUE. However, you can use a Timer configurable service to specify an alternative timeout queue, which provides greater control over the storage of messages. For information about using an alternative timeout queue, see "Configuring the storage of events for timeout nodes" on page 760.

When a TimeoutNotification node is started as a result of the broker starting, or by the message flow that contains the node starting, it scans its internal timeout store and purges any non-persistent timeout requests. Notifications are issued for any persistent timeout requests that are now past and that have the IgnoreMissed property set to `False`.

If you use a TimeoutNotification node to generate a WebSphere MQ message to an output node, such as theMQOutput node, provide a valid MQMD. You must also provide a valid MQMD if the TimeoutNotification node is running in automatic mode (as a stand-alone node). If the TimeoutNotification node is running in controlled mode (that is, it is paired with one or more TimeoutControl nodes), you must provide a valid MQMD only if the stored messages do not already have an MQMD. The following ESQL shows how to provide a valid MQMD:

```
CREATE NEXTSIBLING OF OutputRoot.Properties DOMAIN 'MQMD';
SET OutputRoot.MQMD.Version = MQMD_CURRENT_VERSION;
SET OutputRoot.MQMD.Format = 'XML';
```

Look at the following sample for more details about how to use the timeout processing nodes:

- Timeout Processing

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Terminals and properties:

When you have put an instance of the TimeoutNotification node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The terminals of the TimeoutNotification node are described in the following table.

Terminal	Description
Failure	The output terminal to which the message is propagated if a failure is detected during processing in this node. Nodes can be connected to this terminal to process these failures. If this terminal is not connected to another node, messages are not propagated and no logging or safe storage of data occurs.
Out	The output terminal to which messages are propagated after timeouts expire. • If the TimeoutNotification node is running in `Automatic` mode (that is, there are no TimeoutControl nodes paired with this node), the propagated messages contain only a Properties folder and a LocalEnvironment that is populated with the timeout information. • If the TimeoutNotification node is running in `Controlled` mode (that is, TimeoutControl nodes that are paired with this node store timeout requests), the propagated messages contain what was stored by the TimeoutControl nodes, which might be entire request messages or fragments of them. If the TimeoutNotification node is used as the input node to a message flow that generates a WebSphere MQ message (for example, by using an MQOutput node), the message flow must create the necessary MQ headers and data (for example, MQMD).
Catch	The output terminal to which the message is propagated if an exception is thrown downstream. If this terminal is not connected to another node, the following events occur: 1. The TimeoutNotification node writes the error to the local error log. 2. The TimeoutNotification node repeatedly tries to process the request until the problem that caused the exception is resolved.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Description properties of the TimeoutNotification node are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type: TimeoutNotification	The name of the node.
Short description	No	No		A brief description of the node.
Long description	No	No		Text that describes the purpose of the node in the message flow.

The Basic properties of the TimeoutNotification node are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Unique Identifier	Yes	Yes	None	This property specifies a value that is unique within the broker and that is the same as the identifier that is specified for the TimeoutControl nodes with which this node is paired (if there are any). The maximum length of this identifier is 12 characters. This name is also used to identify a Timer configurable service (if one exists) to be used by the node. Do not use the same `Unique Identifier` for more than one TimeoutNotification node.	uniqueIdentifier
Transaction Mode	No	No	`Yes`	The transaction mode for the node. If the transaction mode is `Automatic`, a transaction is based on the persistence of the stored messages, which is controlled by the `Request Persistence` property of the TimeoutControl node with which it is paired. You can set this property to one of the following values: • Select `Yes` if you want a transaction to be started. • Select `No` if you do not want a transaction to be started. • Select `Automatic` only if you have set `Operation Mode` to `Controlled`. Whether a transaction is started depends on the persistence of the stored timeout requests, which is controlled by the value of `Request Persistence` in the TimeoutControl node with which it is paired.	
Operation Mode	No	No	`Automatic`	This property indicates whether this node is paired with any paired TimeoutControl nodes. Valid values are: • If you select `Automatic` the node is not paired with any TimeoutControl nodes. The node generates timeout requests with an interval that is controlled by the setting of the `Timeout Value` property, which must be a positive integer. • If you select `Controlled` the node processes all timeout requests that have been stored by the TimeoutControl nodes with which it is paired.	
Timeout Interval	No	Yes	1	The interval (in seconds) between timeout requests. This property is relevant only if `Operation Mode` is set to `Automatic`. The value of this property must be a positive integer. If the `Operation Mode` is set to `Automatic`, the value of the `Timeout Interval` property is overridden by the **`Timeout interval`** property, if set, in the Timer configurable service.	timeoutInterval

The properties of the Parser Options for the TimeoutNotification node are described in the following table.

Property	M	C	Default	Description
Parse Timing	No	No	On Demand	This property controls when the timeout message is parsed. Valid values are On Demand, Immediate, and Complete. By default, this property is set to On Demand, which causes parsing of the message to be delayed. To cause the message to be parsed immediately, see "Parsing on demand" on page 4173.
Build tree using XML schema data types	No	No	Cleared	This property controls whether the XMLNSC parser creates syntax elements in the message tree with data types taken from the XML Schema. You can select this property only if you set the Validate property on the **Validation** tab to Content or Content and Value.
Use MQRFH2C Compact Parser for MQRFH2 Domain	No	No	Cleared	This property controls whether the MQRFH2C Compact Parser, instead of the MQRFH2 parser, is used for MQRFH2 headers.
Use XMLNSC Compact Parser for XMLNS Domain	No	No	Cleared	This property controls whether the XMLNSC Compact Parser is used for messages in the XMLNS Domain. If you set this property, the message data appears under XMLNSC in nodes that are connected to the output terminal when the input RFH2 header or default properties Domain is XMLNS.
Retain Mixed Content	No	No	None	This property controls whether the XMLNSC parser creates elements in the message tree when it encounters mixed text in a timeout message. If you select the check box, elements are created for mixed text. If you clear the check box, mixed text is ignored and no elements are created.
Retain Comments	No	No	None	This property controls whether the XMLNSC parser creates elements in the message tree when it encounters comments in a timeout message. If you select the check box, elements are created for comments. If you clear the check box, comments are ignored and no elements are created.
Retain Processing Instructions	No	No	None	This property controls whether the XMLNSC parser creates elements in the message tree when it encounters processing instructions in a timeout message. If you select the check box, elements are created for processing instructions. If you clear the check box, processing instructions are ignored and no elements are created.
Opaque elements	No	No	Blank	This property is used to specify a list of elements in the timeout message that are to be opaquely parsed by the XMLNSC parser. Opaque parsing is performed only if validation is not enabled (that is, if Validate is None); entries that are specified in Opaque Elements are ignored if validation is enabled.

The Validation properties of the TimeoutNotification node are described in the following table.

If a message is propagated to the Failure terminal of the node, it is not validated. For more information, see "Validating messages" on page 1478 and "Validation properties" on page 4169.

Property	M	C	Default	Description	**mqsiapplybaroverride command property**
Validate	No	Yes	None	This property controls whether validation takes place. Valid values are None, Content, and Content And Value.	validateMaster

Property	M	C	Default	Description	mqsiapplybaroverride command property
Failure Action	No	No	Exception	This property controls what happens if validation fails. You can set this property only if you set Validate to Content or Content and Value. Valid values are User Trace, Local Error Log, Exception, and Exception List.	

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

When you design timeout flows, the decisions that you make can affect the performance of your brokers and applications.

Related tasks:

"Deciding which nodes to use" on page 1457
WebSphere Message Broker includes many message processing nodes that you can use in your message flows.

"Validating messages" on page 1478
The broker provides validation based on the message model for predefined messages.

"Manipulating messages in the XMLNSC domain" on page 2546
If you are writing ESQL to process messages in the XMLNSC domain, it is helpful to learn about the structure of the message tree that the XMLNSC parser builds.

"Handling errors in message flows" on page 2823
The broker provides basic error handling for all your message flows. If basic processing is not sufficient, and you want to take specific action in response to certain error conditions and situations, you can enhance your message flows to provide your own error handling.

Related reference:

"Parsing on demand" on page 4173
On-demand parsing, referred to as partial parsing, is used to parse an input message bit stream only as far as is necessary to satisfy the current reference. The parsers that can perform partial parsing of input messages are the JSON, MRM, XML, XMLNS, and XMLNSC parsers.

"Validation properties" on page 4169
You can control validation by setting properties on the Validate and Parser Options tabs for the nodes that are listed in the following table.

"TimeoutControl node" on page 4932
Use the TimeoutControl node to process an input message that contains a timeout request.

"Example XML timeout request message" on page 2812
The format used here is XML, but you can use any format that is supported by an installed parser.

"Configurable services properties" on page 3766
The supplied configurable services, and the configurable services that you create, are defined by their names and properties. You can use the supplied services.

Trace node

Use the Trace node to generate trace records that you can use to monitor the behavior of a message flow.

This topic contains the following sections:
- "Purpose"
- "Using this node in a message flow" on page 4943
- "Terminals and properties" on page 4943

Purpose:
Trace records can incorporate text, message content, and date and time information, to help you to monitor the behavior of the message flow.

You can write the records to the user trace file, another file, or the local error log (which contains error and information messages written by all other WebSphere Message Broker components). If you write traces to the local error log, you can issue a message from the default message catalog that is supplied with WebSphere Message Broker, or you can create your own message catalog.

The operation of the Trace node is independent of the setting of user tracing for the message flow that contains it. In particular, records that are written by the Trace node to the user trace log are written even if user trace is not currently active for the message flow.

The Trace node is contained in the **Construction** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:
Look at the following samples to see how to use this node:
- Airline Reservations
- Aggregation
- Timeout Processing

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Include a Trace node to help diagnose errors in your message flow. By tracing the contents of the message at various points in the flow, you can determine the sequence of processing. You can configure the Trace node to record the content of a message, and to check the action of a specific node on the message. For example, you can include a Trace node immediately after a Compute node to check that the output message has the expected format.

You can also use the Trace node to provide information in error handling in your message flows. For example, you can use this node to record failures in processing because of errors in the content or format of a message.

When you have tested the message flow and proved that its operation is correct, remove Trace nodes from your message flow, or switch them off.

Terminals and properties:
When you have put an instance of the Trace node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The terminals of the Trace node are described in the following table.

Terminal	Description
In	The input terminal that accepts a message for processing by the node.
Out	The output terminal through which the message is propagated.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Description properties of the Trace node are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type: Trace	The name of the node.
Short Description	No	No		A brief description of the node.
Long Description	No	No		Text that describes the purpose of the node in the message flow.

The Basic properties of the Trace node are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Destination	Yes	No	`User Trace`	The destination of the trace record that is written by the node. The `Destination` refers to the computer that hosts the broker on which the Trace node is deployed: • To write the trace record to the local system error log, select `Local Error Log`. The information that you include in the trace record is written to one of the following locations: – Windows On Windows systems, data is written to the Event log (Application View) – Linux UNIX On Linux and UNIX systems, data is written to the `syslog` – z/OS On z/OS systems, data is written to the operator console UNIX On UNIX systems, syslog entries are restricted in length and messages are truncated by the newline character. To record a large amount of data in a log, set the destination to `File` or `User Trace` instead. If you select `Local Error Log`, indicate the number of the trace message that is to be written, and the message catalog in which the message is defined. – If you leave `Message Catalog` blank, the default message catalog is used as the source of the message that is to be written. You must also enter the error number of the record in `Message Number`. Numbers `3051` to `3099` are reserved in the default catalog for this use. The text of each of these messages in the default message catalog is identical, but if you use a different number in this range for each situation that you trace, you can identify the exact cause of the error. The default message number is `3051`. – If you create your own message catalog, enter the fully qualified file name for your catalog in `Message Catalog`. You must also enter the appropriate number for the message in the catalog that you want to write to the local error log in `Message Number`. On some systems, message numbers that end `00` are reserved for system use; do not include messages with numbers such as `3100` in your message catalog.	

Property	M	C	Default	Description	mqsiapplybaroverride command property

				• To write the trace record to the system-generated user trace log, select `User Trace`.
				These records are written regardless of the setting of the User Trace property for the deployed message flow.
				The location of the trace logs depends on your environment:
				Windows **Windows**
				If you set the work path using the **-w** parameter of the **mqsicreatebroker** command, the location is `workpath\log`.
				If you have not specified the broker work path, the location is:`%ALLUSERSPROFILE%\Application Data\IBM\MQSI\common\log` where `%ALLUSERSPROFILE%` is the environment variable that defines the system working directory. The default directory depends on the operating system:
				– On Windows XP and Windows Server 2003: `C:\Documents and Settings\All Users\Application Data\IBM\MQSI\common\log`
				– On Windows Vista and Windows Server 2008: `C:\ProgramData\IBM\MQSI\common\log`
				The actual value might be different on your computer.
				Linux UNIX **Linux and UNIX**
				`/var/mqsi/common/log`
				z/OS **z/OS**
				`/component_filesystem/log`
				The file name is made up of the broker name, the broker UUID, and a suffix of `userTrace.bin` (for example, `broker.e51906cb-dd00-0000-0080-b10e69a5d551.userTrace.bin.0`). Use the **mqsireadlog** and **mqsiformatlog** commands before you view the user trace log.	

Property	M	C	Default	Description	mqsiapplybaroverride command property
				• To write the trace record to a file of your choice, select `File`. If you select this option, you must also set `File Path` to the fully qualified path name for the trace. If you do not set the path, the location of the file depends on the system; for example, on z/OS, the file is created in the home directory of the broker service ID. You can use any name for the trace file; for example, `c:\user\trace\trace.log` If you specify a file that does not exist already, the file is created. However, directories are not created by this process, so the full path must exist. The file is written as text, in the format specified by the `Pattern` property. You do not need to run the **mqsireadlog** or **mqsiformatlog** commands against the file. If a file write error occurs during processing (because of an out of space condition, for example), a single warning message, BIP4065, is written to the local system error log, and the message flow continues to process messages without logging further errors. Check the error log carefully for such a message. • If you do not want to write trace records, select `None`. You can also switch off Trace nodes.	
File Path	No	Yes		The fully qualified file name of the file to which to write records. This property is valid only if `Destination` is set to `File`.	filePath

Property	M	C	Default	Description	mqsiapplybaroverride command property

Pattern	No	No		The data that is to be included in the trace record. Create an ESQL pattern to specify what information to write. If you write the trace record to the local error log, the pattern governs the information that is written in the text of the message number that is selected. If you use the default message catalog, and a number between 3051 and 3099, the pattern information is inserted as &1 in the message text.
				• You can write plain text, which is copied into the trace record exactly as you have entered it.
				• You can identify parts of the message to write to the trace record, specifying the full field identifiers enclosed between the characters ${ and }. To record the entire message, specify ${Root}.
				• Use the ESQL functions to provide additional information; for example, use the ESQL function CURRENT_DATE to record the date, time, or both, at which the trace record is written.
				
				The pattern shown here includes some of the options that are available. The pattern writes an initial line of text, records two elements of the current message, and adds a simple timestamp:
				`Message passed through with the following fields:`
				`Store name is ${Body.storedetailselement.storename}`
				`Total sales are ${Body.totalselement.totalsales}`
				`Time is: ${EXTRACT(HOUR FROM CURRENT_TIMESTAMP)}`
				`:${EXTRACT(MINUTE FROM CURRENT_TIMESTAMP)}`
				
				The resulting trace record is:
				`Message passed through with the following fields:`
				`Store name is 'SRUCorporation'`
				`Total sales are '34.98'`
				`Time is: 11:19`
				
				A pattern that contains syntax errors does not prevent a message flow that contains the Trace node from deploying, but the node writes no trace records.	

Message Catalog	No	No		The name of the message catalog from which the error text for the error number of the exception is extracted. The default value (blank) indicates that the message is taken from the message catalog that is supplied with WebSphere Message Broker. See “Creating message catalogs” on page 3138 for more information.	
Message Number	No	No	3051	The error number of the message that is written.	

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

Use the Throw node to throw an exception in a message flow.

"TryCatch node" on page 4949
Use the TryCatch node to provide a special handler for exception processing.

"Local error logs" on page 6867
WebSphere Message Broker components use the local error log (also known as the system log) to record information about major activities within the system. When an error occurs, check the local error log first.

"User trace" on page 6873
User trace is one of two types of optional trace that are available in WebSphere Message Broker and provides more information than that provided by the entries that are written to the Administration log. User trace is inactive by default; you must activate it explicitly by using a command, or by selecting options in the

WebSphere Message Broker Toolkit.

"**mqsireadlog** command" on page 3905
Use the **mqsireadlog** command to retrieve trace records for the specified component.

"**mqsiformatlog** command" on page 3880
Use the **mqsiformatlog** command to process the XML log created by **mqsireadlog**. The command retrieves and formats any messages that the XML log contains into a form suitable for the locale of the user who runs the command.

"CURRENT_DATE function" on page 5179

TryCatch node

Use the TryCatch node to provide a special handler for exception processing.

This topic contains the following sections:

Purpose:
Initially, the input message is routed on the Try terminal, which you must connect to the remaining non-error processing nodes of the message flow. If a downstream node (which can be a Throw node) throws an exception, the TryCatch node catches it and routes the original message to its Catch terminal. Connect the Catch terminal to further nodes to provide error processing for the message after an exception. If the Catch terminal is connected, the message is propagated to it. If the Catch terminal is not connected, the message is discarded.

The TryCatch node is contained in the **Construction** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:
Look at the following sample to see how to use this node:

- Error Handler

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Use the Throw and TryCatch nodes when you use the Compute node to calculate a total. You can create a message that is sent to your system administrator when the total that is calculated exceeds the maximum value for the Total field.

Connecting the terminals:
The TryCatch node has no configurable properties that affect its operation. You determine how it operates by connecting the output terminals to subsequent nodes in your message flow.

1. Connect the Try terminal to the first node in the sequence of nodes that provides the normal (non-error) phase of processing of this message. This

sequence can contain one or more nodes that perform any valid processing. The sequence of nodes can optionally conclude with an output node.

2. Connect the Catch terminal to the first node in the sequence of nodes that provides the error processing for this message flow. This sequence can contain one or more nodes that perform any valid processing. The sequence of nodes can optionally conclude with an output node.

   When an exception is thrown in the message flow, either by the explicit use of the Throw node or the ESQL THROW statement, or by the broker raising an implicit exception when it detects an error that the message flow is not programmed to handle, control returns to the TryCatch node.

   The node propagates the message to the sequence of nodes connected to the Catch terminal (the catch flow) and the error handling that you have designed is initiated. The content of the message tree that is propagated is identical to the content that was propagated to the Try terminal, which is the content of the tree when the TryCatch node first received it. The node enhances the message tree with the new exception information that it has written to the exception list tree. Any modifications or additions that the nodes in try flow made to the message tree are not present in the message tree that is propagated to the catch flow.

Terminals and properties:
When you have put an instance of the TryCatch node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view.

The TryCatch node terminals are described in the following table.

Terminal	Description
In	The input terminal that accepts a message for processing by the node.
Catch	The output terminal to which the message is propagated if an exception is thrown downstream and caught by this node.
Try	The output terminal to which the message is propagated if it is not caught.

The following table describes the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The TryCatch node Description properties are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type: TryCatch	The name of the node.
Short Description	No	No		A brief description of the node.
Long Description	No	No		Text that describes the purpose of the node in the message flow.

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

TwineballInput node

Use the TwineballInput node to discover how the WebSphere Adapters nodes work.

This topic contains the following sections:

Purpose:
The TwineballInput node is provided for educational purposes and helps you to see how the WebSphere Adapters nodes work. The TwineballInput node is a sample node with its own sample EIS. You cannot use the TwineBall nodes to connect to the external SAP, Siebel, and PeopleSoft EIS systems. Do not use this node in production.

The TwineballInput node is contained in the **WebSphere Adapters** drawer of the message flow node palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

You can use the **mqsisetdbparms** command in the following format to configure an account name with a user name and password for the Twineball adapter.

```
mqsisetdbparms broker name -n adapter name -u user name -p password
```

For example:

```
mqsisetdbparms BRK1 -n eis::TwineballInbound.inadapter -u mqbroker -p ********
```

Look at the following sample to see how to use this node:

- Twineball Example EIS Adapter

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Terminals and properties:
When you have put an instance of the TwineballInput node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view. If you double-click a TwineballInput node, you open the Adapter Connection wizard. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The TwineballInput node terminals are described in the following table.

Terminal	Description
Out	Business object events from the adapter are sent to the Out terminal.
Failure	If an error happens in the TwineballInput node, the message is propagated to the Failure terminal. Information about the error, and business object events can also be propagated to the Failure terminal.
Catch	Business object events are sent to the Catch terminal if they cause an uncaught exception in the message flow. If the Catch terminal is not connected, the retry process is activated to handle the business object.

The following table describes the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file at deployment).

The TwineballInput node Description properties are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type, TwineballInput.	The name of the node.
Short Description	No	No		A brief description of the node.
Long Description	No	No		Text that describes the purpose of the node in the message flow.

The TwineballInput node Basic properties are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Adapter component	Yes	Yes		The name of the adapter component that contains configuration properties for the adapter. Either enter a name of an adapter file or click **Browse** to select an adapter file from the list of files that are available in referenced message set projects.	adapterComponent

The TwineballInput node Routing properties are described in the following table.

Property	M	C	Default	Description
Set destination list	No	No	Selected	This property specifies whether to add the method binding name to the route to label destination list. If you select this check box, the method binding name is added so that you can use a RouteToLabel node in the message flow after the TwineballInput node.
Label prefix	No	No		The prefix to add to the method name when routing to label. Add a label prefix to avoid a clash of corresponding label nodes when you include multiple WebSphere Adapters input nodes in the same message flow. By default, there is no label prefix, so that the method name and label name are identical.

The TwineballInput node Input Message Parsing properties are described in the following table.

Property	M	C	Default	Description
Message domain	No	No	DataObject	The domain that is used to parse the incoming message. By default, the message that is propagated from the TwineballInput node is in the DataObject domain. You cannot specify a different domain.
Message set	Yes	No	Set automatically	The name of the message set in which the incoming message is defined. This field is set automatically from the Adapter component property. If you set this property, then subsequently update the project dependencies to remove this message set reference, a warning is issued. Either update the `Message set` property, or restore the reference to this message set project.
Message type	No	No		The name of the incoming message. The node detects the message type automatically. You cannot set this property.
Message format	No	No		The name of the physical format of the incoming message. You cannot set this property.

The TwineballInput node Transactional properties are described in the following table.

Property	M	C	Default	Description
Transaction mode	No	No	Yes	The transaction mode on this input node determines whether the rest of the nodes in the flow operate under sync point.

The Instances properties of the TwineballInput node are described in the following table. For a full description of these properties, see “Configurable message flow properties” on page 4020.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Additional instances pool	No	Yes	`Use Pool Associated with Message Flow`	The pool from which additional instances are obtained. • If you select `Use Pool Associated with Message Flow`, additional instances are obtained from the message flow value. • If you select `Use Pool Associated with Node`, additional instances are allocated from the node's additional instances based on the number specified in the `Additional instances` property.	componentLevel
Additional instances	No	Yes	`0`	The number of additional instances that the node can start if the `Additional instances pool` property is set to `Use Pool Associated with Node`. By default, no additional instances are given to the node.	additionalInstances

The TwineballInput node Retry properties are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Retry mechanism	No	No	`Failure`	This property specifies how retry processing is handled when a failure is rolled back to the TwineballInput node. • If you select `Failure`, retry processing is not performed so that you cannot set the remaining properties. • If you select `Short and long retry`, retry processing is performed first at the interval that is specified by the `Short retry interval` property, and if that is unsuccessful, it is then performed at the interval that is specified by the `Long retry interval` property.	
Retry threshold	No	Yes	0	The maximum number of times that retry processing is performed for short retry.	retryThreshold
Short retry interval	No	Yes	0	The interval between short retry attempts.	shortRetryThreshold
Long retry interval	No	Yes	0	The interval between long retry attempts.	longRetryThreshold

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

TwineballRequest node

Use the TwineballRequest node to discover out how WebSphere Adapters nodes work.

This topic contains the following sections:
- "Purpose"
- "Terminals and properties" on page 4956

Purpose:
The TwineballRequest node is provided for educational purposes and helps you to see how the WebSphere Adapters nodes work. The TwineballRequest node is a sample node with its own sample EIS. You cannot use the TwineBall nodes to connect to the external SAP, Siebel, and PeopleSoft EIS systems. Do not use this node in production.

The TwineballRequest node is contained in the **WebSphere Adapters** drawer of the message flow node palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

You can use the **mqsisetdbparms** command in the following format to configure an account name with a user name and password for the Twineball adapter.

```
mqsisetdbparms broker name -n adapter name -u user name -p password
```

For example:

```
mqsisetdbparms BRK1 -n eis::TwineballOutbound.outadapter -u mqbroker -p ********
```

Look at the following sample to see how to use this node:

- Twineball Example EIS Adapter

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Terminals and properties:
When you have put an instance of the TwineballRequest node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view. If you double-click a TwineballRequest node, you open the Adapter Connection wizard. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The TwineballRequest node terminals are described in the following table.

Terminal	Description
In	The input terminal that accepts the request business object.
Out	The output terminal to which the response business object is sent if it represents successful completion of the request, and if further processing is required within this message flow.
Failure	If an error happens in the TwineballRequest node, the message is propagated to the Failure terminal. Information about the error, and business object events can also be propagated to the Failure terminal.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk on the panel if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The TwineballRequest node Description properties are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type, TwineballRequest	The name of the node.
Short Description	No	No		A brief description of the node.
Long Description	No	No		Text that describes the purpose of the node in the message flow.

The TwineballRequest node Basic properties are described in the following table.

Property	M	C	Default	Description	`mqsiapplybaroverride` command property
Adapter component	Yes	No		The name of the adapter component that contains configuration properties for the adapter. Either enter a name of an adapter file, or click **Browse** to select an adapter file from the list of files that are available in referenced message set projects.	

Property	M	C	Default	Description	mqsiapplybaroverride command property
Default method	Yes	Yes		The default method binding to use.	defaultMethod

The TwineballRequest node Response Message Parsing properties are described in the following table.

Property	M	C	Default	Description
Message domain	No	No	DataObject	The domain that is used to parse the response message. By default, the response message that is propagated from the TwineballRequest node is in the DataObject domain. You cannot specify a different domain.
Message set	Yes	No	Set automatically	The name of the message set in which the incoming message is defined. This field is set automatically from the Adapter component property. If you set this property, then subsequently update the project dependencies to remove this message set reference, a warning is issued. Either update the `Message set` property, or restore the reference to this message set project.
Message type	No	No		The name of the response message. The node detects the message type automatically. You cannot set this property.
Message format	No	No		The name of the physical format of the response message. You cannot set this property.

The TwineballRequest node Transactionality properties are described in the following table.

Property	M	C	Default	Description
Transaction mode	No	No	Automatic	This property specifies how updates are handled. If you select `Yes`, updates are performed in a single transaction. If you select `No`, updates are performed independently.

The TwineballRequest node Request properties are described in the following table.

Property	M	C	Default	Description
Method Location	Yes	No	$LocalEnvironment/ Adapter/MethodName	The location of the business method (such as createPurchaseOrder or deletePurchaseOrder) that is used to trigger the TwineballRequest node to perform an action on the external system.
Data Location	Yes	No	$Body	The location in the incoming message tree from which data is retrieved to form the request that is sent from the TwineballRequest node to the EIS.

The TwineballRequest node Result properties are described in the following table.

Property	M	C	Default	Description
Output data location	No	No	$OutputRoot	The message tree location to which the TwineballRequest node sends output.

Property	M	C	Default	Description
Copy local environment	No	No	Selected	This property controls how the local environment is copied to the output message. If you select the check box, at each node in the message flow, a new copy of the local environment is created in the tree, and it is populated with the contents of the local environment from the preceding node. If a node changes the local environment, the upstream nodes do not see those changes because they have their own copies. This behavior might be an issue if you are using a FlowOrder node, or if you use the propagate command on a Compute node. If you clear the check box, each node does not generate its own copy of the local environment, but it uses the local environment that is passed to it by the previous node. If a node changes the local environment, those changes are seen by the upstream nodes.

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

Use the **mqsisetdbparms** command to associate a specific user ID and password (or SSH identity file) with one or more resources that are accessed by the broker.

Validate node

Use the Validate node to check that the message that arrives on its input terminal is as expected. You can use this node to check that the message has the expected message template properties, and to check that the content of the message is correct by selecting message validation.

This topic contains the following sections:

Purpose:
The checks that you can perform depend on the domain of the message.

Check	Domain
Check message domain	All domains
Check message set	XMLNSC, MRM, and IDOC only
Check message type	MRM only
Validate message body	XMLNSC, MRM and IDOC only

You can check the message against one or more of message domain, message set, or message type. The property is checked only if you select its corresponding check box, which means that a property that contains an empty string can be compared.

You can check the content of the message by giving a value to the `Validate` property. Validation takes place if the `Validate` property is set to a value other than `None`, which is the default value.

For validation failures to be returned to the Validate node from the parser, set the `Failure Action` property to either `Exception` or `Exception List`. Otherwise, validation failures are just logged.

If all the specified checks pass, the message is propagated to the Match terminal of the node.

If any of the checks fail, the message is propagated to the Failure terminal. If the Failure terminal is not connected to some failure handling processing, an exception is generated.

The Validate node replaces the Check node, which is deprecated in WebSphere Message Broker Version 6.0 and subsequent releases. The Validate node works in the same way as the Check node, but it has additional Validation properties to allow the validation of message content by parsers that support that capability.

The Validate node is contained in the **Validation** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:
Use the Validate node to confirm that a message has the correct message template properties, and has valid content, before propagating the message to the rest of the flow. Subsequent nodes can then rely on the message being correct, without doing their own error checking.

You can also use the Validate node to ensure that the message is routed appropriately through the message flow. For example, configure the node to direct a message that requests stock purchases through a different route from that required for a message that requests stock sales.

Another routing example is the receipt of electronic messages from your staff at your head office. These messages are used for multiple purposes (for example, to request technical support or stationery, or to advise you about new customer leads). These messages can be processed automatically because your staff complete a standard form. If you want these messages to be processed separately from other messages that are received, use the Validate node to ensure that only staff messages that have a specific message type are processed by this message flow.

Terminals and properties:
When you have put an instance of the Validate node into a message flow, you can configure it. For more information, see "Configuring a message flow node" on page 1503. The properties of the node are displayed in the Properties view. All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The terminals of the Validate node are described in the following table.

Terminal	Description
In	The input terminal that accepts a message for processing by the node.
Failure	The output terminal to which the message is routed if the incoming message does not match the specified properties.
Match	The output terminal to which the message is routed if the incoming message matches the specified properties.

The following tables describe the properties of the node. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Description properties of the Validate node are described in the following table.

Property	M	C	Default	Description
Node name	No	No	Validate	The name of the node.
Short description	No	No		A brief description of the node.
Long description	No	No		Text that describes the purpose of the node in the message flow.

The Validate node Basic properties are described in the following table.

Property	M	C	Default	Description
Domain	No	No		The name of the domain. Select one of the following values from the list of the `Domain` property: • XMLNSC • SOAP • DataObject • XMLNS • JMSMap • JMSStream • MIME • MRM • BLOB You can also specify a user-defined parser, if appropriate.
Check domain	Yes	No	Cleared	If you select this check box, the incoming message is checked against the `Domain` property.
Set	No	No		The name or identifier of the message set to which the incoming message belongs. If you are using the XMLNSC, DataObject, SOAP, MRM, or IDOC parser and want to check that the incoming message belongs to a particular message set, select `Check set` and select one of the values from the list of the `Set` property. This list is populated when you select XMLNSC, DataObject, SOAP, MRM, or IDOC as the message domain. Leave `Set` clear for the other parsers. If you set this property, then subsequently update the project dependencies to remove this message set reference, a warning is issued. Either update the `Set` property, or restore the reference to this message set project.
Check set	Yes	No	Cleared	If you select the check box, the incoming message is checked against the `Set` property. If you are using the XMLNSC,DataObject, SOAP, MRM, or IDOC parser and want to check that the incoming message belongs to a particular message model, select `Check set` and select one of the values from the list of the `Set` property.
Type	No	No		The message name. If you are using the MRM parser and want to check that the incoming message is a particular message type, select `Check type` and enter the name of the message in the `Type` property. Leave `Type` clear for the other parsers.
Check type	Yes	No	Cleared	If you select the check box, the incoming message is checked against the `Type` property. If you are using the MRM parser and want to check that the incoming message is a particular message type, select `Check type` and enter the name of the message in the `Type` property.

The Validation properties of the Validate node are described in the following table.

If you are using the XMLNSC, DataObject, SOAP, MRM, or IDOC parser and want to validate the body of messages against the message set, select the required validation properties on the **Validation** tab. For more details, see “Validating messages” on page 1478 and “Validation properties” on page 4169.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Validate	No	Yes	None	This property controls whether validation takes place. Valid values are None, Content and Value, Content, and Inherit.	validateMaster
Failure Action	No	No	Exception	This property controls what happens if validation fails. You can set this property only if you set Validate to Content or Content and Value. Valid values are User Trace, Local Error Log, Exception, and Exception List.	

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

Use the Check node to compare the template of a message that is arriving on its input terminal with a message template that you supply when you configure the Check node.

Warehouse node

Use the Warehouse node to interact with a database in the specified ODBC data source.

This topic contains the following sections:
- "Purpose"
- "Using this node in a message flow"
- "Terminals and properties" on page 4964

Purpose:
The Warehouse node is a specialized form of the Database node that stores the entire message, parts of the message, or both, in a table within the database. You define what is stored by creating mappings that use the data from the input message to identify the action that is required.

You can use the Warehouse node for various purposes. For example:
- To maintain an audit trail of messages that are passing through the broker
- For offline or batch processing of messages that have passed through the broker (data mining)
- As a source from which to reprocess selected messages in the broker

Use standard database query and mining techniques to retrieve messages that you have stored in the warehouse. (No explicit support is provided by WebSphere Message Broker.)

You must have created or identified the following items:
- Input data in the form of a message set and message
- An ODBC connection to the database
- A database and database table to store the message
- At least two columns in the table: one for the binary object (the message), and one for the timestamp

The Warehouse node is contained in the **Database** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:
When you use the Warehouse node, you can store the following elements in the database that is associated with the node:
- The entire message, optionally with an associated timestamp. The message is stored as a binary object, with the timestamp in a separate column. This option has two advantages:
  - There is no need to decide beforehand how to use the warehoused data because after the data is stored, it can be retrieved, and data mining tools applied.

  - You do not need to define a specific database schema for every type of message that might pass through the broker. In a complex system, many different message types might be processed, and the time involved in defining a unique schema for each message type can become prohibitive. You can precede each Warehouse node with a Compute node that converts each message into a canonical warehouse format with a common schema, or you can store the whole message as a binary object.
- Selected parts of the message, optionally with an associated timestamp, which requires a defined database schema for that message type. The message is mapped to true type so, for example, a character string in the message is stored as a character string in the database.

Terminals and properties:
When you have put an instance of the Warehouse node into a message flow, you can configure it. For more information, see "Configuring a message flow node" on page 1503. The properties of the node are displayed in the Properties view. (If you double-click a Warehouse node, you open the New Message Map dialog box.) All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

The terminals of the Warehouse node are described in the following table.

Terminal	Description
In	The input terminal that accepts a message for processing by the node.
Failure	The output terminal to which the input message is propagated if a failure is detected during the computation. If you have selected `Treat warnings as errors`, the node propagates the message to this terminal even if the processing completes successfully.
Out	The output terminal that outputs the message following the execution of the database statement.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The Warehouse node Description properties are described in the following table.

Property	M	C	Default	Description
Node name	No	No	Warehouse	The name of the node.
Short description	No	No		A brief description of the node.
Long description	No	No		Text that describes the purpose of the node in the message flow.

The Warehouse node Basic properties are described in the following table.

Property	M	C	Default	Description	**mqsiapplybaroverride command property**
Data source	No	Yes		The ODBC data source name of the database that contains the tables to which you refer in the mappings that are associated with this node (identified by the `Field mapping` property). This name identifies the appropriate database as it is known on the system on which this message flow is to run. The broker connects to this database with user ID and password information that you have specified on the **mqsisetdbparms** command.	dataSource

Property	M	C	Default	Description	mqsiapplybaroverride command property
Field mapping	Yes	No	`Warehouse`	The name of the mapping routine that contains the statements that are to be executed against the database or the message tree. By default, the name that is assigned to the mapping routine is identical to the name of the mappings file in which the routine is defined. The default name for the file is the name of the message flow concatenated with the name of the node when you include it in the message flow (for example, `MFlow1_Warehouse.msgmap` for the first Warehouse node in message flow MFlow1). You cannot specify a value that includes spaces. If you click **Browse** next to this entry field, a dialog box displays that lists all available mapping routines that can be accessed by this node. Select the routine that you want and click **OK**; the routine name is set in `Field mapping`. To work with the mapping routine that is associated with this node, double-click the node, or right-click the node and select **Open Mappings**. If the mapping routine does not exist, it is created for you with the default name in the default file. If the file exists, you can also open file *`flow_name_node_name`*`.msgmap` in the Broker Development view. The content of the mapping routine determines what is stored in the database, and in what format. You can, for example, store all or just a part of each message. You can also store the data as binary data, or store each field in the same format as it is in the message (for example, a character field in the message is stored as character in the database). A mapping routine is specific to the type of node with which it is associated; you cannot use a mapping routine that you have developed for a Warehouse node with any other node that uses mappings (for example, a DataInsert node). If you create a mapping routine, you cannot call it from any other mapping routine, although you can call it from an ESQL routine. For more information about working with mapping files, and defining their content, see “Using message mappings” on page 2228.	

Property	M	C	Default	Description	mqsiapplybaroverride command property
Transaction	Yes	No	Automatic	The transaction mode for the node. Select the value that you require: • If you select Automatic (the default), the message flow, of which the Warehouse node is a part, is committed if it is successful; that is, the actions that you define in the mappings are taken and the message continues through the message flow. If the message flow fails, it is rolled back. Therefore, selecting Automatic means that the ability to commit or roll back the action of the Warehouse node on the database depends on the success or failure of the entire message flow. • If you select Commit, any uncommitted actions that are taken in this message flow are committed on the database that is connected to this node, irrespective of the success or failure of the message flow as a whole. The changes to the database are committed even if the message flow itself fails.	
Treat warnings as errors	Yes	No	Cleared	For database warning messages to be treated as errors, and the node to propagate the output message to the Failure terminal, select Treat warnings as errors. The check box is cleared by default. When you select the check box, the node handles all positive return codes from the database as errors and generates exceptions in the same way as it does for the negative, or more serious, errors. If you do not select the check box, the node treats warnings as typical return codes, and does not raise any exceptions. The most significant warning raised is not found, which can be handled as a typical return code safely in most circumstances.	
Throw exception on database error	Yes	No	Selected	For the broker to generate an exception when a database error is detected, select Throw exception on database errors. The check box is selected by default. If you clear the check box, you must handle the error in the message flow to ensure the integrity of the broker and the database; the error is ignored if you do not handle it through your own processing, because you have chosen not to invoke the default error handling by the broker; for example, you can connect the Failure terminal to an error processing subroutine.

Use the DataInsert node to interact with a database in the specified ODBC data source.

XSLTransform node

Use the XSLTransform node to transform an XML message to another form of message, according to the rules provided by an XSL (Extensible Stylesheet Language) style sheet, and to set the `Message domain`, `Message set`, `Message type`, and `Message format` for the generated message.

This node was formerly known as the XMLTransformation node.

This topic contains the following sections:
- "Purpose"
- "Using this node in a message flow" on page 4969
- "Configuring the XSLTransform node" on page 4970
- "Terminals and properties" on page 4970

Purpose:

You can specify the location of the style sheet to apply to this transformation in three ways:

- Use the content of the XML data within the message itself to transform the message according to a style sheet that the message itself defines.
- Set a value in the LocalEnvironment folder. You must set this value in a node that precedes the XSLTransform node (for example, a Compute node). You can therefore use a variety of inputs to determine which style sheet to use for this message, such as the content of the message data, or a value in a database.
- Use node properties to ensure that the transformation that is defined by this single style sheet is applied to every message that is processed by this node.

An XSLT (Extensible Stylesheet Language for Transformations) compiler is used for the transformation if the style sheet is not embedded within the message, and the node cache level (node property Stylesheet Cache Level) is greater than zero. If the XSLT is cached, the performance is improved because the XSLT is not parsed every time it is used.

If the prologue of the input message body contains an XML encoding declaration, the XSLTransform node ignores the encoding, and always uses the CodedCharSetId in the message property folder to decode the message.

The XSLTransform node is contained in the **Transformation** drawer of the palette, and is represented in the WebSphere Message Broker Toolkit by the following icon:

Using this node in a message flow:
For an example of how to use this node, consider two news organizations that exchange information on a regular basis. One might be a television station, the other a newspaper. Although the information is similar, the vocabulary that is used by the two is different. This node can transform one format to the other by applying the rules of the specified style sheet. If you specify the style sheet in the message (either the XML data or the LocalEnvironment), the same node can perform both transformations.

You cannot use relative path external entities that are defined in the DTD of input messages (for example, `<!DOCTYPE note [<!ENTITY chap1 SYSTEM "chap1.xml">]>`). Use an absolute path definition.

The XSLTransform node supports a number of local environment message tree variables, which you can use to dynamically alter the values that are set in the node's properties. For more details, see “Using local environment variables to set properties” on page 4976.

You can use style sheets in two different ways with the XSLTransform node. For more details, see “Deployed and non-deployed style sheets” on page 4978.

If you have large XML messages and receive an `out of memory` error, use the **`mqsireportproperties`** command to see the current value of the Java Heap size for the XSLT engine:

```
mqsireportproperties brokerName -e executionGroupLabel
                                -o ComIbmJVMManager -n jvmMaxHeapSize
```

Use the **mqsichangeproperties** command to increase the Java Heap size:

```
mqsichangeproperties brokerName -e executionGroupLabel
                                -o ComIbmJVMManager -n jvmMaxHeapSize -v newSize
```

In the previous examples, replace *brokerName*, *executionGroupLabel*, and *newSize* with the appropriate values.

The value that you choose for *newSize* depends on the amount of physical memory that your computer has, and how much you are using Java. A value in the range 512 MB (536870912) to 1 GB (1073741824) is typically sufficient.

Look at the following sample for more details about how to use the XSLTransform node:

- XSL Transform

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

Configuring the XSLTransform node:
When you have put an instance of the XSLTransform node into a message flow, you can configure it; see . The properties of the node are displayed in the Properties view.

All mandatory properties for which you must enter a value (those that do not have a default value defined) are marked with an asterisk.

Terminals and properties:
The XSLTransform node terminals are described in the following table.

Terminal	Description
In	The input terminal that accepts the message for processing by the node.
Failure	The output terminal to which the original message is routed if an error is detected during transformation.
Out	The output terminal to which the successfully transformed message is routed.

The following tables describe the node properties. The column headed M indicates whether the property is *mandatory* (marked with an asterisk if you must enter a value when no default is defined); the column headed C indicates whether the property is *configurable* (you can change the value when you add the message flow to the BAR file to deploy it).

The XSLTransform node Description properties are described in the following table.

Property	M	C	Default	Description
Node name	No	No	The node type	The name of the node.
Short description	No	No		A brief description of the node.
Long description	No	No		Text that describes the purpose of the node in the message flow.

The XSLTransform node Stylesheet properties are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Stylesheet name	No	Yes		The name of the style sheet, which is used if the style sheet specification is searched for in node properties. To specify a style sheet by using node properties, enter the required value for Stylesheet name. Specify a principal style sheet using one of the following methods: • Click **Browse** next to `Stylesheet name`. The identified principal style sheet and all its relatively-referenced descendant style sheets are added automatically to the BAR file when you add a message flow to a BAR file (if both they and their parent style sheets are available). • To identify an already deployed, or ready to be deployed, style sheet, use the `Stylesheet name` property, and leave the `Stylesheet directory` property blank. • In the Message Flow editor, drag an `.xslt` file onto the XSLTransform node; the `Stylesheet name` is set automatically.	stylesheetName

The XSLTransform node Advanced properties are described in the following table.

Property	M	C	Default	Description	mqsiapplybaroverride command property
Stylesheet directory	No	Yes		The path where the style sheet is located. This path is used by all location methods. If the style sheet identification is fully qualified, the `Stylesheet directory` property is ignored; otherwise, the value that you set in this property is added to the beginning of the specification, regardless of where it is found.	stylesheetPath

Property	M	C	Default	Description	mqsiapplybaroverride command property
Stylesheet cache level	No	No	5	The number of compiled or parsed style sheets that are stored in this instance of the node. Enter a positive integer between zero (0) and 100. The default value is 5. If you set this property to zero (0), no style sheet is cached, and style sheets are interpreted rather than compiled. If your message flow does not set the style sheet dynamically by using the local environment, the same style sheet is always used, and any value greater than zero ensures that it is compiled. If your message flow does set the style sheet dynamically, you can tune the value to improve performance. If you set this property to a character other than a positive integer, a flow configuration exception error message is issued. The style sheet cache is retained for the life of the node, and is cleared when the node is deleted from the flow, when the flow is deleted, or when the execution group is stopped. If you change a cached style sheet (by redeploying or replacing the file in the file system), the XSLTransform node that is holding the cache replaces the cached version with the modified (latest) version before a new message is processed. If a deployed style sheet is redeployed, or an external style sheet is replaced in the file system, the update is detected but you cannot replace a style sheet that is deployed in a BAR file by changing the deployed style sheet on disk. To change a style sheet that is deployed in a BAR file, you must redeploy the BAR file. If you are changing several style sheets, stop the relevant message flows before you make any changes. If you do not stop the relevant message flows before you make the changes, the order of the changes cannot be guaranteed by running message flows, which might cause an incompatibility between the style sheets that are changed. Use the **mqsireload** command to reload a style sheet; however, this command does not prevent incompatibility. Consider performance when you set this property. Typically, when you set this property to a number greater than the default value of 5, performance is faster because style sheet re-compilation is less likely. However, cached style sheets use Java virtual machine (JVM) heap space; if you keep too many cached style sheets, the JVM is likely to slow. In addition, if the cached style sheets are not used regularly and you set this property to a large number, performance can be affected because compiling style sheets increases processor usage. Therefore, to decide on the most suitable value for this property, you must balance how many style sheets you use with the size of the style sheets, the size of the JVM heap space, and your usage pattern. For more information about the JVM heap space, see "JVM heap sizing" on page 3269.	

The XSLTransform node Output Message Parsing properties are described in the following table.

Property	M	C	Default	Description
Message domain	No	No	BLOB	The message domain that is associated with the output message. To associate a specific parser with the output message, specify the new domain in Message domain. The default value is BLOB. This domain is applied to the output message. Alternatively, use Inherit to associate the parser that owned the input message. XML is deprecated; use XMLNSC instead. You can also specify a user-defined parser if appropriate.
Message set	No	No		The message set that is associated with the output message. If you are using the MRM parser, or the XMLNSC parser in validating mode, select the Message set that you want to use. This list is populated with available message sets when you select MRM or XMLNSC as the domain. If you set this property, then subsequently update the project dependencies to remove this message set reference, a warning is issued. Either update the Message set property, or restore the reference to this message set project.
Message type	No	No		The message type that is associated with the output message. If you are using the MRM parser, select the correct message from the list in Message type. This list is populated with messages that are defined in the Message set that you have selected.
Message format	No	No		The message format that is associated with the output message. If you are using the MRM parser, select the XML physical format for the output message from the list in Message format. This list includes all the physical formats that you have defined for this Message set.
Character set	No	No		The numeric value of the character set for the output message. To specify a character set for the output message by using node properties, specify the required value for Character set. The value that you specify must be numeric; for example, specify 1200 to encode the output message as UTF-16.

The XSLTransform node Parser Options are described in the following table.

Property	M	C	Default	Description
Parse timing	No	No	On Demand	This property controls when an output message is parsed. Valid values are On Demand, Immediate, and Complete. Parse timing is, by default, set to On Demand, which causes parsing of the message to be delayed. To cause the message to be parsed immediately, see “Parsing on demand” on page 4173.
Build tree using XML schema data types	No	No	Cleared	This property controls whether the XMLNSC parser creates syntax elements in the message tree with data types taken from the XML Schema. You can select this property only if you set the Validate property to Content or Content and Value. For more information, see “Manipulating messages in the XMLNSC domain” on page 2546.
Use XMLNSC compact parser for XMLNS domain	No	No	No	This property controls whether the XMLNSC Compact Parser is used for output messages in the XMLNS Domain. If you set this property, the message data appears under XMLNSC in nodes that are connected to the output terminal when the input MQRFH2 header or Domain is XMLNS.

The XSLTransform node Validation properties are described in the following table. Set the validation properties for the parser to validate the body of messages against the Message set. (If a message is propagated to the Failure terminal of the node, it is not validated.) For more details, see “Validating messages” on page 1478 and “Validation properties” on page 4169.

Property	M	C	Default	Description
Validate	No	Yes	`None`	This property controls whether validation takes place of the output message. Valid values are `None`, `Content`, `Content and Value`, and `Inherit`.
Failure action	No	No	`Exception`	This property controls what happens if validation of the output message fails. You can set this property only if you set `Validate` to `Content and Value` or `Content`. Valid values are `User Trace`, `Local Error Log`, `Exception`, and `Exception List`.

The XSLTransform node Detail Trace properties are described in the following table.

Property	M	C	Default	Description
Trace setting	Yes	No	`Off`	This property is deprecated. Start user trace instead. The user trace contains the same XSL trace information. If you set this property, it does not affect user trace. In previous versions of WebSphere Message Broker, this property controls whether tracing is on or off. If tracing is on, low level tracing is recorded in a file.

The Monitoring properties of the node are described in the following table.

Property	M	C	Default	Description
Events	No	No	None	Events that you have defined for the node are displayed on this tab. By default, no monitoring events are defined on any node in a message flow. Use **Add**, **Edit**, and **Delete** to create, change or delete monitoring events for the node; see "Configuring monitoring event sources using monitoring properties" on page 3327 for details. You can enable and disable events that are shown here by selecting or clearing the **Enabled** check box.

"Handling errors in message flows" on page 2823
The broker provides basic error handling for all your message flows. If basic processing is not sufficient, and you want to take specific action in response to certain error conditions and situations, you can enhance your message flows to provide your own error handling.

"Adding files to a broker archive" on page 3223
To deploy files to an execution group, include them in a broker archive (BAR) file.

"Setting the JVM heap size" on page 3254
When you start an execution group, it creates a Java virtual machine (JVM) for executing a Java user-defined node.

Related reference:

"User trace" on page 6873
User trace is one of two types of optional trace that are available in WebSphere Message Broker and provides more information than that provided by the entries that are written to the Administration log. User trace is inactive by default; you must activate it explicitly by using a command, or by selecting options in the WebSphere Message Broker Toolkit.

"Adding keywords to XSL style sheets"
Embedded keywords in an XSL style sheet; their location is not restricted. You can also add a keyword as an XML comment.

"**mqsichangeproperties** command" on page 3756
Use the **mqsichangeproperties** command to modify broker properties and properties of broker resources.

"**mqsicreatebroker** command" on page 3831
Use the **mqsicreatebroker** command to create a broker and its associated resources.

"**mqsireload** command" on page 3909
Use the **mqsireload** command to request the broker to stop and restart execution groups.

"**mqsireportproperties** command" on page 3937
Use the **mqsireportproperties** command to display properties that relate to a broker, an execution group, or a configurable service.

"Compute node" on page 4340
Use the Compute node to construct one or more new output messages.

"RegistryLookup node" on page 4646
Use the RegistryLookup node to retrieve any type of entity held in the WebSphere Service Registry and Repository (WSRR). The entities that match the specified search criteria are stored in the local environment. The input message is not modified.

Adding keywords to XSL style sheets:

Embedded keywords in an XSL style sheet; their location is not restricted. You can also add a keyword as an XML comment.

XML comments must have the following format:

```
$MQSI keyword = value MQSI$
```

The example shows how to add the keyword of **author** with the value `John` to an XML style sheet:

```
<?xml version="1.0" encoding="UTF-8">
<!-- $MQSI author = John MQSI$ -->
<xsl:stylesheet version="1.0"
xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
<xsl:output method="text" encoding="UTF-8"/>
<xsl:template match="/">
<xsl:value-of select="message"/>
</xsl:template>
</xsl:stylesheet>
```

Restrictions within keywords

Do not use the following characters within keywords, because they might cause unpredictable behavior:

```
^ $ . | \ < > ? + * = & [ ] ( )
```

You can use these characters in the values that are associated with keywords; for example:

- `$MQSI RCSVER=$id$ MQSI$` is acceptable
- `$MQSI $name=Fred MQSI$` is not acceptable

"Guidance for defining keywords" on page 4017
You can add extra information to an object in the form of one or more keywords.

"XSLTransform node" on page 4968
Use the XSLTransform node to transform an XML message to another form of message, according to the rules provided by an XSL (Extensible Stylesheet Language) style sheet, and to set the `Message domain`, `Message set`, `Message type`, and `Message format` for the generated message.

Using local environment variables to set properties:

The XSLTransform node supports a number of local environment message tree variables, which you can use to dynamically alter the values that are set in the node's properties.

The following table lists each local environment variable against the name of the node property that it overrides:

Local environment variable name	Node property name
XSL.StyleSheetName	Stylesheet name
XSL.MessageDomain	Message domain
XSL.MessageSet	Message set
XSL.MessageType	Message type
XSL.MessageFormat	Message format
XSL.OutputCharSet	Character set

This node searches for the name of the style sheet to be used by interrogating, in the following order:

1. The input message.

   The node searches the message XML data for information about the location of the style sheet. For example, the XML data might contain:

   ```
   <?xml-stylesheet type="text/xsl" href="me.xsl"?>
   ```

and "me.xsl" is then used as the name of the style sheet.

2. The local environment.

   If no style sheet name is found in the input message, the node searches the local environment that is associated with the current message for style sheet information stored in an element called XSL.StyleSheetName.

   This node was available in Version 6.0, and element ComIbmXslXmltStylesheetname was used for the name of the style sheet, therefore the current node checks both elements. If both are present, the value in XSL.StyleSheetName takes precedence.

3. The node properties.

   If no style sheet name is found in the input message or local environment, the node uses the `Stylesheet name` and `Stylesheet directory` properties to determine the correct values.

The node searches for the message domain, message set, message type, and message format to use for the output message by interrogating, in the following order:

1. The local environment.

   The node searches the local environment that is associated with the current message for message domain, message set, message type, and message format information stored in elements called XSL.MessageDomain, XSL.MessageSet, XSL.MessageType, and XSL.MessageFormat.

2. The node's properties.

   If no message domain, message set, message type, or message format information is found in these local environment variables, the node uses the `Message domain`, `Message set`, `Message type`, and `Message format` properties to determine the correct values.

If the node cannot determine the message domain from either XSL.MessageDomain or the `Message domain` property, the default value of BLOB is used. No default values exist for message set, message type, and message format.

The node searches for the character set to use for the output message by interrogating, in the following order:

1. The local environment.

   The node searches the local environment that is associated with the current message for character set information stored in an element called XSL.OutputCharSet; for example, to encode the output of the transformation as UTF-8, enter the value `1208` as a string in this element.

   This node was available in Version 6.0, and element ComIbmXslXmltOutputcharset was used for the output character set, therefore the current node checks both elements. If both are present, the value in XSL.OutputCharSet takes precedence.

2. The node's properties.

   If no character set information is found in the local environment, the node uses the `Character set` property to determine the correct value.

   If you set a value for `Character set`, the value that you enter must be numeric; for example, to encode the output of the transformation as UTF-16, enter `1200`.

If the node cannot determine the output character set from either of these two sources, because either no value is set or the selection priorities are set to zero, the default value of 1208 (UTF-8) is used.

Be aware of the following factors if the input to the XSLTransform node is generated from the XMLNSC parser or the MRM parser. The XMLNSC parser discards certain information in XML documents, such as processing instructions and comments, if you do not set properties to retain this information in a preceding node. To ensure that the XSLTransform node transforms the message correctly, set the `Retain mixed content`, `Retain comments`, and `Retain processing instructions` properties correctly on the preceding node (for example, an MQInput node). The MRM parser also discards this information, but you cannot retain information for this parser, therefore avoid using the MRM domain if such information is vital to your transformation.

Related concepts:

"Parsers" on page 1072
A parser is a program that interprets the physical bit stream of an incoming message, and creates an internal logical representation of the message in a tree structure. The parser also regenerates a bit stream for an outgoing message from the internal message tree representation.

"Local environment tree structure" on page 1056
The local environment tree is a part of the logical message tree in which you can store information while the message flow processes the message.

Use the XSLTransform node to transform an XML message to another form of message, according to the rules provided by an XSL (Extensible Stylesheet Language) style sheet, and to set the `Message domain`, `Message set`, `Message type`, and `Message format` for the generated message.

Deployed and non-deployed style sheets:

You can use style sheets in two different ways with the XSLTransform node.

Deployed style sheets
: Deployed style sheets are style sheets that you import into a broker archive (BAR) file and deploy to target systems. Deployed style sheets are managed by the broker. A *principal style sheet* is the root style sheet that is referenced in a message flow; for example, a reference to a principal style sheet in the Eclipse workspace, `C:\\project1\a\b.xsl` must be specified as `a/b.xsl` (or `./a/b.xsl`). A principal style sheet can reference (include or import) its descendent style sheets.

Non-deployed style sheets
: Non-deployed style sheets are style sheets that you store in a location where the XSLTransform node can access them. Non-deployed style sheets are not managed by the broker.

Deployment of deployed style sheets or XML files

Before you can configure the XSLTransform node, you must understand how to work with style sheets. A style sheet can refer to both another XML file and a style sheet. To use deployed style sheets or XML files:

1. Make sure that the files have the correct file name extensions.

   Style sheets that are to be deployed must have either `.xsl` or `.xslt` as their file extension, and XML files to be deployed must have `.xml` as their file extension.

2. Import the files into the Eclipse workspace.

   Import into an Eclipse workspace project all style sheets and XML files that are to be deployed. Put location-dependent descendant style sheets, or XML files that are to be deployed, in the correct directory structure relative to their parent style sheets. Do not put in the Eclipse workspace location-dependent descendants that you do not want to deploy.

3. Make sure that all references to the files are relative.

   Typically, all references to a deployed style sheet must be made relative, no matter where they are displayed. A reference to a principal style sheet must be made relative to the root of the relevant Eclipse workspace project.

   The only exception is when you specify a principal style sheet as the `Stylesheet name` property on an XSLTransform node; you can use an absolute path that points to the correct directory structure in the Eclipse workspace. If the principal style sheet is found, the system resets the node property automatically to the correct relative value.

   The system also performs an automatic deployment of the principal style sheet, together with all of its location-dependent descendant style sheets that are available in the relevant Eclipse workspace project. All references to the location-dependent descendant style sheets (or XML files) of a principal style sheet must be made relative to the location of their parent style sheets. For example, if style sheet `//project1/a/b.xsl` references style sheet `//project1/a/c/d.xsl`, the reference must be changed to `c/d.xsl` (or `./c/d.xsl`).

4. Handle non-deployed child style sheets or XML files.

   Style sheets can refer to other style sheets. If you have a relatively-referenced child style sheet (or XML file) that is not to be deployed, yet its parent is, make sure that the child style sheet is placed in the correct location under *workpath*`/XSL/external` (*workpath*`/XML/external`), where *workpath* is the full path to the working directory of the broker. You can use the `MQSI_WORKPATH` environment variable to find the location of the workpath on your system; for example, on Windows XP systems, the default workpath is `MQSI_WORKPATH=C:\Documents and Settings\All Users\Application Data\IBM\MQSI`.

   A broker automatically associates the execution group deployed storage tree, *workpath*`/`**`XSL`**`/external`, and *workpath*`/`**`XML`**`/external` tree, together. Therefore if, for example, the document `b/c.xml` is not found in the broker's deployed storage, the broker automatically searches for a reference to it in the *workpath*`/XML/external/a/b` directory in the deployed principal style sheet `a/style.xsl`. Relative path references must also be used for files that have been deployed but which are not available in the workspace.

5. Deploy the files.

   Deploy manually only those style sheets or XML files that are not picked up by the system (the WebSphere Message Broker Toolkit provides warnings about

these files). If you click **Browse** for the node, or provide the full path of the location of the style sheet in the Eclipse workspace, the style sheet is included automatically in the BAR file.

To deploy manually, add the files to be deployed to a broker archive. For more information, see "Adding files to a broker archive" on page 3223 and "Adding keywords to XSL style sheets" on page 4975.

For every execution group that uses the XSLTransform node, perform one of the following actions:

- Include the style sheet in the *workpath*/XSL/external directory on the broker; do not include the style sheet in the BAR file.

  If a style sheet in the *workpath*/XSL/external directory shares the same path and name with a deployed style sheet, the deployed style sheet is used.
- Include the style sheet in the BAR file and deploy the BAR file. If multiple BAR files include the same style sheet name, the style sheet from the last BAR file that was deployed is used.
- Deploy the style sheet in its own BAR file. If the BAR files use XSLTransform nodes, but do not include the style sheet, the WebSphere Message Broker Toolkit issues warning messages.

Message mappings define the blueprint for creating a message.

Related reference:

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

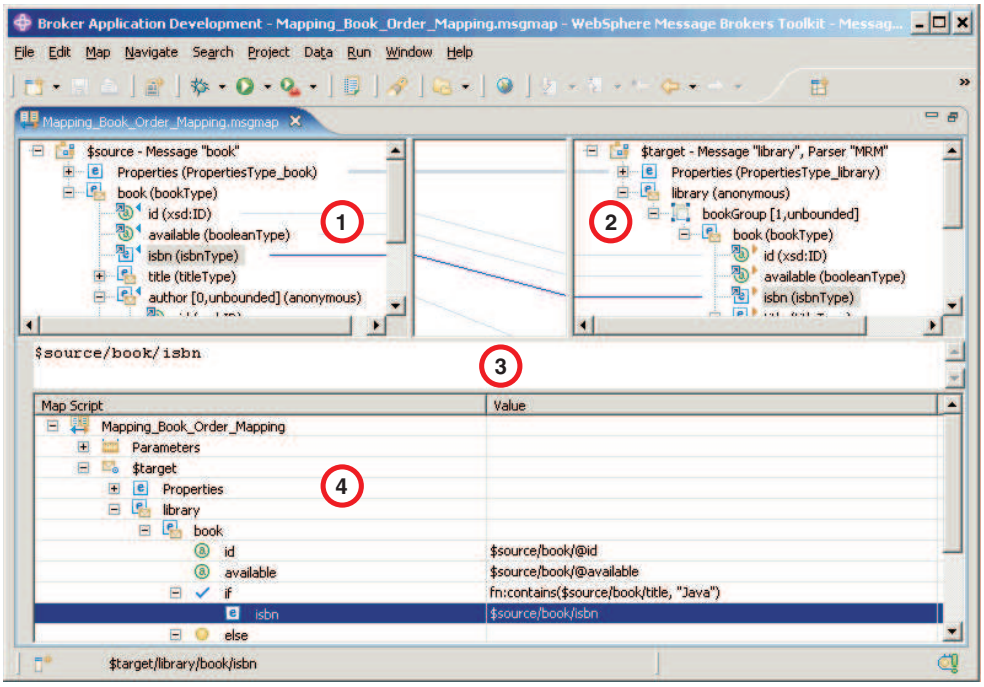
Message Mapping editor:

You use the Message Mapping editor to create and edit message mappings.

You can use the Message Mapping editor to set values for:

- The message destination
- Message headers
- Message content

Here is an example of the Message Mapping editor. There are separate panes for working with sources, targets and expressions, as well as a spreadsheet view.



1. **Source pane:** displays a source message or database table
2. **Target pane:** displays a target message
3. **Edit pane:** displays the expression to be used to derive the target element value
4. **Spreadsheet pane:** displays a summary of the mappings in spreadsheet columns (each target field and its value)

Use the Message Mapping editor to perform various mapping tasks.

Wizards and dialog boxes are provided for tasks such as adding mappable elements, working with ESQL, and working with submaps. Mappings that are created with the Message Mapping editor are automatically validated and compiled, ready for adding to a broker archive (BAR) file, and subsequent deployment to WebSphere Message Broker.

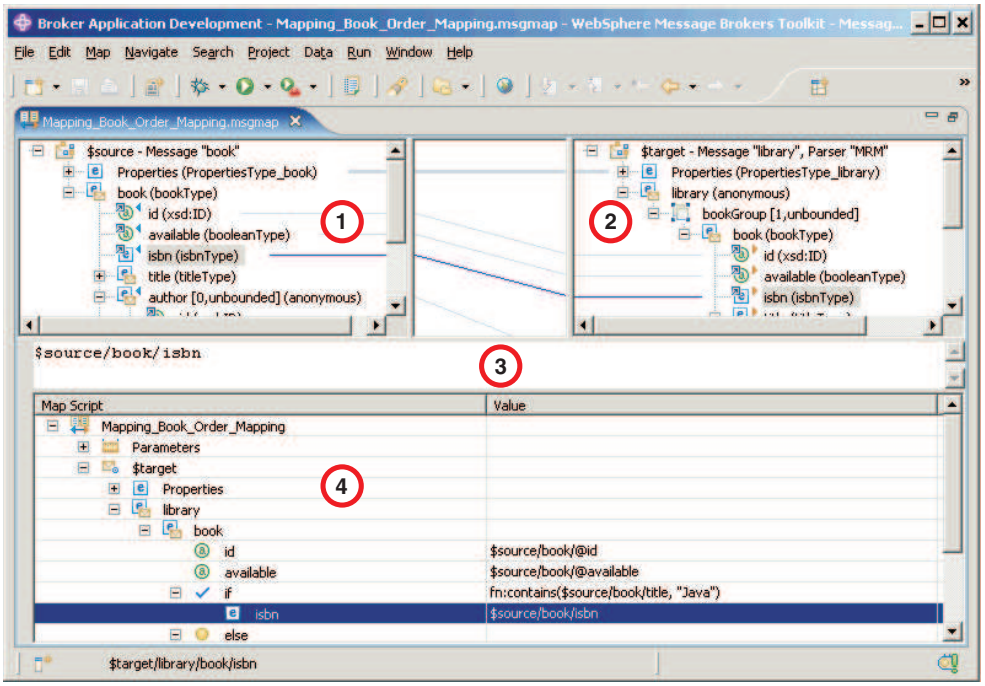
Message Mapping editor Source pane:

Details of the elements present in the Source pane of the Message Mapping Editor.

The following example shows the "Message Mapping editor" on page 4981. The pane that is labelled as 1 in the example is the Source pane:



The following list describes the elements that are present in the Source pane:

- A source message is identified by $source.
- A source database is identified by $db:select.
- A database stored procedure is identified by $db:proc.
- A database user-defined function is identified by $db:func.
- A mapped entry is indicated by a blue triangle alongside the element. In this example, Customer_ID and Order_Date are mapped.
- Square brackets contain minimum and maximum occurrences of an element.
- An optional field is indicated by [0,1]. In this example, First_Class is optional.
- A repeating field is indicated by [minoccurs, maxoccurs].
- A choice field is indicated by a choice line; under the choice line are the possible choices. In this example, First_Class, Second_Class, and Airmail are choices of Delivery_Method.
- The type of each element is indicated in round brackets after the element name.
- If the message schema uses namespaces, the namespace prefix is shown before the element name, separated by a colon.

Use the Source pane to invoke a number of actions, a list of which is displayed when you right-click within the Source pane. The following table describes the available actions.

Action	Description	Related tasks
Undo	Undo previous action	
Redo	Redo previous action	
Revert	Discard	
Open Declaration (message)	Display the element definition from the message set. For this action to be available, select any source message element except LocalEnvironment or Headers.	
Open Declaration (database)	Display the database, schema, or table definition from the database. For this action to be available, select any source database object.	
Show Derived Types	Hide or display derived types for an element in the source or target pane. For this action to be available, select a target element displayed as a specialization folder in the source pane.	
Show Substituting elements	Hide or display the substituting elements of the head element in the source or target pane. For this action to be available, select a target element displayed as a substitutions folder in the source pane.	
Add Sources	Add a message definition or a database table to a source. For this action to be available, select any source object.	"Adding messages or message components to the source or target" on page 2273, "Adding a database as a source or target" on page 2274
Go To	For this action to be available, select any source object.	
Delete (message)	Remove a message and any existing maps from the source. For this action to be available, select the source message ($source).	

Action	Description	Related tasks
Delete (database)	Remove a database and any existing maps from the source. For this action to be available, select the source database root ($db:select).	
Delete (database stored procedure)	Remove a database stored procedure and any existing maps from the source. For this action to be available, select the database stored procedure root ($db:proc).	
Delete (database user-defined function)	Remove a database user-defined function and any existing maps from the source. For this action to be available, select the database user-defined function root ($db:func).	
Map from Source	Create a map between the focus source element and the focus target element. For this action to be available, select compatible source and target elements.	"Mapping a target element from source message elements" on page 2254, "Mapping from source: by selection" on page 2240
Map by Name	Create a map between the focus source element and the focus target element. For this action to be available, select compatible source and target elements.	"Mapping a target element from source message elements" on page 2254, "Mapping from source: by name" on page 2241
Accumulate	If the source and target fields contain numeric data types, this action maps all occurrences of a repeating source field to a non-repeating target, resulting in the sum of all the source elements. For this action to be available, select the source and target element.	"Configuring a repeating source and a non-repeating target" on page 2266
Create New Submap	For this action to be available, select source and target elements that are either elements of complex types or wildcard elements. The following example shows the "Message Mapping editor" on page 4981. The pane that is labelled as 3 in the example is the Edit pane:

When you have selected a source or target element, use the Edit pane to enter an expression. Right-click inside the Edit pane to invoke a list of available actions, most of which are standard Windows functions, such as cut, copy, and paste. Click **Edit** > **Content Assist** (or press Ctrl+Space) to access ESQL Content Assist, which provides a drop-down list of functions that are available in a Mapping node.

To display the definition associated with a selected element or database object, right-click in the Edit pane, and click **Open Declaration**. The appropriate editor opens to display the definition associated with the element or database definition.

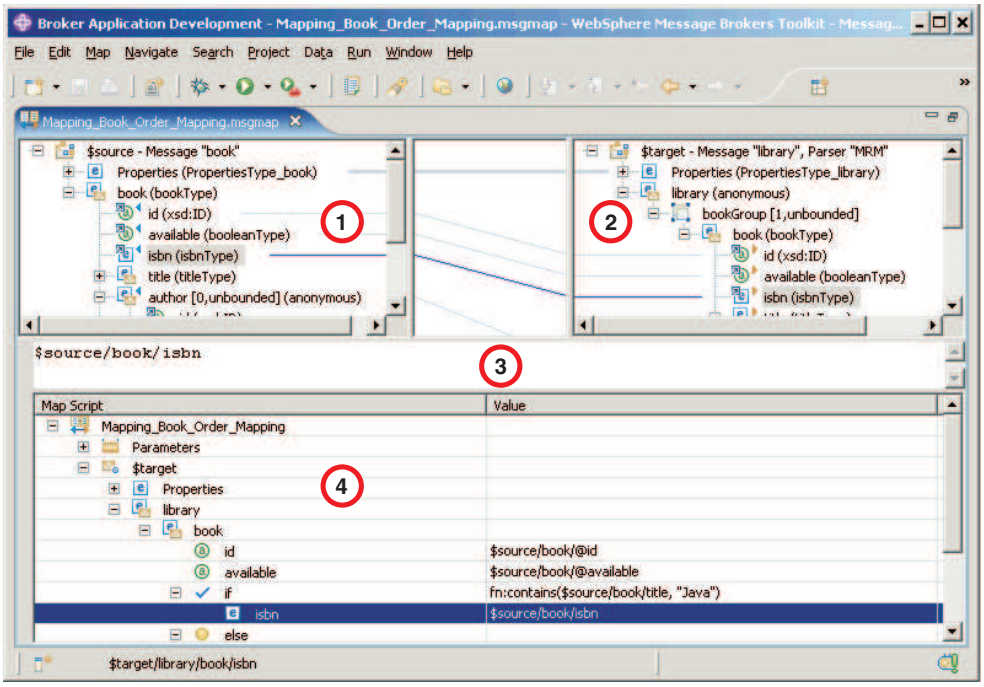
Message Mapping editor Spreadsheet pane:

Details of the actions available to you in the Spreadsheet pane of the Message Mapping Editor.

The following example shows the "Message Mapping editor" on page 4981. The pane that is labelled as 4 in the example is the Spreadsheet pane:



Use the Spreadsheet pane to invoke a number of actions, a list of which is displayed when you right-click within the Spreadsheet pane. The following table describes the available actions.

Action	Description	Related tasks
Undo	Undo previous action	
Redo	Redo previous action	
Revert	Discard	
Open Declaration (message)	Display the element definition from the message set. For this action to be available, select any message element except LocalEnvironment or Headers.	
Open Declaration (database)	Display the database, schema, or table definition from the database. For this action to be available, select any database object.	
Add Sources and Targets	Add a message definition to a target.	"Adding messages or message components to the source or target" on page 2273, "Adding a database as a source or target" on page 2274
Copy	Copy the selected item to the clipboard.	

Action	Description	Related tasks
Paste	Paste the item from the clipboard.	
Delete	Remove a row from the Spreadsheet.	
For	Define a repeating condition.	“Configuring a repeating source and a non-repeating target” on page 2266, “Configuring a repeating source and a repeating target” on page 2269
If	Define what must evaluate to 'true' to process subsequent mappings.	“Configuring a repeating source and a non-repeating target” on page 2266, “Configuring conditional mappings” on page 2265
ElseIf	Define what must evaluate to 'true' to process subsequent mappings if previous If or Elseif does not evaluate to 'true'..	“Configuring a repeating source and a non-repeating target” on page 2266, “Configuring conditional mappings” on page 2265
Else	Placeholder to process subsequent mappings if previous If or ElseIf does not evaluate to 'true'.	“Configuring conditional mappings” on page 2265
Select Data Source	Define a database to be used in the mapping.	
Insert Children	Expand a structure so that each of its children has a row in the spreadsheet.	
Insert Sibling After	Create a number of new rows in the spreadsheet to set the values of specific instances of a repeating field. Can also be used to insert any non-repeating element, attribute or database column if valid at the selected location.	“Configuring a non-repeating source and a repeating target” on page 2268
Insert Sibling Before	Create a number of new rows in the spreadsheet to set the values of specific instances of a repeating field. Can also be used to insert any non-repeating element, attribute or database column if valid at the selected location.	“Configuring a non-repeating source and a repeating target” on page 2268
Replace	Substitute an element, attribute or database column in the spreadsheet with a similar item, retaining the mapping expression and any child mapping statements.	
Save	Save the .msgmap file.

Mapping node:

The Mapping node has one or more mappings that are stored in message map files (with a `.msgmap` file extension). These files are configured using the Message Mapping editor.

A Mapping node must contain the following inputs and outputs:

- Zero or one source (input) messages
- Zero or more source (input) databases
- One or more target (output) messages

You must define, in message definition files in a message set, the source and target messages that are to be mapped. You can specify the parser of the source message at run time (for example, in an MQRFH2 header), but the target message is built using the runtime parser that is specified by the *Message Domain* property of the message set.

If a message mapping is between elements of different types, you might need to include casts in your mapping definitions, depending on which runtime parser is specified by the *Message Domain* property of your message set.

The Mapping node uses a language to manipulate messages that are based on XPath.

To develop message mappings for a Mapping node, use the Message Mapping editor, which provides separate panes for working with sources, targets and expressions.

Message mappings define the blueprint for creating a message.

Related reference:

"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Mapping node syntax: In a Mapping node, the source message, if present, is identified in the "Message Mapping editor" on page 4981 by $source.

The message tree is represented in XPath format. For example, if you have an element called Body within a source message called Envelope, this is represented in the Mapping node as:

```
$source/soap11:Envelope/soap11:Body
```

where *soap11* is a namespace prefix.

The first target message is identified by $target; additional target messages are identified by $target_1, $target_2, and so on.

The first source database is identified by $db:select; additional source databases are identified by $db:select_1, $db:select_2, and so on.

The first source database stored procedure is identified by $db:proc; additional source stored procedures are identified by $db:proc_1, $db:proc_2, and so on.

The first source database user-defined function is identified by $db:func; additional source user-defined functions are identified by $db:func_1, $db:func_2, and so on.

The database element is represented in the following format:

```
$db:select.DB.SCH.TAB.COL1
```

where:

DB is the database name

SCH is the database schema name

TAB is the table name

COL1 is the column name

You can also use the Mapping node to:

- make comparisons

- perform arithmetic
- create complex conditions

The comparison operators are:

= equals

!= not equals

> greater than

>= greater than or equals

< less than

<= less than or equals

The arithmetic operators are:

+ plus

- minus

* multiply

div divide

Conditional operators ‘or' and ‘and' are supported (these are case-sensitive).

The following objects can be mapped:

- LocalEnvironment
  - Destination
  - WrittenDestination
  - File
  - SOAP
  - TCPIP
  - ServiceRegistry
  - Adapter
  - Wildcard
  - Variables
- Message headers (optional)
  - MQ Headers
  - HTTP Headers
  - JMSTransport
  - email Headers
- Message elements
- Database columns

Database objects with names that do not conform to the XML NCName format

Some database objects have names that do not conform to the XML NCName format (for example, the names contains characters like '#', or '$'). To reference such database objects use the `msgmap:db-path` function.

For more information, see “Predefined mapping functions” on page 5007

Mapping node functions:

You can configure your message mappings to use a variety of predefined and user-defined functions.

The following predefined functions are available to use in your message maps:

- ESQL - prefixed esql:
- XPath - prefixed fn:
- Mapping - prefixed msgmap:
- Schema casts - prefixed xs:

Not all ESQL functions can be used in a Mapping node. For information about which functions are supported, and for a description of how to achieve equivalent processing for ESQL functions that are not supported, see the ESQL topics. For information about the predefined ESQL functions, see "ESQL mapping functions" on page 4998.

The fn:true() function (which always returns true) and the fn:false() function (which always returns false) are examples of XPath functions. You can get more information about the other XPath functions and XPath syntax from the online W3C XML Path Language document. For information about the predefined XPath functions, see "Predefined XPath mapping functions" on page 5001.

For information about the predefined mapping functions, see "Predefined mapping functions" on page 5007. See "Mapping node casts" on page 5009 for a list of the schema casts.

The Mapping node can also:

- Set the value of a target to a WebSphere MQ constant. The expression to set the value looks similar to a function with $mq: used as the prefix.
- Call a Java method directly. The expression to set the value looks similar to a function with java: used as a prefix.

ESQL mapping functions:

Some predefined ESQL functions are available for use with message maps.

This table details the predefined ESQL mapping functions that are available to use with message maps:

Name	ESQL equivalent	Notes
Numeric functions: abs absval acos asin atan atan2 bitand bitnot bitor bitxor ceil ceiling cos cosh cot degrees exp floor in log log10 mod power radians rand sign sin sinh sqrt tan tanh truncate	ESQL function of the name same name such as ABS and ABSVAL.	The same parameters apply as for ESQL.
String functions: left length lower lcase ltrim replace replicate right rtrim space translate upper ucase	ESQL function of the same name such as LEFT and LENGTH.	The same parameters apply as for ESQL.
Field functions: bitstream fieldname fieldnamespace fieldtype fieldvalue lastmove samefield	ESQL function of the same name such as BITSTREAM and FIELDNAME.	The same parameters apply as for ESQL.

Name	ESQL equivalent	Notes
asbitstream	These signatures are supported: ASBITSTREAM(*FieldRef*) ASBITSTREAM(*FieldRef*, *typeExp*, *setExp*, *formatExp*) ASBITSTREAM(*FieldRef*, *typeExp*, *setExp*, *formatExp*, *encodingExp*, *ccsidExp*) ASBITSTREAM(*FieldRef*, *typeExp*, *setExp*, *formatExp*, *encodingExp*, *ccsidExp*, *options*)	*FieldRef* is a source field reference such as $source/po:PurchaseOrder *typeExp* is a string literal of the name of the message body, such as purchaseOrder, optionally qualified with a namespace URI, such as {http://www.ibm.com}:purchaseOrder *setExp* is a string literal of the name of the message set, such as PurchaseOrder *formatExp* is a string literal of the wire format of the message, such as XML1 *encodingExp* and *ccsidExp* evaluate to integers with values corresponding to ESQL ENCODING and CCSID constants. *options* is an ESQL constant or bit-or of ESQL constant that evaluates to an integer.
cardinality	CARDINALITY	The same parameters apply as for ESQL.
coalesce	COALESCE	The same parameters apply as for ESQL.
current-date	CURRENT_DATE	No parameters apply.
current-gmtdate	CURRENT_GMTDATE	No parameters apply.
current-gmttime	CURRENT_GMTTIME	No parameters apply.
current-gmttimestamp	CURRENT_ GMTTIMESTAMP	No parameters apply.
current-time	CURRENT_TIME	No parameters apply.
current-timestamp	CURRENT_TIMESTAMP	No parameters apply.
date	DATE	
for	FOR (expression)	Optional parameters are not supported.
gmttime	GMTTIME	
gmttimestamp	GMTTIMESTAMP	

interval-year	INTERVAL YEAR	The same parameters apply as for ESQL. Some examples:
		
		`esql:interval-minute('90')`
		`esql:interval-year-to-month('1-06')`

interval-year-to-month	INTERVAL YEAR TO MONTH	
interval-month	INTERVAL MONTH	
interval-day	INTERVAL DAY	
interval-day-to-hour	INTERVAL DAY TO HOUR	
interval-day-to-minute	INTERVAL DAY TO MINUTE	
interval-day-to-second	INTERVAL DAY TO SECOND	
interval-hour	INTERVAL HOUR	
interval-hour-to-minute	INTERVAL HOUR TO MINUTE	
interval-hour-to-second	INTERVAL HOUR TO SECOND	
interval-minute	INTERVAL MINUTE	
interval-minute-to-second	INTERVAL MINUTE TO SECOND	
interval-second	INTERVAL SECOND	

is-null	Operand IS NULL	Some examples:
		
		`esql:is-null($source/po:purchaseOrder/po:comment)`
		`esql:is-null ($db:select.ACME.PARTS.INVENTORY.LAST_TRANSACTION)`

like	source LIKE pattern	For example: `esql:like ($source/po:purchaseOrder/shipTo/first_name,'Fred')`
	source LIKE pattern ESCAPE EscapeChar	For example: `esql:like ($source/po:purchaseOrder/shipTo /zip,'L6F$_1C7','$')`
local-timezone	LOCAL_TIMEZONE	

Name	ESQL equivalent	Notes
nullif	NULLIF	The same parameters apply as for ESQL.
overlay	OVERLAY Str1 PLACING Str2 FROM Start	For example: `esql:overlay ($source/po:purchaseOrder/shipTo/city,'abc',2)`
	OVERLAY Str1 PLACING Str2 FROM Start For Length	For example: `esql:overlay ($source/po:purchaseOrder/shipTo/city,'abcde',2,3)`
position	POSITION searchExp IN SourceExp	For example: `esql:position ('aet',$source/po:purchaseOrder/shipTo/first_name)`
	POSITION searchExp IN SourceExp FROM FromExp	For example: `esql:position ('do',$source/po:purchaseOrder/shipTo/last_name,1)`
	POSITION searchExp IN SourceExp FROM FromExp REPEAT RepeatExp	For example: `esql:position ('a',$source/po:purchaseOrder/billTo /first_name,1,2)`
round	ROUND	Optional parameters are not supported.
sqlcode	SQLCODE	No parameters apply.
sqlerrortext	SQLERRORTEXT	
sqlnativeerror	SQLNATIVEERROR	
sqlstate	SQLSTATE	
time	TIME	
timestamp	TIMESTAMP	The same parameters apply as for ESQL. For example: `esql:gmttimestamp ('1999-12-31 23:59:59.999999')`
trim-leading	TRIM LEADING FROM Source	For example: `esql:trim-leading ($source/po:purchaseOrder/shipTo/state)`
	TRIM LEADING Singleton FROM Source	For example: `esql:trim-leading ('G',$source/po:purchaseOrder/shipTo/zip)`
trim-trailing	TRIM TRAILING FROM Source	For example: `esql:trim-trailing ($source/po:purchaseOrder/billTo/last_name)`
	TRIM TRAILING Singleton FROM Source	For example: `esql:trim-trailing ('e',$source/po:purchaseOrder/billTo/street)`
trim-both	TRIM BOTH FROM Source	For example: `esql:trim-both ($source/po:purchaseOrder/shipTo/city)`
	TRIM BOTH Singleton FROM Source	For example: `esql:trim-both (",$source/po:purchaseOrder/shipTo/city)`

Name	ESQL equivalent	Notes
trim	TRIM Source	For example: `esql:trim ($source/po:purchaseOrder/shipTo/city)`
	TRIM Singleton FROM Source	For example: `esql:trim (",$source/po:purchaseOrder/shipTo/city)`
uuidasblob	UUIDASBLOB	Takes zero or more parameters as in ESQL.
uuidaschar	UUIDASCHAR

This table details the predefined XPath functions that are available for use with message maps. You can get more information about XPath functions and XPath syntax from the online W3C XML Path Language document.

Name	Parameters	Notes
true		
false		

Name	Parameters	Notes
sum	Source field from the message or database or “XPath "for" expression” on page 5005.	Source supports an XPath predicate. An XPath predicate is an expression enclosed in square brackets, serving to filter a sequence, retaining some items and discarding others. Predicates are supported on the XPath aggregate functions of `avg`, `count`, `max`, `min`, and `sum`. Predicates must be in one of the two forms: • An integer literal – aggregation is done for elements whose context position equals the integer. • A Boolean expression – aggregation is done for elements that make the Boolean expression evaluate to true. See “Aggregating XPath expressions conditionally” on page 5003 for more information.
avg		
max		
min		
count		
concat	Two or more strings.	You cannot use `fn:concat($source/myElem)` to concatenate instances of 'myElem'.
not	1- Expression resolved to a Boolean value.	
exists	Source field from the message or database.	
empty		
substring	1- String 2- One-based starting index 3- Length	For example: `fn:substring ($source/po:purchaseOrder/billTo/street, 3, 5)`
substring-before	Two strings	Returns the substring of the first string that precedes the first occurrence of the second string.
substring-after	Two strings	Returns the substring of the first string that follows the first occurrence of the second string.
starts-with	Two strings	Returns a Boolean value indicating whether the first string starts with the second string.
ends-with	Two strings	Returns a Boolean value indicating whether the first string ends with the second string.
contains	Two strings	Returns a Boolean value indicating whether the first string contains the second string.
year-from-dateTime	1- xs:dateTime	For example: `fn:month-from-dateTime (xs:dateTime($source/po:purchaseOrder /shipTo/datetime))` where `$source/po:purchaseOrder/shipTo/datetime` is xs:string.
month-from-dateTime		
day-from-dateTime		
hours-from-dateTime		
minutes-from-dateTime		
seconds-from-dateTime		
year-from-date	1-xs:date	For example: `fn:year-from-date(xs:date ($source/po:purchaseOrder/billTo/date))` where `$source/po:purchaseOrder/billTo/date` is xs:string.
month-from-date		
day-from-date		

Name	Parameters	Notes

hours-from-time	1- xs:time	Some examples:
		
		`fn:hours-from-time(xs:time("13:20:10:5"))`
		`fn:hours-from-time(xs:time ($source/po:purchaseOrder/shipTo/time))`

minutes-from-time		
seconds-from-time		
years-from-duration	1- xdt:dayTimeDuration	For example: `fn:minutes-from-duration (xdt:dayTimeDuration(PT47H30M))`
months-from-duration		
days-from-duration		
hours-from-duration		
minutes-from-duration		
seconds-from-duration

Aggregating XPath expressions conditionally:

You can perform calculations using conditions, called predicates in XPath, on the aggregate functions in the Mapping node. The aggregate functions are `avg`, `count`, `max`, `min`, and `sum`.

About this task

XPath aggregate functions

XPath aggregate functions take a sequence as their argument:

```
fn:count($arg as item()*) as xs:integer
fn:avg($arg as xs:anyAtomicType*) as xs:anyAtomicType?
fn:max($arg as xs:anyAtomicType*) as xs:anyAtomicType?
fn:min($arg as xs:anyAtomicType*) as xs:anyAtomicType?
fn:sum($arg as xs:anyAtomicType*) as xs:anyAtomicType?
```

where the atomic value can be, for example, an integer, a string, or a Boolean value.

In an aggregation

```
fn:sum($source/inventory/category/product/price)
```

the node

```
$source/inventory/category/product/price
```

is put into its typed value, which is a sequence of `Atomictype` `price` values.

In the following aggregation, the argument is a node `tns:price`, which is contained in `tns:product`, which is in turn contained in `tns:category`, and so on.

```
fn:sum($source/tns:Inventory/tns:category/tns:product/tns:price)
```

How aggregation works in this sequence depends upon the scope of the iteration (or `for`) loop for `product` and `category`. For example, if there is no iteration loop, summation is done for all instances of all `prices` in all `products` in all `categories`.

However, if there is an iteration loop on `category`, one summation is calculated for each `category`. The summation is obtained from all `prices` of all `products` of a particular `category` being iterated upon.

You can add a predicate (see predicates for further information) to make the result more specific. For example:

```
fn:sum($source/tns:Inventory/tns:category[$source/tns:Inventory/tns:category/
  tns:c_id='abc' ]/tns:product[3]/tns:price)
```

has a predicate of `tns:c_id='abc'` on `category`, and a predicate of `3` on `product`. The result that you obtain is the third `product` in the `category` that has `tns:c_id='abc'`.

In both of the preceding examples, whether the expression contains a condition or not, you reference one source item only; it is `price` that is aggregated.

Predicates are supported only when they are used in message sources. For example, the `[ boolean expression ]` must be used within a segment of a path that represents a message source. Predicates are not supported in `$db:select` or `$db:proc`.

Consider a more complicated scenario, where product prices are kept in a database table, and the input message contains the quantity of the product being ordered. The objective is to calculate a total price by adding up all prices multiplied by quantity.

It might seem to be straightforward to write the following aggregation function:

```
fn:sum($source/inventory/product/quantity × $db:select/PRICE_TB/PRICE)
```

However, the first step of evaluating an XPath arithmetic expression is to evaluate its operands. If any operand is evaluated into a sequence of more than one item,

either only the first item is used in the arithmetic expression, or an error is raised; for further information, see Arithmetic expressions.

You, therefore, cannot add up the product of `quantity` and `PRICE` for each `product`. If you want to aggregate the result of an arithmetic expression, see "XPath "for" expression."

Use the Mapping node to construct one or more new messages and populate them with various types of information.

XPath "for" expression:

You can use the `for` expression to perform specific calculations as the argument of an aggregation function in the Mapping node.

About this task

For expressions

To perform a specific operation you can use the XPath `for` expression iteration facility. For more information, see the for expression online document.

You can express a sequence of price multiplied by quantity in many ways using the `for` expression. For example:

- `for $i in $source/inventory/category/product return $i/price * $i/quantity`

  You can use a similar expression when all operands of the return expression (`price` and `quantity`) are defined in the same repeatable container (`product`). Only one variable is needed in the `for` expression.
- ```
  for $i in $db:select, $j in $source/inventory/category/product
  [$i.db1.sch2.PRICE_TB.PROD_ID=$j/product_id]
  return $i.db1.sch2.PRICE_TB.PRICE * $j/quantity
  ```

  You can use a similar expression when some operands of the return expression (`price`) are kept in a database table, and other operands (`quantity`) are kept in a message. At least one variable is needed for the path to a database result set, and another variable is needed for the path to a repeatable XML element.
  ```

- `for $i in $source/order_info/product1, $j in $source/price_record/product2 [$i/product_id=$j/product_id] return $i/quantity * $j/price`

  You can use a similar expression when the operands (`price` and `quantity`) are defined in different repeatable elements (`product1` and `product2`) in the source message.

When you have an expression that represents a sequence of items, aggregation can be done by using the `for` expression as the argument of the aggregation function.

Example

Examples

Obtain the average cost, which is price multiplied by quantity, for all products:

```
fn:avg(for $i in $source/inventory/category/product
   return $i/price * $i/quantity)
```

Obtain the total cost of all products where prices are from a database, and quantities are from a message and paired up based on a product identifier:

```
fn:sum(for $i in $db:select, $j in $source/inventory/category/product
   [$i.db1.sch2.PRICE_TB.PROD_ID=$j/product_id]
   return $i.db1.sch2.PRICE_TB.PRICE * $j/quantity)
```

Obtain the length of the longest product identifier text:

```
fn:max(for $i in $source/inventory/category/product
   return esql:length($i/id))
```

Obtain the minimum price when the price was stored in a message as a string, and convert each source item into a numeric value before using an aggregate function:

```
fn:min(for $i in $source/inventory/category/product
   return xs:decimal($i/price))
```

The aggregation functions that are supported in WebSphere Message Broker can be expressed using a `for` expression.

For example, you might have:

```
fn:sum($source/inventory/category/product/price)
```

This expression is equivalent to:

```
fn:sum(for $i in $source/inventory/category/product
   return $i/price)
```

"Message mapping overview" on page 2229
Message mappings define the blueprint for creating a message, where the created message is known as the target message.

Related tasks:

"Aggregating XPath expressions conditionally" on page 5003
You can perform calculations using conditions, called predicates in XPath, on the aggregate functions in the Mapping node. The aggregate functions are `avg`, `count`, `max`, `min`, and `sum`.

"Using message mappings" on page 2228
Message mappings define the blueprint for creating a message.

Related reference:

"Predefined XPath mapping functions" on page 5001
Some XPath functions are available for use with message maps.
"Mapping node" on page 4571
Use the Mapping node to construct one or more new messages and populate them with various types of information.

Predefined mapping functions:

Some predefined mapping functions are provided for use with message maps.

This table details the predefined mapping functions that are available to use with message maps.

Name	Parameters	Return	Notes
cdata-element	One string	Nothing	Create an XML element with CData content in the following target message domains: • XMLNSC • SOAP • XMLNS • XML • JMSMap • JMSStream For example: `msgmap:cdata-element('<date><month>05 </month><day>11</day><year>2008</year></date>')`

db-path	These signatures are supported:
	msgmap:db-path(*databasePath*)
	msgmap:db-path(*databasePath, delimiter*)
		Nothing	Used when the database path does not conform to the XML NCName format. For example, the database path contains characters like '#', or '$'.
			databasePath is a reference to either a `$db:select` statement, a `$db:insert` statement, a `$db:update` statement, a `$db:delete` statement, a `$db:proc` statement, or a `$db:func` statement.
			delimiter is a string literal used between the segments in the database path. *delimiter* has a default value of '.'.
			For example:
			`msgmap:db-path("$db:select.DB#1.SCH$#1. CustInfo.Name")`
			In this case, the default value, '.', is used as the delimiter.
			`msgmap:db-path("$db:select/DB#1/SCH$#1/ Cust.Info/Name", "/")`
			In this case, '/' is used as the delimiter because the database table name includes the default value.

Name	Parameters	Return	Notes

occurrence	Source field from the message or database	The index of the source field.	Often used in a condition statement when source repeats to execute specific statements for a specific occurrence. For example:
			`msgmap:occurrence ($source/po:purchaseOrder /items)=2`
			
			means the second field,
			`po:purchaseOrder`
			
			is being processed. Use code similar to the previous example if you want to specify a particular source occurrence. If you only want to assign the index value to a target you can specify the following code:
			`msgmap:occurrence ($source/po:purchaseOrder /items)`

exact-type	1- Source field from the message or database
	2- Namespace prefix
	3- Name of the type
		True if the source is of the specified type in the specified namespace.	Often used in a condition to execute specific statements for a specific source type. For example:
			`msgmap:exact-type ($source/tn1:msg2,'tn1', 'extendedMsgType')`
			
			The namespace prefix can be '*', indicating that only the name of the type is to be checked. For example:
			`msgmap:exact-type($source/tn1:msg2,'*', 'extendedMsgType')`
			
			returns true if the element
			`$source/tn1:msg2`
			
			has a type of
			`extendedMsgType`
			
			in any namespace.

empty-element()	None	Nothing	Creates an XML element with an empty tag. For example, if an element is named MyElement and the mapping expression for MyElement is set to msgmap:empty-element(), the output message will contain an element with no content: `<MyElement/>` Call this function only for an XML element.

Name	Parameters	Return	Notes
element-from-bitstream	These signatures are supported: msgmap:element-from-bitstream(*StreamRef*) msgmap:element-from-bitstream(*StreamRef*, *typeExp*, *setExp*, *formatExp*) msgmap:element-from-bitstream(*StreamRef*, *typeExp*, *setExp*, *formatExp*, *encodingExp*, *ccsidExp*) msgmap:element-from-bitstream(*StreamRef*, *typeExp*, *setExp*, *formatExp*, *encodingExp*, *ccsidExp*, *options*)	Nothing	Used to parse a bit stream. This function can be called only for a message element target. The parsed bit stream is placed in the target message tree as the target element. *StreamRef* is a reference to a BLOB of stream, such as $source/BLOB or $db:select.dsn.schema.table.column *typeExp* is a string literal of the name of the message body, such as purchaseOrder, optionally qualified with a namespace URI, such as {http://www.ibm.com}:purchaseOrder *setExp* is a string literal of the name of the message set, such as PurchaseOrder *formatExp* is a string literal of the wire format of the message, such as XML1 *encodingExp* and *ccsidExp* evaluate to integers with values corresponding to ESQL ENCODING and CCSID constants *options* is an ESQL constant or bit-or of ESQL constants that evaluate to an integer.

Use the Mapping node to construct one or more new messages and populate them with various types of information.

Mapping node casts:

Source and target elements can be of different types in a Mapping node.

Depending on which runtime parsers are used, automatic casting cannot be done. In these cases, use one of the cast functions shown in the following table.

Function name	Signature	Parameter type
xs:anyURI	xs:anyURI(*&exp*) xs:anyURI(*&exp*, *&ccsid*) xs:anyURI(*&exp*, *&ccsid*, *&encoding*)	*$exp* is a reference to a source element of one of the following types: • xs:base64Binary • xs:boolean • xs:date • xs:dateTime • xs:dayTimeDuration • xs:decimal • xs:double • xs:duration • xs:float • xs:gDay • xs:gMonth • xs:gMonthDay • xs:gYear • xs:gYearMonth • xs:hexBinary • xs:int • xs:integer • xs:long • xs:QName • xs:string • xs:time • xs:yearMonthDuration *&ccsid* is one of the following values: • $source/Properties/CodedCharSetId • $source/MQMD/CodedCharSetId • An integer. For example, 1208 for UTF-8 *&encoding* is one of the following values: • $source/Properties/Encoding • $source/MQMD/Encoding • $mq:MQENC_WINDOWS (546) • $mq:MQENC_UNIX (273) • $mq:MQENC_390 (785) • Other $mq:MQENC_* constants and their BIT OR

Function name	Signature	Parameter type
xs:base64Binary	xs:base64Binary(*&exp*) xs:base64Binary(*&exp*, *&ccsid*) xs:base64Binary(*&exp*, *&ccsid*, *&encoding*)	*$exp* is a reference to a source element of one of the following types: • xs:hexBinary • xs:int • xs:string *&ccsid* is one of the following values: • $source/Properties/CodedCharSetId • $source/MQMD/CodedCharSetId • An integer. For example, 1208 for UTF-8 *&encoding* is one of the following values: • $source/Properties/Encoding • $source/MQMD/Encoding • $mq:MQENC_WINDOWS (546) • $mq:MQENC_UNIX (273) • $mq:MQENC_390 (785) • Other $mq:MQENC_* constants and their BIT OR
xs:boolean	xs:boolean(*&exp*)	*$exp* is a reference to a source element of type xs:string.
xs:date	xs:date(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:dateTime • xs:gDay • xs:gMonth • xs:gMonthDay • xs:gYear • xs:gYearMonth • xs:string
xs:dateTime	xs:dateTime(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:date • xs:string • xs:time
xs:dayTimeDuration	xs:dayTimeDuration(*&exp*)	*$exp* is a reference to a source element of type xs:string.

Function name	Signature	Parameter type
xs:decimal	xs:decimal(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:decimal • xs:float • xs:int • xs:integer • xs:string
xs:double	xs:double(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:duration • xs:float • xs:int • xs:string
xs:duration	xs:duration(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:decimal • xs:float • xs:int • xs:string
xs:float	xs:float(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:double • xs:duration • xs:int • xs:string
xs:gDay	xs:gDay(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:date • xs:dateTime • xs:gMonth • xs:gMonthDay • xs:gYear • xs:gYearMonth • xs:string

Function name	Signature	Parameter type
xs:gMonth	xs:gMonth(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:date • xs:dateTime • xs:gDay • xs:gMonthDay • xs:gYear • xs:gYearMonth • xs:string
xs:gMonthDay	xs:gMonthDay(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:date • xs:dateTime • xs:gDay • xs:gMonth • xs:gYear • xs:gYearMonth • xs:string
xs:gYear	xs:gYear(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:date • xs:dateTime • xs:gDay • xs:gMonth • xs:gMonthDay • xs:gYearMonth • xs:string
xs:gYearMonth	xs:gYearMonth(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:date • xs:dateTime • xs:gDay • xs:gMonth • xs:gMonthDay • xs:gYear • xs:string

Function name	Signature	Parameter type
xs:hexBinary	xs:hexBinary(*&exp*) xs:hexBinary(*&exp*, *&ccsid*) xs:hexBinary(*&exp*, *&ccsid*, *&encoding*)	*$exp* is a reference to a source element of one of the following types: • xs:base64Binary • xs:int • xs:string *&ccsid* is one of the following values: • $source/Properties/CodedCharSetId • $source/MQMD/CodedCharSetId • An integer. For example, 1208 for UTF-8 *&encoding* is one of the following values: • $source/Properties/Encoding • $source/MQMD/Encoding • $mq:MQENC_WINDOWS (546) • $mq:MQENC_UNIX (273) • $mq:MQENC_390 (785) • Other $mq:MQENC_* constants and their BIT OR
xs:int	xs:int(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:base64Binary • xs:decimal • xs:duration • xs:float • xs:hexBinary • xs:string
xs:integer	xs:integer(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:base64Binary • xs:decimal • xs:duration • xs:int • xs:string

Function name	Signature	Parameter type
xs:long	xs:long(*&exp*)	*$exp* is a reference to a source element of one of the following types: • xs:base64Binary • xs:decimal • xs:duration • xs:float • xs:hexBinary • xs:string

Function name	Signature	Parameter type
xs:QName	xs:QName(*&exp*) xs:QName(*&exp*, *&ccsid*) xs:QName(*&exp*, *&ccsid*, *&encoding*)	*$exp* is a reference to a source element of one of the following types: • xs:anyURI • xs:base64Binary • xs:boolean • xs:date • xs:dateTime • xs:dayTimeDuration • xs:decimal • xs:double • xs:duration • xs:float • xs:gDay • xs:gMonth • xs:gMonthDay • xs:gYear • xs:gYearMonth • xs:hexBinary • xs:int • xs:integer • xs:long • xs:string • xs:time • xs:yearMonthDuration *&ccsid* is one of the following values: • $source/Properties/CodedCharSetId • $source/MQMD/CodedCharSetId • An integer. ESQL reference

SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

This section covers the following topics:

"Syntax diagrams" on page 3677
This describes the formats that are available for viewing ESQL syntax diagrams.

"ESQL data types in message flows" on page 5020
This describes the valid data types for ESQL.

"ESQL field reference overview" on page 5049
This topic describes the syntax of field references.

"Special characters, case sensitivity, and comments in ESQL" on page 5305
This describes the special characters you use when writing ESQL statements.

"ESQL operators" on page 5056
This describes the operators that are available.

"ESQL reserved keywords" on page 5307
This lists the reserved keywords which you cannot use for variable names.

"ESQL non-reserved keywords" on page 5307
This lists the keywords that are not reserved, as well as those reserved for future releases, which you can use if you choose.

"ESQL functions" on page 5168
This topic lists the functions available in ESQL, and what they do.

"ESQL constants" on page 5302
This topic lists the constants available in ESQL, and what they do.

"ESQL statements" on page 5067
This topic lists the different statement types available in ESQL, and what they do.

"Calling ESQL functions" on page 5168
This topic describes all the ESQL functions in detail.

"ESQL variables" on page 5048
This topic describes the types of ESQL variable and their lifetimes.

"Broker properties that are accessible from ESQL and Java" on page 5302
This topic lists the broker attributes that can be accessed from ESQL code.

An XML format message that is used in many of the ESQL examples in these topics is shown in “Example message” on page 5311.

For information about how you can use ESQL statements and functions to configure Compute, Database, and Filter nodes, see “Writing ESQL” on page 2413.

Syntax diagrams:
The syntax for commands and ESQL statements and functions is presented in the form of a railroad diagram. The diagram tells you what you can do with the command, statement, or function and indicates relationships between different options and, sometimes, different values of an option.

For details about how to read a railroad diagram, see “How to read railroad diagrams” on page 3677.

Related reference:

“Commands” on page 3672
All WebSphere Message Broker Toolkit and runtime commands that are provided on distributed systems are listed, grouped by function, with references to command details.

ESQL data types in message flows:

All data that is referred to in message flows must be one of the defined types.

The defined types are:
- “ESQL BOOLEAN data type” on page 5021
- “ESQL datetime data types” on page 5021
- “ESQL NULL data type” on page 5032
- “ESQL numeric data types” on page 5033
- “ESQL REFERENCE data type” on page 5037
- “ESQL ROW data type” on page 5038
- “ESQL string data types” on page 5040

Related concepts:

“Message flows overview” on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

“ESQL data types” on page 2373
A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

Related tasks:

Table summarizing the mappings from ESQL to Java.

ESQL BOOLEAN data type:

The BOOLEAN data type holds a Boolean value.

The Boolean value can have the following values:
- TRUE
- FALSE
- UNKNOWN

Boolean literals consist of the keywords TRUE, FALSE, and UNKNOWN. The literals can appear in uppercase or lowercase. For further information about UNKNOWN, see the "IF statement" on page 5134.

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

Develop message flows to process your business messages and data.

"Using numeric operators with datetime values" on page 2439
The following examples show the ESQL that you can code to manipulate datetime values with numeric operators.

"Calculating a time interval" on page 2441
You can use ESQL to calculate the time interval between two events, and to set a timer to be triggered after a specified interval.

Related reference:

"ESQL DATE data type"
The `DATE` data type holds a Gregorian calendar date (year, month, and day).

"ESQL GMTTIME data type" on page 5024
The `GMTTIME` data type is similar to the `TIME` data type, except that its values are interpreted as values in Greenwich Mean Time.

"ESQL GMTTIMESTAMP data type" on page 5026
The `GMTTIMESTAMP` data type is similar to the `TIMESTAMP` data type, except that the values are interpreted as values in Greenwich Mean Time.

"ESQL INTERVAL data type" on page 5027
The `INTERVAL` data type holds an interval of time.

"ESQL TIME data type" on page 5023
The `TIME` data type holds a time of day in hours, minutes, seconds, and fractions of a second.

"ESQL TIMESTAMP data type" on page 5025
The `TIMESTAMP` data type holds a DATE and a TIME in years, months, days, hours, minutes, seconds, and fractions of a second.

ESQL DATE data type:

The `DATE` data type holds a Gregorian calendar date (year, month, and day).

The format of a `DATE` literal is the word `DATE` followed by a space, followed by a date in single quotation marks in the form 'yyyy-MM-dd'. For example:

```
DECLARE MyDate DATE;
SET MyDate = DATE '2000-02-29';
```

Do not omit leading zeros from the year, month, and day.

Related concepts:

"ESQL data types" on page 2373
A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

Related reference:

“ESQL TIME data type”
The TIME data type holds a time of day in hours, minutes, seconds, and fractions of a second.

“ESQL GMTTIME data type” on page 5024
The GMTTIME data type is similar to the TIME data type, except that its values are interpreted as values in Greenwich Mean Time.

“ESQL TIMESTAMP data type” on page 5025
The TIMESTAMP data type holds a DATE and a TIME in years, months, days, hours, minutes, seconds, and fractions of a second.

“ESQL GMTTIMESTAMP data type” on page 5026
The GMTTIMESTAMP data type is similar to the TIMESTAMP data type, except that the values are interpreted as values in Greenwich Mean Time.

“ESQL INTERVAL data type” on page 5027
The INTERVAL data type holds an interval of time.

“DECLARE statement” on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL TIME data type:

The TIME data type holds a time of day in hours, minutes, seconds, and fractions of a second.

The format of a TIME literal is the word TIME followed by a space, followed by a time in single quotation marks in the form 'hh:mm:ss.ffffff'. For example:

```
DECLARE MyTime TIME;
SET MyTime = TIME '11:49:23.656';
```

Each of the hour, minute, and second fields in a TIME literal must always be two digits; the optional fractional seconds field can be up to 6 digits in length.

The PutTime reported by WebSphere MQ on z/OS and other times or timestamps can be inconsistent if the CVT field is not set correctly.

The TIMESTAMP data type holds a DATE and a TIME in years, months, days, hours, minutes, seconds, and fractions of a second.

"ESQL GMTTIMESTAMP data type" on page 5026
The GMTTIMESTAMP data type is similar to the TIMESTAMP data type, except that the values are interpreted as values in Greenwich Mean Time.

"ESQL INTERVAL data type" on page 5027
The INTERVAL data type holds an interval of time.

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL GMTTIME data type:

The GMTTIME data type is similar to the TIME data type, except that its values are interpreted as values in Greenwich Mean Time.

GMTTIME literals are defined in a similar way to TIME values. For example:

```
DECLARE MyGetGmttime GMTTIME;
SET MyGetGmttime = GMTTIME '12:00:00';
```

The PutTime reported by WebSphere MQ on z/OS and other times or timestamps can be inconsistent if the CVT field is not set correctly.

The INTERVAL data type holds an interval of time.

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL TIMESTAMP data type:

The TIMESTAMP data type holds a DATE and a TIME in years, months, days, hours, minutes, seconds, and fractions of a second.

The format of a TIMESTAMP literal is the word TIMESTAMP followed by a space, followed by a time stamp in single quotation marks in the form 'yyyy-MM-dd HH:mm:ss.SSSSSS'. For example:

```
DECLARE MyTimeStamp TIMESTAMP;
SET MyTimeStamp = TIMESTAMP '1999-12-31 23:59:59';
```

The year field must always be four digits in length. The month, day, hour, and minute fields must always be two digits. (Do not omit leading zeros.) The optional fractional seconds field can be 0 - 6 digits long.

For a description of the characters used when formatting a time stamp in the ESQL CAST function, see "Formatting and parsing dateTimes as strings" on page 5253

The PutTime reported by WebSphere MQ on z/OS and other times or time stamps can be inconsistent if the CVT field is not set correctly.

“ESQL TIMESTAMP data type” on page 5025
The `TIMESTAMP` data type holds a DATE and a TIME in years, months, days, hours, minutes, seconds, and fractions of a second.

“ESQL INTERVAL data type”
The `INTERVAL` data type holds an interval of time.

“DECLARE statement” on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL INTERVAL data type:

The `INTERVAL` data type holds an interval of time.

This data type has a number of subtypes:
- YEAR
- YEAR TO MONTH
- MONTH
- DAY
- DAY TO HOUR
- DAY TO MINUTE
- DAY TO SECOND
- HOUR
- HOUR TO MINUTE
- HOUR TO SECOND
- MINUTE
- MINUTE TO SECOND
- SECOND

All these subtypes describe intervals of time and all can take part in the full range of operations of the INTERVAL type; for example, addition and subtraction operations with values of type DATE, TIME, or TIMESTAMP.

Use the CAST function to convert from one subtype to another, except for intervals described in years and months, or months, which cannot be converted to those described in days, hours, minutes, and seconds.

The split between months and days arises because the number of days in each month varies. An interval of one month and a day is not meaningful, and cannot be sensibly converted into an equivalent interval in numbers of days only.

An interval literal is defined by the syntax:

```
INTERVAL <interval string> <interval qualifier>
```

The format of interval string and interval qualifier are defined by the following table.

Interval qualifier	Interval string format	Example
YEAR	'<year>' or '<sign> <year>'	'10' or '-10'
YEAR TO MONTH	'<year>-<month>' or '<sign> <year>-<month>'	'2-06' or '- 2-06'
MONTH	'<month>' or '<sign> <month>'	'18' or '-18'
DAY	'<day>' or '<sign> <day>'	'30' or '-30'
DAY TO HOUR	'<day> <hour>' or '<sign> <day> <hour>'	'1 02' or '-1 02'
DAY TO MINUTE	'<day> <hour>:<minute>' or '<sign> <day> <hour>:<minute>'	'1 02:30' or '-1 02:30'
DAY TO SECOND	'<day> <hour>:<minute>:<second>' or '<sign> <day> <hour>:<minute>:<second>'	'1 02:30:15' or '-1 02:30:15.333'
HOUR	'<hour>' or '<sign> <hour>'	'24' or '-24'
HOUR TO MINUTE	'<hour>:<minute>' or '<sign> <hour>:<minute>'	'1:30' or '-1:30'
HOUR TO SECOND	'<hour>:<minute>:<second>' or '<sign> <hour>:<minute>:<second>'	'1:29:59' or '-1:29:59.333'
MINUTE	'<minute>' or '<sign> <minute>'	'90' or '-90'
MINUTE TO SECOND	'<minute>:<second>' or '<sign> <minute>:<second>'	'89:59' or '-89:59'
SECOND	'<second>' or '<sign> <second>'	'15' or '-15.7'

Where an interval contains both a year and a month value, a hyphen is used between the two values. In this instance, the month value must be within the range `[0, 11]`. If an interval contains a month value and no year value, the month value is unconstrained.

A space is used to separate days from the rest of the interval.

If an interval contains more than one of HOUR, MINUTE, and SECOND, a colon is needed to separate the values and all except the leftmost are constrained as follows:

HOUR
: 0-23

MINUTE
: 0-59

SECOND
: 0-59.999...

The largest value of the left-most value in an interval is +/- 2147483647.

Some examples of valid interval values are:

- 72 hours
- 3 days: 23 hours

- 3600 seconds
- 90 minutes: 5 seconds

Some examples of invalid interval values are:

- 3 days: 36 hours

  A day field is specified, so the hours field is constrained to `[0,23]`.
- 1 hour: 90 minutes

  An hour field is specified, so minutes are constrained to `[0,59]`.

Here are some examples of interval literals:

```
INTERVAL '1' HOUR
INTERVAL '90' MINUTE
INTERVAL '1-06' YEAR TO MONTH
```

"CAST function" on page 5245

Representation of ESQL datetime data types:

When your application sends a message to a broker, the way in which the message data is interpreted depends on the content of the message itself and the configuration of the message flow. If your application sends a message to be interpreted either by the generic XML parser, or the MRM parser, that is tailored by an XML physical format, the application can include date or time data that is represented by any of the XML Schema primitive datetime data types.

The XML Schema data type of each piece of data is converted to an ESQL data type, and the element that is created in the logical message tree is of the converted type. If the datetime data in an input message does not match the rules of the chosen schema data type, the values that the parser writes to the logical message tree are modified even if the message is in the MRM domain and you have configured the message flow to validate the input message. (Validation is not available for generic XML messages.)

This has the following effect on the subfields of the input datetime data:

- If any of the subfields of the input message are missing, a default value is written to the logical message tree. This default is substituted from the full timestamp that refers to the beginning of the current epoch: 1970-01-01 00:00:00.
- If the input message contains information for subfields that are not present in the schema, the additional data is discarded. If this occurs, no exception is raised, even if a message in the MRM domain is validated.
- After the data is parsed, it is cast to one of three ESQL datetime data types. These are DATE, TIME, and TIMESTAMP.
  - If a datetime value contains only date subfields, it is cast to an ESQL DATE.
  - If a datetime value contains only time subfields, it is cast to an ESQL TIME.
  - If a datetime value contains both date and time subfields, it is cast to an ESQL TIMESTAMP.

The following examples illustrate these points.

Input data XML Schema data type	**Schema rules**	**Input value in the bit stream**	**Value written to the logical tree (ESQL data type in brackets)**
xsd:dateTime	CCYY-MM-DDThh:mm:ss	2002-12-31T23:59:59	2002-12-31 23:59:59 (TIMESTAMP)
		--24	1970-01-24 (DATE)
		23:59:59	23:59:59 (TIME)
xsd:date	CCYY-MM-DD	2002-12-31	2002-12-31 (DATE)
		2002-12-31T23:59:59	2002-12-31 (DATE)
		-06-24	1970-06-24 (DATE)
xsd:time	hh:mm:ss	14:15:16	14:15:16 (TIME)
xsd:gDay	---DD	---24	1970-01-24 (DATE)
xsd:gMonth	--MM	--12	1970-12-01 (DATE)
xsd:gMonthDay	--MM-DD	--12-31	1970-12-31 (DATE)
xsd:gYear	CCYY	2002	2002-01-01 (DATE)
xsd:gYearMonth	CCYY-MM	2002-12	2002-12-01 (DATE)

Validation with missing subfields: When you consider which schema datetime data type to use, consider that, if the message is in the MRM domain, and you configure the message flow to validate messages, missing subfields can cause validation exceptions.

The schema data types Gday, gMonth, gMonthDay, gYear, and gYearMonth are used to record particular recurring periods of time. There is potential confusion when validation is turned on, because the recurring periods of time that are used in these schema data types are stored by ESQL as specific points in time.

For example, when the 24th of the month, which is a gDay (a monthly day) type, is written to the logical tree, the missing month and year subfields are supplied from the epoch (January 1970) to provide the specific date 1970-01-24. If you code ESQL to manipulate this date, for example by adding an interval of 10 days, and then generate an output message that is validated, an exception is raised. This is because the result of the calculation is 1970-02-03 which is invalid because the month subfield of the date no longer matches the epoch date.

Use within an MRM domain: In MRM it is possible to define an element that has the logical type of dateTime.

When a dateTime element is parsed, a field is created in the message tree that has the ESQL datatype of CURRENT_TIME or CURRENT_TIMESTAMP. However, the CURRENT_TIME and CURRENT_TIMESTAMP data types do not have the functionality to store timezone information, and the MRM does not adjust the time according to the input timezone and the timezone of the broker.

Although the CURRENT_TIME and CURRENT_TIMESTAMP data types cannot store timezone information, the MRM stores this information as part of the underlying field. This means that if the field is copied between message trees, the timezone information is copied with it, allowing this information to be preserved on output.

Note that the information is preserved only if the field is copied to a field of the same name.

However, if any new field is derived from the original field, the new field does not have the timezone information. This means that if such a field is cast as a character, the new field assumes the timezone of the broker, but its value is not adjusted for any difference between the input timezone and the timezone of the broker.

For example, an input dateTime element containing `2009-02-20T06:08:07-08:00` could be copied from the input message tree to the output message tree and appear in an output message in exactly the same format. However, if the element is cast as character, using format `IU`, by a broker running GMT the result would be `2009-02-20T06:08:07.000Z`.

"CURRENT_TIMESTAMP function" on page 5180

ESQL NULL data type:

All ESQL data types (except REFERENCE) support the concept of the null value. A value of null means that the value is unknown, undefined, or uninitialized. Null values can arise when you refer to message fields that do not exist, access database columns for which no data has been supplied, or use the keyword NULL, which supplies a null literal value.

Null is a distinct state and is not the same as any other value. In particular, for integers it is not the same thing as the value 0 and for character variables it is not the same thing as a string of zero characters. The rules of ESQL arithmetic take null values into account, and you are typically unaware of their existence. Generally, but not always, these rules mean that, if any operand is null, the result is null.

If an expression returns a null value its data type is not, in general, known. All null values, whatever their origin, are therefore treated equally.

This can be regarded as their belonging to the data type NULL , which is a data type that can have just one value, null.

An expression always returns NULL if any of its elements are NULL.

Testing for null values

To test whether a field contains a null value, use the IS operator described in **Operator=**.

The effect of setting a field to NULL:
Take care when assigning a null value to a field. For example, the following command *deletes* the `Name` field:

```
SET OutputRoot.XMLNS.Msg.Data.Name = NULL;  -- this deletes the field
```

The correct way to assign a null value to a field is as follows:

```
SET OutputRoot.XMLNS.Msg.Data.Name VALUE = NULL;
-- this assigns a NULL value to a field without deleting it
```

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL numeric data types:

ESQL supports several data types that handle numeric values, including DECIMAL, FLOAT, and INTEGER.

The following data types are collectively known as **numeric** data types:
- "ESQL DECIMAL data type" on page 5034
- "ESQL FLOAT data type" on page 5036
- "ESQL INTEGER data type" on page 5037

Notes:

1. INTEGER and DECIMAL types are represented exactly inside the broker; FLOAT types are inherently subject to rounding error without warning. Do not use FLOAT if you need absolute accuracy, for example, to represent money.
2. Various casts are possible between different numeric types. These can result in loss of precision, if exact types are cast into FLOAT.

For information about numeric functions see "ESQL numeric functions" on page 5183.

"ESQL DECIMAL data type"

"ESQL FLOAT data type" on page 5036

"ESQL INTEGER data type" on page 5037

"ESQL numeric functions" on page 5183
A list of the numeric functions that ESQL supports.

ESQL DECIMAL data type:
The **DECIMAL** data type holds an exact representation of a decimal number. Decimals have precision, scale, and rounding. Precision is the total number of digits of a number:

- The minimum precision is 1
- The maximum precision is 34

Scale is the number of digits to the right of the decimal point:

- The minimum scale (-exponent) is -999,999,999
- The maximum scale (-exponent) is +999,999,999

You cannot define precision and scale when declaring a DECIMAL, because they are assigned automatically. It is only possible to specify precision and scale when casting to a DECIMAL.

Scale, precision, and rounding:
The following scale, precision, and rounding rules apply:

- Unless rounding is required to keep within the maximum precision, the scale of the result of an addition or subtraction is the greater of the scales of the two operands.
- Unless rounding is required to keep within the maximum precision, the scale of the result of a multiplication is the sum of the scales of the two operands.
- The precision of the result of a division is the smaller of the number of digits needed to represent the result exactly and the maximum precision.
- All addition, subtraction, multiplication, and division calculations round the least significant digits, as necessary, to stay within the maximum precision
- All automatic rounding is *banker's* or *half even symmetric* rounding. The rules of this are:
  - When the first dropped digit is 4 or less, the first retained digit is unchanged
  - When the first dropped digit is 6 or more, the first retained digit is incremented

- When the first dropped digit is 5, the first retained digit is incremented if it is odd, and unchanged if it is even. Therefore, both 1.5 and 2.5 round to 2 while 3.5 and 4.5 both round to 4
- Negative numbers are rounded according to the same rule

Decimal literals:
Decimal literals that consist of an unquoted string of digits only, that is, that contain neither a decimal point nor an exponent (for example 12345) are of type INTEGER if they are small enough to be represented as integers. Otherwise they are of type DECIMAL.

Decimal literals that consist of an unquoted string of digits, optionally a decimal point, and an exponent (for example 123e1), are of type FLOAT if they are small enough to be represented as floats. Otherwise they are of type DECIMAL.

Decimal literals that consist of the keyword DECIMAL and a quoted string of digits, with or without a decimal point and with or without an exponent, are of type DECIMAL, for example, DECIMAL '42', DECIMAL '1.2346789e+203'.

The strings in this type of literal can also have the values:
- 'NAN', not a number
- 'INF', 'INFINITY'
- '+INF', '+INFINITY'
- '-INF', '-INFINITY'
- 'MAX'
- 'MIN'

(in any mixture of case) to denote the corresponding values.

Note, if you do not specify sufficient precision digits, that INF is returned, as shown in the following example:

```
SET VAL = CAST('123456' AS DECIMAL(3,0))
```

Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL FLOAT data type:
The FLOAT data type holds a 64-bit, base 2, fraction and exponent approximation to a real number. This gives a range of values between +-1.7E–308 and +- 1.7E+308.

Float literals consist of an unquoted string of digits and either a decimal point (for example 123.4) or an exponent (for example 123e4) or both (for example 123.4e5) . They are of type FLOAT if they are small enough to be represented as floats. Otherwise they are of type DECIMAL

Rounding:
When you CAST a FLOAT to an INTEGER, either implicitly or explicitly, the FLOAT is truncated; that is, the numbers after the decimal point are removed and no rounding occurs.

When you CAST a FLOAT to a DECIMAL or CHARACTER, either implicitly or explicitly, the FLOAT can be rounded to a maximum precision of 15 digits.

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

"ESQL data types" on page 2373
A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

"Message mapping overview" on page 2229
Message mappings define the blueprint for creating a message, where the created message is known as the target message.

"ESQL DECIMAL data type" on page 5034

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable

and, optionally, its initial value.

ESQL INTEGER data type:
The INTEGER data type holds an integer number in 64-bit two's complement form. This gives a range of values between -9223372036854775808 and +9223372036854775807.

Integer literals consist of an unquoted string of digits only; that is, they contain neither a decimal point nor an exponent; for example, 12345. They are of type INTEGER if they are small enough to be represented as integers. Otherwise they are of type DECIMAL.

In addition to this format, you can write integer literals in hexadecimal notation; for example, 0x1234abcd. You can write the hexadecimal letters A to F, and the "x" after the initial zero, in uppercase or lowercase. If you use hexadecimal format, the number must be small enough to fit into an integer. (That is, it cannot be a decimal.)

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL REFERENCE data type:

The REFERENCE data type holds the location of a field in a message. It cannot hold the location of a constant, a database table, a database column, or another reference.

For compatibility with earlier versions, reference variables can also point at scalar variables

A reference literal is an hierarchic path name, consisting of a list of path elements separated by periods. The first element in the list is known as the correlation name, and identifies a reference, row, or scalar variable. Any subsequent elements apply to references to message trees only, and identify field types, names, and indexes within the message tree relative to the field pointed to by the correlation name.

Note: If you use a REFERENCE, you are able to modify any element, even if the element is part of an input tree.

For example:

```
InputRoot.MQMD.Priority
```

is a field reference literal that refers to the Priority field contained within an MQMD structure within an input message.

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

You can use ESQL field references to form paths to message body elements.

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL ROW data type:

The ROW data type holds a *tree structure*. A row in a database is a particular type of tree structure, but the ROW data type is not restricted to holding data from database rows.

In a database, a row is a fixed, ordered, set of scalar values. A *scalar* is defined as a single entity value or a string.

A database table is an unordered set of rows and therefore represents a two dimensional "array" of scalar values, in which one dimension is fixed and the other is variable. In ESQL, a row is an open-ended, ordered, set of named values in

which each value can be scalar, or another row. That is, a row is an open-ended tree structure with no restrictions on dimensions or regularity. Consider the following diagram:

```
Root
  Row
    PartNumber  = 1
    Description = 'Chocolate bar'
    Price       = 0.30
  Row
    PartNumber  = 2
    Description = 'Biscuit'
    Price       = 0.35
  Row
    PartNumber  = 3
    Description = 'Fruit'
    Price       = 0.42
```

In the example, *Root* contains three elements all named "Row". Each of these elements in turn contains three elements with different names and values. This diagram equally describes an instance of an ESQL row data type (that is, a tree structure) or the contents of a database table.

ROW and LIST

The ROW data type is a normal data type. You can use the DECLARE statement to create ROW variables in the same way as you create INTEGER or CHARACTER variables. There is also a more general concept of a ROW data type. In the previous example, *Root* is the root element of a ROW variable. Each of the elements called "Row", while not the root element of ROW variables, is a root element of substructures. Many ESQL operations (and particularly the SELECT function) work with the general concept of ROW and operate equally on whole trees or parts of trees.

There is also a general concept of a LIST data type. The set of elements called "Row" can be regarded as a list. Some ESQL operations (particularly SELECT) work with the general concept of list.

InputRoot, *OutputRoot*, and so on, are examples of ROW variables that are automatically declared and present in the data structure, ready for use.

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL BIT data type:
The BIT data type holds a variable length string of binary digits. It is commonly used to represent arbitrary binary data that does not contain an exact number of bytes. A bit string literal consists of the letter B, followed by a string of binary digits enclosed in single quotation marks, as in the following example:

```
B'0100101001'
```

Any number of digits, which must be either 0 or 1, can be specified. The initial B can be specified in uppercase or lowercase.

Related concepts:

"Message flows overview" on page 1022
A message flow is a sequence of processing steps that run in the broker when an input message is received.

"ESQL data types" on page 2373

"ESQL CHARACTER data type" on page 5042

"ESQL BLOB data type"

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL BLOB data type:
The BLOB data type holds a variable length string of 8-bit bytes. It is commonly used to represent arbitrary binary data. A BLOB literal consists of the letter X, followed by a string of hexadecimal digits enclosed in single quotation marks, as in the following example:

```
X'0123456789ABCDEF'
```

There must be an even number of digits in the string, because two digits are required to define each byte. Each digit can be one of the hexadecimal digits 0-9 and A-F. Both the initial X and the hexadecimal letters can be specified in uppercase or lowercase.

ESQL-to-Java data-type mapping table:

Table summarizing the mappings from ESQL to Java.

The following table summarizes the mappings from ESQL to Java.

Notes:

- Only the Java scalar wrappers are passed to Java.
- The ESQL scalar types are mapped to Java data types as object wrappers, or object wrapper arrays, depending upon the direction of the procedure parameter. Each wrapper array contains exactly one element.
- Scalar object wrappers are used to allow NULL values to be passed to and from Java methods.

ESQL data types [1]	**Java IN data types**	**Java INOUT and OUT data types**
INTEGER, INT	java.lang.Long	java.lang.Long []
FLOAT	java.lang.Double	java.lang.Double[]
DECIMAL	java.math.BigDecimal	java.math.BigDecimal[]
CHARACTER, CHAR	java.lang.String	java.lang.String[]
BLOB	byte[]	byte[][]
BIT	java.util.BitSet	java.util.BitSet[]
DATE	com.ibm.broker.plugin.MbDate	com.ibm.broker.plugin.MbDate[]
TIME [2]	com.ibm.broker.plugin.MbTime	com.ibm.broker.plugin.MbTime[]
GMTTIME [2]	com.ibm.broker.plugin.MbTime	com.ibm.broker.plugin.MbTime[]
TIMESTAMP [2]	com.ibm.broker.plugin.MbTimestamp	com.ibm.broker.plugin.MbTimestamp[]
GMTTIMESTAMP [2]	com.ibm.broker.plugin.MbTimestamp	com.ibm.broker.plugin.MbTimestamp[]
INTERVAL	Not supported	Not supported
BOOLEAN	java.lang.Boolean	java.lang.Boolean[]
REFERENCE (to a message tree) [3] [4] [5] [6]	com.ibm.broker.plugin.MbElement	com.ibm.broker.plugin.MbElement[] **(Supported for INOUT. Not supported for OUT)**
ROW	Not supported	Not supported
LIST	Not supported	Not supported

1. Variables that are declared to be CONSTANT (or references to variables that are declared to be CONSTANT) are not allowed to have the direction INOUT or OUT.
2. The time zone set in the Java variable is not important; you obtain the required time zone in the output ESQL.
3. The reference parameter cannot be NULL when passed into a Java method.
4. The reference cannot have the direction OUT when passed into a Java method.
5. If an *MbElement* is passed back from Java to ESQL as an INOUT parameter, it must point to a location in the same message tree as that pointed to by the *MbElement* that was passed into the called Java method.

For example, if an ESQL reference to `OutputRoot.XML.Test` is passed into a Java method as an INOUT *MbElement*, but a different *MbElement* is passed back to ESQL when the call returns, the different element must also point to somewhere in the `OutputRoot` tree.

6. An *MbElement* cannot be returned from a Java method with the RETURNS clause, because no ESQL routine can return a reference. However, an *MbElement* can be returned as an INOUT direction parameter, subject to the conditions described in point 5.

A REFERENCE to a scalar variable can be used in the CALL of a Java method, provided that the data type of the variable to which the reference refers matches the corresponding data type in the Java program signature.

ESQL to XML Schema data type mapping:

Mapping from XML Schema simple type to ESQL message tree data type.

The following table shows the mapping that WebSphere Message Broker parsers use when converting between the simple types of XML Schema and the data types of the message tree. The mapping applies to all parsers that use an XML Schema model when parsing and serializing.

XML Schema simple type	Data type in message tree
anyURI	CHARACTER
base64Binary	BLOB
boolean	BOOLEAN
byte	INTEGER
date	DATE
dateTime	TIMESTAMP
dayTimeDuration	INTERVAL
decimal	DECIMAL
double	FLOAT
duration	INTERVAL
ENTITIES	List of CHARACTER
ENTITY	STRING
float	FLOAT
gDay	DATE
gMonth	DATE
gMonthDay	DATE
gYear	DATE
gYearMonth	DATE
hexBinary	BLOB
ID	CHARACTER

XML Schema simple type	Data type in message tree
IDREF	CHARACTER
IDREFS	List of CHARACTER
int	INTEGER
integer	DECIMAL
language	CHARACTER
long	INTEGER
Name	CHARACTER
NCName	CHARACTER
negativeInteger	DECIMAL
NMTOKEN	CHARACTER
NMTOKENS	List of CHARACTER
nonNegativeInteger	DECIMAL
nonPositiveInteger	DECIMAL
normalizedString	CHARACTER
NOTATION	CHARACTER
positiveInteger	DECIMAL
QName	CHARACTER
short	INTEGER
string	CHARACTER
time	TIME
token	CHARACTER
unsignedByte	INTEGER
unsignedInt	INTEGER
unsignedLong	DECIMAL
unsignedShort	INTEGER
yearMonthDuration	INTERVAL

A parser is supplied for the body of a message in the MRM domain; it associates each field with a specific data type.

"ESQL data types in message flows" on page 5020
All data that is referred to in message flows must be one of the defined types.

ESQL-to-XPath mapping table:

A table that summarizes the mappings from ESQL to XPath.

ESQL	XPath 1.0	XPath 1.0 usage notes
BOOLEAN data types		
True	True()	Equivalent to Boolean "1" or "True"
False	False()	Equivalent to Boolean "0" or "False"
Unknown	No equivalent	
Date Time data types	No equivalent	
NULL data type	No equivalent	
Numeric data types		
DECIMAL	12678967.543233 with or without quotation marks	Cannot express an exponent or a leading plus sign.
FLOAT	1.7976931348623158 with or without quotation marks	Cannot express an exponent or a leading plus sign.
INTEGER	9223372036854775807 with or without quotation marks	Cannot express an exponent or a leading plus sign.
REFERENCE data type	FilterExpression '/' RelativeLocationPath	For example, `$InputRoot/MQMD/Priority`
String data types		
BIT	No equivalent	
BLOB	No equivalent	
CHARACTER	Literal	For example `'a "b"'` or `"a 'b'"`
`NAME`	`$NAME`	Can assign such a variable any valid value, of type Boolean, number, or string.
Simple comparison operators		
>	>	
<	<	
>=	>=	
'='	'='	
<>	!=	
Complex comparison operators	No equivalent	
Logical operators		
AND	and	
OR	or	
NOT	not (operand)	The not function returns true if its argument is false, and false otherwise.
Numeric operators		
Unary -	- Unary expression	
+	+	
-	-	
*	*	Multiplication operator
/	div	
String operator	No equivalent	
Date time functions	No equivalent	

ESQL	XPath 1.0	XPath 1.0 usage notes
Numeric functions		
FLOOR	floor (number)	
CEIL and CEILING	ceiling (number)	
ROUND	No equivalent	
String manipulation functions		
SUBSTRING	substring(string, number, number)	
TRANSLATE	translate(string, string, string)

Related reference:

"Built-in nodes" on page 4293
WebSphere Message Broker supplies built-in nodes that you can use to define your message flows.

"ESQL reference" on page 5019
SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

ESQL variables:

ESQL variables can be described as *external variables*, *normal variables*, or *shared variables*; their use is defined in the DECLARE statement.

Types of variable

External

External variables (defined with the EXTERNAL keyword) are also known as *user-defined properties* (see "User-defined properties in ESQL" on page 2376). They exist for the entire lifetime of a message flow and are visible to all messages that pass through the flow. You can define *external variables* only at the module and schema level. You can modify their initial values (optionally set by the DECLARE statement) by using the Message Flow editor, or at deployment time, by using the Broker Archive editor. You can query and set the values of user-defined properties at run time by using the Administration API for WebSphere Message Broker (also known as the CMP API). For more information, see "Setting message flow user-defined properties at run time in a CMP application" on page 985.

Normal

Normal variables have a lifetime of just one message passing through a node. They are visible to that message only. To define a *normal variable*, omit both the EXTERNAL and SHARED keywords.

Shared

Shared variables (defined with the SHARED keyword) can be used to implement an in-memory cache in the message flow; see "Optimizing message flow response times" on page 3264. *Shared variables* have a long lifetime and are visible to multiple messages that pass through the flow; see "Long-lived variables" on page 2378. They exist for the lifetime of the execution group process, the lifetime of the flow or node, or the lifetime of the node's SQL that declares the variable (whichever is the shortest). They are initialized when the first message passes through the flow or node after each broker startup.

See also the ATOMIC option of the "BEGIN ... END statement" on page 5070. The BEGIN ATOMIC construct is useful when a number of changes have to be made to a shared variable and when it is important to prevent other instances seeing the intermediate states of the data.

Related concepts:

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

"ESQL variables" on page 2374
An ESQL variable is a data field that is used to help process a message.

"User-defined properties in ESQL" on page 2376
Access user-defined properties (UDPs) as variables in your ESQL program by specifying the EXTERNAL keyword on a DECLARE statement. For example, the ESQL statement `DECLARE today EXTERNAL CHARACTER 'monday'` defines a user-defined property called today with an initial value monday.

"User-defined properties" on page 1147
A user-defined property (UDP) is a property that is defined when you construct a message flow by using the Message Flow editor. This property can be used by the ESQL or Java program inside message flow nodes, such as a Compute node.

"Long-lived variables" on page 2378
You can use appropriate long-lived ESQL data types to cache data in memory.

Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

"Setting message flow user-defined properties at run time in a CMP application" on page 985
Use the CMP API to query, discover, and set message flow user-defined properties dynamically at run time. You can use the CMP API to set properties with a data type of character.

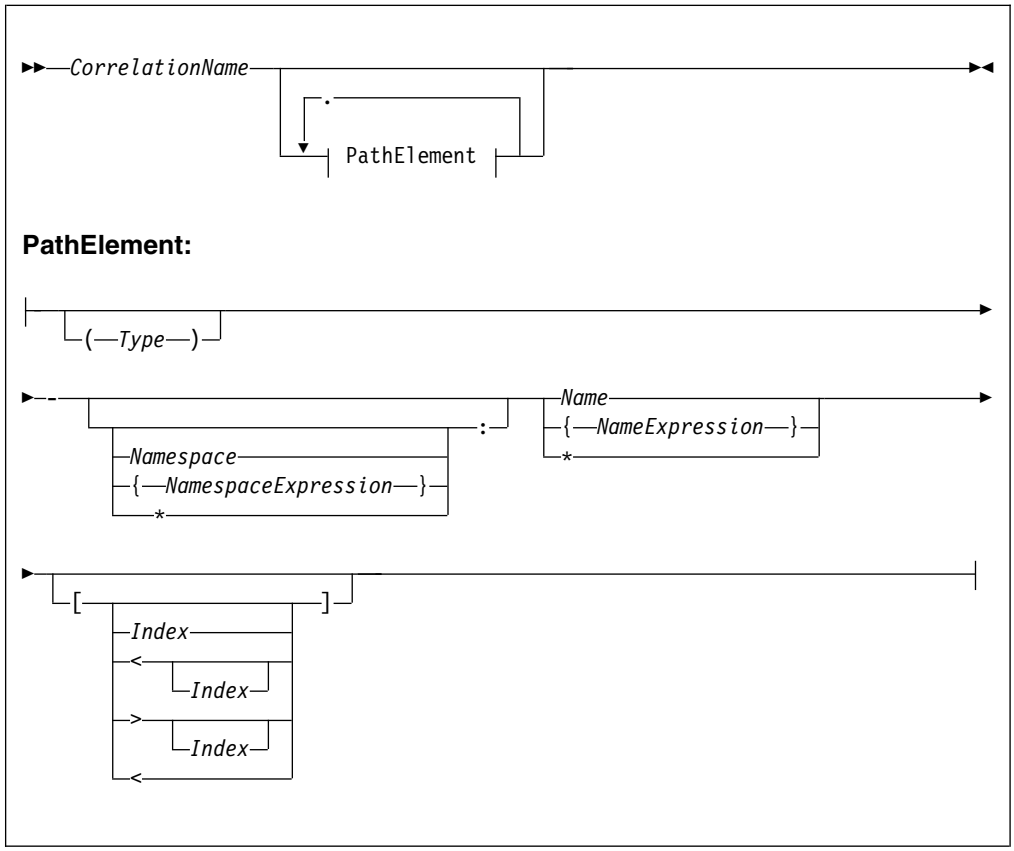
Related reference:

"DECLARE statement" on page 5117
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

ESQL field reference overview:

You can use ESQL field references to form paths to message body elements.

The full syntax for field references is shown in the following examples:



A field reference consists of a correlation name, followed by zero or more Path Elements separated by periods (.). The correlation name identifies a well-known starting point and must be the name of a constant, a declared variable (scalar, row or reference), or one of the predefined start points; for example, InputRoot. The path Fields define a path from the start point to the desired field.

See:

- "Namespace" on page 5051 for the meaning of the different combinations of namespace and name
- "Target field references" on page 5054 for the meaning of the different combinations of field references
- "Index" on page 5051 for the meaning of the different combinations of index clauses
- "Type" on page 5052 for the meaning of the different combinations of types

For example:

```
InputRoot.XMLNS.Data.Invoice
```

starts the broker at the location InputRoot (that is, the root of the input message to a Compute node) and then performs a sequence of navigations. First, it navigates from root to the first child field called XMLNS, then to the first child field of the XMLNS field called Data. Finally, the broker navigates to the first child field of the Data field called Invoice. Whenever this field reference occurs in an ESQL program, the invoice field is accessed.

This form of field reference is simple, convenient, and is the most commonly used. However, it does have two limitations:

- Because the names used must be valid ESQL identifiers, you can use only names that conform to the rules of ESQL. That is, the names can contain only alphanumeric characters including underscore, the first character cannot be numeric, and names must be at least one character long. You can avoid these limitations by enclosing names not conforming to these rules in double quotation marks. For example:

  ```
  InputRoot.XMLNS."Customer Data".Invoice
  ```

  If you need to refer to fields that contain quotation marks, use two pairs of quotation marks around the reference. For example:

  ```
  Body.Message."""hello"""
  ```

  Some identifiers are reserved as keywords but, with the exception of the correlation name, you can use them in field references without the use of double quotation marks
- Because the names of the fields appear in the ESQL program, they must be known when the program is written. This limitation can be avoided by using the alternative syntax that uses braces ({ ... }). This syntax allows you to use any expression that returns a non-null value of type character.

  For example:

  ```
  InputRoot.XMLNS."Customer Data".{'Customer-' ||
   CurrentCustomer}.Invoice
  ```

  in which the invoices are contained in a folder with a name is formed by concatenating the character literal Customer- with the value in CurrentCustomer (which in this example must be a declared variable of type character).

You can use the asterisk (*) wildcard character in a path element to match any name. For example:

```
InputRoot.XMLNS.*.Invoice.Value
```

matches any path element in which the invoices are contained.

Note that enclosing anything in double quotation marks in ESQL makes it an identifier; enclosing anything in single quotation marks makes it a character literal. You must enclose all character strings in single quotation marks.

Namespace:
Field names can belong to namespaces. Field references provide support for namespaces as follows:

- Each field of each field reference that contains a name clause can also contain a namespace clause defining the namespace to which the specified name belongs.
- Each namespace name can be defined by either a simple identifier or by an expression (enclosed in curly braces). If an identifier is the name of a declared namespace constant, the value of the constant is used. If an expression is used, it must return a non-null value of type character.
- A namespace clause of * explicitly states that namespace information is to be ignored when locating Fields in a tree.
- A namespace clause consisting of only : explicitly targets the notarget namespace. The clause has no identifier, expression or wildcard (*).

For example:

```
DECLARE sp1 NAMESPACE 'http://www.ibm.com/space1';

/* Namespace declaration to associate prefix 'space1' with the namespace */

SET OutputRoot.XMLNS.TestCase.(XML.NamespaceDecl)xmlns:space1 = 'http://www.ibm.com/space1';
SET OutputRoot.XMLNS.TestCase.sp1:data1 = 'Hello!';
```

generates:

```
<TestCase xmlns:space1="http://www.ibm.com/space1">
<space1:data1>Hello!</space1:data1>
</TestCase>
```

Index:
Each field of a field reference can contain an index clause. This clause is denoted by brackets ([...]) and accepts any expression that returns a non-null value of type integer. This clause identifies which of several fields with the same name is to be selected. Fields are numbered, starting at one. If this clause is not present, it is assumed that the first field is required. Therefore, the following two examples have exactly the same meaning:

```
InputRoot.XMLNS.Data[1].Invoice
InputRoot.XMLNS.Data.Invoice[1]
```

This construct is most commonly used with an index variable, so that a loop steps though all such fields in sequence. For example:

```
WHILE count < 32 DO
     SET TOTAL = TOTAL + InputRoot.XMLNS.Data.Invoice[count].Amount;
     SET COUNT = COUNT + 1
END WHILE;
```

Use this kind of construct with care, because it implies that the broker must count the fields from the beginning each time round the loop. If the repeat count is large, performance will be poor. In such cases, a better alternative is to use a field reference variable.

Index expressions can optionally be preceded by a less-than sign (<), indicating that the required field is to be indexed from the last field, not the first. In this case, the index 1 refers to the last field and the index 2 refers to the penultimate field. For completeness, you can use a greater-than sign to indicate counting from the first field. The following example shows ESQL code that handles indexes where there are four fields called Invoice.

```
InputRoot.XMLNS.Data.Invoice       -- Selects the first
InputRoot.XMLNS.Data.Invoice[1]    -- Selects the first
InputRoot.XMLNS.Data.Invoice[>]    -- Selects the first
InputRoot.XMLNS.Data.Invoice[>1]   -- Selects the first
InputRoot.XMLNS.Data.Invoice[>2]   -- Selects the second
InputRoot.XMLNS.Data.Invoice[<]    -- Selects the fourth
InputRoot.XMLNS.Data.Invoice[<1]   -- Selects the fourth
InputRoot.XMLNS.Data.Invoice[<2]   -- Selects the third
InputRoot.XMLNS.Data.Invoice[<3]   -- Selects the second
```

An index clause can also consist of an empty pair of brackets ([]). This selects all fields with matching names. Use this construct with functions and statements that expect lists (for example, the SELECT, CARDINALITY, SINGULAR, and EXISTS functions, or the SET statement) .

Type:
Each field of a field reference can contain a type clause. These are denoted by parentheses (( )), and accept any expression that returns a non-null value of type integer. The presence of a type expression restricts the fields that are selected to those of the matching type. This construct is most commonly used with generic XML, where there are many field types and it is possible for one XML field to contain both attributes and further XML Fields with the same name.

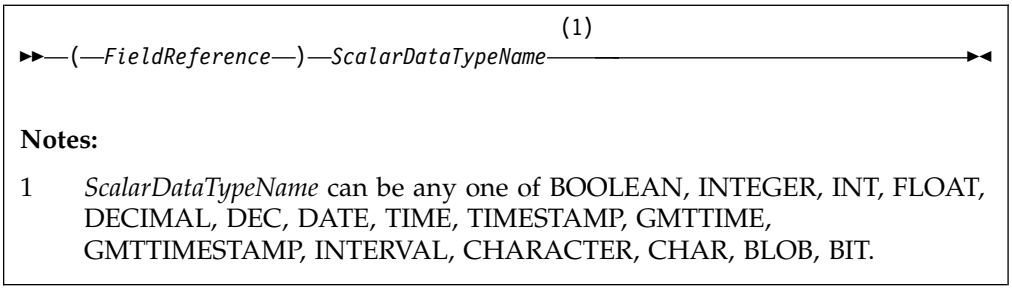
For example:

```
<Item Value = '1234'>
     <Value>5678</Value>
</Item>
```

Here, the XML field Item has two child Fields, both called “Value”. The child Fields can be distinguished by using type clauses:
`Item.(<Domain>.Attribute)Value` to select the attribute, and
`Item.(XML.Element)Value` to select the field, where `<Domain>` is one of XML, XMLNS, or XMLNSC, as determined by the message domain of the source.

Type constraints

A type constraint checks the data type returned by a field reference.



Notes:

1 *ScalarDataTypeName* can be any one of BOOLEAN, INTEGER, INT, FLOAT, DECIMAL, DEC, DATE, TIME, TIMESTAMP, GMTTIME, GMTTIMESTAMP, INTERVAL, CHARACTER, CHAR, BLOB, BIT.

Typically, a type constraint causes the scalar value of the reference to be extracted (in a similar way to the FIELDVALUE function) and an exception to be thrown if the reference is not of the correct type. By definition, an exception will be thrown for all nonexistent fields, because these evaluate to NULL. This provides a convenient and fast way of causing exceptions if essential fields are missing from messages.

However, when type constraints occur in expressions that are candidates for being passed to a database (for example, they are in a WHERE clause), the information is used to determine whether the expression can be given to the database. This can be important if a WHERE clause contains a CAST operating on a database table column. In the absence of a type constraint, such expressions cannot be given to the database because the broker cannot tell whether the database is capable of performing the required conversion. Note, however, that you should always exercise caution when using casts operating on column values, because some databases have exceedingly limited data conversion capabilities.

Field references summary:

***, *[..], (..)*, (..)*[..]**
None of these forms specifies a name or namespace. The target field can have any name, in any namespace or in no namespace. It is located solely by its type, its index, or its type and index, as appropriate.

Name, Name[..], (..)Name, (..)Name[..]
All these forms specify a name but no namespace. The target field is located by namespace and name, and also by type and index where appropriate.

The namespace is taken to be the only namespace in the namespace path containing this name. The only namespace that can be in the path is the notarget namespace.

These forms all existed before namespaces were introduced. Although their behavior has changed in that they now compare both name and namespace, existing transforms should see no change in their behavior because all existing transforms create their Fields in the notarget namespace.

:*, :*[..], (..):*, (..):*[..]
All these forms specify the notarget namespace but no name. The target field is located by its namespace and also by type and index where appropriate.

:Name, :Name[..], (..):Name, (..):Name[..]
All these forms specify a name and the notarget namespace. The target field is located by namespace and name and also by type and index where appropriate.

***:*, *:*[..], (..)*:*, (..)*:*[..]**
None of these forms specifies a name or a namespace. Note that "*:*" is equivalent to "*", and matches no namespace as well as any namespace. The target field can have any name, in any namespace or in no namespace. It is located solely by its type, its index, or its type and index, as appropriate.

***:Name, *:Name[..], (..)*:Name, (..)*:Name[..]**
All these forms specify a name but no namespace. The target field is located by name and also by type and index where appropriate.

Namespace:*, Namespace:*[..], (..)Namespace:*, (..)Namespace:*[..]
All these forms specify a namespace but no name. The target field is located by namespace and also by type and index where appropriate.

Namespace:Name, Namespace:Name[..], (..)Namespace:Name, (..)Namespace:Name[..]
All these forms specify a namespace and name. The target field is located by namespace and name and also by type and index where appropriate.

In all the preceding cases a name, or namespace, provided by an expression contained in braces ({}) is equivalent to a name provided as an identifier.

By definition, the name of the notarget namespace is the empty string. The empty string can be selected by expressions which evaluate to the empty string, the empty identifier "", or by reference to a namespace constant defined as the empty string.

Target field references:
The use of field references usually implies searching for an existing field. However, if the required field does not exist, as is usually the case for field references that are the targets of SET statements and those in the AS clauses of SELECT functions, it is created.

In these situations, there are a variety of circumstances in which the broker cannot tell what the required name or namespace is, and in these situations the following general principles apply :

- If the name clause is absent or does not specify a name, and the namespace clause is absent or does not specify or imply a namespace (that is, there is no name or namespace available), one of the following conditions applies:
  - If the assignment algorithm does **not** copy the name from some existing field, the new field has both its name and namespace set to the empty string and its name flag is **not** set automatically.

    In the absence of a type specification, the field's type is not *Name* or *NameValue*, which effectively indicates that the new field is nameless.
  - Otherwise, if the assignment algorithm copies the name from some existing field, the new field has both its name and namespace copied from the existing field and its *Name* flag is set automatically
- If the name clause is present and specifies a name, but the namespace clause is absent or does not specify or imply a namespace (that is, a name is available but a namespace is not), the new field has its:
  - *Name* set to the given value
  - *Namespace* set to the empty string
  - *Name* flag set automatically

- If the name clause is absent or does not specify a name, but the namespace clause is present and specifies or implies a namespace (that is, a namespace is available but a name is not), the new field has its:
  - *Namespace* set to the given value
  - *Name* set to the empty string
  - *Name* flag set automatically
- If the name clause is present and specifies a name, and the namespace clause is present and specifies or implies a namespace, the new field has its:
  - *Name* set to the given value
  - *Namespace* set to the given value
  - *Name* flag set automatically

There are also cases where the broker creates Fields in addition to those referenced by field references:

- Tree copy: new Fields are created by an algorithm that uses a source tree as a template. If the algorithm copies the name of a source field to a new field, its namespace is copied as well.
- Anonymous select expressions: SELECT clauses are not obliged to have AS clauses; those that do not have them, set the names of the newly created Fields to default values (see "SELECT function" on page 5260).

  These defaults can be derived from field names, column names or can simply be manufactured sequence names. If the name is an field name, this is effectively a tree copy, and the namespace name is copied as above.

  Otherwise, the namespace of the newly-created field is derived by searching the path, that is, the name is be treated as the *NameId* syntax of a field reference.

The effect of setting a field to NULL:

Take care when assigning a null value to a field. For example, the following command *deletes* the `Name` field:

```
SET OutputRoot.XMLNS.Msg.Data.Name = NULL;  -- this deletes the field
```

The correct way to assign a null value to a field is as follows:

```
SET OutputRoot.XMLNS.Msg.Data.Name VALUE = NULL;
-- this assigns a NULL value to a field without deleting it
```

Note: to users on compatibility with earlier versions

For compatibility with earlier versions, the LAST keyword is still supported, but its use is deprecated. LAST cannot be used as part of an index expression: `[LAST]` is valid, and is equivalent to `[<]`, but `[LAST3]` is not valid.

The LAST keyword has been replaced by the following arrow syntax, which allows both a direction of search and index to be specified:

```
Field [> ]                  -- The first field, equivalent to [ 1 ]
Field [> (a + b) * 2 ]
Field [ < ]                  -- The last field, equivalent to [ LAST ]
Field [ < 1 ]                -- The last field, equivalent to [ LAST ]
Field [ < 2 ]                -- The last but one field
Field [ < (a + b) / 3 ]
```

"ESQL reference" on page 5019
SQL is the industry standard language for accessing and updating database data and ESQL is a language derived from SQL Version 3, particularly suited to manipulating both database and message data.

ESQL simple comparison operators:

The simple comparison operators >, <, >=, <=, =, and <>.

This topic describes ESQL's simple comparison operators. For information about ESQL's complex comparison operators, see "ESQL complex comparison operators" on page 5058.

ESQL provides a full set of comparison operators (predicates). Each compares two scalar values and returns a Boolean. If either operand is null the result is null. Otherwise the result is true if the condition is satisfied and false if it is not.

Comparison operators can be applied to all scalar data types. However, if the two operands are of different types, special rules apply. These are described in "Implicit casts" on page 5282.

Some comparison operators also support the comparison of rows and lists, as follows:

Operator>
The first operand is greater than the second.

Operator <
The first operand is less than the second.

Operator>=
The first operand is greater than or equal to the second.

Operator <=
The first operand is less than or equal to the second.

Operator =
The first operand is equal to that of the second.

This operator can also compare rows and lists. See "ROW and LIST comparisons" on page 5271 for a description of list and row comparison.

Operator <>
The first operand is not equal to the second.

This operator can also compare rows and lists. See "ROW and LIST comparisons" on page 5271 for a description of list and row comparison.

The meanings of "equal", "less", and "greater" in this context are as follows:

- For the numeric types (INTEGER, FLOAT, DECIMAL) the numeric values are compared. Thus 4.2 is greater than 2.4 and -2.4 is greater than -4.2.
- For the date/time types (DATE, TIME, TIMESTAMP, GMTTIME, GMTTIMESTAMP but not INTERVAL) a later point in time is regarded as being greater than an earlier point in time. Thus the date 2004-03-31 is greater than the date 1947-10-24.
- For the INTERVAL type, a larger interval of time is regarded as being greater than a smaller interval of time.

For the string types (CHARACTER, BLOB, BIT) the comparison is lexicographic. Starting from the left, the individual elements (each character, byte or bit) are compared. If no difference is found, the strings are equal. If a difference is found, the values are greater if the first different element in the first operand is greater than the corresponding element in the second and less if they are less. In the special case where two strings are of unequal length but equal as far as they go, the longer string is regarded as being greater than the shorter. Thus:

```
'ABD' is greater than 'ABC'
'ABC' is greater than 'AB'
```

Trailing blanks are regarded as insignificant in character comparisons. Thus if you want to ensure that two strings are truly equal you need to compare both the strings themselves and their lengths. For example:

```
'ABC  ' is equal to 'ABC'
```

Note that comparing strings with a length of one is equivalent to comparing individual characters, bytes, or bits. Because ESQL has no single character, byte, or bit data types, it is standard practice to use strings of length one to compare single characters, bytes, or bits.

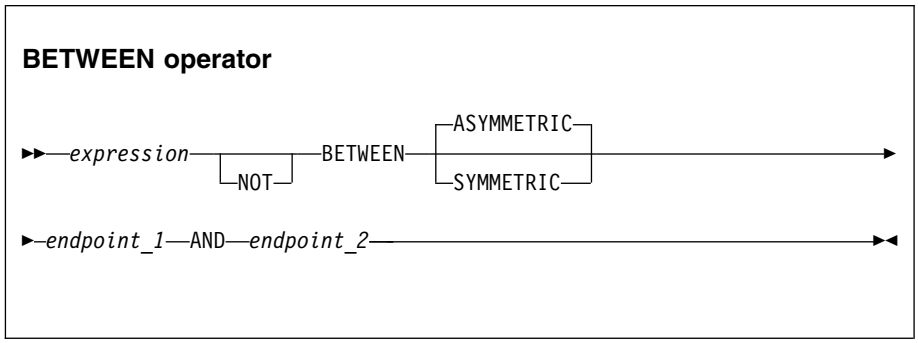
ESQL complex comparison operators:

ESQL supports several operators for complex comparison tasks.

If you want to use ESQL to perform a simple comparison, see "ESQL simple comparison operators" on page 5057.

Operator BETWEEN

Use the BETWEEN operator to test whether a value lies between two boundary values.



This operator exists in two forms, SYMMETRIC and ASYMMETRIC (which is the default if neither is specified). The SYMMETRIC form is equivalent to:

```
(source>= boundary1 AND source <= boundary2) OR
(source>= boundary2 AND source <= boundary1)
```

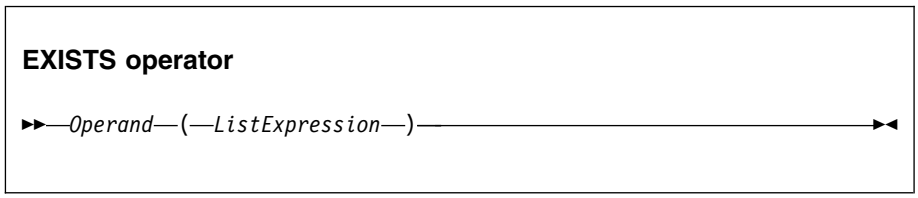
The ASYMMETRIC form is equivalent to:

```
source>= boundary1 AND source <= boundary2
```

The ASYMMETRIC form is simpler but returns only the result that you expect when the first boundary value has a smaller value than the second boundary. It is useful only when the boundary condition expressions are literals.

If the operands are of different types, special rules apply. These rules are described in "Implicit casts" on page 5282.

Operator EXISTS

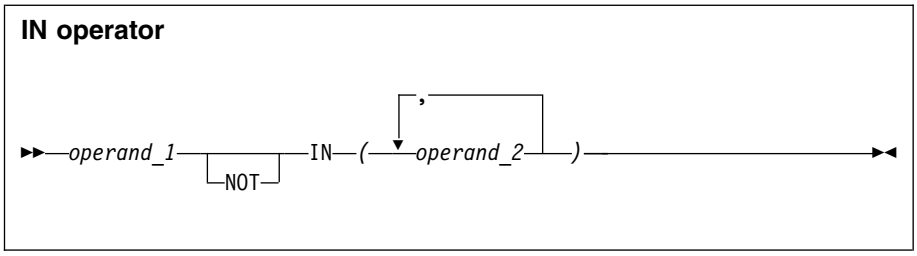


The operator EXISTS returns a Boolean value that indicates whether a SELECT function returned one or more values (TRUE) or none (FALSE).

```
EXISTS(SELECT * FROM something WHERE predicate)
```

Operator IN

Use the operator IN to test whether a value is equal to one of a list of values.



The result is TRUE if the left operand is not NULL and is equal to one of the right operands. The result is FALSE if the left operand is not NULL, and is not equal to one or more of the right operands, none of which have NULL values. Otherwise the result is UNKNOWN. If the operands are of different types, special rules apply. These rules are described in "Implicit casts" on page 5282.

operand_1 must evaluate to a scalar value. *operand_2* can be a sequence of expressions that return scalars of types comparable with *operand_1* or it can be a single expression that returns a LIST. If the LIST is one that is returned from a SELECT function, there can be only a single column in the SelectClause and each ROW in that column is compared with *operand_1* for equality.

The following examples show a sequence of expressions.

- Result1 is set to TRUE because 30 is not present in the given list:

```
SET OutputRoot.XMLNSC.Top.Result1 = 30 NOT IN(34, 42, 45)
```

- Result2 is set to TRUE if the value of var1 is found in var2, var3 or var4:

```
SET OutputRoot.XMLNSC.Top.Result2 = var1 IN(var2, var3, var4);
```

The following examples show a list containing a single column.

- Result3 is set to TRUE if 42 is found in the result set returned from the SELECT statement:

```
SET OutputRoot.XMLNSC.Top.Result3 = 42 IN(
    SELECT A FROM InputRoot.XMLNSC.Top.a[] AS A);
```

- Result4 is set to TRUE because 42 is present in the given list:

```
SET OutputRoot.XMLNSC.Top.Result4 = 42 IN(
    LIST{34,36,37,38,39,40,41,42,43,44});
```

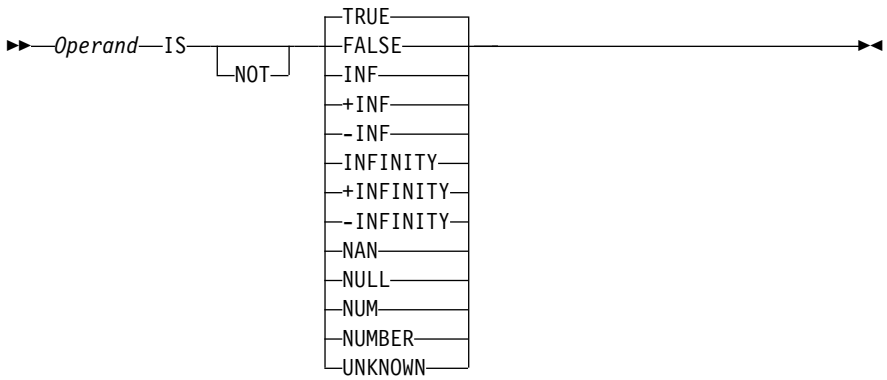
- Result5 is set to TRUE if var1 is found in one of the repeating 'test' elements or its immediate children, if present:

```
SET OutputRoot.XMLNSC.Top.Result5 = var1 IN(
    InputRoot.XMLNSC.Top.test[]);
```

Operator IS

Use the operator IS to test whether an expression has returned a special value.

IS operator



The primary purpose of the IS operator is to test whether a value is NULL. You cannot use the comparison operator (=) to test for a NULL value, because the result of comparing any value with NULL is NULL.

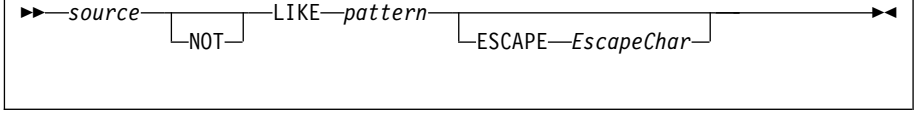
You can also use the IS operand to test for the Boolean values TRUE and FALSE, and to test decimal values for special values. These values are denoted by INF, +INF, -INF, NAN (not a number), and NUM (a valid number) in upper, lower, or mixed case. The alternative forms +INFINITY, -INFINITY, and NUMBER are also accepted.

If applied to non-numeric types, the result is FALSE.

Operator LIKE

Use the LIKE operator to search for strings that match a certain pattern.

LIKE operator



The result is TRUE if none of the operands are NULL and the *source* operand matches the pattern operand. The result is FALSE if none of the operands are NULL and the *source* operand does not match the pattern operand. Otherwise the result is UNKNOWN.

The pattern is specified by a string in which the percent (%) and underscore (_) characters have a special meaning:

- The underscore character matches a single character.

  For example, the following finds matches for IBM and for IGI, but not for International Business Machines or IBM Corp:

  ```
  Body.Trade.Company LIKE 'I__'
  ```

- The percent character % matches a string of zero or more characters.

  For example, the following phrase finds matches for IBM, IGI, International Business Machines, and IBM Corp:

  ```
  Body.Trade.Company LIKE 'I%'
  ```

To use the percent and underscore characters within the expressions that are to be matched, precede the characters with an ESCAPE character, which defaults to the backslash (\) character.

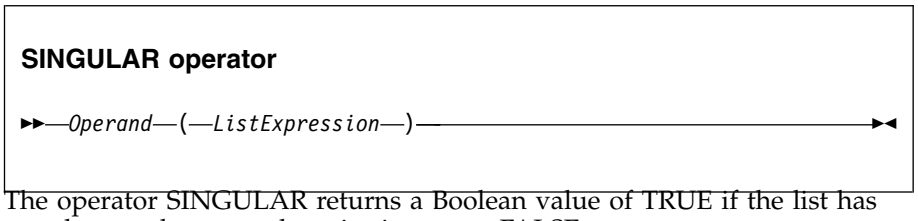
For example, the following predicate finds a match for IBM_Corp.

```
Body.Trade.Company LIKE 'IBM\_Corp'
```

You can specify a different escape character by using the ESCAPE clause. For example, you could also specify the previous example in this way:

```
Body.Trade.Company LIKE 'IBM$_Corp' ESCAPE '$'
```

Operator SINGULAR



The operator SINGULAR returns a Boolean value of TRUE if the list has exactly one element, otherwise it returns FALSE.

ESQL logical operators:

The logical operators AND, OR and NOT.

ESQL provides the following logical operators:

Operator AND
The result is the logical AND of the two operands. Both operands must be Boolean values.

Operator OR
The result is the logical OR of the two operands. Both operands must be Boolean values.

Operator NOT
The result is the logical NOT of the operand, which must be a Boolean value.

NULL and UNKNOWN values are treated as special values by these operators, according to the following rules:

- NULL and UNKNOWN are treated the same.
- If an operand is NULL, the result is NULL unless the operation result is already dictated by the other parameter.

The evaluation of the individual clauses in a statement that includes the AND or OR logical operators is stopped as soon as the overall statement can be resolved. For example, see the following statements:

- `IF A OR B THEN ...`
  - If A is false, B is evaluated.
  - If A is true, B is not evaluated because the statement is already resolved to be true.
- `IF A AND B THEN ...`
  - If A is true, B is evaluated.
  - If A is false, B is not evaluated because the statement is already resolved to be false.

The result of AND and OR operations is defined by the following table:

Value of P	Value of Q	Result of P AND Q	Result of P OR Q
TRUE	TRUE	TRUE	TRUE
TRUE	FALSE	FALSE	TRUE
TRUE	UNKNOWN	UNKNOWN	TRUE
FALSE	TRUE	FALSE	TRUE
FALSE	FALSE	FALSE	FALSE
FALSE	UNKNOWN	FALSE	UNKNOWN
UNKNOWN	TRUE	UNKNOWN	TRUE
UNKNOWN	FALSE	FALSE	UNKNOWN
UNKNOWN	UNKNOWN	UNKNOWN	UNKNOWN

The result of NOT operations is defined by the following table.

Operand	Result of NOT
TRUE	FALSE
FALSE	TRUE
UNKNOWN	UNKNOWN

The numeric operators +, −, *, /, and ||.

"Rules for ESQL operator precedence" on page 5066
How ESQL calculates expressions involving more than one operator.

ESQL numeric operators:

The numeric operators +, −, *, /, and ||.

ESQL provides the following numeric operators:

Unary Operator -
: The result is the negation of the operand (that is, it has the same magnitude as the operand but the opposite sign). You can negate numeric values (INTEGER, DECIMAL and FLOAT) and intervals (INTERVAL).

Operator +
: The result is the sum of the two operands. You can add two numeric values, two intervals, and an interval to a datetime value (DATE, TIME, TIMESTAMP, GMTTIME, and GMTTIMESTAMP).

Operator -
: The result is the difference between the two operands. It is possible to:
  - Subtract one numeric value from another.
  - Subtract one date-time from another. The result is an interval.
  - Subtract one interval from another. The result is an interval.
  - Subtract an interval from a datetime value. The result is a date-time.

When subtracting one date-time from another, you must indicate the type of interval required. You do this by using a qualifier consisting of parentheses enclosing the expression, followed by an interval qualifier. For example:

```
SET OutputRoot.XMLNS.Data.Age  =
          (DATE '2005-03-31' - DATE '1947-10-24') YEAR TO MONTH;
```

Operator *

The result is the product of the two operands. You can multiply numeric values and multiply an interval by a numeric value.

Operator /

The result is the dividend of the two operands. You can divide numeric values and divide an interval by a numeric value.

Operator ||

The result is the concatenation of the two operands. You can concatenate string values (CHARACTER, BIT, and BLOB).

In all cases, if either operand is NULL, the result is NULL. If the operands are of different types, special rules apply. These are described in “Implicit casts” on page 5282.

For examples of how you can use these operators to manipulate datetime values, see “Using numeric operators with datetime values” on page 2439.

"Rules for ESQL operator precedence"
How ESQL calculates expressions involving more than one operator.

Rules for ESQL operator precedence:

How ESQL calculates expressions involving more than one operator.

When an expression involves more than one operator, the order in which the expression is evaluated might affect the result. Consider the following example:

```
SET a = b + c * d;
```

Under ESQL's precedence rules, c is multiplied by d and the result is added to b. This rule states that multiplication takes precedence over addition, so reordering the expression as follows:

```
SET a = c * d + b;
```

makes no difference. ESQL's precedence rules are set out later in this section, but it is generally considered good practice to use parentheses to make the meaning clear. The order of precedence is:

1. Parentheses
2. Unary operators including unary - and NOT
3. Multiplication and division
4. Concatenation
5. Addition and subtraction

Operations at the same level are evaluated from left to right.

ESQL statements:

You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

The following table summarizes the ESQL statements and what they do.

Statement type	Description
Basic statements:	
"BEGIN ... END statement" on page 5070	Gives the statements defined within the BEGIN and END keywords the status of a single statement.
"CALL statement" on page 5077	Invokes a user-written routine that has been defined using a CREATE FUNCTION or CREATE PROCEDURE statement.
"CASE statement" on page 5081	Uses rules defined in WHEN clauses to select a block of statements to execute.
"CREATE FUNCTION statement" on page 5091	Like CREATE PROCEDURE, CREATE FUNCTION defines a user-written routine. (The few differences between CREATE FUNCTION and CREATE ROUTINE are described in the reference material.)
"CREATE MODULE statement" on page 5101	Creates a module (a named container associated with a node).
"CREATE PROCEDURE statement" on page 5103	Like CREATE FUNCTION, CREATE PROCEDURE defines a user-written routine. (The few differences between CREATE FUNCTION and CREATE ROUTINE are described in the reference material.)

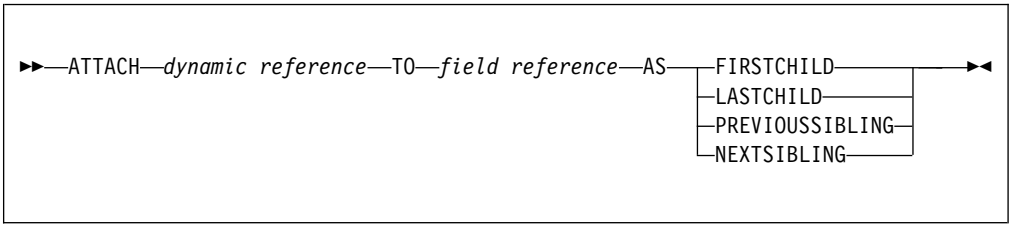
Statement type	Description
“DECLARE statement” on page 5117	Declares one or more variables that can be used to store temporary values.
“IF statement” on page 5134	Processes a set of statements based on the result of evaluating condition expressions.
“ITERATE statement” on page 5139	Abandons processing the current iteration of the containing WHILE, REPEAT, LOOP, or BEGIN statement, and might start the next iteration.
“LEAVE statement” on page 5140	Abandons processing the current iteration of the containing WHILE, REPEAT, LOOP or BEGIN statement, and stops looping.
“LOOP statement” on page 5144	Processes a sequence of statements repeatedly and unconditionally.
“REPEAT statement” on page 5154	Processes a sequence of statements, then evaluates a condition expression. If the expression evaluates to TRUE, executes the statements again.
“RETURN statement” on page 5155	Stops processing the current function or procedure and passes control back to the caller.
“SET statement” on page 5159	Evaluates a source expression, and assigns the result to the target entity.
“THROW statement” on page 5161	Generates a user exception.
“WHILE statement” on page 5167	Evaluates a condition expression, and if it is TRUE executes a sequence of statements.
Message tree manipulation statements:	
“ATTACH statement” on page 5069	Attaches a portion of a message tree into a new position in the message hierarchy.
“CREATE statement” on page 5082	Creates a new message field.
“DELETE statement” on page 5129	Detaches and destroys a portion of a message tree, allowing its memory to be reused.
“DETACH statement” on page 5130	Detaches a portion of a message tree without deleting it.
“FOR statement” on page 5133	Iterates through a list (for example, a message array).
“MOVE statement” on page 5145	Changes the field pointed to by a target reference variable.
Database update statements:	
“DELETE FROM statement” on page 5127	Deletes rows from a table in an external database based on a search condition.
“INSERT statement” on page 5135	Adds a new row to an external database.
“PASSTHRU statement” on page 5147	Takes a character value and passes it as an SQL statement to an external database.
“UPDATE statement” on page 5163	Updates the values of specified rows and columns in a table in an external database.
Node interaction statements:	

Statement type	Description
"PROPAGATE statement" on page 5150	Propagates a message to the downstream nodes within the message flow.
Other statements:	
"BROKER SCHEMA statement" on page 5073	This statement is optional and is used in an ESQL file to explicitly identify the schema that contains the file.
"DECLARE HANDLER statement" on page 5124	Declares an error handler.
"EVAL statement" on page 5131	Takes a character value, interprets it as an SQL statement, and executes it.
"LOG statement" on page 5142	Writes a record to the event or user trace log.
"RESIGNAL statement" on page 5155	Re-throws the current exception (if any). This is used by an error handler, when it cannot handle an exception, to give an error handler in higher scope the opportunity of handling the exception.

ATTACH statement:

The ATTACH statement attaches a portion of a message tree into a new position in the message hierarchy.

Syntax



The following example illustrates how to use the ATTACH statement, together with the DETACH statement described in "DETACH statement" on page 5130, to modify a message structure. The dynamic reference supplied to the DETACH statement must point to a modifiable message tree such as Environment, LocalEnvironment, OutputRoot, OutputExceptionList, or InputLocalEnvironment.

There are some limitations on the use of ATTACH. In general, elements detached from the output trees of a Compute node are not attached to the environment or to input trees.

For example, if you take the following message:

```
<Data>
  <Order>
    <Item>cheese
        <Type>stilton</Type>
    </Item>
    <Item>bread</Item>
  </Order>
  <Order>
```

```
    <Item>garlic</Item>
    <Item>wine</Item>
  </Order>
 </Data>
```

the following ESQL statements:

```
SET OutputRoot = InputRoot;
DECLARE ref1 REFERENCE TO OutputRoot.XMLNSC.Data.Order[1].Item[1];
DETACH ref1;
ATTACH ref1 TO OutputRoot.XMLNSC.Data.Order[2] AS LASTCHILD;
```

result in the following new message structure:

```
<Data>
  <Order>
     <Item>bread</Item>
  </Order>
  <Order>
     <Item>garlic</Item>
     <Item>wine</Item>
     <Item>cheese
        <Type>stilton</Type>
     </Item>
  </Order>
 </Data>
```

For information about dynamic references see “Creating dynamic field references” on page 2431.

The DETACH statement detaches a portion of a message tree without deleting it. This portion can be reattached using the ATTACH statement.

BEGIN ... END statement:

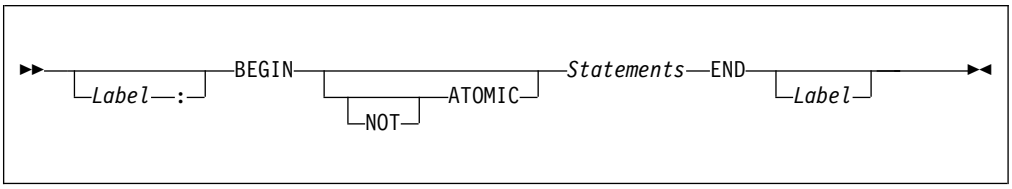
The BEGIN ... END statement gives the statements defined within the BEGIN and END keywords the status of a single statement.

This allows the contained statements to:

- Be the body of a function or a procedure
- Have their exceptions handled by a handler

- Have their execution discontinued by a LEAVE statement

Syntax



The second *Label* can be present only if the first *Label* is present. If both labels are present, they must be identical. Two or more labeled statements at the same level can have the same label, but this partly negates the advantage of the second label. The advantage is that the labels unambiguously and accurately match each END with its BEGIN. However, a labeled statement nested within *Statements* cannot have the same label, because this makes the behavior of the ITERATE and LEAVE statements ambiguous.

Scope of variables

A new local variable scope is opened immediately after the opening BEGIN and, therefore, any variables declared within this statement go out of scope when the terminating END is reached. If a local variable has the same name as an existing variable, any references to that name that occur after the declaration access the local variable. For example:

```
DECLARE Variable1 CHAR 'Existing variable';

-- A reference to Variable1 here returns 'Existing variable'

BEGIN
  -- A reference to Variable1 here returns 'Existing variable'

  DECLARE Variable1 CHAR 'Local variable';  -- Perfectly legal even though
the name is the same

  -- A reference to Variable1 here returns 'Local variable'
END;
```

ATOMIC

If ATOMIC is specified, only one instance of a message flow (that is, one thread) is allowed to execute the statements of a specific BEGIN ATOMIC... END statement (identified by its schema and label), at any one time. If no label is present, the behavior is as if a zero length label had been specified.

The BEGIN ATOMIC construct is useful when a number of changes need to be made to a shared variable and it is important to prevent other instances seeing the intermediate states of the data. Consider the following code example:

```
CREATE PROCEDURE WtiteSharedVariable1(IN NewValue CHARACTER)
SharedVariableMutex1 : BEGIN ATOMIC
  -- Set new value into shared variable
END;

CREATE FUNCTION ReadSharedVariable1() RETURNS CHARACTER
SharedVariableMutex1 : BEGIN ATOMIC
```

```
  DECLARE Value CHARACTER;
  -- Get value from shared variable
  RETURN Value;
END;
```

The last example assumes that the procedure `WriteSharedVariable1` and the function `ReadSharedVariable1` are in the same schema and are used by nodes within the same flow. However, it does not matter whether or not the procedure and function are contained within modules, or whether they are used within the same or different nodes. The broker ensures that, at any particular time, only one thread is executing any of the statements within the atomic sections. This ensures that, for example, two simultaneous writes or a simultaneous read and write are executed serially. Note that:

- The serialization is limited to the flow. Two flows which use BEGIN ATOMIC... END statements with the same schema and label can be executed simultaneously. In this respect, multiple instances within a flow and multiple copies of a flow are not equivalent.
- The serialization is limited by the schema and label. Atomic BEGIN ... END statements specified in different schemas or with different labels do not interact with each other.

Note: You can look at this in a different way, if you prefer. For each combination of message flow, schema, and label, the broker has a mutex that prevents simultaneous access to the statements associated with that mutex.

Do not nest BEGIN ATOMIC... END statements, either directly or indirectly, because this could lead to "deadly embraces". For this reason, do not use a PROPAGATE statement from within an atomic block.

It is not necessary to use the BEGIN ATOMIC construct in flows that will never be deployed with more than one instance (but it might be unwise to leave this to chance). It is also unnecessary to use the BEGIN ATOMIC construct on reads and writes to shared variables. The broker always safely writes a new value to, and safely reads the latest value from, a shared variable. ATOMIC is only required when the application is sensitive to seeing intermediate results.

Consider the following example:

```
DECLARE LastOrderDate SHARED DATE;
...
SET LastOrderDate = CURRENT_DATE;
...
SET OutputRoot.XMLNSC.Data.Orders.Order[1].Date = LastOrderDate;
```

Here we assume that one thread is periodically updating `LastOrderDate` and another is periodically reading it. There is no need to use ATOMIC, because the second SET statement always reads a valid value. If the updating and reading occur very closely in time, whether the old or new value is read is indeterminate, but it is always one or the other. The result will never be garbage.

But now consider the following example:

```
DECLARE Count SHARED INT;
...
SET Count = Count + 1;
```

Here we assume that several threads are periodically executing the SET statement. In this case you do need to use ATOMIC, because two threads might read `Count` in

almost the same instant, and get the same value. Both threads perform the addition and both store the same value back. The end result is thus N+1 and not N+2.

The broker does not automatically provide higher-level locking than this (for example, locking covering the whole SET statement), because such locking is liable to cause “deadly embraces”.

Hint

You can consider the BEGIN ... END statement to be a looping construct, which always loops just once. The effect of an ITERATE or LEAVE statement nested within a BEGIN ... END statement is then as you would expect: control is transferred to the statement following the END. Using ITERATE or LEAVE within a BEGIN ... END statement is useful in cases where there is a long series of computations that needs to be abandoned, either because a definite result has been achieved or because an error has occurred.

BROKER SCHEMA statement:

The BROKER SCHEMA statement is optional; use it in an ESQL file to explicitly identify the schema that contains the file.

Syntax

An ESQL schema is a named container for functions, procedures, modules, and variables. ESQL schema is similar to the namespace concept of C++, XML, and .NET, and to the package concept of Java.

In the absence of a BROKER SCHEMA statement, all functions, procedures, modules, and constants belong to the default schema. The default schema is similar to the default namespace in C++, the no-target namespace in XML Schema, and the default package in Java.

You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

"CREATE MODULE statement" on page 5101
The CREATE MODULE statement creates a module, which is a named container associated with a node.

PATH clause:

The PATH clause specifies a list of additional schemas to be searched when matching function and procedure calls to their implementations. The schema in which the call lies is implicitly included in the PATH clause.

The PATH clause is used to resolve unqualified function and procedure names in the tools according to the following algorithm.

A single function or procedure must match the unqualified name, or the tools report an error. You can correct the error by qualifying the function or procedure name with a *schemaId*:

1. The current module (if any) is searched for a matching function or procedure. Module-scope functions or procedures are visible only within their containing module. If functions or procedures with the same name are found in the current module and schema, module-scope functions or procedures take precedence over schema scoped functions or procedures.
2. The <node schema> (but none of its contained modules) and the <SQL-broker schema> or schemas identified by the PATH clause are searched for a matching function or procedure.

Note: The *schemaId* must be a fully qualified schema name.

When you start a function or procedure, the name that you use must be qualified by the schema name. The behavior depends on the circumstances:

For a module routine:

- If the schema is specified, the named schema routine is started. The scalar built-in functions, excluding CAST, EXTRACT, and the special registers, are considered to be defined within an implicitly declared schema called SQL.
- If the schema is not specified, and the calling statement is in a module routine, and a routine of the given name exists in the local module, then that local routine is started.
- If the schema is not specified, and the calling statement is in a module routine, and a routine of the given name does not exist in the local module, then all of the schemas in the schema path are searched for a routine of the same name.

  If a matching function exists in one schema, it is used. A compile-time error occurs if a matching function exists in more than one schema. If there is no matching function, then the schema SQL is searched.

  This rule and the preceding rule imply that a local module routine takes priority over a built-in routine of the same name.

For a schema routine:

- If the schema is specified, the named schema routine is started. The scalar built-in functions, excluding CAST, EXTRACT, and the special registers, are considered to be defined within an implicitly declared schema called SQL.

- If the schema is not specified, and the caller is a schema routine, and a routine of the given name exists in the local schema, that local routine is started.
- If the schema is not specified, and the calling statement is in a schema routine, and a routine of the given name does not exist in the local schema, then all of the schemas in the schema path are searched for a routine of the same name.

  If a matching function exists in one schema, it is used. A compile-time error occurs if a matching function exists in more than one schema. If there is no matching function, the schema SQL is searched.

  This rule and the preceding rule imply that a local schema routine takes priority over a built-in routine of the same name.

The <node schema> is defined as the schema containing the node's message flow.

The <node schema> is specified in this manner to provide compatibility with earlier versions of WebSphere Message Broker.

When the <node schema> is the only schema referenced, the broker XML message does not include the extra features contained in WebSphere Message Broker V6.1.

Brokers in previous versions of WebSphere Message Broker do not support multiple schemas, for example, subroutine libraries for reuse. To deploy to a broker in a previous version of the product, put all of the ESQL subroutines into the same schema as the message flow and node that start the ESQL subroutines.

Eclipse tooling uses WebSphere Message Broker V6.1 ESQL syntax in content assist and source code validation.

The broker schema of the message flow must contain, at the schema level, any of the following in its ESQL files:
- A schema level function
- A schema level procedure
- A schema level constant
- A module level constant
- A module level variable

Without the presence of any of the preceding items, the Eclipse tooling generates broker ESQL without module and funtion Main wrappers.

Function and procedure names must be unique within their schema or module.

Examples

The following example adds a path to a schema called CommonUtils:

```
BROKER SCHEMA CommonUtils
PATH SpecialUtils;

MODULE ....
```

The next example adds a path to the default schema:

```
PATH CommonUtils, SpecialUtils;

MODULE ....
```

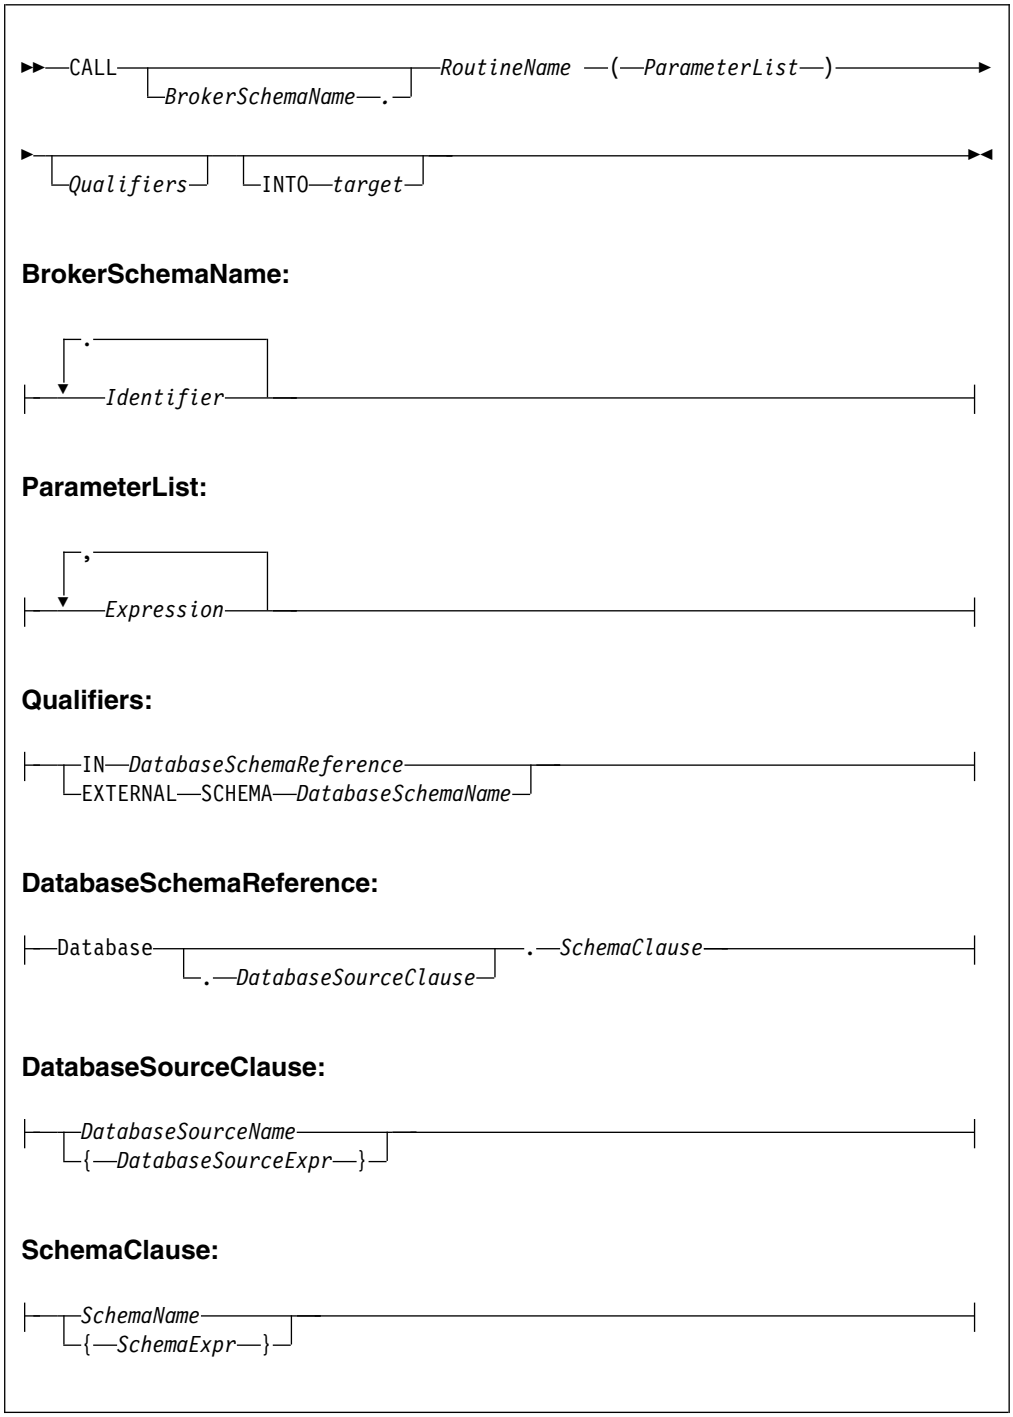
"CREATE MODULE statement" on page 5101
The CREATE MODULE statement creates a module, which is a named container associated with a node.

CALL statement:

The CALL statement calls (invokes) a routine.

Syntax



Using the CALL statement

The CALL statement invokes a routine. A routine is a user-defined function or procedure that has been defined by one of the following:

- A CREATE FUNCTION statement
- A CREATE PROCEDURE statement

As well as standard user-defined functions and procedures, you can also use CALL to invoke built-in (broker-provided) functions and user-defined SQL functions. However, the usual way of invoking these types of function is simply to include their names in expressions.

The called routine must be invoked in a way that matches its definition. For example, if you have defined a routine with three parameters, the first two of type integer and the third of type character, the CALL statement must pass three variables to the routine, each of a data type that matches the definition. This technique is called *exact signature matching*, which means that the signature provided by the CALL statement must match the signature provided by the definition of the routine.

Exact signature matching also applies to the value returned to a routine. If the RETURNS clause is specified on the CREATE FUNCTION statement, or the routine is a built-in function, the INTO clause must be specified on the CALL statement. A return value from a routine cannot be ignored. Conversely, if the RETURNS clause is not specified on the CREATE FUNCTION statement, the INTO clause must not be specified, because there is no return value from the routine.

You can use the CALL statement to invoke a routine that has been implemented in all the following ways:
- ESQL.
- Java.
- As a stored procedure in a database.
- As a built-in (broker-provided) function (although as stated earlier, names are typically included in expressions).

This variety of implementation means that some of the clauses in the CALL syntax diagram are not applicable (or allowed) for all types of routine. It also allows the CALL statement to invoke any type of routine, irrespective of how the routine has been defined.

When the optional *BrokerSchemaName* parameter is not specified, the broker SQL parser searches for the named procedure using the algorithm described in the PATH statement (see the "PATH clause" on page 5075 of the BROKER SCHEMA statement).

When the *BrokerSchemaName* parameter is specified, the broker SQL parser invokes the named procedure in the specified schema without first searching the path. However, if a procedure reference is ambiguous (that is, there are two procedures with the same name in different broker schemas) and the reference is not qualified by the optional *BrokerSchemaName*, the Eclipse toolset generates an error in the Problems view that you must correct to deploy the ambiguous code.

The broker-provided built-in functions are automatically placed in a predefined broker schema called SQL. The SQL schema is always searched last for a routine that has not been matched to a user-defined routine. Therefore, a user-defined module takes precedence over a built-in routine of the same name.

Each broker schema provides a unique symbol or namespace for a routine, so a routine name is unique when it is qualified by the name of the schema to which it belongs.

The INTO clause is used to store the return value from a routine that has been defined with a RETURNS clause, or from a built-in function. The *target* can be an

ESQL variable of a data type that matches the data type on the RETURNS clause, or a dot-separated message reference. For example, both of the following ESQL statements are valid:

```
CALL myProc1() INTO cursor;
CALL myProc1() INTO OutputRoot.XMLNS.TestValue1;
```

The CALL statement passes the parameters into the procedure in the order given to it. Parameters that have been defined as IN or INOUT on the routine's definition are evaluated before the CALL is made, but parameters defined as OUT are always passed in as NULL parameters of the correct type. When the procedure has completed, any parameters declared as OUT or INOUT are updated to reflect any changes made to them during the procedure's execution. Parameters defined as IN are never changed during the cause of a procedure's execution.

Routine overloading is not supported, which means that you cannot create two routines of the same name in the same broker schema. If the broker detects that a routine has been overloaded, it raises an exception. Similarly, you cannot invoke a database stored procedure that has been overloaded. A database stored procedure is overloaded if another procedure of the same name exists in the same database schema. However, you can invoke an overloaded Java method, provided that you create a separate ESQL definition for each overloaded method you want to call, and give each ESQL definition a unique routine name.

Related concepts:

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

"Invoking stored procedures" on page 2503
To invoke a procedure that is stored in a database, use the ESQL CALL statement. The stored procedure must be defined by a CREATE PROCEDURE statement that has a Language clause of DATABASE and an EXTERNAL NAME clause that identifies the name of the procedure in the database and, optionally, the database schema to which it belongs.

Related reference:

"Syntax diagrams" on page 3677

"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

"CREATE PROCEDURE statement" on page 5103
The CREATE PROCEDURE statement defines a callable function or procedure.

"BROKER SCHEMA statement" on page 5073
The BROKER SCHEMA statement is optional; use it in an ESQL file to explicitly identify the schema that contains the file.

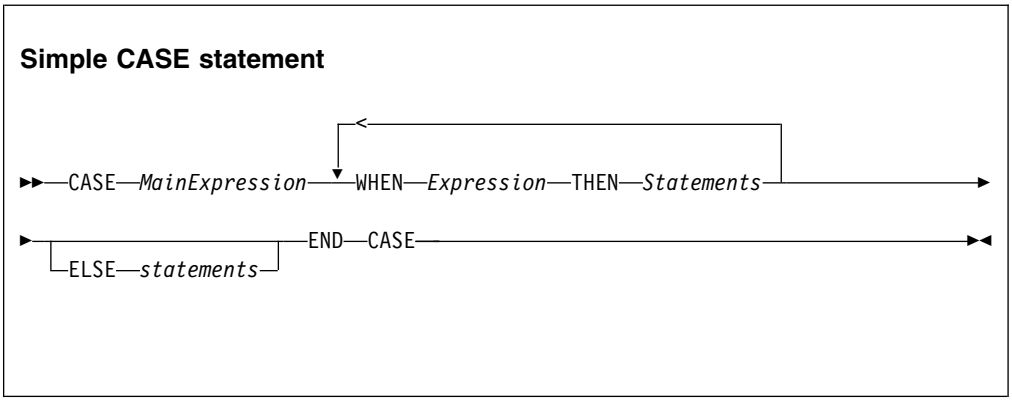
"PATH clause" on page 5075
The PATH clause specifies a list of additional schemas to be searched when matching function and procedure calls to their implementations. The schema in which the call lies is implicitly included in the PATH clause.

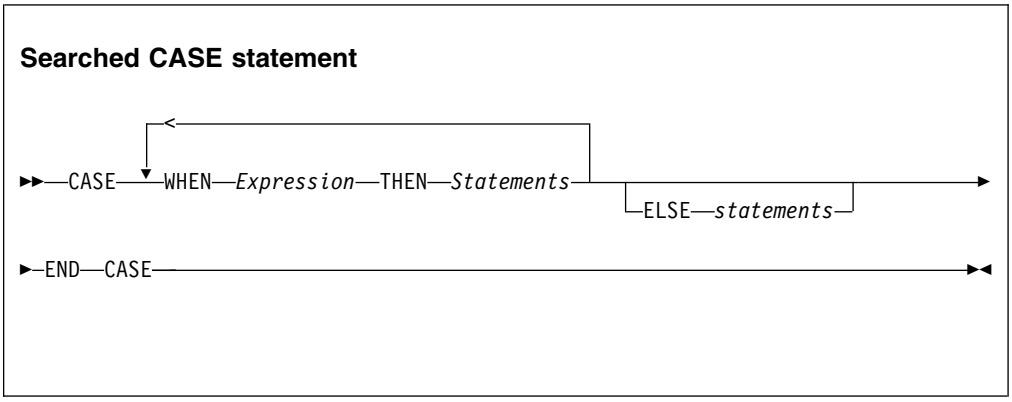
CASE statement:

The CASE statement uses rules defined in WHEN clauses to select a block of statements to process.

There are two forms of the CASE statement: the simple form and the searched form.

Syntax





In the simple form, the main expression is evaluated first. Each WHEN clause expression is evaluated in turn until the result is equal to the main expression's result. That WHEN clause's statements are then processed. If no match is found and the optional ELSE clause is present, the ELSE clause's statements are executed instead. The test values do not have to be literals. The only requirement is that the main expression and the WHEN clause expressions evaluate to types that can be compared.

In the searched form, each WHEN clause expression is evaluated in turn until one evaluates to TRUE. That WHEN clause's statements are then executed. If none of the expressions evaluates to TRUE and the optional ELSE clause is present, the ELSE clause's statements are executed. There does not have to be any similarity between the expressions in each CASE clause. The only requirement is that they all evaluate to a Boolean value.

The ESQL language has both a CASE statement and a CASE function (see "CASE function" on page 5243 for details of the CASE function). The CASE statement

chooses one of a set of statements to execute. The CASE function chooses one of a set of expressions to evaluate and returns as its value the return value of the chosen expression.

Examples

Simple CASE statement:

```
CASE size
  WHEN minimum + 0 THEN
    SET description = 'small';
  WHEN minimum + 1 THEN
    SET description = 'medium';
  WHEN minimum + 2 THEN
    SET description = 'large';
    CALL handleLargeObject();
  ELSE
    SET description = 'unknown';
    CALL handleError();
END CASE;
```

Searched CASE statement:

```
CASE
 WHEN i <> 0 THEN
    CALL handleI(i);
  WHEN j> 1 THEN
    CALL handleIZeroAndPositiveJ(j);
  ELSE
    CALL handleAllOtherCases(j);
END CASE;
```

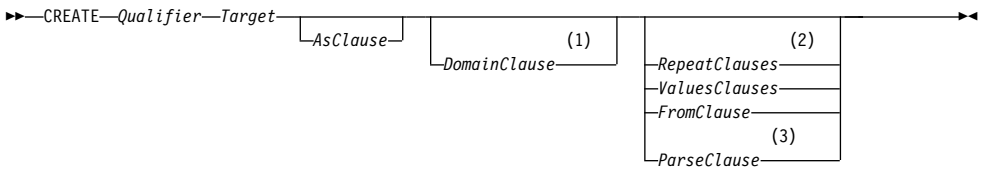
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

"CASE function" on page 5243
CASE is a complex function that has two forms; the simple-when form and the searched-when form. In either form CASE returns a result, the value of which controls the path of subsequent processing.

CREATE statement:

The CREATE statement creates a new message field.

Syntax



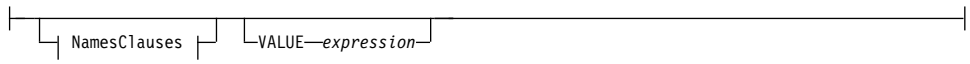
Qualifier:

AsClause:

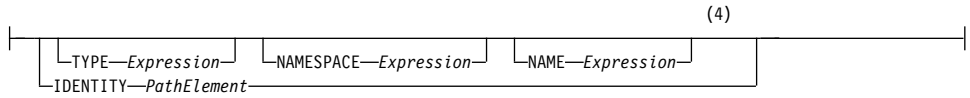
DomainClause:

RepeatClauses:

ValuesClauses:

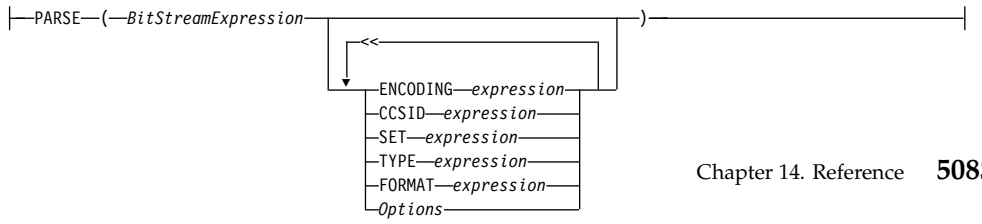


NamesClauses:



FromClause:

ParseClause:



Options:

Notes:

1 Do not use the *DomainClause* and *ParseClause* with the **FIELD** qualifier.

2 Use the *RepeatClauses* only with the **PREVIOUSSIBLING** and **NEXTSIBLING** qualifiers.

3 Each subclause within the *ParseClause* can occur once only.

4 If present, the TYPE, NAMESPACE, and NAME elements must appear in the order shown in the railroad diagram.

The new message field is positioned either at a given location (CREATE FIELD) or relative to a currently existing location (CREATE ... OF...). New fields can be created only when the target field reference points to a modifiable message; for example, Environment, InputLocalEnvironment, OutputLocalEnvironment, OutputRoot, or OutputExceptionList.

If you include a FIELD clause, the field that is specified by Target is navigated to (creating the fields, if necessary) and any values clause, or from clause, is processed. Including a FIELD clause does not necessarily create any fields; it ensures only that the given fields exist.

If you use array indexes in the target field reference, only one instance of a particular field can be created. Therefore, if you write a SET statement that starts:

```
SET OutputRoot.XMLNS.Message.Structure[2].Field = ...
```

at least one instance of Structure must already exist in the message. That is, the only fields in the tree that are created are ones on a direct path from the root to the field identified by the field reference.

If you include a PREVIOUSSIBLING, NEXTSIBLING, FIRSTCHILD, or LASTCHILD clause, the field that is specified by Target is navigated to (creating the fields if necessary) in exactly the same way as for the FIELD clause. A new field is then created and attached in the specified position (for example, as PREVIOUSSIBLING or FIRSTCHILD). A CREATE statement with one of these clauses always creates a new field, and places it in the specified position.

If you use two CREATE FIRSTCHILD OF target statements that specify the same target, the second statement creates a new field as the first child of the target, and displaces the previously created first child to the right in the message tree (so that it is no longer the first child). Similarly, CREATE LASTCHILD OF target navigates to the target field and adds a new field as its rightmost child, displacing the previous last child to the left.

CREATE PREVIOUSSIBLING OF Target creates a field to the immediate left of the field that is specified by Target (so the depth of the tree is not changed); similarly, CREATE NEXTSIBLING OF Target creates a field to the immediate right of the

field that is specified by Target. When creating PREVIOUSSIBLING or NEXTSIBLING, you can use the REPEAT keyword to copy the type and name of the new field from the current field.

AS clause:

If present, the AS clause moves the named reference variable to point at the newly-created field. Use this clause if you want to involve the new field in some further processing.

DOMAIN clause:

If present, the DOMAIN clause associates the new field with a new parser of the specified type. This clause expects a root field name (for example, XMLNS or MQRFH2). If the DOMAIN clause is present, but the value supplied is a zero-length character string, a new parser of the same type as the parser that owns the field specified by target is created. An exception is thrown if the supplied domain name is not CHARACTER data type or its value is NULL. Do not specify the DOMAIN clause with the FIELD clause; it is not certain that a new field is created.

REPEAT clause:

Use the REPEAT clause to copy the new field's type and name from the target field. Alternatively, the new field's type, name, and value can be:

- Copied from any existing field (using the FROM clause)
- Specified explicitly (using the VALUES clause)
- Defined by parsing a bit stream (using the PARSE clause)

In the case of the FROM and PARSE clauses, you can also create children of the new field.

VALUES clause:

For the VALUES clause, the type, name, and value (or any subset of these) can be specified by any expression that returns a suitable data type (INTEGER for type, CHARACTER for name, and any scalar type for value). An exception is thrown if the value supplied for a type or name is NULL.

NAMES clause:

The NAMES clause takes any expression that returns a non-null value of type character. The meaning depends on the presence of NAME and NAMESPACE clauses as follows:

NAMESPACE	NAME	Element named as follows
No	No	The element is nameless (the name flag is not automatically set).
No	Yes	The element is given the name in the default namespace.
Yes	No	The element is given the empty name in the given namespace.
Yes	Yes	The element is given the given name in the given namespace.

The IDENTITY operand takes a single path element in place of the TYPE and NAME clauses, where a path element contains (at most) a type, a namespace, a name, and an index. These elements specify the type, namespace, name, and index of the element to be created and follow all the rules described in the topic for field references (see "ESQL field reference overview" on page 5049). For example:

```
IDENTITY (XMLNS.attribute)Space1:Name1[42]
```

See the following Examples section for information about how to use the IDENTITY operand.

FROM clause:

For the FROM clause, the new field's type, name, and value are taken from the field pointed to by *SourceFieldReference*. Any existing child fields of the target are detached (the field might already exist in the case of a FIELD clause), and the new field is given copies of the source field's children.

PARSE clause:

If a PARSE clause is present, a subtree is built under the newly-created field from the supplied bit stream. The algorithm for building the subtree varies from parser to parser and according to the options specified. All parsers support the mode RootBitStream, in which the tree creation algorithm is the same as that used by an input node.

Some parsers also support a second mode, FolderBitStream, which generates a sub tree from a bit stream created by the ASBITSTREAM function (see "ASBITSTREAM function" on page 5224) that is using that mode.

When you use the PARSE clause, specify a scalar value containing the bit stream that is to be parsed for *BitStreamExpression*. If you use a message tree field reference you must ensure it contains a scalar value that contains the bit stream. An existing message body folder such as `InputRoot.XMLNSC` does not contain a bit stream and therefore cannot be used this to serialize the `XMLNS` folder. If you pass a value other than a scalar containing the bit stream to the PARSE clause for *BitStreamExpression*, the message flow produces a `BIP2906` error message. Instead, you must first call the ASBITSTREAM function to serialize the existing message tree folder. The result of the ASBITSTREAM function can then be passed as the *BitStreamExpression* to the PARSE clause.

The following example shows how to serialize the XMLNSC folder, then use the result of the ASBITSTREAM in the PARSE clause.

```
DECLARE inCCSID INT InputProperties.CodedCharSetId;
DECLARE inEncoding INT InputProperties.Encoding;
DECLARE inBitStream BLOB ASBITSTREAM(InputRoot.XMLNSC, inEncoding, inCCSID);
CREATE LASTCHILD OF OutputRoot DOMAIN('MRM')
       PARSE(inBitStream, inEncoding, inCCSID, 'DP3UK14002001',
             'TestCase', 'XML1', options);
```

When the PARSE statement is processed, any PARSE clause expressions are evaluated. An exception is thrown if any of the following expressions do not result in a non-null value of the appropriate type:

Clause	Type	Default value
OPTIONS	Integer	RootBitStream & ValidateNone
ENCODING	Integer	0

Clause	Type	Default value
CCSID	Integer	0
SET	Character	Zero length string
TYPE	Character	Zero length string
FORMAT	Character	Zero length string

For details of the syntax of the TYPE clause, see "Specifying namespaces in the Message Type property" on page 1208.

Although the OPTIONS clause accepts any expression that returns a value of type integer, it is only meaningful to generate option values from the list of supplied constants, using the BITOR function if more than one option is required.

Once generated, the value becomes an integer and you can save it in a variable or pass it as a parameter to a function, as well as using it directly with a CREATE statement. The list of globally defined constants is:

```
Validate master options...
ValidateContentAndValue
ValidateValue  -- Can be used with ValidateContent
ValidateContent  -- Can be used with ValidateValue
ValidateNone

Validate failure action options...
ValidateException
ValidateExceptionList
ValidateLocalError
ValidateUserTrace

Validate timing options...
ValidateComplete
ValidateImmediate
ValidateDeferred
```

Notes:

1. For full details of the validation options, refer to "Validation properties" on page 4169.
2. The *Validate timing options* correspond to *Parse Timing options* and, in particular, *ValidateDeferred* corresponds to *Parse Timing On Demand*.

C and Java equivalent APIs

Note that equivalent options are not available on:

- The Java plugin node API MBElement methods **createElementAsLastChildFromBitstream()** and **toBitstream()**
- The C plugin node API methods **cniCreateElementAsLastChildFromBitstream()** and **cniElementAsBitstream**.

You can specify only one option from each group, with the exception of ValidateValue and ValidateContent, which you can use together to obtain the content and value validation. If you do not specify an option within a group, the option in bold is used.

The ENCODING clause accepts any expression that returns a value of type integer. However, it is only meaningful to generate option values from the list of supplied constants:

```
MQENC_INTEGER_NORMAL
MQENC_INTEGER_REVERSED
MQENC_DECIMAL_NORMAL
MQENC_DECIMAL_REVERSED
MQENC_FLOAT_IEEE_NORMAL
MQENC_FLOAT_IEEE_REVERSED
MQENC_FLOAT_S390
```

The values used for the CCSID clause follow the normal numbering system. For example, 1200 = UCS-2, 1208 = UTF-8.

For absent clauses, the given default values are used. Use the CCSID and encoding default values because these take their values from the queue manager's encoding and CCSID settings.

Similarly, using the default values for each of the message set, type, and format options is useful, because many parsers do not require message set, type, or format information, and so any valid value is sufficient.

When any expressions have been evaluated, a bit stream is parsed using the results of the expressions.

Note: Because this function has a large number of clauses, an alternative syntax is supported, in which the parameters are supplied as a comma-separated list rather than by named clauses. In this case the expressions must be in the order:

```
ENCODING -> CCSID -> SET -> TYPE -> FORMAT -> OPTIONS
```

The list can be truncated at any point and an entirely empty expression can be used in any clauses where you do not supply a value.

Examples of how to use the CREATE statement

1. The following example creates the specified field:

   ```
   CREATE FIELD OutputRoot.XMLNS.Data;
   ```

2. The following example creates a field with no name, type, or value as the first child of `ref1`:

   ```
   CREATE FIRSTCHILD OF ref1;
   ```

3. The following example creates a field using the specified type, name, and value:

   ```
   CREATE NEXTSIBLING OF ref1 TYPE NameValue NAME 'Price' VALUE 92.3;
   ```

4. The following example creates a field with a type and name, but no value; the field is added before the sibling indicated by the dynamic reference (`ref1`):

   ```
   CREATE PREVIOUSSIBLING OF ref1 TYPE Name NAME 'Quantity';
   ```

5. The following example creates a field named Component, and moves the reference variable targetCursor to point at it:

   ```
   CREATE FIRSTCHILD OF targetCursor AS targetCursor NAME 'Component';
   ```

6. The following example creates a new field as the right sibling of the field pointed to by the reference variable targetCursor having the same type and name as that field. The statement then moves targetCursor to point at the new field:

   ```
   CREATE NEXTSIBLING OF targetCursor AS targetCursor REPEAT;
   ```

7. The following example shows how to use the PARSE clause:

```
DECLARE bodyBlob BLOB ASBITSTREAM(InputRoot.XMLNS, InputProperties.Encoding,
 InputProperties.CodedCharSetId);
DECLARE creationPtr REFERENCE TO OutputRoot;
CREATE LASTCHILD OF creationPtr DOMAIN('XMLNS') PARSE(bodyBlob,
                    InputProperties.Encoding,
 InputProperties.CodedCharSetId);
```

This example can be extended to show the serializing and parsing of a field or folder:

```
DECLARE bodyBlob BLOB ASBITSTREAM(InputRoot.XMLNS.TestCase.myFolder,
                    InputProperties.Encoding,
InputProperties.CodedCharSetId,",",",",FolderBitStream);
DECLARE creationPtr REFERENCE TO OutputRoot;
CREATE LASTCHILD OF creationPtr DOMAIN('XMLNS') PARSE(bodyBlob,
                    InputProperties.Encoding,
InputProperties.CodedCharSetId,",",",",FolderBitStream);
```

8. The following example shows how to use the IDENTITY operand:

```
CREATE FIELD OutputRoot.XMLNS.TestCase.Root IDENTITY (XML.ParserRoot)Root;
CREATE FIELD OutputRoot.XMLNS.TestCase.Root.Attribute
       IDENTITY (XML.Attribute)NSpace1:Attribute VALUE 'Attrib Value';
CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Root
       IDENTITY (XML.Element)NSpace1:Element1[1] VALUE 'Element 1 Value';
CREATE LASTCHILD OF OutputRoot.XMLNS.TestCase.Root
       IDENTITY (XML.Element)NSpace1:Element1[2] VALUE 'Element 2 Value';
```

This produces the following output message:

```
<TestCase>
 <Root xmlns:NS1="NSpace1" NS1:Attribute="Attrib Value">
  <NS1:Element1>Element 1 Value</NS1:Element1>
  <NS1:Element1>Element 2 Value</NS1:Element1>
 </Root>
</TestCase>
```

9. The following example shows how you can use the DOMAIN clause to avoid losing information unique to the XMLNS parser when an unlike parser copy occurs:

```
DECLARE bodyBlob BLOB ASBITSTREAM(InputRoot.XMLNS, InputProperties.Encoding,
InputProperties.CodedCharSetId);
CREATE FIELD Environment.Variables.myXMLTree;
DECLARE creationPtr REFERENCE TO Environment.Variables.myXMLTree;
CREATE FIRSTCHILD OF creationPtr DOMAIN('XMLNS') PARSE(bodyBlob,
                   InputProperties.Encoding,
InputProperties.CodedCharSetId);
```

An example of a CREATE statement

This example provides sample ESQL and an input message, which together produce the output message at the end of the example.

```
CREATE COMPUTE MODULE CreateStatement_Compute
 CREATE FUNCTION Main() RETURNS BOOLEAN
 BEGIN
   CALL CopyMessageHeaders();

       CREATE FIELD OutputRoot.XMLNS.TestCase.description TYPE NameValue VALUE 'This is my TestCase' ;
       DECLARE cursor REFERENCE TO OutputRoot.XMLNS.TestCase;
       CREATE FIRSTCHILD OF cursor Domain('XMLNS')
              NAME 'Identifier' VALUE InputRoot.XMLNS.TestCase.Identifier;
       CREATE LASTCHILD  OF cursor Domain('XMLNS') NAME 'Sport' VALUE InputRoot.XMLNS.TestCase.Sport;
       CREATE LASTCHILD  OF cursor Domain('XMLNS') NAME 'Date' VALUE InputRoot.XMLNS.TestCase.Date;
       CREATE LASTCHILD  OF cursor Domain('XMLNS') NAME 'Type' VALUE InputRoot.XMLNS.TestCase.Type;
       CREATE FIELD         cursor.Division[1].Number TYPE NameValue VALUE 'Premiership';
       CREATE FIELD         cursor.Division[1].Result[1].Number TYPE NameValue VALUE  '1' ;
       CREATE FIELD         cursor.Division[1].Result[1].Home TYPE Name;
       CREATE LASTCHILD OF  cursor.Division[1].Result[1].Home NAME 'Team' VALUE 'Liverpool' ;
       CREATE LASTCHILD OF  cursor.Division[1].Result[1].Home NAME 'Score' VALUE '4';
```

```
        CREATE FIELD         cursor.Division[1].Result[1].Away TYPE Name;
        CREATE LASTCHILD OF  cursor.Division[1].Result[1].Away NAME 'Team' VALUE 'Everton';
        CREATE LASTCHILD OF  cursor.Division[1].Result[1].Away NAME 'Score' VALUE '0';
        CREATE FIELD         cursor.Division[1].Result[2].Number TYPE NameValue VALUE  '2';
        CREATE FIELD         cursor.Division[1].Result[2].Home TYPE Name;
        CREATE LASTCHILD OF  cursor.Division[1].Result[2].Home NAME 'Team' VALUE 'Manchester United';
        CREATE LASTCHILD OF  cursor.Division[1].Result[2].Home NAME 'Score' VALUE '2';
        CREATE FIELD         cursor.Division[1].Result[2].Away TYPE Name;
        CREATE LASTCHILD OF  cursor.Division[1].Result[2].Away NAME 'Team' VALUE 'Arsenal';
        CREATE LASTCHILD OF  cursor.Division[1].Result[2].Away NAME 'Score' VALUE '3';
        CREATE FIELD         cursor.Division[2].Number TYPE NameValue  VALUE '2';
        CREATE FIELD         cursor.Division[2].Result[1].Number TYPE NameValue  VALUE  '1';
        CREATE FIELD         cursor.Division[2].Result[1].Home TYPE Name;
        CREATE LASTCHILD OF  cursor.Division[2].Result[1].Home NAME 'Team' VALUE 'Port Vale';
        CREATE LASTCHILD OF  cursor.Division[2].Result[1].Home NAME 'Score' VALUE '9' ;
        CREATE FIELD         cursor.Division[2].Result[1].Away TYPE Name;
        CREATE LASTCHILD OF  cursor.Division[2].Result[1].Away NAME 'Team' VALUE 'Brentford';
        CREATE LASTCHILD OF  cursor.Division[2].Result[1].Away NAME 'Score' VALUE '5';

 END;

 CREATE PROCEDURE CopyMessageHeaders() BEGIN
  DECLARE I INTEGER 1;
  DECLARE J INTEGER CARDINALITY(InputRoot.*[]);
  WHILE I < J DO
   SET OutputRoot.*[I] = InputRoot.*[I];
   SET I = I + 1;
  END WHILE;
 END;

END MODULE;
```

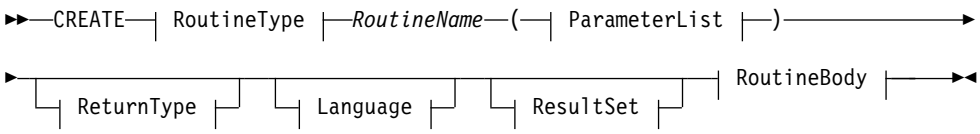
The ASBITSTREAM field function generates a bit stream for the subtree of a given field according to the rules of the parser that owns the field.

CREATE FUNCTION statement:

The CREATE FUNCTION statement defines a callable function or procedure.

You can also use the CREATE PROCEDURE statement to define a callable function or procedure, also known as a routine.

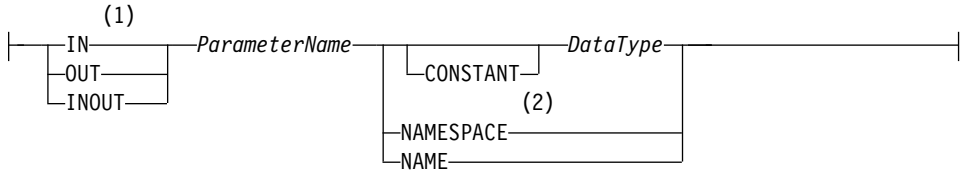
Syntax



RoutineType:

ParameterList:

Parameter:



ReturnType:

Language:

ResultSet:

RoutineBody:

Notes:

1 If the routine type is FUNCTION, the direction indicator (IN, OUT, or INOUT) is optional for each parameter. However, for documentation purposes, it is good programming practice to specify a direction indicator for all new routines; if you do not specify the direction, a default value of IN is used.

2 When the NAMESPACE or NAME clause is used, its value is implicitly CONSTANT and of type CHARACTER. For information about the use of CONSTANT variables, see the "DECLARE statement" on page 5117.

3 If the routine type is FUNCTION, you cannot specify a LANGUAGE of DATABASE.

Overview

The CREATE FUNCTION and CREATE PROCEDURE statements define a callable function or procedure, also known as a routine.

In previous versions of this product, CREATE FUNCTION and CREATE PROCEDURE had different uses and different capabilities. Subsequent enhancements have resulted in the differences listed previously in notes 1 and 3.

Routines are useful for creating reusable blocks of code that can be run independently many times. You can implement them as a series of ESQL statements, a Java method, or a database stored procedure. This flexibility means that some of the clauses in the syntax diagram are not applicable (or allowed) for all types of routine.

Each routine has a name, which must be unique within the schema to which it belongs. Routine names therefore cannot be overloaded; if the broker detects that a routine name has been overloaded, it raises an exception.

The LANGUAGE clause specifies the language the routines body is written in. The options are:

DATABASE
The procedure is called as a database stored procedure.

ESQL
The procedure is called as an ESQL routine.

JAVA
The procedure is called as a static method in a Java class.

Unspecified
If you do not specify the LANGUAGE clause, the default language is ESQL unless you specify the EXTERNAL NAME clause (in which case, the default language is DATABASE).

Restrictions on the use of the LANGUAGE clause exist. You cannot use:

- The ESQL option with an EXTERNAL NAME clause
- The DATABASE or JAVA options without an EXTERNAL NAME clause
- The DATABASE option with a routine type of FUNCTION

Specify the name of the routine by using the *RoutineName* clause, and its parameters by using the *ParameterList* clause. If the LANGUAGE clause specifies ESQL, implement the routine by using a single ESQL statement. This statement is

most useful if it is a compound statement (BEGIN ... END), because it can then contain as many ESQL statements as necessary to fulfill its function.

Alternatively, instead of providing an ESQL body for the routine, you can specify a LANGUAGE clause other than ESQL. You can then use the EXTERNAL NAME clause to provide a reference to the actual body of the routine, wherever it is located externally to the broker. For more information about using the EXTERNAL NAME clause, see "Invoking stored procedures" on page 2503 and Calling a Java routine.

Routines of any LANGUAGE type can have IN, OUT, and INOUT parameters. The caller can pass several values into the routine, and receive back several updated values. These returned parameters are in addition to any RETURNS clause that you have defined for the routine. The RETURNS clause defines the value that the routine returns to the caller.

Routines that are implemented in different languages have their own restrictions on which data types can be passed in or returned; these restrictions are documented later in this section. The data type of the returned value must match the data type of the value that is defined to be returned from the routine. Also, if a routine is defined to have a return value, the caller of the routine cannot ignore it. For more information, see "CALL statement" on page 5077.

Routines can be defined in either a module or a schema. Routines that are defined in a module are local in scope to the current node, which means that only code belonging to that same module (or node) can invoke them. Routines that are defined in a schema, however, can be invoked by using either of the following options:

- Code in the same schema
- Code in any other schema, if either of the following conditions applies:
  - The other schemas PATH clause contains the path to the called routine
  - The called routine is invoked by using its fully qualified name (which is its name, prefixed by its schema name, separated by a period)

Thus, if you need to invoke the same routine in more than one node, define it in a schema.

For any language or routine type, the method of invocation of the routine must match the manner of declaration of the routine. If the routine has a RETURNS clause, use either the FUNCTION invocation syntax or a CALL statement with an INTO clause. Conversely, if a routine has no RETURNS clause, you must use a CALL statement without an INTO clause.

Parameter directions

Parameters that are passed to routines always have a direction associated with them, which is one of the following types:

IN The value of the parameter cannot be changed by the routine. A NULL value for the parameter is allowed, and can be passed to the routine.

OUT
When it is received by the called routine, the parameter that is passed into the routine always has a NULL value of the correct data type. This value is set irrespective of its value before the routine is called. The routine is allowed to change the value of the parameter.

INOUT
INOUT is both an IN and an OUT parameter. It passes a value into the routine, and the value that is passed in can be changed by the routine. A NULL value for the parameter is allowed, and can be passed both into and out of the routine.

If the routine type is FUNCTION, the direction indicator (IN, OUT, INOUT) is optional for each parameter. However, it is good programming practice to specify a direction indicator for all new routines of any type for documentation purposes.

ESQL variables that are declared to be CONSTANT (or references to variables declared to be CONSTANT) are not allowed to have the direction OUT or INOUT.

ESQL routines

ESQL routines are written in ESQL, and have a LANGUAGE clause of ESQL. The body of an ESQL routine is typically a compound statement of the form BEGIN ... END, that contains multiple statements for processing the parameters that are passed to the routine.

ESQL example 1

The following example shows the same procedure as in "Database routine example 1" on page 5112, but is implemented as an ESQL routine and not as a stored procedure. The CALL syntax and results of this routine are the same as found in:

```
CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  OUT parm2  CHARACTER,
  INOUT parm3 CHARACTER )
BEGIN
   SET parm2 = parm3;
   SET parm3 = parm1;
 END;
```

ESQL example 2

This example procedure shows the recursive use of an ESQL routine. It parses a tree, visiting all places at and below the specified starting point, and reports what it has found:

```
SET OutputRoot.MQMD = InputRoot.MQMD;

  DECLARE answer CHARACTER;
  SET     answer = '';

  CALL navigate(InputRoot.XMLNS, answer);
  SET OutputRoot.XMLNS.Data.FieldNames = answer;

  CREATE PROCEDURE navigate (IN root REFERENCE, INOUT answer CHARACTER)
  BEGIN
    SET answer = answer || 'Reached Field... Type:'
    || CAST(FIELDTYPE(root) AS CHAR)||
    ': Name:' || FIELDNAME(root) || ': Value :' || root || ': ';

    DECLARE cursor REFERENCE TO root;
    MOVE cursor FIRSTCHILD;
    IF LASTMOVE(cursor) THEN
      SET answer = answer || 'Field has children... drilling down ';
    ELSE
      SET answer = answer || 'Listing siblings... ';
```

```
    END IF;

    WHILE LASTMOVE(cursor) DO
      CALL navigate(cursor, answer);
      MOVE cursor NEXTSIBLING;
    END WHILE;

    SET answer = answer || 'Finished siblings... Popping up ';
  END;
```

When given the following input message:

```
<Person>
  <Name>John Smith</Name>
  <Salary period='monthly' taxable='yes'>-1200</Salary>
</Person>
```

the procedure produces the following output, which has been manually formatted:

```
  Reached Field... Type:16777232: Name:XML: Value :: Field has children...
  drilling down
  Reached Field... Type:16777216: Name:Person: Value :: Field has children...
  drilling down
  Reached Field... Type:16777216: Name:Name:
  Value :John Smith: Field has children... drilling down
  Reached Field... Type:33554432: Name::
  Value :John Smith: Listing siblings... Finished siblings... Popping up
  Finished siblings... Popping up
  Reached Field... Type:16777216: Name:Salary:
  Value :-1200: Field has children... drilling down
  Reached Field... Type:50331648: Name:period:
  Value :monthly: Listing siblings... Finished siblings... Popping up
  Reached Field... Type:50331648: Name:taxable:
  Value :yes: Listing siblings... Finished siblings... Popping up
  Reached Field... Type:33554432: Name::
  Value :-1200: Listing siblings... Finished siblings... Popping up
  Finished siblings... Popping up
  Finished siblings... Popping up
  Finished siblings... Popping up
```

Java routines

A Java routine is implemented as a Java method, and has a LANGUAGE clause of JAVA. For Java routines, the *ExternalRoutineName* must contain the class name and method name of the Java method to be called. Specify the *ExternalRoutineName* like the following example:

```
>>--"-- className---.---methodName--"-------------><
```

where *className* identifies the class that contains the method and *methodName* identifies the method to invoke. If the class is part of a package, the class identifier part must include the complete package prefix; for example,“com.ibm.broker.test.MyClass.myMethod”

To find the Java class, the broker uses the search method that is described in “Deploying Java classes” on page 5099.

Any Java method that you want to invoke must have the following basic signature:

```
public static <return-type> <method-name> (< 0 - N parameters>)
```

Where <return-type> must be in the list of Java IN data types in the table in “ESQL to Java data type mapping” on page 5098 (excluding the REFERENCE type, which is not permitted as a return value), or the Java void data type. The

parameter data types must also be in the "ESQL to Java data type mapping" on page 5098 table. In addition, the Java method is not allowed to have `exception throws` clause in its signature.

The Java methods signature must match the ESQL routines declaration of the method. You must also observe the following rules:

- Ensure that the Java method name, including the class name and any package qualifiers, matches the procedures EXTERNAL NAME.
- If the Java return type is void, do not put a RETURNS clause on the ESQL routines definition. Conversely, if the Java return type is not void, you must put a RETURNS clause on the ESQL routines definition.
- Ensure that every parameters type and direction matches the ESQL declaration, according to the rules listed in the table in "ESQL to Java data type mapping" on page 5098.
- Ensure that the methods return type matches the data type of the RETURNS clause.
- Enclose EXTERNAL NAME in quotation marks because it must contain at least "class.method".
- If you want to invoke an overloaded Java method, you must create a separate ESQL definition for each overloaded method and give each ESQL definition a unique routine name.

You can use the Java user-defined node API in your Java method, if you observe the restrictions documented in "Restrictions on Java routines" on page 5099. For more information about using the Java API, see "Compiling a Java user-defined node" on page 3074.

Java routine example 1

This routine contains three parameters of varying directions, and returns an integer, which maps to a Java return type of `java.lang.Long`.

```
CREATE FUNCTION  myProc1( IN P1 INTEGER, OUT P2 INTEGER, INOUT P3 INTEGER )
 RETURNS INTEGER
 LANGUAGE JAVA
 EXTERNAL NAME "com.ibm.broker.test.MyClass.myMethod1";
```

You can use the following ESQL to invoke `myProc1`:

```
CALL myProc1( intVar1, intVar2, intVar3) INTO intReturnVar3;
-- or
SET intReturnVar3 = myProc1( intVar1, intVar2, intVar3);
```

Java routine example 2

This routine contains three parameters of varying directions and has a Java return type of `void`.

```
CREATE PROCEDURE myProc2( IN P1 INTEGER, OUT P2 INTEGER, INOUT P3 INTEGER )
 LANGUAGE JAVA
 EXTERNAL NAME "com.ibm.broker.test.MyClass.myMethod2";
```

You must use the following ESQL to invoke `myProc2`:

```
CALL myProc2(intVar1, intVar2, intVar3);
```

The following Java class provides a method for each of the preceding Java examples:

```
package com.ibm.broker.test;

class MyClass {
public static Long myMethod1( Long P1, Long[] P2 Long[] P3) { ... }
public static void myMethod2( Long P2, Long[] P2 Long[] P3) { ... }

 /* When either of these methods is called:
    P1 might or might not be NULL (depending on the value of intVar1).
    P2[0] is always NULL (whatever the value of intVar2).
    P3[0] might or might not be NULL (depending on the value of intVar3).
    This is the same as with LANGUAGE ESQL routines.
    When these methods return:
         intVar1 is unchanged
         intVar2 might still be NULL or might have been changed
         intVar3 might contain the same value or might have been changed.
     This is the same as with LANGUAGE ESQL routines.

    When myMethod1 returns: intReturnVar3 is either  NULL (if the
    method returns NULL) or it contains the value returned by the
    method.
 */
}
```

ESQL to Java data type mapping

The following table summarizes the mappings from ESQL to Java.

Notes:

- Only the Java scalar wrappers are passed to Java.
- The ESQL scalar types are mapped to Java data types as object wrappers, or object wrapper arrays, depending upon the direction of the procedure parameter. Each wrapper array contains exactly one element.
- Scalar object wrappers are used to allow NULL values to be passed to and from Java methods.

ESQL data types [1]	**Java IN data types**	**Java INOUT and OUT data types**
INTEGER, INT	java.lang.Long	java.lang.Long []
FLOAT	java.lang.Double	java.lang.Double[]
DECIMAL	java.math.BigDecimal	java.math.BigDecimal[]
CHARACTER, CHAR	java.lang.String	java.lang.String[]
BLOB	byte[]	byte[][]
BIT	java.util.BitSet	java.util.BitSet[]
DATE	com.ibm.broker.plugin.MbDate	com.ibm.broker.plugin.MbDate[]
TIME [2]	com.ibm.broker.plugin.MbTime	com.ibm.broker.plugin.MbTime[]
GMTTIME [2]	com.ibm.broker.plugin.MbTime	com.ibm.broker.plugin.MbTime[]
TIMESTAMP [2]	com.ibm.broker.plugin.MbTimestamp	com.ibm.broker.plugin.MbTimestamp[]
GMTTIMESTAMP [2]	com.ibm.broker.plugin.MbTimestamp	com.ibm.broker.plugin.MbTimestamp[]
INTERVAL	Not supported	Not supported
BOOLEAN	java.lang.Boolean	java.lang.Boolean[]
REFERENCE (to a message tree) [3] [4] [5] [6]	com.ibm.broker.plugin.MbElement	com.ibm.broker.plugin.MbElement[] **(Supported for INOUT. Not supported for OUT)**
ROW	Not supported	Not supported

ESQL data types [1]	Java IN data types	Java INOUT and OUT data types
LIST	Not supported	Not supported

1. Variables that are declared to be CONSTANT (or references to variables that are declared to be CONSTANT) are not allowed to have the direction INOUT or OUT.
2. The time zone set in the Java variable is not important; you obtain the required time zone in the output ESQL.
3. The reference parameter cannot be NULL when passed into a Java method.
4. The reference cannot have the direction OUT when passed into a Java method.
5. If an *MbElement* is passed back from Java to ESQL as an INOUT parameter, it must point to a location in the same message tree as that pointed to by the *MbElement* that was passed into the called Java method.

   For example, if an ESQL reference to `OutputRoot.XML.Test` is passed into a Java method as an INOUT *MbElement*, but a different *MbElement* is passed back to ESQL when the call returns, the different element must also point to somewhere in the `OutputRoot` tree.
6. An *MbElement* cannot be returned from a Java method with the RETURNS clause, because no ESQL routine can return a reference. However, an *MbElement* can be returned as an INOUT direction parameter, subject to the conditions described in point 5.

A REFERENCE to a scalar variable can be used in the CALL of a Java method, provided that the data type of the variable to which the reference refers matches the corresponding data type in the Java program signature.

Restrictions on Java routines

The following restrictions apply to Java routines that are called from ESQL:

- The Java method must be threadsafe (reentrant).
- Database connections must be JDBC type 2 or type 4. Furthermore, database operations are not part of a broker transaction and therefore cannot be controlled by an external resource coordinator (as is the case in an XA environment).
- The Java user-defined node API must be used only by the same thread that invoked the Java method.

  You can create threads inside your method. However, created threads must not use the Java APIs, and you must return control back to the broker.

  All restrictions that apply to the usage of the Java API also apply to Java methods that are called from ESQL.
- Java methods that are called from ESQL must not use the `MbNode` class. Therefore, they cannot create objects of type `MbNode`, or call any of the methods on an existing `MbNode` object.
- WebSphere MQ or JMS work done inside a Java method that is called from ESQL must be done in accordance with the guidelines for performing WebSphere MQ and JMS work in a user-defined node. See "Planning user-defined input nodes" on page 2995.

Deploying Java classes

You can deploy your Java classes to a broker within a Java Archive (JAR) file, by using one of the following two methods:

1. **Add the JAR file to the broker archive (BAR) file**

The most efficient and flexible method of deploying to the broker is to add your JAR file to the BAR file. You can do this manually or automatically using the WebSphere Message Broker Toolkit.

If the WebSphere Message Broker Toolkit finds the correct Java class inside a referenced Java project open in the workspace, it automatically compiles the Java class into a JAR file and adds it to the BAR file. This procedure is the same procedure that you follow to deploy a JavaCompute node inside a JAR, as described in "User-defined node class loading" on page 3120.

When you deploy a JAR file from the WebSphere Message Broker Toolkit, the flow that has been redeployed reloads the JAR file contained in the BAR file.

The files are also reloaded if the message flow that references a Java class is stopped and restarted. Ensure that you stop and restart (or redeploy) all flows that reference the JAR file that you want to update. This action avoids the problem of some flows running with the old version of the JAR file and other flows running with the new version.

The WebSphere Message Broker Toolkit deploys only JAR files; it does not deploy stand-alone Java class files.

2. **Store the JAR file in either of the following locations:**
   a. The *workpath*/shared-classes/ folder on the machine running the broker
   b. The CLASSPATH environment variable on the computer running the broker

   You must complete this action manually; you cannot use the WebSphere Message Broker Toolkit.

   In this method, redeploying the message flow does not reload the referenced Java classes; neither does stopping and restarting the message flow. The only way to reload the classes in this case is to stop and restart the broker itself.

To enable the broker to find a Java class, ensure that it is in one of the preceding locations. If the broker cannot find the specified class, it generates an exception.

Although you have the choices shown previously when you deploy the JAR file, by using the WebSphere Message Broker Toolkit to deploy the BAR file provides the greatest flexibility when redeploying the JAR file.

Database routines

CREATE FUNCTION does not support database routines. Use CREATE PROCEDURE to define a database routine.

Related concepts:

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

Related tasks:

"Developing ESQL" on page 2370
Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

"Invoking stored procedures" on page 2503
To invoke a procedure that is stored in a database, use the ESQL CALL statement. The stored procedure must be defined by a CREATE PROCEDURE statement that has a Language clause of DATABASE and an EXTERNAL NAME clause that identifies the name of the procedure in the database and, optionally, the database schema to which it belongs.

"Compiling a Java user-defined node" on page 3074
When you have created the code for your Java user-defined node, you must compile it for your operating system.

"Adding files to a broker archive" on page 3223
To deploy files to an execution group, include them in a broker archive (BAR) file.

The CALL statement calls (invokes) a routine.

"CREATE PROCEDURE statement" on page 5103
The CREATE PROCEDURE statement defines a callable function or procedure.

"ESQL-to-Java data-type mapping table" on page 5043
Table summarizing the mappings from ESQL to Java.

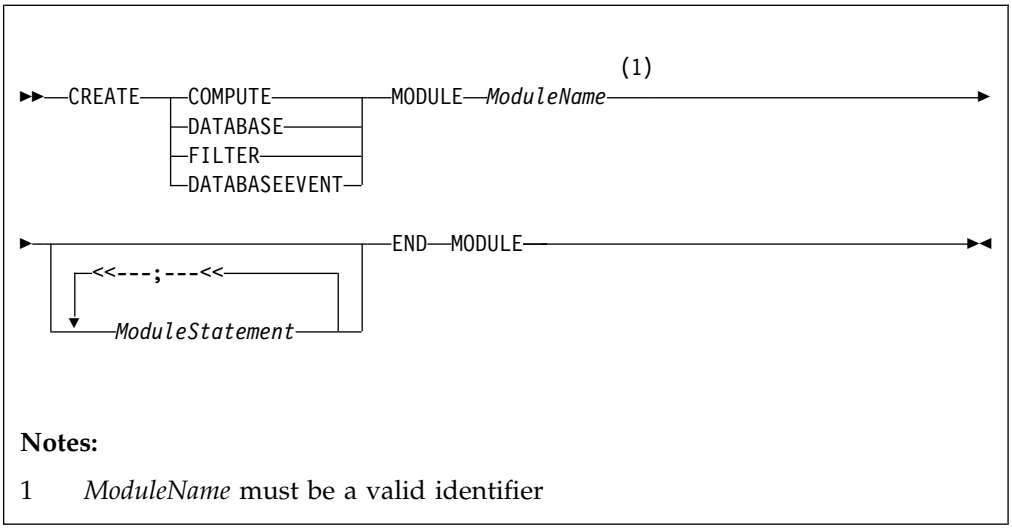
Related information:

Java user-defined extensions API

CREATE MODULE statement:

The CREATE MODULE statement creates a module, which is a named container associated with a node.

Syntax



Notes:

1 *ModuleName* must be a valid identifier

A module in the Eclipse tools is referred to from a message processing node by name. The module must be in the <node schema>.

Module names occupy the same symbol space as functions and procedures defined in the schema. That is, modules, functions, and procedures contained by a schema must all have unique names.

Note: You are warned if there is no module associated with an ESQL node. You cannot deploy a flow containing a node in which a module is missing.

The modules for the Compute node, Database node, and Filter node must all contain exactly one function called Main. This function should return a Boolean. It is the entry point used by a message flow node when processing a message.

The modules for the DatabaseInput node must contain the following entry points:

ReadEvents
This procedure gets details of events to be processed from your event store.

BuildMessage
This procedure builds the message that will be propagated to the flow.

EndEvent
This procedure updates the event table to ensure that this event is not processed again.

Correlation name	Compute module	Filter module	Database module	DatabaseEvent module
Database	x	x	x	x
Environment	x	x	x	x
Root		x	x	x
Body		x	x	
Properties		x	x	x
ExceptionList		x	x	x
LocalEnvironment		x	x	x
InputRoot	x			
InputBody	x			
InputProperties	x			
InputExceptionList	x			
InputLocalEnvironment	x			
OutputRoot	x			
OutputExceptionList	x			
OutputLocalEnvironment	x			
DestinationList	Deprecated synonym for LocalEnvironment			
InputDestinationList	Deprecated synonym for InputLocalEnvironment			
OutputDestinationList	Deprecated synonym for OutputLocalEnvironment

"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

"CALL statement" on page 5077
The CALL statement calls (invokes) a routine.

"BROKER SCHEMA statement" on page 5073
The BROKER SCHEMA statement is optional; use it in an ESQL file to explicitly identify the schema that contains the file.

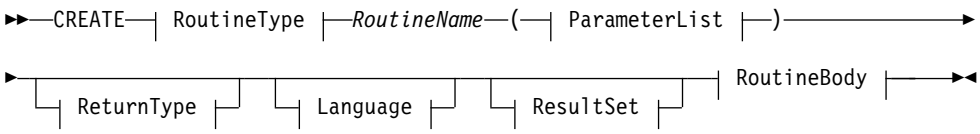
"PATH clause" on page 5075
The PATH clause specifies a list of additional schemas to be searched when matching function and procedure calls to their implementations. The schema in which the call lies is implicitly included in the PATH clause.

CREATE PROCEDURE statement:

The CREATE PROCEDURE statement defines a callable function or procedure.

You can also use the CREATE FUNCTION statement to define a callable function or procedure, also known as a routine.

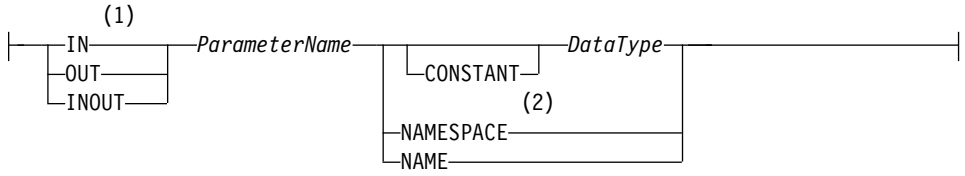
Syntax



RoutineType:

ParameterList:

Parameter:



ReturnType:

Language:

ResultSet:

RoutineBody:

Notes:

1 If the routine type is FUNCTION, the direction indicator (IN, OUT, or INOUT) is optional for each parameter. However, for documentation purposes, it is good programming practice to specify a direction indicator for all new routines; if you do not specify the direction, a default value of IN is used.

2 When the NAMESPACE or NAME clause is used, its value is implicitly CONSTANT and of type CHARACTER. For information about the use of CONSTANT variables, see the "DECLARE statement" on page 5117.

3 If the routine type is FUNCTION, you cannot specify a LANGUAGE of DATABASE.

Parameter directions

Parameters that are passed to routines always have a direction associated with them, which is one of the following types:

IN The value of the parameter cannot be changed by the routine. A NULL value for the parameter is allowed, and can be passed to the routine.

OUT
When it is received by the called routine, the parameter that is passed into the routine always has a NULL value of the correct data type. This value is set irrespective of its value before the routine is called. The routine is allowed to change the value of the parameter.

INOUT
INOUT is both an IN and an OUT parameter. It passes a value into the routine, and the value that is passed in can be changed by the routine. A NULL value for the parameter is allowed, and can be passed both into and out of the routine.

If the routine type is FUNCTION, the direction indicator (IN, OUT, INOUT) is optional for each parameter. However, it is good programming practice to specify a direction indicator for all new routines of any type for documentation purposes.

ESQL variables that are declared to be CONSTANT (or references to variables declared to be CONSTANT) are not allowed to have the direction OUT or INOUT.

ESQL routines

ESQL routines are written in ESQL, and have a LANGUAGE clause of ESQL. The body of an ESQL routine is typically a compound statement of the form BEGIN ... END, that contains multiple statements for processing the parameters that are passed to the routine.

ESQL example 1

The following example shows the same procedure as in "Database routine example 1" on page 5112, but is implemented as an ESQL routine and not as a stored procedure. The CALL syntax and results of this routine are the same as found in:

```
CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  OUT parm2  CHARACTER,
  INOUT parm3 CHARACTER )
```

```
BEGIN
   SET parm2 = parm3;
   SET parm3 = parm1;
 END;
```

ESQL example 2

This example procedure shows the recursive use of an ESQL routine. It parses a tree, visiting all places at and below the specified starting point, and reports what it has found:

```
SET OutputRoot.MQMD = InputRoot.MQMD;

  DECLARE answer CHARACTER;
  SET     answer = '';

  CALL navigate(InputRoot.XMLNS, answer);
  SET OutputRoot.XMLNS.Data.FieldNames = answer;

  CREATE PROCEDURE navigate (IN root REFERENCE, INOUT answer CHARACTER)
  BEGIN
    SET answer = answer || 'Reached Field... Type:'
    || CAST(FIELDTYPE(root) AS CHAR)||
    ': Name:' || FIELDNAME(root) || ': Value :' || root || ': ';

    DECLARE cursor REFERENCE TO root;
    MOVE cursor FIRSTCHILD;
    IF LASTMOVE(cursor) THEN
      SET answer = answer || 'Field has children... drilling down ';
    ELSE
      SET answer = answer || 'Listing siblings... ';
    END IF;

    WHILE LASTMOVE(cursor) DO
      CALL navigate(cursor, answer);
      MOVE cursor NEXTSIBLING;
    END WHILE;

    SET answer = answer || 'Finished siblings... Popping up ';
  END;
```

When given the following input message:

```
<Person>
  <Name>John Smith</Name>
  <Salary period='monthly' taxable='yes'>-1200</Salary>
</Person>
```

the procedure produces the following output, which has been manually formatted:

```
  Reached Field... Type:16777232: Name:XML: Value :: Field has children...
  drilling down
  Reached Field... Type:16777216: Name:Person: Value :: Field has children...
  drilling down
  Reached Field... Type:16777216: Name:Name:
  Value :John Smith: Field has children... drilling down
  Reached Field... Type:33554432: Name::
  Value :John Smith: Listing siblings... Finished siblings... Popping up
  Finished siblings... Popping up
  Reached Field... Type:16777216: Name:Salary:
  Value :-1200: Field has children... drilling down
  Reached Field... Type:50331648: Name:period:
  Value :monthly: Listing siblings... Finished siblings... Popping up
  Reached Field... Type:50331648: Name:taxable:
  Value :yes: Listing siblings... Finished siblings... Popping up
  Reached Field... Type:33554432: Name::
```

```
Value :-1200: Listing siblings... Finished siblings... Popping up
Finished siblings... Popping up
Finished siblings... Popping up
Finished siblings... Popping up
```

Java routines

A Java routine is implemented as a Java method, and has a LANGUAGE clause of JAVA. For Java routines, the *ExternalRoutineName* must contain the class name and method name of the Java method to be called. Specify the *ExternalRoutineName* like the following example:

```
>>--"-- className---.---methodName--"-------------><
```

where *className* identifies the class that contains the method and *methodName* identifies the method to invoke. If the class is part of a package, the class identifier part must include the complete package prefix; for example,"`com.ibm.broker.test.MyClass.myMethod`"

To find the Java class, the broker uses the search method that is described in "Deploying Java classes" on page 5099.

Any Java method that you want to invoke must have the following basic signature:

```
public static <return-type> <method-name> (< 0 - N parameters>)
```

Where `<return-type>` must be in the list of Java IN data types in the table in "ESQL to Java data type mapping" on page 5098 (excluding the REFERENCE type, which is not permitted as a return value), or the Java void data type. The parameter data types must also be in the "ESQL to Java data type mapping" on page 5098 table. In addition, the Java method is not allowed to have `exception throws` clause in its signature.

The Java methods signature must match the ESQL routines declaration of the method. You must also observe the following rules:

- Ensure that the Java method name, including the class name and any package qualifiers, matches the procedures EXTERNAL NAME.
- If the Java return type is void, do not put a RETURNS clause on the ESQL routines definition. Conversely, if the Java return type is not void, you must put a RETURNS clause on the ESQL routines definition.
- Ensure that every parameters type and direction matches the ESQL declaration, according to the rules listed in the table in "ESQL to Java data type mapping" on page 5098.
- Ensure that the methods return type matches the data type of the RETURNS clause.
- Enclose EXTERNAL NAME in quotation marks because it must contain at least "class.method".
- If you want to invoke an overloaded Java method, you must create a separate ESQL definition for each overloaded method and give each ESQL definition a unique routine name.

You can use the Java user-defined node API in your Java method, if you observe the restrictions documented in "Restrictions on Java routines" on page 5099. For more information about using the Java API, see "Compiling a Java user-defined node" on page 3074.

Java routine example 1

This routine contains three parameters of varying directions, and returns an integer, which maps to a Java return type of `java.lang.Long`.

```
CREATE FUNCTION  myProc1( IN P1 INTEGER, OUT P2 INTEGER, INOUT P3 INTEGER )
 RETURNS INTEGER
 LANGUAGE JAVA
 EXTERNAL NAME "com.ibm.broker.test.MyClass.myMethod1";
```

You can use the following ESQL to invoke `myProc1`:

```
CALL myProc1( intVar1, intVar2, intVar3) INTO intReturnVar3;
-- or
SET intReturnVar3 = myProc1( intVar1, intVar2, intVar3);
```

Java routine example 2

This routine contains three parameters of varying directions and has a Java return type of `void`.

```
CREATE PROCEDURE myProc2( IN P1 INTEGER, OUT P2 INTEGER, INOUT P3 INTEGER )
 LANGUAGE JAVA
 EXTERNAL NAME "com.ibm.broker.test.MyClass.myMethod2";
```

You must use the following ESQL to invoke `myProc2`:

```
CALL myProc2(intVar1, intVar2, intVar3);
```

The following Java class provides a method for each of the preceding Java examples:

```
package com.ibm.broker.test;

class MyClass {
public static Long myMethod1( Long P1, Long[] P2 Long[] P3) { ... }
public static void myMethod2( Long P2, Long[] P2 Long[] P3) { ... }

 /* When either of these methods is called:
    P1 might or might not be NULL (depending on the value of intVar1).
    P2[0] is always NULL (whatever the value of intVar2).
    P3[0] might or might not be NULL (depending on the value of intVar3).
    This is the same as with LANGUAGE ESQL routines.
    When these methods return:
         intVar1 is unchanged
         intVar2 might still be NULL or might have been changed
         intVar3 might contain the same value or might have been changed.
     This is the same as with LANGUAGE ESQL routines.

    When myMethod1 returns: intReturnVar3 is either  NULL (if the
    method returns NULL) or it contains the value returned by the
    method.
 */
}
```

ESQL to Java data type mapping

The following table summarizes the mappings from ESQL to Java.

Notes:

- Only the Java scalar wrappers are passed to Java.
- The ESQL scalar types are mapped to Java data types as object wrappers, or object wrapper arrays, depending upon the direction of the procedure parameter. Each wrapper array contains exactly one element.

- Scalar object wrappers are used to allow NULL values to be passed to and from Java methods.

ESQL data types [1]	**Java IN data types**	**Java INOUT and OUT data types**
INTEGER, INT	java.lang.Long	java.lang.Long []
FLOAT	java.lang.Double	java.lang.Double[]
DECIMAL	java.math.BigDecimal	java.math.BigDecimal[]
CHARACTER, CHAR	java.lang.String	java.lang.String[]
BLOB	byte[]	byte[][]
BIT	java.util.BitSet	java.util.BitSet[]
DATE	com.ibm.broker.plugin.MbDate	com.ibm.broker.plugin.MbDate[]
TIME [2]	com.ibm.broker.plugin.MbTime	com.ibm.broker.plugin.MbTime[]
GMTTIME [2]	com.ibm.broker.plugin.MbTime	com.ibm.broker.plugin.MbTime[]
TIMESTAMP [2]	com.ibm.broker.plugin.MbTimestamp	com.ibm.broker.plugin.MbTimestamp[]
GMTTIMESTAMP [2]	com.ibm.broker.plugin.MbTimestamp	com.ibm.broker.plugin.MbTimestamp[]
INTERVAL	Not supported	Not supported
BOOLEAN	java.lang.Boolean	java.lang.Boolean[]
REFERENCE (to a message tree) [3] [4] [5] [6]	com.ibm.broker.plugin.MbElement	com.ibm.broker.plugin.MbElement[] **(Supported for INOUT. Not supported for OUT)**
ROW	Not supported	Not supported
LIST	Not supported	Not supported

1. Variables that are declared to be CONSTANT (or references to variables that are declared to be CONSTANT) are not allowed to have the direction INOUT or OUT.
2. The time zone set in the Java variable is not important; you obtain the required time zone in the output ESQL.
3. The reference parameter cannot be NULL when passed into a Java method.
4. The reference cannot have the direction OUT when passed into a Java method.
5. If an *MbElement* is passed back from Java to ESQL as an INOUT parameter, it must point to a location in the same message tree as that pointed to by the *MbElement* that was passed into the called Java method.

   For example, if an ESQL reference to `OutputRoot.XML.Test` is passed into a Java method as an INOUT *MbElement*, but a different *MbElement* is passed back to ESQL when the call returns, the different element must also point to somewhere in the `OutputRoot` tree.
6. An *MbElement* cannot be returned from a Java method with the RETURNS clause, because no ESQL routine can return a reference. However, an *MbElement* can be returned as an INOUT direction parameter, subject to the conditions described in point 5.

A REFERENCE to a scalar variable can be used in the CALL of a Java method, provided that the data type of the variable to which the reference refers matches the corresponding data type in the Java program signature.

Restrictions on Java routines

The following restrictions apply to Java routines that are called from ESQL:

- The Java method must be threadsafe (reentrant).
- Database connections must be JDBC type 2 or type 4. Furthermore, database operations are not part of a broker transaction and therefore cannot be controlled by an external resource coordinator (as is the case in an XA environment).
- The Java user-defined node API must be used only by the same thread that invoked the Java method.

  You can create threads inside your method. However, created threads must not use the Java APIs, and you must return control back to the broker.

  All restrictions that apply to the usage of the Java API also apply to Java methods that are called from ESQL.
- Java methods that are called from ESQL must not use the `MbNode` class. Therefore, they cannot create objects of type `MbNode`, or call any of the methods on an existing `MbNode` object.
- WebSphere MQ or JMS work done inside a Java method that is called from ESQL must be done in accordance with the guidelines for performing WebSphere MQ and JMS work in a user-defined node. See "Planning user-defined input nodes" on page 2995.

Deploying Java classes

You can deploy your Java classes to a broker within a Java Archive (JAR) file, by using one of the following two methods:

1. **Add the JAR file to the broker archive (BAR) file**

   The most efficient and flexible method of deploying to the broker is to add your JAR file to the BAR file. You can do this manually or automatically using the WebSphere Message Broker Toolkit.

   If the WebSphere Message Broker Toolkit finds the correct Java class inside a referenced Java project open in the workspace, it automatically compiles the Java class into a JAR file and adds it to the BAR file. This procedure is the same procedure that you follow to deploy a JavaCompute node inside a JAR, as described in "User-defined node class loading" on page 3120.

   When you deploy a JAR file from the WebSphere Message Broker Toolkit, the flow that has been redeployed reloads the JAR file contained in the BAR file.

   The files are also reloaded if the message flow that references a Java class is stopped and restarted. Ensure that you stop and restart (or redeploy) all flows that reference the JAR file that you want to update. This action avoids the problem of some flows running with the old version of the JAR file and other flows running with the new version.

   The WebSphere Message Broker Toolkit deploys only JAR files; it does not deploy stand-alone Java class files.
2. **Store the JAR file in either of the following locations:**

   a. The *workpath*`/shared-classes/` folder on the machine running the broker

   b. The CLASSPATH environment variable on the computer running the broker

   You must complete this action manually; you cannot use the WebSphere Message Broker Toolkit.

   In this method, redeploying the message flow does not reload the referenced Java classes; neither does stopping and restarting the message flow. The only way to reload the classes in this case is to stop and restart the broker itself.

To enable the broker to find a Java class, ensure that it is in one of the preceding locations. If the broker cannot find the specified class, it generates an exception.

Although you have the choices shown previously when you deploy the JAR file, by using the WebSphere Message Broker Toolkit to deploy the BAR file provides the greatest flexibility when redeploying the JAR file.

Database routines

Database routines are implemented as database stored procedures. Database routines have a LANGUAGE clause of DATABASE, and must have a routine type of PROCEDURE.

When writing stored procedures in languages like C, you must use NULL indicators to ensure that your procedure can process the data correctly.

Although the database definitions of a stored procedure vary between the databases, the ESQL used to invoke them does not. The names given to parameters in the ESQL do not have to match the names they are given on the database side. However, the external name of the routine, including any package or container specifications, must match its defined name in the database.

The DYNAMIC RESULT SETS clause is allowed only for database routines. It is required only if a stored procedure returns one or more result sets. The integer parameter to this clause must be 0 (zero) or more, and specifies the number of result sets to be returned.

The optional RETURNS clause is required if a stored procedure returns a single scalar value.

The EXTERNAL NAME clause specifies the name by which the database knows the routine. Can be either a qualified or an unqualified name, where the qualifier is the name of the database schema in which the procedure is defined. If you do not provide a schema name, the database connection user name is used as the schema in which to locate the procedure. If the required procedure does not exist in this schema, you must provide an explicit schema name, either on the routine definition or on the CALL to the routine at run time. For more information about dynamically choosing the schema that contains the routine, see the “CALL statement” on page 5077. When a qualified name is used, the name must be in quotation marks.

A fully qualified routine typically takes the form:

```
EXTERNAL NAME "mySchema.myProc";
```

However, if the procedure belongs to an Oracle package, the package is treated as part of the procedures name. Therefore you must provide a schema name and the package name, in the form:

```
EXTERNAL NAME "mySchema.myPackage.myProc";
```

This form allows the schema, but not the package name, to be chosen dynamically in the CALL statement.

If the name of the procedure contains SQL wildcards (which are the percent (%) character and the underscore (_) character), the procedure name is modified by the broker to include the database escape character immediately before each wildcard character. This technique ensures that the database receives the wildcards as literal

characters. For example, assuming that the database escape character is a backslash, the following clause is modified by the broker so that "mySchema.Proc_" is passed to the database.

```
EXTERNAL NAME "mySchema.Proc_";
```

All external procedures have the following restrictions:

- A stored procedure cannot be overloaded on the database side. A stored procedure is considered overloaded if there is more than one procedure of the same name in the same database schema. If the broker detects that a procedure has been overloaded, it raises an exception.
- Parameters cannot be of the ESQL REFERENCE, ROW, LIST, or INTERVAL data types.
- User-defined types cannot be used as parameters or as return values.

For LANGUAGE DATABASE routines, the *ExternalRoutineName* is not optional and contains the schema name, package name, and procedure name of the routine to be called. Specify the *ExternalRoutineName* as follows:

```
>>--"schemaName---.---packageName---.---procedureName--"-------------><
```

where:

- *schemaName* is optional.
- *packageName* is optional and applies only to Oracle data sources. If you supply a *packageName* you must supply a *schemaName.*
- *procedureName* is not optional.

Database routine example 1

The following example shows an ESQL definition of a stored procedure that returns a single scalar value and an OUT parameter:

```
CREATE PROCEDURE myProc1(IN P1 INT, OUT P2 INT)
RETURNS INTEGER
LANGUAGE DATABASE
EXTERNAL NAME "myschema.myproc";
```

Use this ESQL to invoke the myProc1 routine:

```
/*using CALL statement invocation syntax*/
CALL myProc1(intVar1, intVar2) INTO intReturnVar3;

/*or using function invocation syntax*/
SET intReturnVar3 = myProc1(intVar1, intVar2);
```

Database routine example 2

The following ESQL code demonstrates how to define and call DB2 stored procedures:

```
ESQL Definition:
DECLARE inputParm CHARACTER;
DECLARE outputParm CHARACTER;
DECLARE inputOutputParm CHARACTER;

SET inputParm = 'Hello';
SET inputOutputParm = 'World';
CALL swapParms( inputParm, outputParm, inputOutputParm );

CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  OUT parm2  CHARACTER,
```

```
  INOUT parm3 CHARACTER
)
LANGUAGE DATABASE
EXTERNAL NAME dbSwapParms;
```

To register this stored procedure with DB2, copy the following script to a file (for example, `test1.sql`)

```
-- DB2 Example Stored Procedure
DROP PROCEDURE dbSwapParms @
CREATE PROCEDURE dbSwapParms
( IN in_param CHAR(32),
  OUT out_param CHAR(32),
  INOUT inout_param CHAR(32))
LANGUAGE SQL
BEGIN
SET out_param = inout_param;
    SET inout_param = in_param;
END @
```

Now run the file from the DB2 command prompt:

```
db2 -td@ -vf test1.sql
```

Expect the following results from running this code:

- The value of the IN parameter does not (and cannot, by definition) change.
- The value of the OUT parameter becomes “World”.
- The value of the INOUT parameter changes to “Hello”.

Database routine example 3

The following ESQL code demonstrates how to define and call Oracle stored procedures:

```
ESQL Definition:
DECLARE inputParm CHARACTER;
DECLARE outputParm CHARACTER;
DECLARE inputOutputParm CHARACTER;

SET inputParm = 'Hello';
SET inputOutputParm = 'World';
CALL swapParms( inputParm, outputParm, inputOutputParm );

CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  OUT parm2  CHARACTER,
  INOUT parm3 CHARACTER
)
LANGUAGE DATABASE
EXTERNAL NAME dbSwapParms;
```

To register this stored procedure with Oracle, copy the following script to a file (for example, `test1.sql`)

```
CREATE OR REPLACE PROCEDURE dbSwapParms
( in_param IN VARCHAR2,
  out_param OUT VARCHAR2,
  inout_param IN OUT VARCHAR2 )
AS
BEGIN
  out_param := inout_param;
  inout_param := in_param;
END;
/
```

Now run the file:

```
sqlplus userID/password  @test1.sql
```

Expect the following results from running this code:
- The value of the IN parameter does not (and cannot, by definition) change.
- The value of the OUT parameter becomes “World”.
- The value of the INOUT parameter changes to “Hello”.

Database routine example 4

The following ESQL code demonstrates how to define and call SQL Server stored procedures:

```
ESQL Definition:
DECLARE inputParm CHARACTER;
DECLARE outputParm CHARACTER;
DECLARE inputOutputParm CHARACTER;

SET inputParm = 'Hello';
SET inputOutputParm = 'World';
CALL swapParms( inputParm, outputParm, inputOutputParm );

CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  INOUT parm2  CHARACTER,
  INOUT parm3 CHARACTER
)
LANGUAGE DATABASE
EXTERNAL NAME dbSwapParms;
```

To register this stored procedure with SQL Server, copy the following script to a file (for example, `test1.sql`)

```
-- SQLServer Example Stored Procedure
DROP PROCEDURE dbSwapParms
go
CREATE PROCEDURE dbSwapParms
 @in_param     CHAR(32),
 @out_param    CHAR(32) OUT,
 @inout_param  CHAR(32) OUT
AS
  SET NOCOUNT ON
  SET @out_param   = @inout_param
  SET @inout_param = @in_param
go
```

Now run file:

```
isql -UuserID -Ppassword -Sserver -ddatasource -itest1.sql
```

SQL Server considers `OUTPUT` parameters from stored procedures as `INPUT/OUTPUT` parameters. If you declare them as `OUT` parameters in your ESQL you encounter a type mismatch error at run time. To avoid that mismatch you must declare SQL Server `OUTPUT` parameters as `INOUT` in your ESQL.

Use the `SET NOCOUNT ON` option, as shown in the preceding example, with SQL stored procedures for the following reasons:

1. To limit the amount of data returned from SQL Server to the broker.
2. To allow result sets to be returned correctly.

Expect the following results from running this code:
- The value of the IN parameter does not (and cannot, by definition) change.
- The value of the OUT parameter becomes “World”.

- The value of the INOUT parameter changes to “Hello”.

Database routine example 5

The following ESQL code demonstrates how to define and call Sybase stored procedures:

```
ESQL Definition:
DECLARE inputParm CHARACTER;
DECLARE outputParm CHARACTER;
DECLARE inputOutputParm CHARACTER;

SET inputParm = 'Hello';
SET inputOutputParm = 'World';
CALL swapParms( inputParm, outputParm, inputOutputParm );

CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  INOUT parm2  CHARACTER,
  INOUT parm3 CHARACTER
)
LANGUAGE DATABASE
EXTERNAL NAME dbSwapParms;
```

To register this stored procedure with Sybase, copy the following script to a file (for example, `test1.sql`)

```
-- SYBASE Example Stored Procedure
DROP PROCEDURE dbSwapParms
go
CREATE PROCEDURE dbSwapParms
 @in_param     CHAR(32),
 @out_param    CHAR(32) OUT,
 @inout_param  CHAR(32) OUT
AS
  SET @out_param   = @inout_param
  SET @inout_param = @in_param
go
```

Now run file:

```
isql -U<userID> -P<password> -S<server> -D<datasource> -itest1.sql
```

Sybase considers `OUTPUT` parameters from stored procedures as `INPUT/OUTPUT` parameters. If you declare them as `OUT` parameters in your ESQL, you encounter a type mismatch error at run time. To avoid that mismatch, declare Sybase `OUTPUT` parameters as `INOUT` in your ESQL.

Expect the following results from running this code:
- The value of the IN parameter does not (and cannot, by definition) change.
- The value of the OUT parameter becomes “World”.
- The value of the INOUT parameter changes to “Hello”.

Database routine example 6

The following ESQL code demonstrates how to define and call Informix stored procedures:

```
ESQL Definition:
DECLARE inputParm CHARACTER 'Hello';
DECLARE outputParm CHARACTER;
DECLARE inputOutputParm CHARACTER 'World';
CALL swapParms( inputParm, outputParm, inputOutputParm );
```

```
CREATE PROCEDURE swapParms (
  IN parm1 CHARACTER,
  INOUT parm2  CHARACTER,
  INOUT parm3 CHARACTER
)
LANGUAGE DATABASE
EXTERNAL NAME dbSwapParms;
```

To register this stored procedure with Informix, copy the following script to a file (for example, `test1.sql`)

```
DROP SPECIFIC PROCEDURE dbSwapParms;
CREATE PROCEDURE dbSwapParms
  (       inParm     CHAR(20),
   OUT    outParm    CHAR(20),
   INOUT  inoutParm  CHAR(20))

   SPECIFIC dbSwapParms

    LET outParm   = inoutParm;
    LET inoutParm = inParm;
END PROCEDURE;
```

Now run file:

From the Informix server shell environment enter:

```
dbaccess <dataBaseName> <fully qualified path/test1.sql>
```

Expect the following results from running this code:
- The value of the IN parameter does not (and cannot, by definition) change.
- The value of the OUT parameter becomes “World”.
- The value of the INOUT parameter changes to “Hello”.

The following restrictions apply to Informix stored procedures:
- Procedures that use the Informix INTERVAL datatype cannot be invoked from the broker.
- Procedures can return only one result set.
- Procedures that return a result set must contain only IN parameters.
- Procedures cannot return CLOBs or BLOBs in result sets or as scalar return values.
- Procedures can return either a result set or a scalar value, but not both.

Database routine example 7

This example shows how to call a stored procedure that returns two result sets, in addition to an out parameter:

```
CREATE PROCEDURE myProc1 (IN P1 INT, OUT P2 INT)
  LANGUAGE DATABASE
  DYNAMIC RESULT SETS 2
  EXTERNAL NAME "myschema.myproc";
```

Use the following ESQL to invoke `myProc1`:

```
/* using a field reference */
CALL myProc1(intVar1, intVar2, Environment.RetVal[], OutputRoot.XMLNS.A[])
/* using a reference variable*/
CALL myProc1(intVar1, intVar2, myReferenceVariable.RetVal[], myRef2.B[])
```

DECLARE statement:

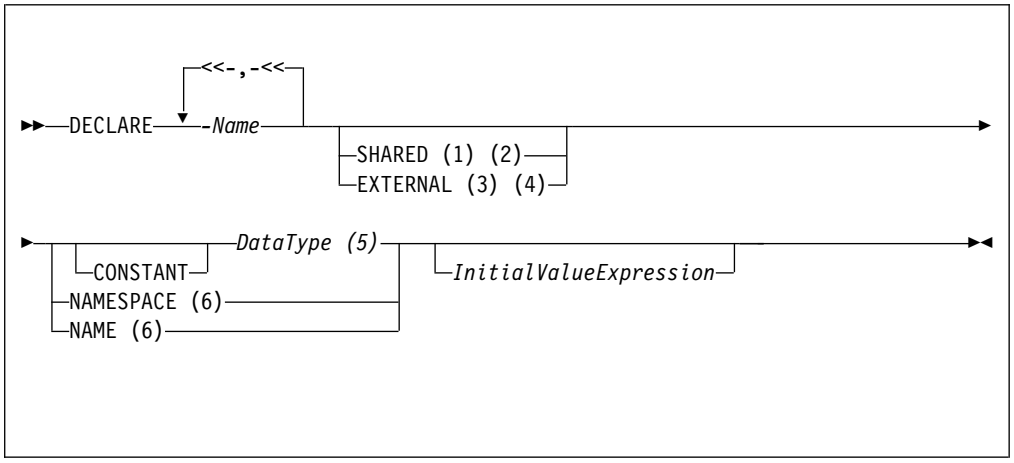
Use the DECLARE statement to define a variable, the data type of the variable and, optionally, its initial value.

You can define three types of variable with the DECLARE statement:

- External
- Normal
- Shared

For further information, see "ESQL variables" on page 5048.

Syntax



Notes:

1. The SHARED keyword is not valid within a function or procedure.
2. You cannot specify SHARED with a *DataType* of REFERENCE TO. To store a message tree in a shared variable, use the ROW data type.
3. EXTERNAL variables are implicitly constant.
4. It is good programming practice to give an EXTERNAL variable an initial value.
5. If you specify a *DataType* of REFERENCE TO, you must specify an initial value (of either a variable or a tree) in *InitialValueExpression*.
6. When you use the NAMESPACE and NAME clauses, their values are implicitly constant and of type CHARACTER.

Follow the links to see more information about all these parameters:

- "CONSTANT"
- "DataType" on page 5119
- "EXTERNAL" on page 5119
- "NAME" on page 5120
- "NAMESPACE" on page 5121
- "SHARED" on page 5121

CONSTANT

Use CONSTANT to define a constant. You can declare constants within schemas, modules, routines, or compound statements (both implicit and explicit). The behavior of these cases is shown in the following list:

- Within a compound statement, constants and variables occupy the same namespace.
- Within expressions, a constant or variable that is declared within a compound statement overlays all constants and variables of the same name that are declared in containing compound statements, modules, and schemas.
- Within field reference namespace fields, a namespace constant that is declared within a compound statement overlays all namespace constants of the same name that are declared in containing compound statements.

A constant or variable that is declared within a routine overlays any parameters of the same name, as well as all constants and variables of the same name that are declared in a containing module or schema.

DataType

The values that you can specify for *DataType* are:
- BOOLEAN
- INT
- INTEGER
- FLOAT
- DECIMAL
- DATE
- TIME
- TIMESTAMP
- GMTTIME
- GMTTIMESTAMP
- INTERVAL. This value does not apply to external variables (EXTERNAL keyword specified).
- CHAR
- CHARACTER
- BLOB
- BIT
- ROW. This value does not apply to external variables (EXTERNAL keyword specified).
- REFERENCE TO. This value does not apply to external or shared variables (EXTERNAL or SHARED keyword specified).

EXTERNAL

Use EXTERNAL to denote a user-defined property (UDP). A UDP is a user-defined constant whose initial value (optionally set by the DECLARE statement) can be modified, at design time, by the Message Flow editor (see "Message Flow editor" on page 6810) or overridden, at deployment time, by the Broker Archive editor (see "Broker Archive editor" on page 6794). The value of a UDP cannot be modified by ESQL.

When a UDP is given an initial value on the DECLARE statement, this value becomes its default. However, any value that you specify in the Message Flow editor at design time, or in the Broker Archive editor at deployment time (even a zero length string) overrides any initial value that was coded on the DECLARE statement.

For example, if you code:

```
DECLARE deployEnvironment EXTERNAL CHARACTER 'Dev';
```

you have defined a UDP variable of `deployEnvironment` with an initial value `Dev`.

Add the UDP to the message flow by using the UDP tab in the message flow editor. When you add the flow to the BAR file, the UDP is there as an attribute of the flow; you must name the attribute to be the same as the ESQL variable in the DECLARE statement (in this case, `deployEnvironment`) to ensure that the initial value that you set is unchanged.

All the UDPs in a message flow must have a value, given either on the DECLARE statement or by the Message Flow or Broker Archive editor; otherwise a

deployment-time error occurs. At run time, after the UDP has been declared, its value can be queried by subsequent ESQL statements.

You can define a UDP for a subflow. A UDP has global scope and is not specific to a particular subflow. If you reuse a subflow in a message flow, and those subflows have identical UDPs, you cannot set the UDPs to different values.

The advantage of UDPs is that their values can be changed at deployment time. For example, if you use the UDPs to hold configuration data, it means that you can configure a message flow for a particular computer, task, or environment at deployment time, without having to change the code at the node level. UDPs can also be modified at run time by using the CMP API.

You can declare UDPs only in modules or schemas; that is, you can use the DECLARE statement with the EXTERNAL keyword only at the MODULE or SCHEMA level. If you use a DECLARE statement with the EXTERNAL keyword within a PROCEDURE or FUNCTION, a `BIP2402E` exception occurs when you deploy the message flow.

The following types of broker node can access UDPs:
- Compute node
- Database node
- Filter node
- Nodes that are derived from these node types

Take care when specifying the data type of a UDP, because a CAST is used to change the value to the requested *DataType*.

For an overview of UDPs, see "User-defined properties in ESQL" on page 2376.

Example 1:

```
DECLARE mycolor EXTERNAL CHARACTER 'blue';
```

Example 2:

```
DECLARE TODAYSCOLOR EXTERNAL CHARACTER;
SET COLOR = TODAYSCOLOR;
```

where `TODAYSCOLOR` is a user-defined property that has a `TYPE` of `CHARACTER` and a `VALUE` set by the Message Flow editor.

NAME

Use NAME to define an alias (an alternative name) by which a variable can be known.

Example 1:

```
-- The following statement gives Schema1 an alias of 'Joe'.
DECLARE Schema1 NAME 'Joe';
-- The following statement produces a field called 'Joe'.
SET OutputRoot.XMLNS.Data.Schema1 = 42;

-- The following statement inserts a value into a table called Table1
-- in the schema called 'Joe'.
INSERT INTO Database.Schema1.Table1 (Answer) VALUES 42;
```

Example 2:

```
-- At Module scope define ColourElementName and set it external
-- so that its default value of 'black' can be overridden as a UDP
DECLARE ColourElementName EXTERNAL NAME 'black';

-- Use the ColourElementName in a function
CREATE FIRSTCHILD OF OutputRoot.XMLNSC.TestCase.ColourElementName
                     Domain('XMLNSC')
                     NAME 'Node1' VALUE '1';
```

If the owning message flow has been configured with a UDP named `ColourElementName` of type `String`, which has been given the value `red`, the following output message is generated:

```
<xml version="1.0"?>
<TestCase>
  <red>
    <Node1>1</Node1>
  </red>
```

NAMESPACE

Use NAMESPACE to define an alias (an alternative name) by which a namespace can be known.

Example:

This example illustrates a namespace declaration, its use as a *SpaceId* in a path, and its use as a character constant in a namespace expression:

```
DECLARE prefixOne NAMESPACE 'http://www.example.com/PO1';

-- On the right hand side of the assignment a namespace constant
-- is being used as such while, on the left hand side, one is
-- being used as an ordinary constant (that is, in an expression).

SET OutputRoot.XMLNS.{prefixOne}:{'PurchaseOrder'} =
               InputRoot.XMLNS.prefixOne:PurchaseOrder;
```

SHARED

Use SHARED to define a shared variable. Shared variables are private to the flow (if declared within a schema) or node (if declared within a module), but are shared between instances of the flow (threads). No type of variable is visible beyond the flow level; for example, you cannot share variables across execution groups.

You can use shared variables to implement an in-memory cache in the message flow; see “Optimizing message flow response times” on page 3264. Shared variables have a long lifetime and are visible to multiple messages passing through a flow; see “Long-lived variables” on page 2378.

Shared variables exist for the lifetime of the:

- Execution group process
- Flow or node, or
- Node ESQL code that declares the variable

(whichever is the shortest). They are initialized when the first message passes through the flow or node after each broker startup.

You cannot define a shared variable within a function or procedure.

The advantages of shared variables, relative to databases, are that:

- Write access is much faster.
- Read access to small data structures is faster.
- Access is direct; that is, there is no need to use a special function (SELECT) to get data, or special statements (INSERT, UPDATE, or DELETE) to modify data. You can refer to the data directly in expressions.

The advantages of databases, relative to shared variables, are that:

- The data is persistent.
- The data is changed transactionally.

These read/write variables are ideal for users who are prepared to sacrifice the persistence and transactional advantages of databases in order to obtain better performance, because they have a longer life than only one message and perform better than a database.

Because SHARED variables can be updated by multiple additional instances, you must ensure that you do not change SHARED variables that might cause unexpected results, for example, if the variable is being used as a counter.

As SHARED variables are initialized once on the first message through a node, it is possible to initialize a SHARED ROW variable once with the results from a Database query. The following code shows an example of how this is achieved:

```
 CREATE SCHEMA testSchema
    DECLARE mySharedRow SHARED ROW;
    DECLARE initialized SHARED BOOLEAN myINIT();

    CREATE COMPUTE MODULE testModule

    CREATE FUNCTION Main() RETURNS BOOLEAN
    BEGIN
    SET OutputRoot.XMLNSC.Top.TEST.Result1 VALUE = initialized;
    SET OutputRoot.XMLNSC.Top.TEST.Result2 = mySharedRow;
  END;

END MODULE;

CREATE FUNCTION myINIT( ) RETURNS BOOLEAN
BEGIN
    LOG EVENT VALUES('myINIT CALLED');
    SET mySharedRow.Top[] = SELECT A.MyCol1, A.MyCol2 from Database.Test AS A;
    RETURN TRUE;
END;
```

You can prevent other instances seeing the intermediate stages of the data by using a BEGIN ATOMIC construct; see “BEGIN ... END statement” on page 5070.

Your user program can make an efficient read, or write, copy of an input message in the input node by using shared-row variables, which simplifies the technique for handling large messages.

Restriction:

Subtrees cannot be copied directly from one shared row variable to another shared row variable. Subtrees can be copied indirectly by using a non-shared row variable. Scalar values extracted from one shared row variable (by using the FIELDVALUE function) can be copied to another shared row variable.

Sample program

The following sample shows how to use both shared and external variables:

- Message Routing

You can view information about samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit or the online information center. You can run samples only when you use the information center that is integrated with the WebSphere Message Broker Toolkit.

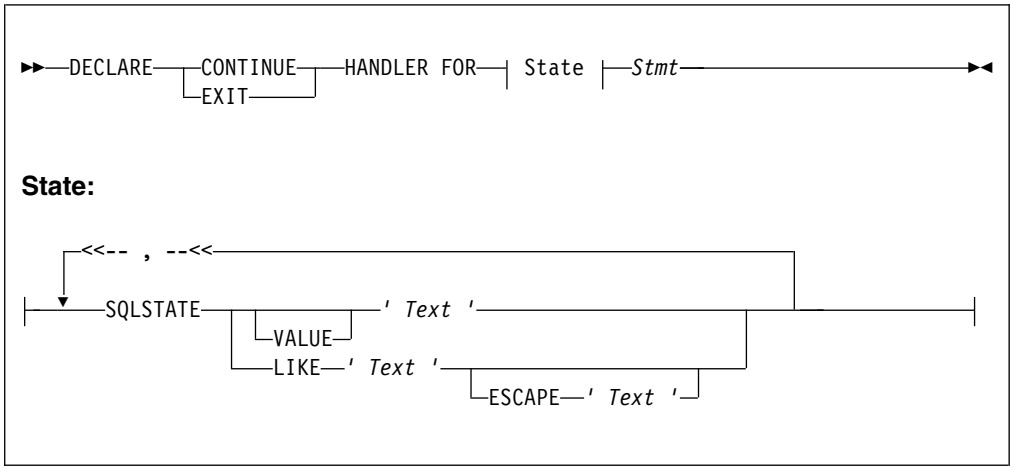
"BEGIN ... END statement" on page 5070
The BEGIN ... END statement gives the statements defined within the BEGIN and END keywords the status of a single statement.

DECLARE HANDLER statement:

The DECLARE HANDLER statement creates an error handler for handling exceptions.

Syntax



You can declare handlers in both explicitly declared (BEGIN...END) scopes and implicitly declared scopes (for example, the ELSE clause of an IF statement). However, all handler declarations must be together at the top of the scope, before any other statements.

If there are no exceptions, the presence of handlers has no effect on the behavior or performance of an SQL program. If an exception occurs, WebSphere Message Broker compares the SQL state of the exception with the SQL states associated with any relevant handlers, until either the exception leaves the node (just as it would if there were no handlers) or a matching handler is found. Within any one scope, handlers are searched in the order they are declared; that is, first to last. Scopes are searched from the innermost to outermost.

The SQL state values provided in DECLARE... HANDLER... statements can be compared directly with the SQL state of the exception or can be compared using wildcard characters. To compare the state values directly, specify either VALUE or no condition operator. To make a wildcard comparison, use the underscore and percent characters to represent single and multiple character wildcards,

respectively, and specify the LIKE operator. The wildcard method allows all exceptions of a general type to be handled without having to list them exhaustively.

If a matching handler is found, the SQLSTATE and other special registers are updated (according to the rules described later in this section) and the handler's statement is processed.

As the handler's statement must be a single statement, it is typically a compound statement (such as BEGIN...END) that contains multiple other statements. There is no special behavior associated with these inner statements and there are no special restrictions. They can, for example, include RETURN, ITERATE, or LEAVE; these affect their containing routines and looping constructs in the same way as if they were contained in the scope itself.

Handlers can contain handlers for exceptions occurring within the handler itself

If processing of the handler's code completes without throwing further unhandled exceptions, execution of the normal code is resumed as follows:

- For EXIT handlers, the next statement processed is the first statement after the handler's scope.
- For CONTINUE handlers, it is the first directly-contained statement after the one that produced the exception.

Each handler has its own SQLCODE, SQLSTATE, SQLNATIVEERROR, and SQLERRORTEXT special registers. These come into scope and their values are set just before the handler's first statement is executed. They remain valid until the handler's last statement has been executed. Because there is no carry over of SQLSTATE values from one handler to another, handlers can be written independently.

Handlers absorb exceptions, preventing their reaching the input node and thus causing the transaction to be committed rather than rolled back. A handler can use a RESIGNAL or THROW statement to prevent this.

See “SQLSTATE function” on page 5173 for a list of the valid SQLSTATES that you can use in a HANDLER.

Example 1

The following example demonstrates proper use of a USER EXCEPTION, and passing SQLCODE, SQLSTATE, SQLNATIVEERROR and SQLERRORTEXT from the exception to the handler. The example also uses the SQLSTATE to catch the specific exception:

```
DECLARE retryCount INTEGER 0;
DECLARE afterCount INTEGER 0;

WHILE retryCount <= 10 DO
  DECLARE EXIT HANDLER FOR SQLSTATE VALUE 'U11222'
  BEGIN
    /* This demonstrates how to pass data to the HANDLER in the SQL
       special registers */
    SET OutputRoot.XMLNSC.Top.WHILE.mySQLCODE = SQLCODE;
    SET OutputRoot.XMLNSC.Top.WHILE.mySQLSTATE = SQLSTATE;
    SET OutputRoot.XMLNSC.Top.WHILE.mySQLNATIVEERROR = SQLNATIVEERROR;
    SET OutputRoot.XMLNSC.Top.WHILE.mySQLERRORTEXT = SQLERRORTEXT;
```

```
    SET retryCount = retryCount + 1;

    /* If we are an EXIT HANDLER, control is now passed to back to the
       WHILE statement */
  END;

  /* In a real scenario this could be a PROPAGATE statement, and the exception
     could be thrown by a 'downstream' node. In this case the HANDLER would
     normally cope with a wider range of exception, for example, using LIKE '%' */
  THROW USER EXCEPTION VALUES( -1, 'U11222', 42, 'error text' );

  /* This is the next statement executed if it is a CONTINUE HANDLER */
  SET afterCount = afterCount + 1;

END WHILE;

SET OutputRoot.XMLNSC.Top.WHILE.retryCount = retryCount;
SET OutputRoot.XMLNSC.Top.WHILE.afterCount = afterCount;

With EXIT (as above) the output is:
<Top>
  <WHILE>
    <mySQLCODE>-1</mySQLCODE>
    <mySQLSTATE>U11222</mySQLSTATE>
    <mySQLNATIVEERROR>42</mySQLNATIVEERROR>
    <mySQLERRORTEXT>error text</mySQLERRORTEXT>
    <retryCount>11</retryCOUNT>
    <afterCount>0</afterCOUNT>
  </WHILE>
</Top>

Changing the HANDLER to be CONTINUE (DECLARE CONTINUE HANDLER FOR SQLSTATE VALUE
'U11222') then the output is:
<Top>
  <WHILE>
    <mySQLCODE>-1</mySQLCODE>
    <mySQLSTATE>U11222</mySQLSTATE>
    <mySQLNATIVEERROR>42</mySQLNATIVEERROR>
    <mySQLERRORTEXT>error text</mySQLERRORTEXT>
    <retryCount>11</retryCOUNT>
    <afterCount>11</afterCOUNT>
  </WHILE>
</Top>
```

You see the difference in `afterCount` in the output message.

Example 2

```
-- Drop the tables so that they can be re-created with the latest definition.
-- If the program has never been run before, errors will occur because you
-- can't drop tables that don't exist. We ignore these.
  BEGIN
    DECLARE CONTINUE HANDLER FOR SQLSTATE LIKE'%' BEGIN END;

    PASSTHRU 'DROP TABLE Shop.Customers' TO Database.DSN1;
    PASSTHRU 'DROP TABLE Shop.Invoices'  TO Database.DSN1;
    PASSTHRU 'DROP TABLE Shop.Sales'     TO Database.DSN1;
    PASSTHRU 'DROP TABLE Shop.Parts'     TO Database.DSN1;
  END;
```

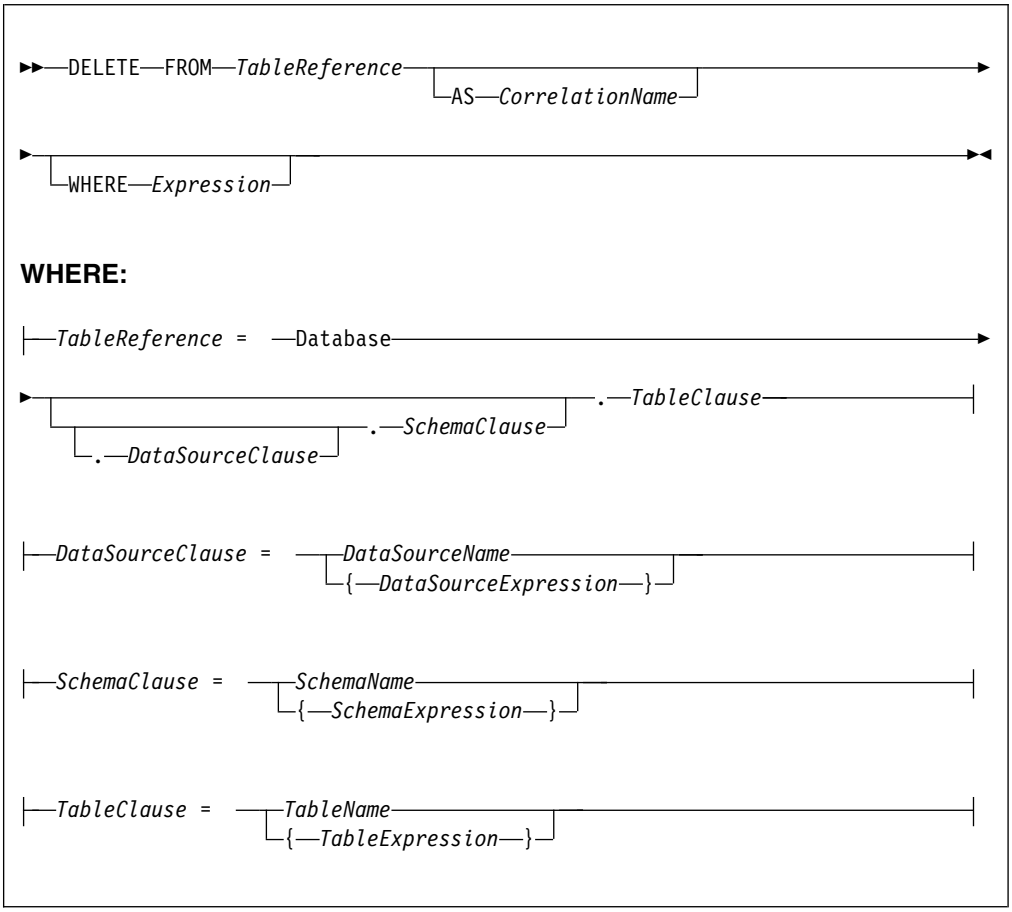
"SQLSTATE function" on page 5173
SQLSTATE is a database state function that returns a 5 character data type of CHARACTER with a default value of '00000' (five zeros as a string).

DELETE FROM statement:

The DELETE FROM statement deletes rows from a table in an external database, based on a search condition.

Syntax



All rows for which the WHERE clause expression evaluates to TRUE are deleted from the table identified by *TableReference*.

Each row is examined in turn and a variable is set to point to the current row. Typically, the WHERE clause expression uses this variable to access column values and thus cause rows to be retained or deleted according to their contents. The variable is referred to by *CorrelationName* or, in the absence of an AS clause, by *TableName*.

Table reference

A table reference is a special case of the field references that are used to refer to message trees. It always starts with the word "Database" and can contain any of the following elements:

- A table name only
- A schema name and a table name
- A data source name (that is, the name of a database instance), a schema name, and a table name

In each case, the name can be specified directly or by an expression enclosed in braces ({...}). A directly-specified data source, schema, or table name is subject to name substitution. That is, if the name used has been declared to be a known name, the value of the declared name is used rather than the name itself (see "DECLARE statement" on page 5117).

If a schema name is not specified, the default schema for the broker's database user is used.

If a data source name is not specified, the database pointed to by the node's `data source` attribute is used.

The WHERE clause

The WHERE clause expression can use any of the broker's operators and functions in any combination. It can refer to table columns, message fields, and any declared variables or constants.

However, be aware that the broker treats the WHERE clause expression by examining the expression and deciding whether the whole expression can be evaluated by the database. If it can, it is given to the database. In order to be evaluated by the database, it must use only those functions and operators supported by the database.

The WHERE clause can, however, refer to message fields, correlation names declared by containing SELECT functions, and to any other declared variables or constants within scope.

If the whole expression cannot be evaluated by the database, the broker looks for top-level AND operators and examines each sub-expression separately. It then attempts to give the database those sub-expressions that it can evaluate, leaving the broker to evaluate the rest. You need to be aware of this situation for two reasons:

1. Apparently trivial changes to WHERE clause expressions can have large effects on performance. You can determine how much of the expression was given to the database by examining a user trace.
2. Some databases' functions exhibit subtle differences of behavior from those of the broker.

Handling errors

It is possible for errors to occur during delete operations. For example, the database might not be operational. In these cases, an exception is thrown (unless the node has its `throw exception on database error` property set to FALSE). These exceptions set appropriate SQL code, state, native error, and error text values and can be dealt with by error handlers (see the DECLARE HANDLER statement).

For further information about handling database errors, see "Capturing database state" on page 2512.

Examples

The following example assumes that the `dataSource` property has been configured and that the database it identifies has a table called SHAREHOLDINGS, with a column called ACCOUNTNO.

```
DELETE FROM Database.SHAREHOLDINGS AS S
       WHERE S.ACCOUNTNO = InputBody.AccountNumber;
```

This example removes all the rows from the SHAREHOLDINGS table where the value in the ACCOUNTNO column (in the table) is equal to that in the `AccountNumber` field in the message. This operation might delete zero, one, or more rows from the table.

The next example shows the use of calculated data source, schema, and table names:

```
-- Declare variables to hold the data source, schema, and table names and
-- set their default values
DECLARE Source CHARACTER 'Production';
DECLARE Schema CHARACTER 'db2admin';
DECLARE Table  CHARACTER 'DynamicTable1';

-- Code which calculates their actual values comes here

-- Delete rows from the table
DELETE FROM Database.{Source}.{Schema}.{Table} As R WHERE R.Name = 'Joe';
```

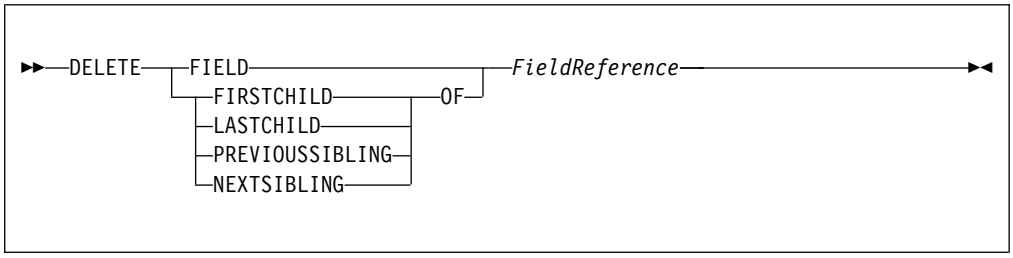
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

DELETE statement:

The DELETE statement detaches and destroys a portion of a message tree, allowing its memory to be reused. This statement is particularly useful when handling very large messages.

Syntax



If the target field does not exist, the statement does nothing and normal processing continues. If any reference variables point into the deleted portion, they are disconnected from the tree so that no action involving them has any effect, and the LASTMOVE function returns FALSE. Disconnected reference variables can be reconnected by using a MOVE... TO... statement.

Example

```
DELETE FIELD OutputRoot.XMLNS.Data.Folder1.Folder12;
DELETE LASTCHILD OF Cursor;
```

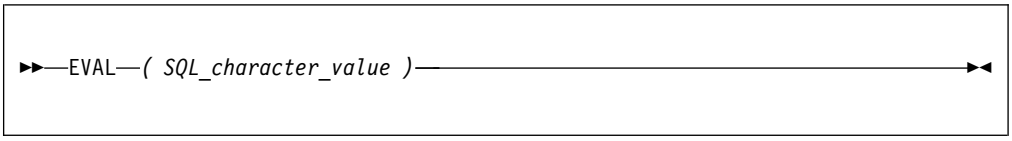
The ATTACH statement attaches a portion of a message tree into a new position in the message hierarchy.

EVAL statement:

The EVAL statement takes a character value, interprets it as an SQL statement, and processes that statement.

For details of the EVAL function, see “EVAL function” on page 5294.

Syntax



EVAL takes one parameter in the form of an expression, evaluates this expression, and casts the resulting value to a character string if it is not one already. The expression that is passed to EVAL must therefore be able to be represented as a character string.

After this first stage evaluation is complete, the behavior of EVAL depends on whether it is being used as a complete ESQL statement, or in place of an expression that forms part of an ESQL statement:

- If it is a complete ESQL statement, the character string derived from the first stage evaluation is processed as if it were an ESQL statement.
- If it is an expression that forms part of an ESQL statement, the character string is evaluated as if it were an ESQL expression and EVAL returns the result.

User defined procedures cannot be defined within an EVAL statement but EVAL can be used to call a user-defined procedure that is in scope where the EVAL statement is used.

If you use the EVAL statement to call out to a user-defined procedure that is not called from anywhere else in the ESQL for a given node, you need to add the following code to your ESQL, to ensure that the user-defined procedure being called is included when the code is compiled:

```
IF (FALSE) THEN CALL procedure(<parameters>); END IF;
```

Note, that in the preceding code, you must replace `procedure()` with the named procedure in question.

In the following examples, A and B are integer scalar variables, and scalarVar1 and OperatorAsString are character string scalar variables.

The following examples are valid uses of EVAL:

- `SET OutputRoot.XMLNS.Data.Result = EVAL(A+B);`

  The expression A+B is acceptable because, although it returns an integer value, integer values are representable as character strings, and the necessary cast is performed before EVAL continues with its second stage of evaluation.
- `SET OutputRoot.XMLNS.Data.Result  = EVAL('A' || operatorAsString || 'B');`
- `EVAL('SET ' || scalarVar1 || ' = 2;');`

  The semicolon included at the end of the final string literal is necessary, because if EVAL is being used in place of an ESQL statement, its first stage evaluation must return a string that represents a valid ESQL statement, including the terminating semicolon.

Variables declared in an EVAL statement do not exist outside that EVAL statement.

The real power of EVAL is that it allows you to dynamically construct ESQL statements or expressions. In the second and third examples above, the value of scalarVar1 or operatorAsString can be set according to the value of an incoming message field, or other dynamic value, allowing you to effectively control what ESQL is processed without requiring a potentially lengthy IF-THEN ladder.

However, consider the performance implications in using EVAL. Dynamic construction and processing of statements or expressions is necessarily more time-consuming than simply processing pre-constructed ones. If performance is vital, you might prefer to write more specific, but faster, ESQL.

The following are not valid uses of EVAL:

- `SET EVAL(scalarVar1) = 2;`

  In this example, EVAL is being used to replace a field reference, not an expression.
- `SET OutputRoot.XMLNS.Data.Result[] = EVAL((SELECT T.x FROM Database.y AS T));`

  In this example, the `(SELECT T.x FROM Database.y)` passed to EVAL returns a list, which is not representable as a character string.

The following example is acceptable because `(SELECT T.x FROM Database.y AS T)` is a character string literal, not an expression in itself, and therefore is representable as a character string.

```
SET OutputRoot.XMLNS.Data.Result[]
 = EVAL('(SELECT T.x FROM Database.y AS T)');
```

Functions that are referenced only in an EVAL statement, and not in the rest of the ESQL module, might not be included in the BAR file. In the following examples, the function MyFunction must be referenced somewhere else in the ESQL module, otherwise the BAR file might fail to deploy.

```
EVAL('CALL MyFunction(parm1, parm2);');
```

```
DECLARE functionName CHARACTER 'Function';
DECLARE callStmt CHARACTER 'CALL My' || functionName || '(parm1, parm2);';
EVAL(callStmt);
```

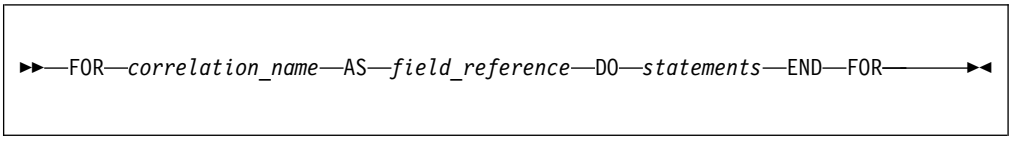
The EVAL function takes a character value and interprets that value as an ESQL expression that returns a value.

FOR statement:

The FOR statement iterates through a list (for example, a message array).

Syntax



For each iteration, the FOR statement makes the correlation variable (*correlation_name* in the syntax diagram) equal to the current member of the list (*field_reference*), then executes the block of statements. The advantage of the FOR statement is that it iterates through a list without your having to write any sort of loop construct (and eliminates the possibility of infinite loops).

For example the following ESQL:

```
SET OutputRoot.MQMD=InputRoot.MQMD;

SET Environment.SourceData.Folder[1].Field1 = 'Field11Value';
SET Environment.SourceData.Folder[1].Field2 = 'Field12Value';
SET Environment.SourceData.Folder[2].Field1 = 'Field21Value';
SET Environment.SourceData.Folder[2].Field2 = 'Field22Value';

DECLARE i INTEGER 1;
FOR source AS Environment.SourceData.Folder[] DO
     CREATE LASTCHILD OF OutputRoot.XMLNSC.Data.ResultData.MessageArrayTest.Folder[i]
            NAME 'FieldA' VALUE '\' || source.Field1 || '\' || CAST(i AS CHAR);
```

```
    CREATE LASTCHILD OF OutputRoot.XMLNSC.Data.ResultData.MessageArrayTest.Folder[i]
           NAME 'FieldB' VALUE '\' || source.Field2 || '\' || CAST(i AS CHAR);
    SET i = i + 1;
END FOR;
```

generates the output message:

```
<Data>
 <ResultData>
  <MessageArrayTest>
   <Folder>
    <FieldA>Field11Value\1</FieldA>
    <FieldB>Field12Value\1</FieldB>
   </Folder>
   <Folder>
    <FieldA>Field21Value\2</FieldA>
    <FieldB>Field22Value\2</FieldB>
   </Folder>
  </MessageArrayTest>
 </ResultData>
</Data>
```

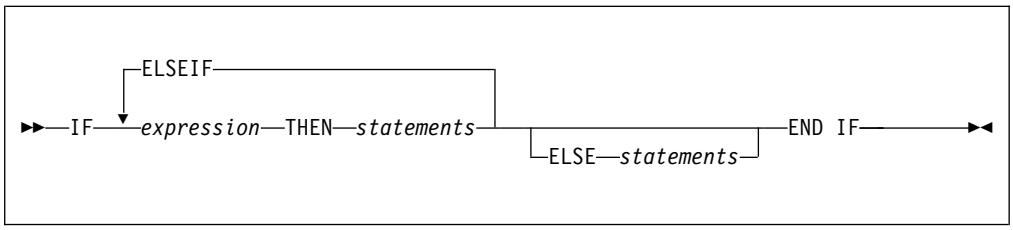
"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

IF statement:

The IF statement executes one set of statements based on the result of evaluating condition expressions.

Syntax



Each expression is evaluated in turn until one results in TRUE; the corresponding set of statements is then executed. If none of the expressions returns TRUE, and the optional ELSE clause is present, the ELSE clause's statements are executed.

UNKNOWN and FALSE are treated the same: the next condition expression is evaluated. ELSEIF is one word with no space between the ELSE and the IF. However, you can nest an IF statement within an ELSE clause: if you do, you can terminate both statements with END IF.

Example

```
IF i = 0 THEN
   SET size = 'small';
ELSEIF i = 1 THEN
   SET size = 'medium';
ELSEIF j = 4 THEN
   SET size = 'large';
ELSE
   SET size = 'unknown';
END IF;
```

```
IF J> MAX THEN
  SET J = MAX;
  SET Limit = TRUE;
END IF;
```

When you want to access the contents of a message, for reading or writing, use the structure and arrangement of the elements in the tree that is created by the parser from the input bit stream.

Related reference:

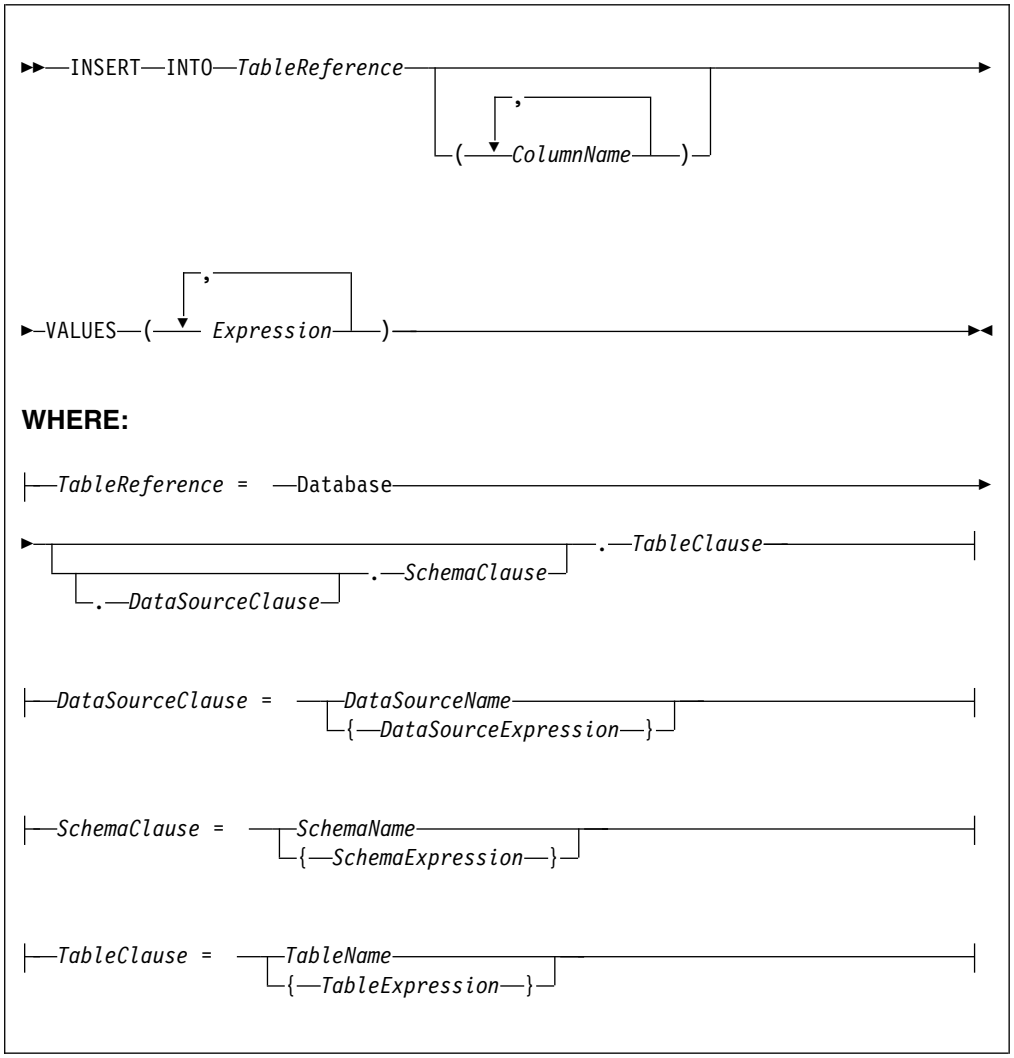
"Syntax diagrams" on page 3677

"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

INSERT statement:

The INSERT statement inserts a row into a database table.

Syntax



A single row is inserted into the table identified by *TableReference*. The *ColumnName* list identifies those columns in the target table that are to be given specific values. These values are determined by the expressions within the VALUES clause (the first expression gives the value of the first named column, and so on). The number of expressions in the VALUES clause must be the same as the number of named columns. Any columns present in the table but not mentioned in the list are given their default values.

Table reference

A table reference is a special case of the field references that are used to refer to message trees. It always starts with the word "Database" and can contain any of the following elements:

- A table name only
- A schema name and a table name
- A data source name (that is, the name of a database instance), a schema name, and a table name

In each case, the name can be specified directly or by an expression enclosed in braces ({...}). A directly-specified data source, schema, or table name is subject to

name substitution. That is, if the name used has been declared to be a known name, the value of the declared name is used rather than the name itself (see "DECLARE statement" on page 5117).

If a schema name is not specified, the default schema for the broker's database user is used.

If a data source name is not specified, the database pointed to by the node's `data source` attribute is used.

Handling errors

Errors can occur during insert operations. For example, the database might not be operational, or the table might have constraints defined that the new row would violate. In these cases, an exception is thrown, unless you have cleared the node property Throw Exception on Database Error. These exceptions set appropriate values for the following items, and can be dealt with by error handlers (see the DECLARE HANDLER statement):

- SQL code
- State
- Native error
- Error text

For further information about handling database errors, see "Capturing database state" on page 2512.

Examples

The following example assumes that the Data Source property of the Database node has been configured, and that the database it identifies has a table called TABLE1 with columns A, B, and C.

Given a message with the following generic XML body:

```
<A>
 <B>1</B>
 <C>2</C>
 <D>3</D>
</A>
```

The following INSERT statement inserts a new row into the table with the values 1, 2, and 3 for the columns A, B, and C:

```
INSERT INTO Database.TABLE1(A, B, C) VALUES (Body.A.B, Body.A.C, Body.A.D);
```

The next example shows the use of calculated data source, schema, and table names:

```
-- Declare variables to hold the data source, schema, and table names
-- and set their default values
DECLARE Source CHARACTER 'Production';
DECLARE Schema CHARACTER 'db2admin';
DECLARE Table  CHARACTER 'DynamicTable1';

-- Code which calculates their actual values comes here

-- Insert the data into the table
INSERT INTO Database.{Source}.{Schema}.{Table} (Name, Value) values ('Joe', 12.34);
```

Inserting a bit stream into a database

If the database column into which you want to insert data is set to a binary data type such as BLOB, the input message must be represented in bitstream form. If the input message is in the BLOB domain, use the following ESQL code:

```
DECLARE msgBitStream BLOB InputRoot.BLOB.BLOB;
INSERT INTO Database.TABLE1(MSGDATA) VALUES (msgBitStream);
```

Alternatively, if the input message is in an XML domain such as XMLNS, then the message tree must be serialized before the INSERT statement. To serialize the message tree and insert the contents into the database, use the following ESQL code:

```
DECLARE propRef REFERENCE TO InputRoot.Properties;
DECLARE msgBitStream BLOB ASBITSTREAM(InputRoot.XMLNS, propRef.Encoding, propRef.CodedCharSetId);
INSERT INTO Database.TABLE1(MSGDATA) VALUES (msgBitStream);
```

If the input messages received by your message flow come from different code pages, the CodedCharSetID and Encoding information is lost if you use the previous example. To capture CodedCharSetID and Encoding information, you can extend the table with two numeric columns to store the CodedCharSetID and Encoding data. To extend the table, modify the ESQL from the previous example to insert the CodedCharSetID and Encoding data into separate database columns:

```
DECLARE propRef REFERENCE TO InputRoot.Properties;
DECLARE inCCSID INT propRef.CodedCharSetId;
DECLARE inEncoding INT propRef.Encoding;
DECLARE msgBitStream BLOB ASBITSTREAM(InputRoot.XMLNS, inEncoding, inCCSID);
INSERT INTO Database.TABLE1(MSGDATA, MSGENCODING, MSGCCSID) VALUES
(msgBitStream, inEncoding, inCCSID);
```

As an extension to the previous example, if you require the entire message to be stored along with its MQMD header, and use it later for reconstructing the entire message in another message flow on a different platform using a different code page and encoding, the database table can be extended to hold all the numeric fields of the MQMD header.

For example, a message flow running on AIX inserts a message bit stream into the database table and another message flow running on Windows retrieves it and attempts to reconstruct the message along with the stored MQMD header.

The following set of numeric fields are contained in the MQMD header:

```
BackoutCount (MQLONG)
CodedCharSetId (MQLONG)
Encoding (MQLONG)
Expiry (MQLONG)
Feedback (MQLONG)
MsgFlags (MQLONG)
MsgSeqNumber (MQLONG)
MsgType (MQLONG)
Offset (MQLONG)
OriginalLength (MQLONG)
Persistence (MQLONG)
Priority (MQLONG)
PutApplType (MQLONG)
Report (MQLONG)
Version (MQLONG)
```

The following example uses CodedCharSetID, Encoding, Priority, and MsgSeqNumber:

```
DECLARE propRef REFERENCE TO InputRoot.Properties;
DECLARE mqmdRef REFERENCE TO InputRoot.MQMD;
DECLARE inCCSID INT propRef.CodedCharSetId;
```

```
DECLARE inEncoding INT propRef.Encoding;

DECLARE inPriority INT mqmdRef.Priority;
DECLARE inMsgSeqNumber INT mqmdRef.MsgSeqNumber;

DECLARE msgBitStream BLOB ASBITSTREAM(InputRoot, inEncoding, inCCSID);

INSERT INTO Database.TABLE1(MSGDATA, MSGENCODING, MSGCCSID, MSGPRIORITY,MSGSEQNUMBER)
VALUES (msgBitStream, inEncoding, inCCSID, inPriority, inMsgSeqNumber);
```

If you want to insert an XML message into a database column that has a CHAR or VARCHAR data type, the ESQL must be modified to convert the input message to the CHAR data type before the `INSERT` statement. In the following example, a `CAST` is used to transform the serialized message to the CHAR data type. The `CodedCharSetID` and `Encoding` data are inserted into separate database columns.

```
DECLARE propRef REFERENCE TO InputRoot.Properties;
DECLARE inCCSID INT propRef.CodedCharSetId;
DECLARE inEncoding INT propRef.Encoding;
DECLARE msgBitStream BLOB ASBITSTREAM(InputRoot.XMLNS, inEncoding, inCCSID);
DECLARE msgChar CHAR CAST(msgBitStream AS CHAR CCSID inCCSID);
INSERT INTO Database.TABLE1(MSGDATA, MSGENCODING, MSGCCSID) VALUES (msgChar, inEncoding, inCCSID);
```

For examples of how to extract a message bit stream from a database, based on the two previous examples, see “Selecting bitstream data from a database” on page 2493.

If an error occurs when the broker accesses an external database, you can either let the broker throw an exception during node processing or use ESQL statements to process the exception within the node itself.

Related reference:

“Syntax diagrams” on page 3677

“ESQL statements” on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

ITERATE statement:

The ITERATE statement stops the current iteration of the containing WHILE, REPEAT, LOOP, or BEGIN statement identified by Label.

The containing statement evaluates its loop condition (if any), and either starts the next iteration or stops looping, as the condition dictates.

Syntax

Example

In the following example, the loop iterates four times; that is the line identified by the comment Some statements 1 is passed through four times. However, the line identified by the comment Some statements 2 is passed through twice only because of the action of the IF and ITERATE statements. The ITERATE statement does **not** bypass testing the loop condition. Take particular care that the action of the ITERATE does not bypass the logic that makes the loop advance and eventually terminate. The loop count is incremented at the start of the loop in this example:

```
DECLARE i INTEGER;
SET i = 0;
X : REPEAT
  SET i = i + 1;

  -- Some statements 1

  IF i IN(2, 3) THEN
    ITERATE X;
  END IF;

  -- Some statements 2

UNTIL
  i>= 4
END REPEAT X;
```

ITERATE statements do not have to be directly contained by their labelled statement, making ITERATE statements particularly powerful.

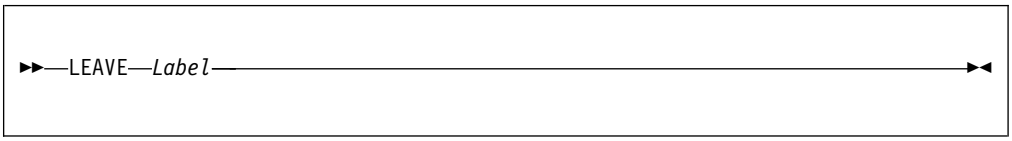
LEAVE statement:

The LEAVE statement stops the current iteration of the containing WHILE, REPEAT, LOOP, or BEGIN statement identified by Label.

The containing statement's evaluation of its loop condition (if any) is bypassed and looping stops.

Syntax



Examples

In the following example, the loop iterates four times:

```
DECLARE i INTEGER;
SET i = 1;
X : REPEAT
  ...
  IF i>= 4 THEN
    LEAVE X;
  END IF;

  SET i = i + 1;
UNTIL
  FALSE
END REPEAT;
```

LEAVE statements do not have to be directly contained by their labelled statement, making LEAVE statements particularly powerful.

```
DECLARE i INTEGER;
SET i = 0;
X : REPEAT                    -- Outer loop
  ...
  DECLARE j INTEGER;
  SET j = 0;
  REPEAT                      -- Inner loop
    ...
    IF i>= 2 AND j = 1 THEN
      LEAVE X;                -- Outer loop left from within inner loop
    END IF;
    ...
    SET j = j + 1;
  UNTIL
    j>= 3
  END REPEAT;

  SET i = i + 1;
UNTIL
  i>= 3
END REPEAT X;
                              -- Execution resumes here after the leave
```

Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

Related reference:

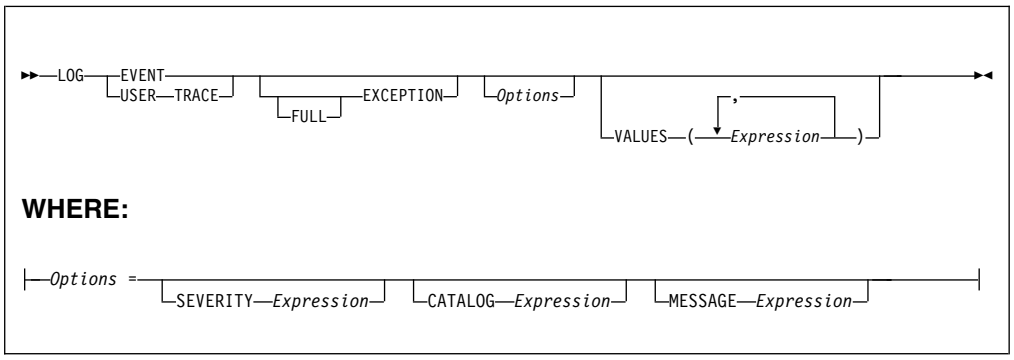
"Syntax diagrams" on page 3677

"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

LOG statement:

Use the LOG statement to write a record to the event log or to the user trace.

Syntax



CATALOG
CATALOG is an optional clause; if you omit it, CATALOG defaults to the WebSphere Message Broker current version catalog. To use the current version message catalog explicitly, use BIPmsgs on all operating systems.

EVENT
A record is written to the event log, and also to the user trace, if user tracing is enabled.

EXCEPTION
The current exception, if any, is logged.

For more information on exceptions, see "Errors and exception handling" on page 2973.

FULL
The complete nested exception report is logged, just as if the exception had reached the input node. If FULL is not specified, any wrapping exceptions are ignored, and only the original exception is logged. Therefore, you can have either a full report or simply the actual error report without the extra information regarding what was going on at the time. A current exception only exists within handler blocks (see "Handling errors in message flows" on page 2823).

MESSAGE
The number of the message to be used. If specified, the MESSAGE clause can contain any expression that returns a non-NULL, integer, value.

If you omit MESSAGE, its value defaults to the first message number (2951) in a block of messages that is provided for use by the LOG and THROW statements in the WebSphere Message Broker catalog. If you specify a message number, you can use message numbers 2951 through 2999. Alternatively, you can generate your own catalog.

SEVERITY
The severity associated with the message. If specified, the SEVERITY clause can contain any expression that returns a non-NULL, integer, value. If you omit the clause, its value defaults to 1.

USER TRACE
A record is written to the user trace, whether user trace is enabled or not.

VALUES
Use the optional VALUES clause to provide values for the data inserts in your message. You can insert any number of pieces of information, but the messages supplied (2951 - 2999) cater for a maximum of ten data inserts.

Note the general similarity of the LOG statement to the THROW statement.

```
-- Write a message to the event log specifying the severity, catalog and message
-- number. Four inserts are provided
LOG EVENT SEVERITY 1 CATALOG 'BIPmsgs' MESSAGE 2951 VALUES(1,2,3,4);

-- Write to the trace log whenever a divide by zero occurs
BEGIN
  DECLARE a INT 42;
  DECLARE b INT 0;
  DECLARE r INT;

  BEGIN
    DECLARE EXIT HANDLER FOR SQLSTATE LIKE 'S22012' BEGIN
      LOG USER TRACE EXCEPTION VALUES(SQLSTATE, 'DivideByZero');

      SET r = 0x7FFFFFFFFFFFFFFF;
    END;

    SET r = a / b;
  END;

  SET OutputRoot.XMLNS.Data.Result = r;
END;
```

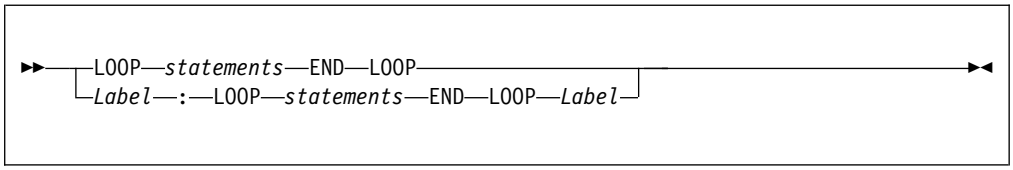
LOOP statement:

The LOOP statement executes the sequence of statements repeatedly and unconditionally.

Ensure that the logic of the program provides some means of terminating the loop. You can use either LEAVE or RETURN statements.

Syntax



If present, *Label* gives the statement a name. This has no effect on the behavior of the LOOP statement, but allows *statements* to include ITERATE and LEAVE statements or other labelled statements, which in turn include ITERATE and LEAVE. The second *Label* can be present only if the first *Label* is present and, if it is, the labels must be identical.

Two or more labelled statements at the same level can have the same *Label* but this partly negates the advantage of the second *Label*. The advantage is that it unambiguously and accurately matches each END with its LOOP. However, a labelled statement within *statements* cannot have the same label, because this makes the behavior of the ITERATE and LEAVE statements ambiguous.

The LOOP statement is useful in cases where the required logic dictates that a loop is always exited part way through. This is because, in these cases, the testing of a loop condition that occurs in REPEAT or WHILE statements is both unnecessary and wasteful.

Example

```
DECLARE i INTEGER;
SET i = 1;
X : LOOP
  ...
  IF i>= 4 THEN
    LEAVE X;
  END IF;
  SET i = i + 1;
END LOOP X;
```

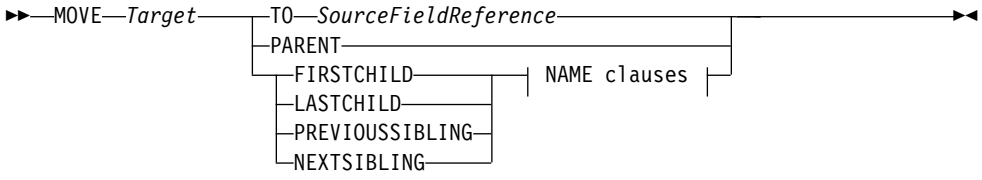
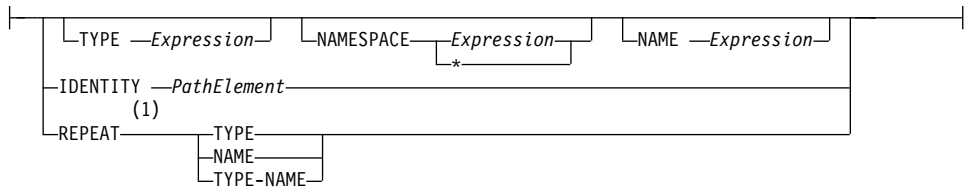
MOVE statement:

The MOVE statement changes the field to which the *Target* reference variable points.

Syntax



NAME clauses:



Notes:

1 The *RepeatClause* can be used only with the **PREVIOUSSIBLING** and **NEXTSIBLING** qualifiers.

If you include a TO clause, this clause changes the target reference to point to the same entity as that pointed to by source; this can either be a message field or a declared variable.

If you include a PARENT, PREVIOUSSIBLING, NEXTSIBLING, FIRSTCHILD, or LASTCHILD clause, the MOVE statement attempts to move the target reference variable in the direction specified relative to its current position. If any field exists in the given direction, the move succeeds. If there is no such field, the move fails; that is the reference variable continues to point to the same field or variable as before, and the LASTMOVE function returns false. You can use the LASTMOVE function to determine the success or failure of a move.

If a TYPE clause, NAME clause, or both are present, the target is again moved in the direction specified (PREVIOUSSIBLING or NEXTSIBLING, or FIRSTCHILD or LASTCHILD) but to a field with the given type, name, or both. This is particularly useful when the name or type (or both) of the target field is known, because this reduces the number of MOVE statements required to navigate to a field. This is because fields that do not match the criteria are skipped over; this can also include unexpected message tree fields, for example, those representing white space.

If the specified move cannot be made (that is, a field with the given type or name does not exist), the target remains unchanged and the LASTMOVE function returns false. The TYPE clause, NAME clause, or both clauses can contain any expression that returns a value of a suitable data type (INTEGER for type and CHARACTER for name). An exception is thrown if the value supplied is NULL.

Two further clauses, NAMESPACE and IDENTITY enhance the functionality of the NAME clause.

The NAMESPACE clause takes any expression that returns a non-null value of type character. It also takes an * indicating any namespace. Note that this cannot be confused with an expression because * is not a unary operator in ESQL.

The meaning depends on the presence of NAME and NAMESPACE clauses as follows:

NAMESPACE	NAME	Element located by...
No	No	Type, index, or both
No	Yes	Name in the default namespace
*	Yes	Name
Yes	No	Namespace
Yes	Yes	Name and namespace

The IDENTITY clause takes a single path element in place of the TYPE, NAMESPACE, and NAME clauses and follows all the rules described in the topic for field references (see "ESQL field reference overview" on page 5049).

When using MOVE with PREVIOUSSIBLING or NEXTSIBLING, you can specify REPEAT, TYPE, and NAME keywords that move the target to the previous or next field with the same type and name as the current field. The REPEAT keyword is particularly useful when moving to a sibling of the same kind, because you do not have to write expressions to define the type and name.

Example

```
MOVE cursor FIRSTCHILD TYPE Name NAME 'Field1';
```

This example moves the reference variable cursor to the first child field of the field to which the cursor is currently pointing, that has the type *Name* and the name *Field1*.

See "FIELDTYPE function" on page 5231 for a list of the types you can use.

The MOVE statement never creates new fields.

A common usage of the MOVE statement is to step from one instance of a repeating structure to the next. The fields within the structure can then be accessed by using a relative field reference. For example:

```
WHILE LASTMOVE(sourceCursor) DO
  SET targetCursor.ItemNumber  = sourceCursor.item;
  SET targetCursor.Description = sourceCursor.name;
  SET targetCursor.Price       = sourceCursor.prc;
  SET targetCursor.Tax         = sourceCursor.prc * 0.175;
```

```
  SET targetCursor.quantity    = 1;
  CREATE NEXTSIBLING OF targetCursor AS targetCursor REPEAT;
  MOVE sourceCursor NEXTSIBLING REPEAT TYPE NAME;
END WHILE;
```

For more information about reference variables, and an example of moving a reference variable, see “Creating dynamic field references” on page 2431.

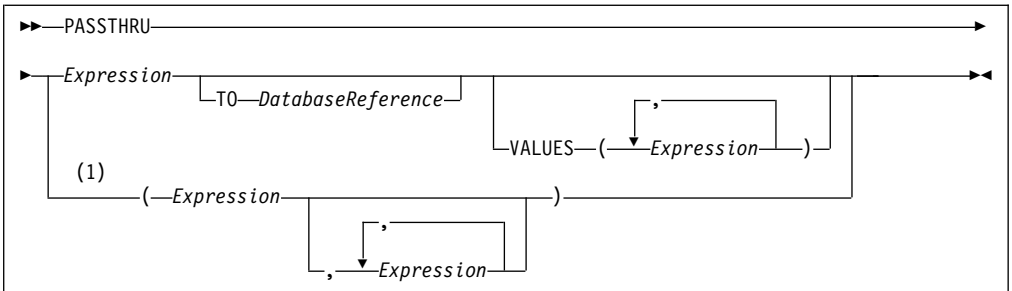
PASSTHRU statement:

The PASSTHRU statement evaluates an expression and runs the resulting character string as a database statement.



WHERE:

Notes:

1 The lower half of the main syntax diagram (the second of the two ways of coding the *Expression* to be passed to PASSTHRU) describes syntax retained for backward compatability.

Usage

The main use of the PASSTHRU statement is to issue administrative commands to databases (for example, to create a table).

Note: Do not use PASSTHRU to call stored procedures; instead, use the CALL statement because PASSTHRU imposes limitations (you cannot use output parameters, for example).

The first expression is evaluated and the resulting character string is passed to the database pointed to by *DatabaseReference* (in the TO clause) for execution. If the TO clause is not specified, the database pointed to by the node's `data source` attribute is used.

Use question marks (?) in the database string to denote parameters. The parameter values are supplied by the VALUES clause.

If the VALUES clause is specified, its expressions are evaluated and passed to the database as parameters; (that is, the expressions' values are substituted for the question marks in the database statement).

If only one VALUE expression exists, the result might or might not be a list. If it is a list, the list's scalar values are substituted sequentially for the question marks. If it is not a list, the single scalar value is substituted for the (single) question mark in the database statement. If more than one VALUE expression exists, none of the expressions evaluate to a list; their scalar values are substituted sequentially for the question marks instead.

Because the database statement is constructed by the user program, it is not essential to use parameter markers (that is, the question marks) or the VALUES clause, because the whole of the database statement could be supplied, as a literal string, by the program. However, use parameter markers whenever possible because this reduces the number of different statements that need to be prepared and stored in the database and the broker.

Database reference

A database reference is a special instance of the field references that is used to refer to message trees. It consists of the word **Database** followed by the name of a data source (that is, the name of a database instance).

You can specify the data source name directly or by an expression enclosed in braces ({...}). A directly-specified data source name is subject to name substitution. That is, if the name used has been declared to be a known name, the value of the declared name is used rather than the name itself (see "DECLARE statement" on page 5117).

If you have created a message flow that contains one of the following nodes, and the ESQL that is associated with this node includes a PASSTHRU statement and a database reference, you must specify a value for the `Data source` property of the relevant node:

- Compute
- Database
- Filter

Handling errors

It is possible for errors to occur during PASSTHRU operations. For example, the database might not be operational or the statement might be invalid. In these cases, an exception is thrown (unless the node has its `Throw exception on database error` property cleared). These exceptions set appropriate SQL code, state, native error, and error text values and can be dealt with by error handlers (see the DECLARE HANDLER statement).

For further information about handling database errors, see "Capturing database state" on page 2512.

Examples

The following example creates the table `Customers` in schema `Shop` in database DSN1:

```
PASSTHRU 'CREATE TABLE Shop.Customers (
  CustomerNumber INTEGER,
  FirstName      VARCHAR(256),
  LastName       VARCHAR(256),
  Street         VARCHAR(256),
  City           VARCHAR(256),
  Country        VARCHAR(256)
)' TO Database.DSN1;
```

If, as in the last example, the ESQL statement is specified as a string literal, you must put single quotation marks around it. If, however, it is specified as a variable, omit the quotation marks. For example:

```
SET myVar = 'SELECT * FROM user1.stocktable';
SET OutputRoot.XMLNS.Data[] = PASSTHRU(myVar);
```

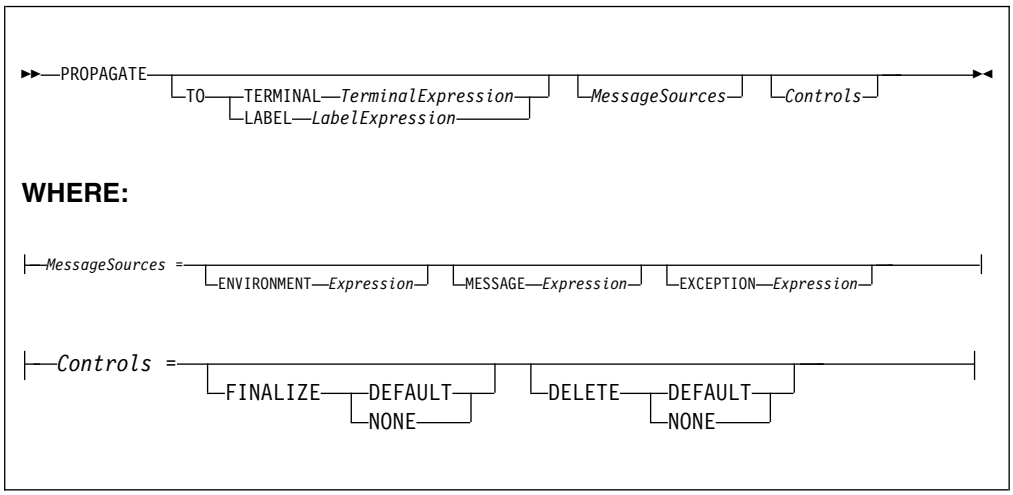
The following example "drops" (that is, deletes) the table `Customers` from schema `Shop` in database DSN1:

```
PASSTHRU 'DROP TABLE Shop.Customers' TO Database.DSN1;
```

PROPAGATE statement:

The PROPAGATE statement propagates a message to the downstream nodes.

Syntax



You can use the PROPAGATE statement in Compute and Database nodes, but not in Filter nodes. The additions to this statement assist in error handling - see "Coding ESQL to handle errors" on page 2506.

TO TERMINAL clause

If the TO TERMINAL clause is present, *TerminalExpression* is evaluated. If the result is of type CHARACTER, a message is propagated to a terminal according to the rule:

```
'nowhere' : no propagation
'failure' : Failure
 'out'    : Out
 'out1'   : Out1
 'out2'   : Out2
 'out3'   : Out3
 'out4'   : Out4
```

Tip: Terminal names are case sensitive so, for example, Out1 does not match any terminal.

If the result of *TerminalExpression* is of type INTEGER, a message is propagated to a terminal according to the rule:

```
-2 : no propagation
-1 : Failure
 0 : Out
 1 : Out1
 2 : Out2
 3 : Out3
 4 : Out4
```

If the result of *TerminalExpression* is neither a CHARACTER nor an INTEGER, the broker throws an exception.

If there is neither a TO TERMINAL nor a TO LABEL clause, the broker propagates a message to the Out terminal.

Tip: Using character values in terminal expressions leads to the most natural and readable code. Integer values, however, are easier to manipulate in loops and marginally faster.

TO LABEL clause

If the TO LABEL clause is present, *LabelExpression* is evaluated. If the result is of type CHARACTER **and** there is a Label node with a Label property that matches *LabelExpression*, in the same flow, the broker propagates a message to that node.

Tip: Labels, like terminals, are case sensitive. Also, note that, as with route to Label nodes, it is the Label Name property of the Label node that defines the target, not the node's label itself.

If the result of *LabelExpression* is NULL or not of type CHARACTER, or there is no matching Label node in the flow, the broker throws an exception.

If there is neither a TO TERMINAL nor a TO LABEL clause, the broker propagates a message to the out terminal.

MessageSources clauses

The MessageSources clauses select the message trees to be propagated. This clause is only applicable to the Compute node (it has no effect in the Database node).

The values that you can specify in MessageSources clauses are:

```
ENVIRONMENT :
  InputLocalEnvironment
  OutputLocalEnvironment

Message :
  InputRoot
  OutputRoot

ExceptionList :
  InputExceptionList
  OutputExceptionList
```

If there is no MessageSources clause, the node's Compute mode property is used to determine which messages are propagated.

FINALIZE clause

Finalization is a process that fixes header chains and makes the Properties folder match the headers. If present, the FINALIZE clause allows finalization to be controlled.

This clause is only applicable to the Compute node (it has no effect in a Database node).

The Compute node allows its output message to be changed by other nodes (by the other nodes changing their input message). However, a message created by a Compute node cannot be changed by another node after:

- It has been finalized
- It has reached any output or other node which generates a bit-stream

If FINALIZE is set to DEFAULT, or the FINALIZE clause is absent, the output message (but not the Environment, Local Environment or Exception List) is finalized before propagation.

If FINALIZE is set to NONE, no finalization takes place. This option is required if you want to preserve and allow updates of the entire output

message tree by the nodes downstream in the message flow and is used with DELETE NONE as described in the next section.

DELETE clause

The DELETE clause allows the clearing of the output local environment, message, and exception list to be controlled.

The DELETE clause is only applicable to the Compute node (it has no effect in a Database node).

If DELETE is set to DEFAULT, or the DELETE clause is absent, the output local environment, message, and exception list are all cleared and their memory recovered immediately after propagation.

If DELETE is set to NONE, nothing is cleared. Use DELETE NONE if you want the downstream nodes to be able to see a single instance of output local environment message, and exception list trees. Each propagate starts with the content of these trees as created by the previous propagate rather than starting with empty trees. If you also want these nodes to update the output tree, DELETE NONE must be used with the FINALIZE NONE option described in the previous section.

Note that the output trees that are finalized are cleared, regardless of which ones are propagated.

Propagation is a synchronous process. That is, the next statement is not executed until all the processing of the message in downstream nodes has completed. Be aware that this processing might throw exceptions and, if these exceptions are not caught, they will prevent the statement following the PROPAGATE call being reached. This behavior might be what the logic of your flow requires but, if it is not, you can use a handler to catch the exception and perform the necessary actions. Note that exceptions thrown downstream of a propagate, if not caught, will also prevent the final automatic actions of a Compute or Database node (for example, issuing a COMMIT Transaction set to Commit) from taking place.

If you are using the PROPAGATE statement in your node it is important that you use a `RETURN FALSE;` to prevent automatic propagation of the message to the next node in the message flow.

```
DECLARE i INTEGER 1;
DECLARE count INTEGER;
SET count = CARDINALITY(InputRoot.XMLNS.Invoice.Purchases."Item"[])

WHILE i <= count DO
  --use the default tooling-generated procedure for copying message headers
  CALL CopyMessageHeaders();
  SET OutputRoot.XMLNS.BookSold.Item = InputRoot.XMLNS.Invoice.Purchases.Item[i];
  PROPAGATE;
  SET i = i+1;
END WHILE;
RETURN FALSE;
```

The following messages are produced on the Out terminal by the PROPAGATE statement:

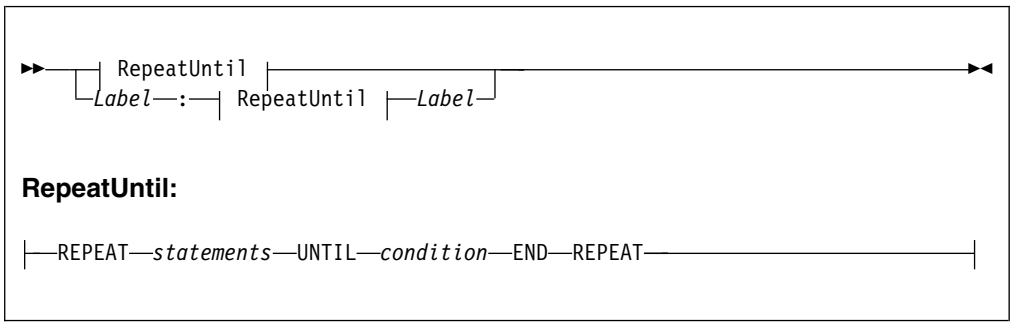
The RETURN statement ends processing. What happens next depends on the

programming context in which the RETURN statement is issued.
"Example message" on page 5311

REPEAT statement:

The REPEAT statement processes a sequence of statements, then evaluates the condition expression.

Syntax



The REPEAT statement repeats the steps until condition is TRUE. Ensure that the logic of the program is such that the loop terminates. If the condition evaluates to UNKNOWN, the loop does **not** terminate.

If present, the *Label* gives the statement a name. This has no effect on the behavior of the REPEAT statement, but allows statements to include ITERATE and LEAVE statements or other labelled statements, which in turn include ITERATE and LEAVE. The second *Label* can be present only if the first *Label* is present and, if it is, the labels must be identical. Two or more labelled statements at the same level can have the same label, but this partly negates the advantage of the second *Label*. The advantage is that it unambiguously and accurately matches each END with its REPEAT. However, a labelled statement within statements cannot have the same label because this makes the behavior of the ITERATE and LEAVE statements ambiguous.

Example

```
DECLARE i INTEGER;
SET i = 1;
X : REPEAT
  ...
  SET i = i + 1;
UNTIL
  i>= 3
END REPEAT X;
```

RESIGNAL statement:

The RESIGNAL statement rethrows the current exception, if one exists.

Syntax

You can use RESIGNAL only in error handlers.

Typically, RESIGNAL is used when an error handler catches an exception that it cannot handle. The handler uses RESIGNAL to rethrow the original exception so that a handler in higher-level scope has the opportunity to handle it.

Because the handler throws the original exception, rather than a new (and therefore different) one:

1. The higher-level handler is not affected by the presence of the lower-level handler.
2. If no higher-level handler is present, you get a full error report in the event log.

Example

```
RESIGNAL;
```

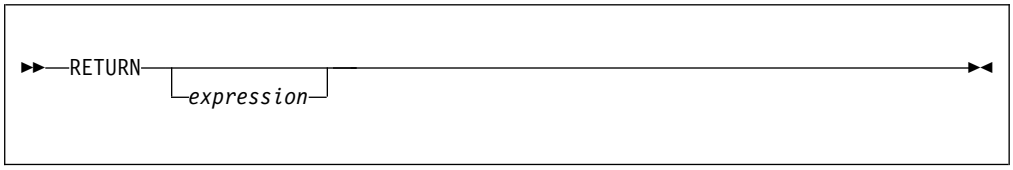
RETURN statement:

The RETURN statement ends processing. What happens next depends on the programming context in which the RETURN statement is issued.

Syntax



Main Function

When used in the Main function, the RETURN statement stops processing of the module and returns control to the next node in a message flow. In the Main function the return statement must contain an *expression* of BOOLEAN type. The behavior of the RETURN statement in the Main function is dependant on the node. In the Compute node for example, if *expression* is anything other than TRUE, propagation of the message is stopped. In the Filter node, however, the message is propagated to the terminal matching the value of *expression*: TRUE, FALSE and UNKNOWN. The following table describes the differences between the RETURN statement when used in the Main function of the Compute, Filter, and Database nodes.

Node	RETURN TRUE;	RETURN FALSE;	RETURN UNKNOWN (if BOOLEAN type) or RETURN NULL;	RETURN;
Compute	Propagate message to Out terminal.	Stop propagation	Stop propagation	Deploy failure (BIP2912E: Type mismatch on RETURN)
Database	Propagate message to Out terminal.	Stop propagation	Stop propagation	Deploy failure (BIP2912E: Type mismatch on RETURN)
Filter	Propagate message to True terminal	Propagate message to False terminal	Propagate message to Unknown terminal	Deploy failure (BIP2912E: Type mismatch on RETURN)

User defined functions and procedures

When used in a function or a procedure, the RETURN statement stops processing of that function and returns control to the calling expression. The *expression*, which must be present if the function or procedure has been declared with a RETURNS clause, is evaluated and acts as the return value of the function. The data type of the returned value must be the same as that in the function's declaration. The following table describes the differences between the RETURN statement when used in user defined functions and procedures.

	RETURN *expression*;	**RETURN NULL; (or return** *expression* **that evaluates to NULL)**	**RETURN;**	**No RETURN statement**
User defined function or procedure with a RETURNS clause	Returns control to the calling expression with the value of *expression*	Returns control to the calling expression with NULL	Deploy failure (BIP2912E: Type mismatch on RETURN)	Returns control to the calling expression with NULL after all the statements in the function or procedure have been run
User defined function or procedure without a RETURNS clause	Deploy failure (BIP2401E: Syntax error: expected ; but found *expression*)	Deploy failure (BIP2401E: Syntax error: expected ; but found NULL)	Returns control to the calling expression	Returns control to the calling expression after all the statements in the function or procedure have been run

The RETURN statement must be used within the body of a function or procedure that has the RETURNS statement in its declaration. This function can be invoked using the CALL ... INTO statement. The RETURNS statement provides the datatype that the function or procedure returns to the "CALL statement" on page 5077. The CALL ... INTO statement specifies the variable to which the return value is assigned. The example in this topic shows an example of how a RETURNS and CALL ... INTO statement are used together to assign the return statement. If you use the CALL ... INTO statement to call a function or procedure that does not have a RETURNS statement declared, a BIP2912E error message is generated.

Example

The following example, which is based on "Example message" on page 5311, illustrates how the RETURN, RETURNS and CALL...INTO statements can be used:

```
CREATE FILTER MODULE ProcessOrder
 CREATE FUNCTION Main() RETURNS BOOLEAN
  BEGIN

      DECLARE SpecialOrder  BOOLEAN;
      SET  OutputRoot.MQMD = InputRoot.MQMD;
      CALL IsBulkOrder(InputRoot.XMLNS.Invoice.Purchases) INTO SpecialOrder;

      --
      --  more processing could be inserted here
      --  before routing the order to the appropriate terminal
      --
      RETURN SpecialOrder;

  END;

 CREATE FUNCTION IsBulkOrder (P1 REFERENCE)
        RETURNS BOOLEAN
  BEGIN
      -- Declare and initialize variables--
      DECLARE a INT 1;
      DECLARE PriceTotal FLOAT 0.0;
      DECLARE NumItems INT 0;
```

```
    DECLARE iroot REFERENCE TO P1;

    -- Calculate value of order, however if this is a bulk purchase, the          --
    -- order will need to be handled differently (discount given) so return TRUE  --
    -- or FALSE depending on the size of the order                                 --
    WHILE a <= CARDINALITY(iroot.Item[]) DO
           SET  NumItems = NumItems + iroot.Item[a].Quantity;
           SET  PriceTotal = PriceTotal + iroot.Item[a].UnitPrice;
           SET  a = a + 1;
    END WHILE;
    RETURN (PriceTotal/NumItems> 42);

END;

END MODULE;
```

In the example, if the average price of items is greater than 42, TRUE is returned; otherwise FALSE is returned. Thus, a Filter node could route messages describing expensive items down a different path from messages describing inexpensive items. From the example, the `CALL IsBulkOrder(InputRoot.XMLNS.Invoice.Purchases) INTO SpecialOrder;` statement can also be written as `SpecialOrder = IsBulkOrder(InputRoot.XMLNS.Invoice.Purchases);`

If you are using the PROPAGATE statement in your node it is important that you use a `RETURN FALSE;` to prevent automatic propagation of the message to the next node in the message flow. See "PROPAGATE statement" on page 5150 for an example of preventing the implicit propagate at the end of processing in a Compute node.

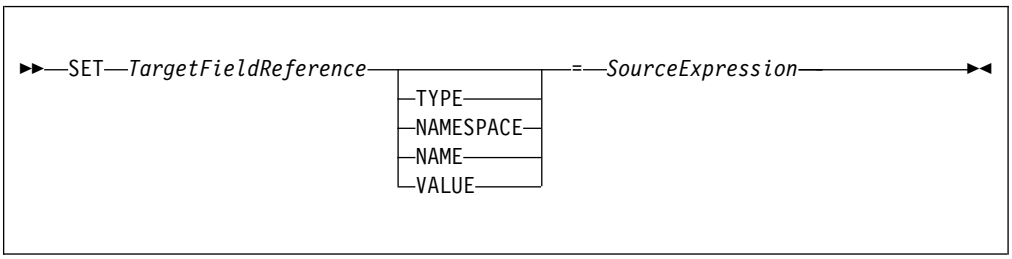
SET statement:

The SET statement assigns a value to a variable.

Syntax



Introduction

TargetFieldReference identifies the target of the assignment. The target can be any of the following:
- A declared scalar variable
- A declared row variable
- One of the predefined row variables (for example, *InputRoot*)
- A field within any kind of row variable (that is, a sub tree or conceptual row)
- A list of fields within any kind of row variable (that is, a conceptual list)
- A declared reference variable that points to any of the above

The target cannot be any kind of database entity.

SourceExpression is an expression that supplies the value to be assigned. It can be any kind of expression and can return a scalar, row or list value.

Assignment to scalar variables

If the target is a declared scalar variable, *SourceExpression* is evaluated and assigned to the variable. If need be, its value is converted to the data type of the variable. If this conversion is not possible, there will be either an error at deploy time or an exception at run time.

Null values are handled in exactly the same way as any other value. That is, if the expression evaluates to null, the value "null" is assigned to the variable.

For scalar variables the TYPE, NAME, NAMESPACE, and VALUE clauses are meaningless and are not allowed.

Assignment to rows, lists, and fields

If the target is a declared row variable, one of the predefined row variables, a field within any kind of row variable, a list of fields within any kind of row variable, or a declared reference variable that points to any of these things, the ultimate target is a field. In these cases, the target field is navigated to (creating the fields if necessary).

If array indices are used in *TargetFieldReference*, the navigation to the target field can only create fields on the direct path from the root to the target field. For example, the following SET statement requires that at least one instance of `Structure` already exists in the message:

```
SET OutputRoot.XMLNS.Message.Structure[2].Field = ...
```

The target field's value is set according to a set of rules, based on:

1. The presence or absence of the TYPE, NAME, NAMESPACE, or VALUE clauses
2. The data type returned by the source expression

1. If no TYPE, NAME, NAMESPACE, or VALUE clause is present (which is the most common case) the outcome depends on whether *SourceExpression* evaluates to a scalar, a row, or a list:
   - If *SourceExpression* evaluates to a scalar, the value of the target field is set to the value returned by *SourceExpression*, except that, if the result is null, the target field is discarded. Note that the new value of the field might not be of the same data type as its previous value.
   - If *SourceExpression* evaluates to a row:
     a. The target field is identified.
     b. The target field's value is set.
     c. The target field's child fields are replaced by a new set, dictated by the structure and content of the list.
   - If SourceExpression evaluates to a list:
     a. The set of target fields in the target tree are identified.
     b. If there are too few target fields, more are created; if there are too many, the extra ones are removed.
     c. The target fields' values are set.
     d. The target fields' child fields are replaced by a new set, dictated by the structure and content of the list.

   For further information on working with elements of type `list` see "Working with elements of type list" on page 2448
2. If a TYPE clause is present, the type of the target field is set to the value returned by *SourceExpression*. An exception is thrown if the returned value is not scalar, is not of type INTEGER, or is NULL.
3. If a NAMESPACE clause is present, the namespace of the target field is set to the value returned by *SourceExpression*. An exception is thrown if the returned value is not scalar, is not of type CHARACTER, or is NULL.
4. If a NAME clause is present, the name of the target field is set to the value returned by *SourceExpression*. An exception is thrown if the returned value is not scalar, is not of type CHARACTER, or is NULL.
5. If a VALUE clause is present, the value of the target field is changed to that returned by *SourceExpression*. An exception is thrown if the returned value is not scalar.

Notes

SET statements are particularly useful in Compute nodes that modify a message, either changing a field or adding a new field to the original message. SET statements are also useful in Filter and Database nodes, to set declared variables or the fields in the Environment tree or Local Environment trees. You can use statements such as the following in a Compute node that modifies a message:

```
SET OutputRoot = InputRoot;
SET OutputRoot.XMLNS.Order.Name = UPPER(InputRoot.XMLNS.Order.Name);
```

This example puts one field in the message into uppercase. The first statement constructs an output message that is a complete copy of the input message. The second statement sets the value of the `Order.Name` field to a new value, as defined by the expression on the right.

If the `Order.Name` field does not exist in the original input message, it does not exist in the output message generated by the first statement. The expression on the right of the second statement returns NULL (because the field referenced inside the UPPER function call does not exist). Assigning the NULL value to a field has the effect of deleting it if it already exists, and so the effect is that the second statement has no effect.

If you want to assign a NULL value to a field without deleting the field, use a statement like this:

```
SET OutputRoot.XMLNS.Order.Name VALUE = NULL;
```

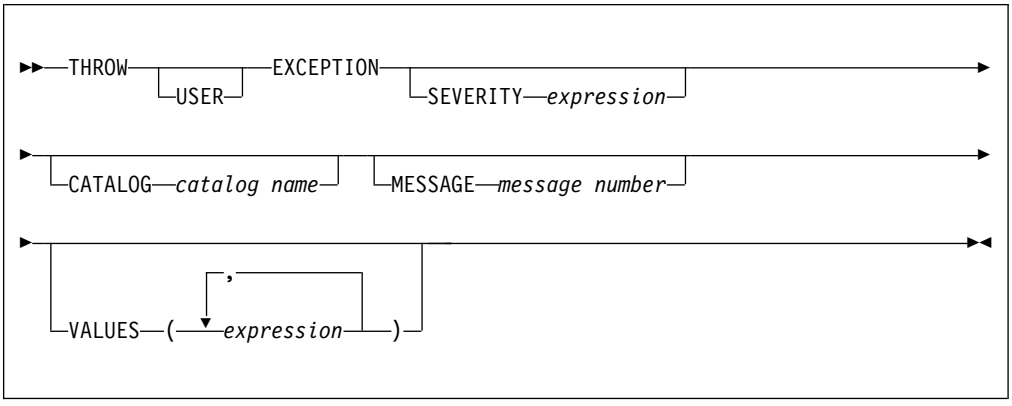
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

THROW statement:

Use the THROW statement to generate a user exception.

Syntax



The USER keyword indicates the type of exception being thrown. (Currently, only USER exceptions are supported, and if you omit the USER keyword the exception defaults to a USER exception anyway.) Specify the USER keyword, even though it currently has no effect, for the following reasons:

- If future broker releases support other types of exception, and the default type changes, your code will not need to be changed.
- It makes it clear that this is a user exception.

SEVERITY is an optional clause that determines the severity associated with the exception. The clause can contain any expression that returns a non-NULL, integer value. If you omit the clause, it defaults to 1.

On Windows you must set SEVERITY to 3, so that the Windows event log reports the error correctly.

CATALOG is an optional clause; if you omit it, CATALOG defaults to the WebSphere Message Broker current version catalog. To use the current version message catalog explicitly, use BIPmsgs on all operating systems.

MESSAGE is an optional clause; if you omit it, it defaults to the first message number of the block of messages provided for using THROW statements in the default catalog (2951). If you enter a message number in the THROW statement, you can use message numbers 2951 to 2999 from the default catalog. Alternatively, you can generate your own catalog by following the instructions in "Creating message catalogs" on page 3138.

Use the optional VALUES field to insert data into your message. You can insert any number of pieces of information, but the messages supplied (2951 - 2999) cater for eight inserts only.

Examples

Here are some examples of how you might use a THROW statement:

- ```
  THROW USER EXCEPTION;
  ```
- ```
  THROW USER EXCEPTION CATALOG 'BIPmsgs' MESSAGE
  2951 VALUES(1,2,3,4,5,6,7,8) ;
  ```
- ```
  THROW USER EXCEPTION CATALOG 'BIPmsgs' MESSAGE
  2951 VALUES('The SQL State: ',
      SQLSTATE, 'The SQL Code: ', SQLCODE, 'The SQLNATIVEERROR: ', SQLNATIVEERROR,
      'The SQL Error Text: ', SQLERRORTEXT ) ;
  ```
- ```
  THROW USER EXCEPTION CATALOG 'BIPmsgs' MESSAGE
  2951 ;
  ```
- ```
  THROW USER EXCEPTION CATALOG 'MyCatalog' MESSAGE
  2951 VALUES('Hello World') ;
  ```
- ```
  THROW USER EXCEPTION MESSAGE
  2951 VALUES('Insert text 1', 'Insert text 2') ;
  ```

For more information about how to throw an exception, and details of `SQLSTATE`, `SQLCODE`, `SQLNATIVEERROR`, and `SQLERRORTEXT`, see "ESQL database state functions" on page 5168.

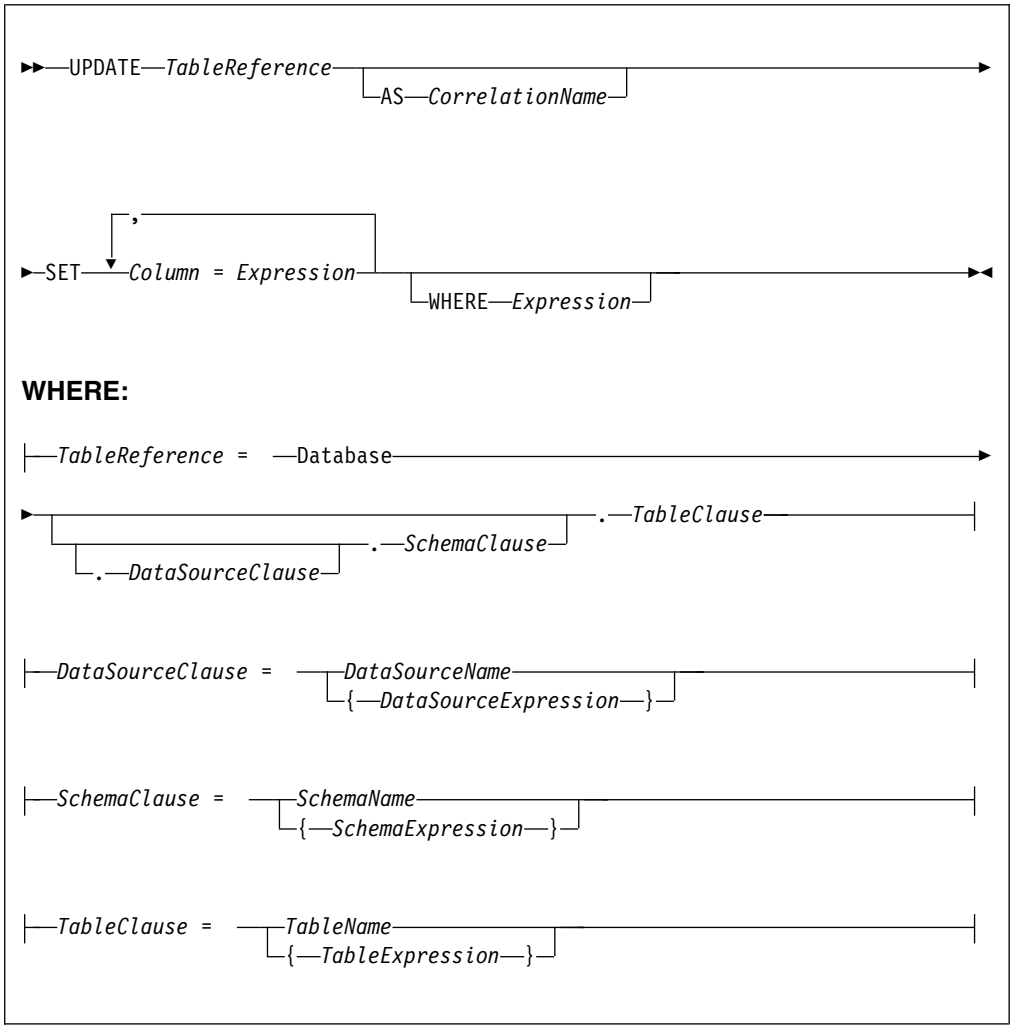
UPDATE statement:

The UPDATE statement changes the values of specified columns, in selected rows, in a table in an external database.

Syntax



All rows for which the WHERE clause expression evaluates to TRUE are updated in the table identified by *TableReference*. Each row is examined in turn and a variable is set to point to the current row. Typically, the WHERE clause expression uses this variable to access column values and thus cause rows to be updated, or retained unchanged, according to their contents. The variable is referred to by *CorrelationName* or, in the absence of an AS clause, by *TableName*. When a row has been selected for updating, each column named in the SET clause is given a new value as determined by the corresponding expression. These expressions can, if you want, refer to the current row variable.

Table reference

A table reference is a special case of the field references that are used to refer to message trees. It always starts with the word “Database” and can contain any of the following elements:

- A table name only
- A schema name and a table name
- A data source name (that is, the name of a database instance), a schema name, and a table name

In each case, the name can be specified directly or by an expression enclosed in braces ({...}). A directly-specified data source, schema, or table name is subject to name substitution. That is, if the name used has been declared to be a known name, the value of the declared name is used rather than the name itself (see "DECLARE statement" on page 5117).

If a schema name is not specified, the default schema for the broker's database user is used.

If a data source name is not specified, the database pointed to by the node's `data source` attribute is used.

The WHERE clause

The WHERE clause expression can use any of the broker's operators and functions in any combination. It can refer to table columns, message fields, and any declared variables or constants.

However, be aware that the broker treats the WHERE clause expression by examining the expression and deciding whether the whole expression can be evaluated by the database. If it can, it is given to the database. In order to be evaluated by the database, it must use only those functions and operators supported by the database.

The WHERE clause can, however, refer to message fields, correlation names declared by containing SELECT functions, and to any other declared variables or constants within scope.

If the whole expression cannot be evaluated by the database, the broker looks for top-level AND operators and examines each sub-expression separately. It then attempts to give the database those sub-expressions that it can evaluate, leaving the broker to evaluate the rest. You need to be aware of this situation for two reasons:

1. Apparently trivial changes to WHERE clause expressions can have large effects on performance. You can determine how much of the expression was given to the database by examining a user trace.
2. Some databases' functions exhibit subtle differences of behavior from those of the broker.

Handling errors

It is possible for errors to occur during update operations. For example, the database might not be operational, or the table might have constraints defined that the new values would violate. In these cases, an exception is thrown (unless the node has its `throw exception on database error` property set to FALSE). These exceptions set appropriate SQL code, state, native error, and error text values and can be dealt with by error handlers (see the DECLARE HANDLER statement).

For further information about handling database errors, see "Capturing database state" on page 2512.

Examples

The following example assumes that the `dataSource` property of the Database node has been configured, and that the database it identifies has a table called

STOCKPRICES, with columns called COMPANY and PRICES. It updates the PRICE column of the rows in the STOCKPRICES table whose COMPANY column matches the value given in the Company field in the message.

```
UPDATE Database.StockPrices AS SP
 SET PRICE = InputBody.Message.StockPrice
 WHERE SP.COMPANY = InputBody.Message.Company
```

In the following example (which make similar assumptions), the SET clause expression refers to the existing value of a column and thus decrements the value by an amount in the message:

```
UPDATE Database.INVENTORY AS INV
 SET QUANTITY = INV.QUANTITY - InputBody.Message.QuantitySold
 WHERE INV.ITEMNUMBER = InputBody.Message.ItemNumber
```

The following example updates multiple columns:

```
UPDATE Database.table AS T
 SET column1 = T.column1+1,
     column2 = T.column2+2;
```

Note that the column names (on the left of the "=") are single identifiers. They must not be qualified with a table name or correlation name. In contrast, the references to database columns in the expressions (to the right of the "=") must be qualified with the correlation name.

The next example shows the use of calculated data source, schema, and table names:

```
-- Declare variables to hold the data source, schema and table names
-- and set their default values
DECLARE Source CHARACTER 'Production';
DECLARE Schema CHARACTER 'db2admin';
DECLARE Table  CHARACTER 'DynamicTable1';
-- Code which calculates their actual values comes here

-- Update rows in the table
UPDATE Database.{Source}.{Schema}.{Table} AS R SET Value = 0;
```

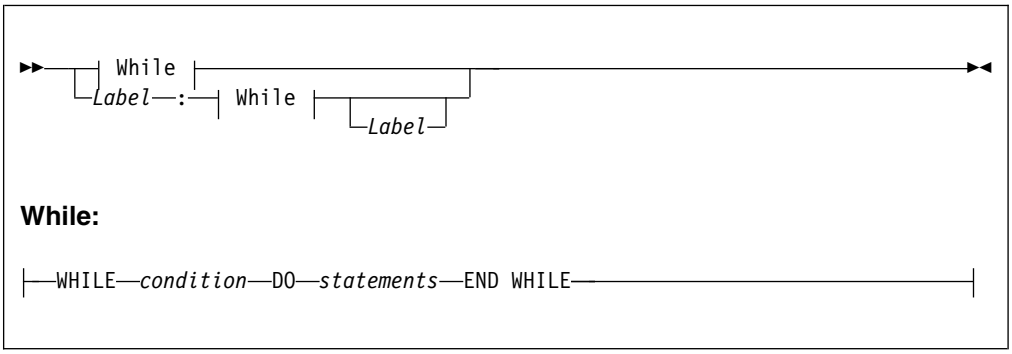
"ESQL statements" on page 5067
You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

WHILE statement:

The WHILE statement evaluates a condition expression, and if it is TRUE executes a sequence of statements.

Syntax



The WHILE statement repeats the steps specified in DO provided that *condition* is TRUE. It is your responsibility to ensure that the logic of the program is such that the loop terminates. If *condition* evaluates to UNKNOWN, the loop terminates immediately.

If present, *Label* gives the statement a name. This has no effect on the behavior of the WHILE statement itself, but allows statements to include ITERATE and LEAVE statements or other labelled statements, which in turn include them. The second *Label* can be present only if the first *Label* is present and if it is, the labels must be identical. It is not an error for two or more labelled statements at the same level to have the same *Label*, but this partly negates the advantage of the second *Label*. The advantage is that it unambiguously and accurately matches each END with its WHILE. However, it is an error for a labelled statement within statements to have the same label, because this makes the behavior of the ITERATE and LEAVE statements ambiguous.

Example

For example:

```
DECLARE i INTEGER;
SET i = 1;
X : WHILE i <= 3 DO
  ...
  SET i = i + 1;
  END WHILE X;
```

Calling ESQL functions:

Most ESQL functions belong to a schema called SQL and this is particularly useful if you have functions with the same name.

For example, if you have created a function called SQRT, you can code:

```
/* call my SQRT function  */

SET Variable1=SQRT (4);

/* call the SQL supplied function */

SET Variable2=SQL.SQRT (144);
```

Most of the functions described in this section impose restrictions on the data types of the arguments that can be passed to the function. If the values passed to the functions do not match the required data types, errors are generated at node configuration time whenever possible. Otherwise runtime errors are generated when the function is evaluated.

ESQL database state functions:
ESQL provides four functions to return database state. These are:

- "SQLCODE function" on page 5169
- "SQLERRORTEXT function" on page 5170

- "SQLNATIVEERROR function" on page 5171
- "SQLSTATE function" on page 5173

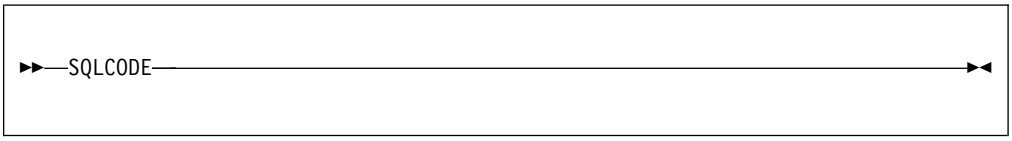
"Capturing database state" on page 2512
If an error occurs when the broker accesses an external database, you can either let the broker throw an exception during node processing or use ESQL statements to process the exception within the node itself.

SQLCODE function:

SQLCODE is a database state function that returns an INTEGER data type with a default value of 0 (zero).

Syntax



Within a message flow, you can access and update an external database resource using the available ESQL database functions in the Filter, Database, and Compute nodes. When making calls to an external database, you might get errors, such as a table does not exist, a database is not available, or an insert for a key that already exists.

When these errors occur, the default action of the broker is to generate an exception. This behavior is determined by how you have set the property *Throw exception on database error*. If this check box is selected, the broker stops processing the node, propagates the message to the node's failure terminal, and writes the details of the error to the ExceptionList. If you want to override the default behavior and handle a database error in the ESQL in the node, clear the *Throw exception on database error* check box. The broker does not throw an exception and you must include the THROW statement to throw an exception if a certain SQL state code is not expected. See "THROW statement" on page 5161 for a description of THROW.

If you choose to handle database errors in a node, you can use the database state function SQLCODE to receive information about the status of the DBMS call made in ESQL. You can include it in conditional statements in current node's ESQL to recognize and handle possible errors.

When these errors occur, the default action of the broker is to generate an exception. This behavior is determined by how you have set the property `Throw exception on database error`. If you select this property, the broker stops processing the node, propagates the message to the node's failure terminal, and writes the details of the error to the ExceptionList. If you want to override the default behavior and handle a database error in the ESQL in the node, clear `Throw exception on database error`. The broker does not throw an exception and you must include the THROW statement to throw an exception if a certain SQL state code is not expected. See “THROW statement” on page 5161 for a description of THROW.

To handle database errors in a node, you can use the database state function SQLSTATE to receive information about the status of the DBMS call made in ESQL. You can include it in conditional statements in current node's ESQL to recognize and handle possible errors.

SQL states

In ESQL, SQL states are variable length character strings. By convention, they are six characters long and contain only the characters 0-9, A-Z . The significance of the six characters is:

Char 1
The origin of the exception

Chars 2 - 3
The class of the exception

Chars 4 - 6
The subclass of the exception

The SQL state of an exception is determined by a two stage process. In the **first stage**, the exception information is examined and any wrapping exceptions (that is,

information that says what the broker was doing at the time the exception occurred) is stepped over until the exception that describes the original error is located.

The **second stage** is as follows:

1. If the selected exception is a database exception, the SQL state is that supplied by the database, but prefixed by the letter “D” to avoid any confusion with exceptions arising in the broker. The SQL code, native error, and error text are those supplied by the database.
2. If the selected exception is a user exception (that is, it originated in a THROW statement), the SQL code, state, native error, and error text are taken from the first four inserts of the exception, in order. The resulting state value is taken as is (not prefixed by a letter such as “U”). The letter “U” is not used by the broker as an origin indicator. If you want to define a unique SQL state rather than to imitate an existing one, use SQL states starting with the letter “U”. If you use SQL states that start with the letter “U”, you can write an error handler to match all user-defined and thrown exceptions with a LIKE'U%' operator.
3. If the selected exception originated in the message transport or in the ESQL implementation itself, the SQL code, state, native error, and error text are as described in the list later in this section.
4. For all other exceptions, the SQL state is '', indicating no origin, no class, and no subclass.

Some exceptions that currently give an empty SQL state might give individual states in future releases. If you want to catch unclassified exceptions, use the “all” wildcard (“%”) for the SQL state on the last handler of a scope. This wildcard will continue to catch the same set of exceptions if previously unclassified exceptions are given new unique SQL states.

The following SQL states are defined:

Dddddd
ddddd is the state returned by the database.

SqlState = 'S22003'
Arithmetic overflow. An operation whose result is a numeric type resulted in a value beyond the range supported.

SqlState = 'S22007'
Date time format not valid. A character string used in a cast from character to a datetime type had either the wrong basic format (for example, '01947-10-24') or had values outside the ranges allowed by the Gregorian calendar (for example, '1947-21-24').

SqlState = 'S22008'
Date time field overflow. An operation whose result is a datetime type resulted in a value beyond the range supported.

SqlState = 'S22012'
Divide by zero. A divide operation whose result data type has no concept of infinity had a zero right operand.

SqlState = 'S22015'
Interval field overflow. An operation whose result is of type INTERVAL resulted in a value beyond the range supported by the INTERVAL data type.

SqlState = 'S22018'
Character value for cast not valid.

SqlState = 'SFN001'
A SELECT function used in an IN predicate returned more than one column when only one column is allowed in this case.

SqlState = 'SPS001'
Target terminal not valid. A PROPAGATE to terminal statement attempted to use a terminal name that is not valid.

SqlState = 'SPS002'
Target label not valid. A PROPAGATE to label statement attempted to use a label that is not valid.

SqlState = 'SPS003'
PROPAGATE statement not valid in this context. Use the RETURN function instead.

SqlState = 'MQW001', SqlNativeError = 0
The bit stream does not meet the requirements for WebSphere MQ messages. No attempt was made to put it to a queue. Retrying and queue administration does not resolve this problem.

SqlState = 'MQW002', SqlNativeError = 0
The target queue or queue manager names were not valid (that is, they could not be converted from Unicode to the queue manager's code page). Retrying and queue emptying does not resolve this problem.

SqlState = 'MQW003', SqlNativeError = 0
Request mode was specified but the “reply to” queue or queue manager names were not valid (that is, could not be converted from Unicode to the message's code page). Retrying and queue emptying does not resolve this problem.

SqlState = 'MQW004', SqlNativeError = 0
Reply mode was specified but the queue or queue manager names taken from the message were not valid (that is, they could not be converted from the given code page to Unicode). Retrying and queue emptying does not resolve this problem.

SqlState = 'MQW005', SqlNativeError = 0
Destination list mode was specified but the destination list supplied does not meet the basic requirements for destination lists. No attempt was made to put any message to a queue. Retrying and queue administration does not resolve this problem.

SqlState = 'MQW101', SqlNativeError = returned by WebSphere MQ
The target queue manager or queue could not be opened. Queue administration might resolve this problem but retrying does not.

SqlState = 'MQW102', SqlNativeError = returned by WebSphere MQ
The target queue manager or queue could not be written to. Retrying and queue administration might resolve this problem.

SqlState = 'MQW201', SqlNativeError = number of destinations with an error
More than one error occurred while processing a destination list. The message might have been put to zero or more queues. Retrying and queue administration might resolve this problem.

Anything that the user has used in a THROW statement
Use `Uuuuuuu` for user exceptions, unless imitating one of the exceptions defined above.

Empty string
All other errors.

If an error occurs when the broker accesses an external database, you can either let the broker throw an exception during node processing or use ESQL statements to process the exception within the node itself.

Related reference:

"SQLCODE function" on page 5169
SQLCODE is a database state function that returns an INTEGER data type with a default value of 0 (zero).

"SQLERRORTEXT function" on page 5170
SQLERRORTEXT is a database state function that returns a CHARACTER data type with a default value of '' (empty string).

"SQLNATIVEERROR function" on page 5171
SQLNATIVEERROR is a database state function that returns an INTEGER data type with a default value of 0 (zero).

ESQL datetime functions:
This topic lists the ESQL datetime functions.

In addition to the functions described here, you can use arithmetic operators to perform various calculations on datetime values. For example, you can use the - (minus) operator to calculate the difference between two dates as an interval, or you can add an interval to a timestamp.

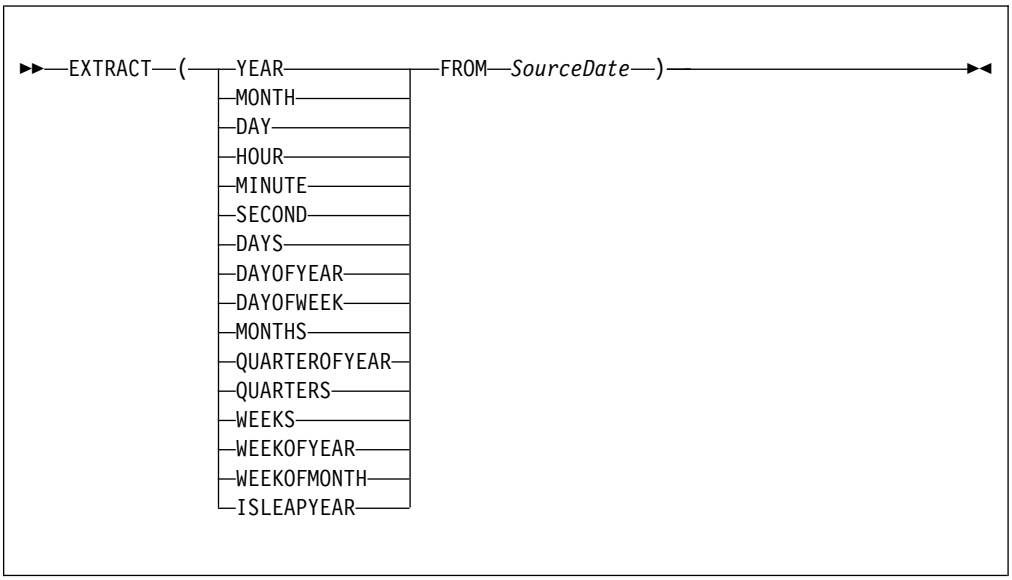
This section covers the following topics:

EXTRACT function:

The EXTRACT function extracts fields (or calculates values) from datetime values and intervals.

The result is INTEGER for YEAR, MONTH, DAY, HOUR, MINUTE, DAYS, DAYOFYEAR, DAYOFWEEK, MONTHS, QUARTEROFYEAR, QUARTERS, WEEKS, WEEKOFYEAR, and WEEKOFMONTH extracts, but FLOAT for SECOND extracts, and BOOLEAN for ISLEAPYEAR extracts. If the *SourceDate* is NULL, the result is NULL regardless of the type of extract.

Syntax



EXTRACT extracts individual fields from datetime values and intervals. You can extract a field only if it is present in the datetime value specified in the second parameter. Either a parse-time or a runtime error is generated if the requested field does not exist within the data type.

The following table describes the extracts that are supported:

Note: All new integer values start from 1.

Table 263.

Extract	Description
YEAR	Year
MONTH	Month
DAY	Day
HOUR	Hour
MINUTE	Minute
SECOND	Second
DAYS	Days encountered between 1st January 0001 and the *SourceDate*.
DAYOFYEAR	Day of year

Table 263. (continued)

Extract	Description
DAYOFWEEK	Day of the week: Sunday = 1, Monday = 2, Tuesday = 3, Wednesday = 4, Thursday = 5, Friday = 6, Saturday = 7.
MONTHS	Months encountered between 1st January 0001 and the *SourceDate*.
QUARTEROFYEAR	Quarter of year: January to March = 1, April to June = 2, July to September = 3, October to December = 4.
QUARTERS	Quarters encountered between 1st January 0001 and the *SourceDate*.
WEEKS	Weeks encountered between 1st January 0001 and the *SourceDate*.
WEEKOFYEAR	Week of year
WEEKOFMONTH	Week of month
ISLEAPYEAR	Whether this is a leap year

Notes:

1. A week is defined as Sunday to Saturday, not any seven consecutive days. You must convert to an alternative representation scheme if required.
2. The source date time epoch is 1 January 0001. Dates before the epoch are not valid for this function.
3. The Gregorian calendar is assumed for calculation.

Example

```
EXTRACT(YEAR FROM CURRENT_DATE)
```

and

```
EXTRACT(HOUR FROM LOCAL_TIMEZONE)
```

both work without error, but

```
EXTRACT(DAY FROM CURRENT_TIME)
```

fails.

```
EXTRACT (DAYS FROM DATE '2000-02-29')
```

calculates the number of days encountered since year 1 to `'2000-02-29'` and

```
EXTRACT (DAYOFYEAR FROM CURRENT_DATE)
```

calculates the number of days encountered since the beginning of the current year but

```
EXTRACT (DAYOFYEAR FROM CURRENT_TIME)
```

fails because CURRENT_TIME does not contain date information.

CURRENT_DATE function:
The CURRENT_DATE datetime function returns the current date.

Syntax

CURRENT_DATE returns a DATE value representing the current date in local time. As with all SQL functions that take no parameters, no parentheses are required or accepted. All calls to CURRENT_DATE within the processing of one node are guaranteed to return the same value.

Related concepts:

"ESQL overview" on page 2371

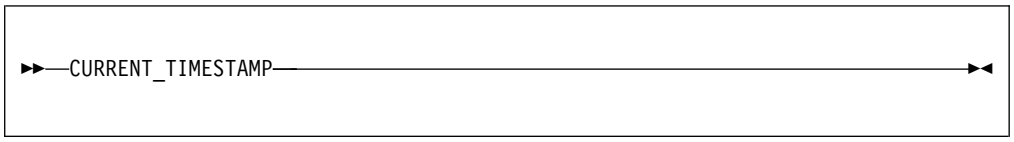
CURRENT_TIMESTAMP function:
The CURRENT_TIMESTAMP datetime function returns the current date and local time.

Syntax



CURRENT_TIMESTAMP returns a TIMESTAMP value representing the current date and local time. As with all SQL functions that take no parameters, no parentheses are required or accepted. All calls to CURRENT_TIMESTAMP within the processing of one node are guaranteed to return the same value.

Example

To obtain the following XML output message:

```
<Body>
<Message>Hello World</Message>
<DateStamp>2006-02-01 13:13:56.444730</DateStamp>
</Body>
```

use the following ESQL:

```
SET OutputRoot.XMLNS.Body.Message = 'Hello World';
SET OutputRoot.XMLNS.Body.DateStamp = CURRENT_TIMESTAMP;
```

Related reference:

"Syntax diagrams" on page 3677

"ESQL datetime functions" on page 5176

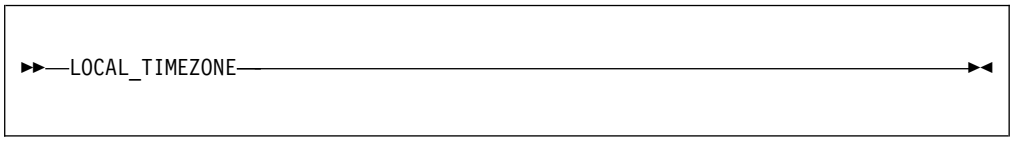
LOCAL_TIMEZONE function:

The LOCAL_TIMEZONE datetime function returns the displacement of the local time zone from GMT.

Syntax



LOCAL_TIMEZONE returns an interval value representing the local time zone displacement from GMT. As with all SQL functions that take no parameters, no parentheses are required or accepted. The value returned is an interval in hours and minutes representing the displacement of the current time zone from Greenwich Mean Time.

The sign of the interval is such that a local time can be converted to a time in GMT by subtracting the result of the LOCAL_TIMEZONE function. However, for calculations involving GMTTIMEs and GMTTIMESTAMPs, ESQL performs this transformation automatically.

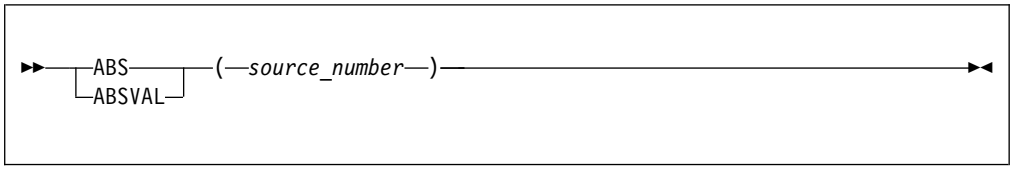
“TANH function” on page 5204

“TRUNCATE function” on page 5205

ABS and ABSVAL functions:
The ABS and ABSVAL numeric functions return the absolute value of a supplied number.

Syntax



The absolute value of the source number is a number with the same magnitude as the source but without a sign. The parameter must be a numeric value. The result is of the same type as the parameter unless it is NULL, in which case the result is NULL.

For example:

```
ABS( -3.7 )
```

returns `3.7`

```
ABS( 3.7 )
```

returns `3.7`

```
ABS( 1024 )
```

returns `1024`

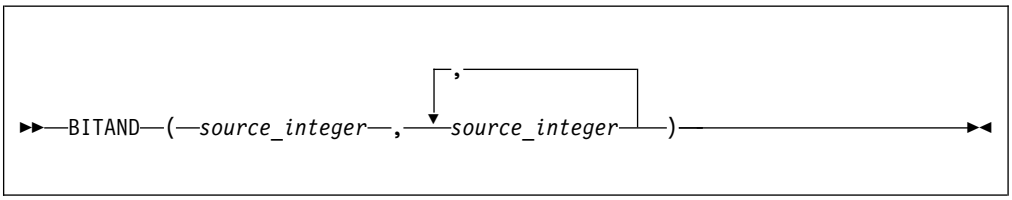
BITAND function:
The BITAND numeric function performs a bitwise AND on the binary representation of two or more numbers.

Syntax



BITAND takes two or more integer values and returns the result of performing the bitwise AND on the binary representation of the numbers. The result is INTEGER unless either parameter is NULL, in which case the result is NULL.

For example:

```
BITAND(12, 7)
```

returns 4 as shown by this worked example:

```
   Binary Decimal
    1100    12
AND 0111     7
________
    0100     4
```

A list of the numeric functions that ESQL supports.

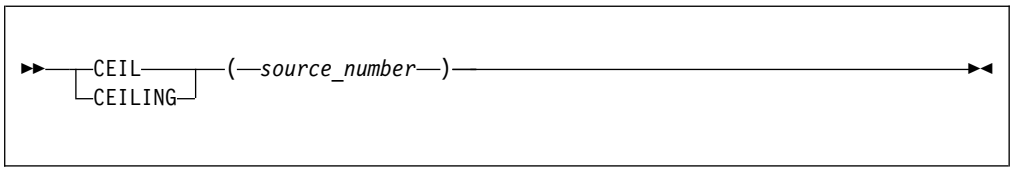
CEIL and CEILING functions:
The CEIL and CEILING numeric functions return the smallest integer equivalent of a decimal number.

Syntax



CEIL and CEILING return the smallest integer value greater than or equal to `source_number`. The parameter can be any numeric data type. The result is of the same type as the parameter unless it is NULL, in which case the result is NULL.

For example:

```
CEIL(1)
```

returns `1`

```
CEIL(1.2)
```

returns `2.0`

```
CEIL(-1.2)
```

returns `-1.0`

If possible, the scale is changed to zero. If the result cannot be represented at that scale, it is made sufficiently large to represent the number.

A list of the numeric functions that ESQL supports.

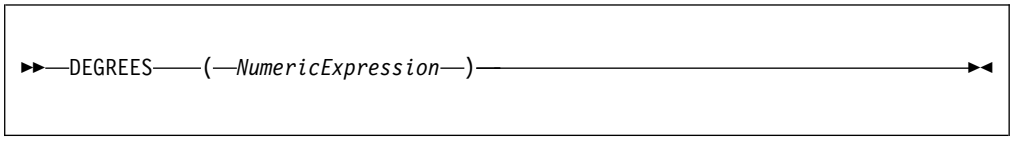
DEGREES function:
The DEGREES numeric function returns the angle of the radians supplied.

Syntax



The DEGREES function returns the angle, in degrees, specified by *NumericExpression* in radians. The parameter can be any built-in numeric data type. The result is FLOAT unless the parameter is NULL, in which case the result is NULL.

Related concepts:

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

A list of the numeric functions that ESQL supports.

EXP function:
The EXP numeric function returns the exponential value of a given number.

Syntax

The EXP function returns the exponential of the value specified by *NumericExpression*. The parameter can be any built-in numeric data type. The result is FLOAT unless the parameter is NULL, in which case the result is NULL.

Related concepts:

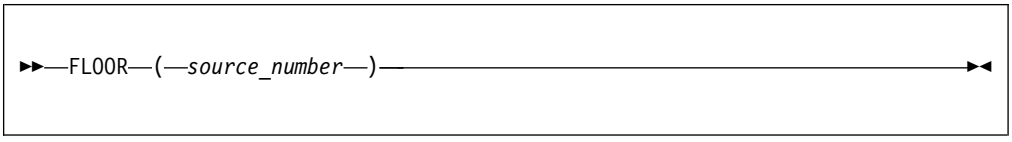
"ESQL numeric functions" on page 5183
A list of the numeric functions that ESQL supports.

FLOOR function:
The FLOOR numeric function returns the largest integer equivalent to a given decimal number.

Syntax



FLOOR returns the largest integer value less than or equal to `source_number`. The parameter can be any numeric data type. The result is of the same type as the parameter unless it is NULL, in which case the result is NULL.

For example:

```
FLOOR(1)
```

returns 1

```
FLOOR(1.2)
```

returns `1.0`

```
FLOOR(-1.2)
```

returns `-2.0`

If possible, the scale is changed to zero. If the result cannot be represented at that scale, it is made sufficiently large to represent the number.

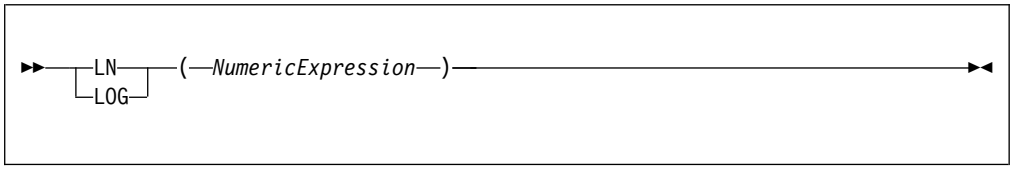
LN and LOG functions:
The LN and LOG equivalent numeric functions return the natural logarithm of a given value.

Syntax



The LN and LOG functions return the natural logarithm of the value specified by *NumericExpression*. The parameter can be any built-in numeric data type. The result is FLOAT unless the parameter is NULL, in which case the result is NULL.

Related concepts:

"ESQL overview" on page 2371

A list of the numeric functions that ESQL supports.

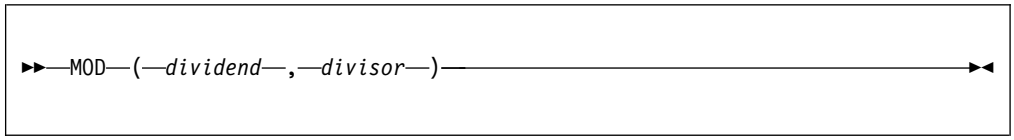
MOD function:
The MOD numeric function returns the remainder when dividing two numbers.

Syntax



MOD returns the remainder when the first parameter is divided by the second parameter. The result is negative only if the first parameter is negative. Parameters must be integers. The function returns an integer. If any parameter is NULL, the result is NULL.

For example:

```
MOD(7, 3)
```

returns 1

```
MOD(-7, 3)
```

returns -1

```
MOD(7, -3)
```

returns 1

```
MOD(6, 3)
```

returns `0`

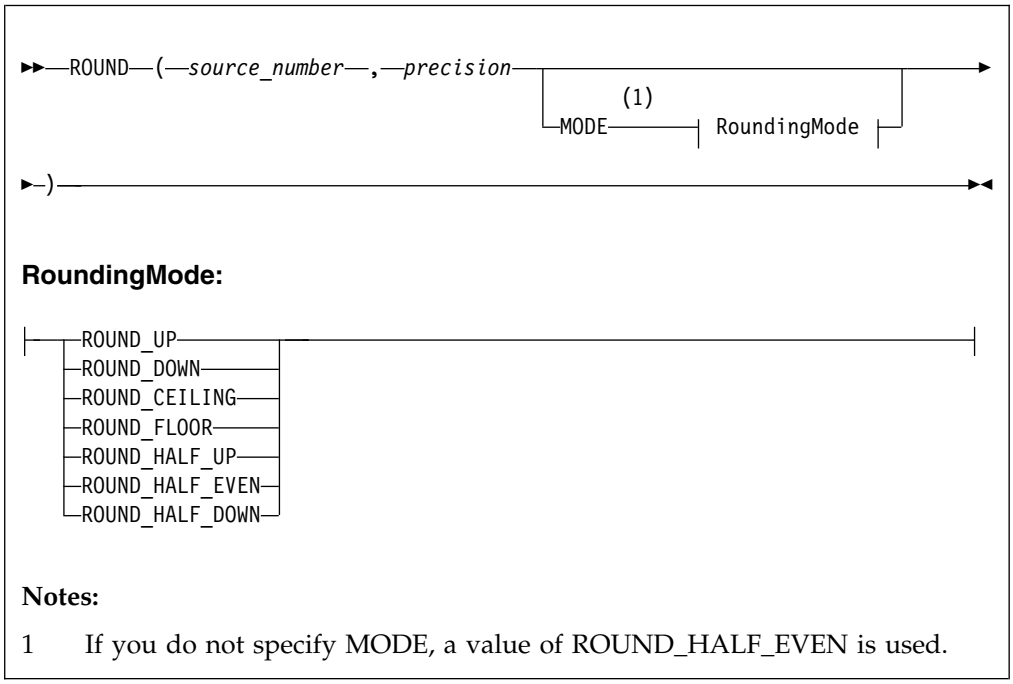
ROUND function:
The ROUND numeric function rounds a supplied value to a given number of places.

Syntax



Notes:

1 If you do not specify MODE, a value of ROUND_HALF_EVEN is used.

If *precision* is a positive number, *source_number* is rounded to *precision* places right of the decimal point. If *precision* is negative, the result is *source_number* rounded to the absolute value of *precision* places to the left of the decimal point.

source_number can be any built-in numeric data type; *precision* must be an integer. The result is of the same data type as the *source_number* parameter unless *source_number* is NULL, in which case the result is NULL.

This means that the result of the function is:
- INTEGER if *source_number* is INTEGER
- FLOAT if *source_number* is FLOAT
- DECIMAL if *source_number* is DECIMAL

When rounding, the *banker's* or *half-even symmetric* rounding rules are used by default, unless a *RoundingMode* is specified.

RoundingMode

RoundingMode can take one of the following values:

ROUND_UP
Round away from zero. Always increments the digit prior to a nonzero discarded fraction. This rounding mode never decreases the magnitude of the calculated value.

ROUND_DOWN
Round towards zero. Never increments the digit prior to a discarded fraction, that is, truncates. This rounding mode never increases the magnitude of the calculated value.

ROUND_CEILING
Round towards positive infinity. If the decimal is positive, behaves as for ROUND_UP; if negative, behaves as for ROUND_DOWN. This rounding mode never decreases the calculated value.

ROUND_FLOOR
Round towards negative infinity. If the decimal is positive, behaves as for ROUND_DOWN; if negative, behaves as for ROUND_UP. This rounding mode never increases the calculated value.

ROUND_HALF_UP
Round towards "nearest neighbor" unless both neighbors are equidistant, in which case round up. Behaves as for ROUND_UP if the discarded fraction is greater than, or equal to, 0.5; otherwise, behaves as for ROUND_DOWN. This is the rounding mode that is typically taught in schools.

ROUND_HALF_DOWN
Round towards "nearest neighbor" unless both neighbors are equidistant, in which case round down. Behaves as for ROUND_UP if the discarded fraction is grater than 0.5; otherwise, behaves as for ROUND_DOWN.

ROUND_HALF_EVEN
Round towards the "nearest neighbor" unless both neighbors are equidistant, in which case, round towards the even neighbor. Behaves as for ROUND_HALF_UP if the digit to the left of the discarded fraction is odd; behaves as for ROUND_HALF_DOWN if it is even. This is the rounding mode that minimizes cumulative error when applied repeatedly over a sequence of calculations, and is sometimes referred to as Banker's rounding.

The following table gives a summary of rounding operations, with a precision of zero, under different rounding modes.

Input number	ROUND UP	ROUND DOWN	ROUND CEILING	ROUND FLOOR	ROUND HALF UP	ROUND HALF DOWN	ROUND HALF EVEN
5.5	6	5	6	5	6	5	6
2.5	3	2	3	2	3	2	2
1.6	2	1	2	1	2	2	2
1.1	2	1	2	1	1	1	1
1.0	1	1	1	1	1	1	1
-1.0	-1	-1	-1	-1	-1	-1	-1
-1.1	-2	-1	-1	-2	-1	-1	-1
-1.6	-2	-1	-1	-2	-2	-2	-2
-2.5	-3	-2	-2	-3	-3	-2	-2

Input number	ROUND UP	ROUND DOWN	ROUND CEILING	ROUND FLOOR	ROUND HALF UP	ROUND HALF DOWN	ROUND HALF EVEN
-5.5	-6	-5	-5	-6	-6	-5	-6

Examples using the default rounding mode (ROUND_HALF_EVEN):

```
ROUND(27.75, 2)
```

returns 27.75

```
ROUND(27.75, 1)
```

returns 27.8

```
ROUND(27.75, 0)
```

returns 28

```
ROUND(27.75, -1)
```

returns 30

Examples using a rounding mode with a precision of zero:

```
ROUND(5.5, 0 MODE ROUND_UP);
```

returns 6

```
ROUND(5.5, 0 MODE ROUND_DOWN);
```

returns 5

```
ROUND(5.5, 0 MODE ROUND_CEILING);
```

returns 6

```
ROUND(5.5, 0 MODE ROUND_FLOOR);
```

returns 5

```
ROUND(5.5, 0 MODE ROUND_HALF_UP);
```

returns 6

```
ROUND(5.5, 0 MODE ROUND_HALF_DOWN);
```

returns 5

```
ROUND(5.5, 0 MODE ROUND_HALF_EVEN);
```

returns 6

```
ROUND(2.5, 0 MODE ROUND_UP);
```

returns 3

```
ROUND(2.5, 0 MODE ROUND_DOWN);
```

returns 2

```
ROUND(2.5, 0 MODE ROUND_CEILING);
```

returns 3

```
ROUND(2.5, 0 MODE ROUND_FLOOR);
```

returns 2

```
ROUND(2.5, 0 MODE ROUND_HALF_UP);
```

returns 3

```
ROUND(2.5, 0 MODE ROUND_HALF_DOWN);
```

returns 2

```
ROUND(2.5, 0 MODE ROUND_HALF_EVEN);
```

returns 2

If possible, the scale is changed to the given value. If the result cannot be represented within the given scale, it is INFINITY.

SQRT function:
The SQRT numeric function returns the square root of a given number.

Syntax

SQRT returns the square root of *source_number*. The parameter can be any built-in numeric data type. The result is a FLOAT. If the parameter is NULL, the result is NULL.

For example:

```
SQRT(4)
```

returns `2E+1`

```
SQRT(2)
```

returns `1.414213562373095E+0`

```
SQRT(-1)
```

throws an exception.

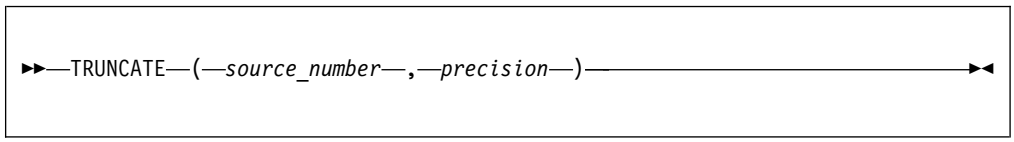
TRUNCATE function:
The TRUNCATE numeric function truncates a supplied decimal number a specified number of places.

Syntax



If *precision* is positive, the result of the TRUNCATE function is *source_number* truncated to *precision* places right of the decimal point. If *precision* is negative, the result is *source_number* truncated to the absolute value of *precision* places to the left of the decimal point.

source_number can be any built-in numeric data type. *precision* must evaluate to an INTEGER. The result is of the same data type as *source_number*. If any parameter is NULL, the result is NULL.

For example:

```
TRUNCATE(27.75, 2)
```

returns `27.75`

```
TRUNCATE(27.75, 1)
```

returns `27.7`

```
TRUNCATE(27.75, 0)
```

returns `27.0`

```
TRUNCATE(27.75, -1)
```

returns `20.0`

If possible, the scale is changed to the given value. If the result cannot be represented within the given scale, it is INF.

ESQL string manipulation functions:

A list of the ESQL string manipulation functions that you can use.

Most of the following functions manipulate all string data types (BIT, BLOB, and CHARACTER). Exceptions to this are UPPER, LOWER, LCASE, UCASE, and SPACE, which operate only on character strings.

In these descriptions, the term *singleton* refers to a single part (BIT, BLOB, or CHARACTER) within a string of that type.

In addition to the functions that are described here, you can use the logical OR operator to perform various calculations on ESQL string manipulation values.

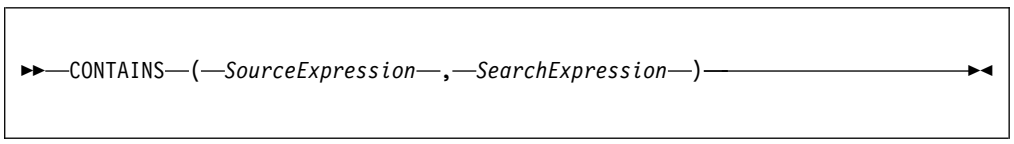
To concatenate two strings, use the "ESQL string operator" on page 5066.

This section covers the following topics:

CONTAINS function:

CONTAINS is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and returns a Boolean value to indicate whether one string is present within another.

Syntax



CONTAINS returns TRUE if the *SearchExpression* is present within the *SourceExpression*, otherwise it returns FALSE.

The parameter strings for both *SourceExpression* and *SearchExpression* can be of the CHARACTER, BLOB, or BIT data type, but must be of the same data type.

If any parameter is NULL, the result is NULL.

Examples

```
CONTAINS('Hello World!', 'ello');
```

returns TRUE.

```
CONTAINS('Hello World!', 'daisy');
```

returns FALSE.

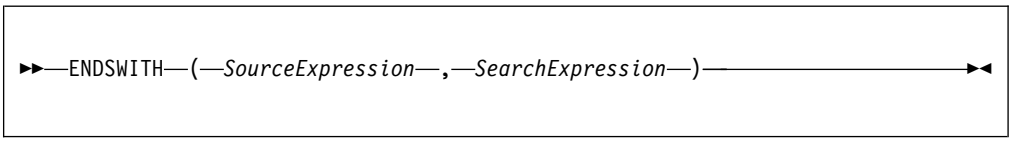
ENDSWITH function:

ENDSWITH is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and returns a Boolean value to indicate whether one string ends with another.

Syntax



ENDSWITH returns TRUE if *SourceExpression* ends with *SearchExpression*, otherwise it returns FALSE.

The parameter strings for both *SearchExpression* and *SourceExpression* can be of the CHARACTER, BLOB, or BIT data type, but must be of the same data type.

If any parameter is NULL, the result is NULL.

Examples

```
ENDSWITH('Hello World!', 'World!');
```

returns TRUE.

```
ENDSWITH('Hello World!', 'World');
```

returns FALSE.

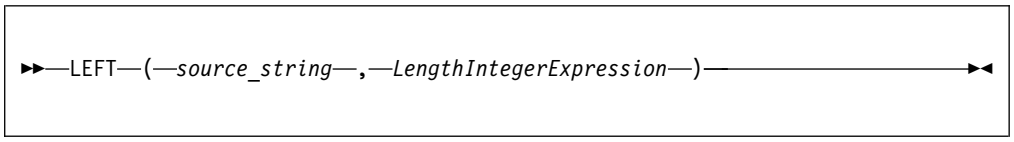
LEFT function:

LEFT is a string manipulation function that returns a string consisting of the source string truncated to the length given by the length expression.

Syntax



The source string can be of the CHARACTER, BLOB or BIT data type and the length must be of type INTEGER. The truncation discards the final characters of the *source_string*

The result is of the same type as the source string. If the length is negative or zero, a zero length string is returned. If either parameter is NULL, the result is NULL

LENGTH function:

The LENGTH function is used for string manipulation on all string data types (BIT, BLOB, and CHARACTER) and returns an integer value giving the number of singletons in *source_string*.

Syntax

It If the *source_string* is NULL, the result is the NULL value. The term *singleton* refers to a single part (BIT, BYTE, or CHARACTER) within a string of that type.

For example:

```
LENGTH('Hello World!');
```

returns 12.

```
LENGTH('');
```

returns 0.

Related concepts:

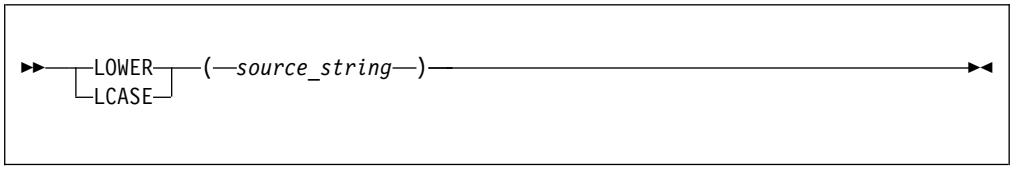
A list of the ESQL string manipulation functions that you can use.

LOWER and LCASE functions:

The LOWER and LCASE functions are equivalent, and manipulate CHARACTER string data; they both return a new character string, which is identical to *source_string*, except that all uppercase letters are replaced with the corresponding lowercase letters.

Syntax



For example:

```
LOWER('Mr Smith')
```

returns `'mr smith'`.

```
LOWER('22 Railway Cuttings')
```

returns `'22 railway cuttings'`.

```
LCASE('ABCD')
```

returns `'abcd'`.

LTRIM function:

LTRIM is a string manipulation function, used for manipulating all data types (BIT, BLOB, and CHARACTER), that returns a character string value of the same data type and content as *source_string*, but with any leading default singletons removed.

Syntax

The term *singleton* is used to refer to a single part (BIT, BLOB, or CHARACTER) within a string of that type.

The LTRIM function is equivalent to TRIM(LEADING FROM *source_string*).

If the parameter is NULL, the result is NULL.

The default singleton depends on the data type of *source_string*:

Table 264.

Character	' ' (space)
BLOB	X'00'
Bit	B'0'

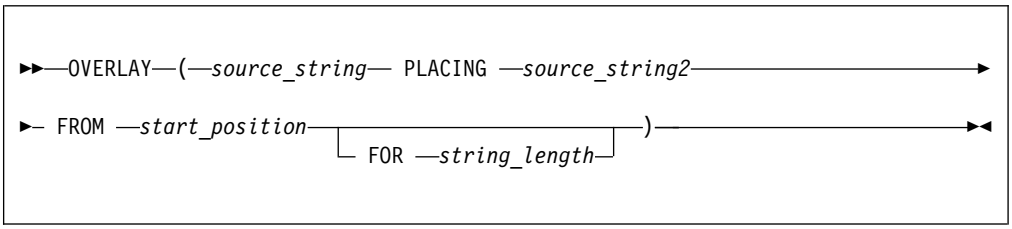
A list of the ESQL string manipulation functions that you can use.

OVERLAY function:

OVERLAY is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER) and replaces part of a string with a substring.

Syntax



OVERLAY returns a new string of the same type as the source and is identical to *source_string*, except that a given substring in the string, starting from the specified numeric position and of the given length, has been replaced by *source_string2*. When the length of the substring is zero, nothing is replaced.

For example:

```
OVERLAY ('ABCDEFGHIJ' PLACING '1234' FROM 4 FOR 3)
```

returns the string `'ABC1234GHIJ'`

If any parameter is NULL, the result is NULL. If *string_length* is not specified, it is assumed to be equal to `LENGTH(source_string2)`.

The result of the OVERLAY function is equivalent to:

```
SUBSTRING(source_string FROM 1 FOR start_position -1 )
  || source_string2 ||
  SUBSTRING(source_string FROM start_position + string_length)
```

where || is the concatenation operator.

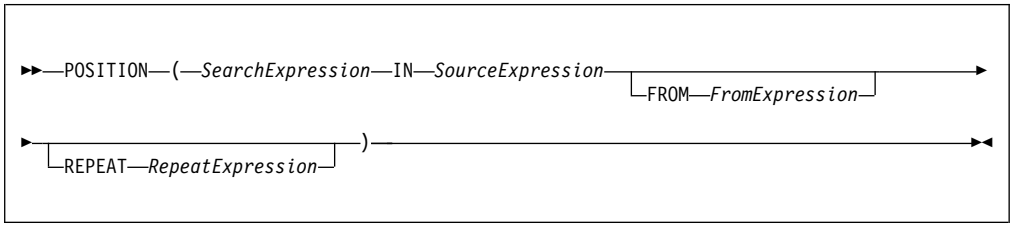
POSITION function:

POSITION is a string manipulation function that manipulates all data types (BIT, BLOB, and CHARACTER), and returns the position of one string within another.

Syntax



POSITION returns an integer giving the position of one string (*SearchExpression*) in a second string (*SourceExpression*). A position of one corresponds to the first character of the source string.

If present, the FROM clause gives a position within the search string at which the search commences. In the absence of a FROM clause, the source string is searched from the beginning.

If present, the REPEAT clause gives a repeat count, returning the position returned to be that of the nth occurrence of the search string within the source string. If the repeat count is negative, the source string is searched from the end.

In the absence of a REPEAT clause, a repeat count of +1 is assumed; that is, the position of the first occurrence, searching from the beginning is returned. If the search string has a length of zero, the result is one.

If the search string cannot be found, the result is zero: if the FROM clause is present, this applies only to the section of the source string being searched; if the REPEAT clause is present this applies only if there are insufficient occurrences of the string.

If any parameter is NULL, the result is NULL.

The search and source strings can be of the CHARACTER, BLOB, or BIT data types but they must be of the same type.

For example:

```
POSITION('Village' IN 'Hursley Village');   returns 9
POSITION('Town' IN 'Hursley Village');   returns 0

POSITION ('B' IN 'ABCABCABCABCABC'); -> returns 2
POSITION ('D' IN 'ABCABCABCABCABC'); -> returns 0

POSITION ('A' IN 'ABCABCABCABCABC' FROM 4); -> returns 4
POSITION ('C' IN 'ABCABCABCABCABC' FROM 2); -> returns 3

POSITION ('B' IN 'ABCABCABCABCABC' REPEAT 2); -> returns 5
POSITION ('C' IN 'ABCABCABCABCABC' REPEAT 4); -> returns 12

POSITION ('A' IN 'ABCABCABCABCABC' FROM 4 REPEAT 2); -> returns 7
POSITION ('AB' IN 'ABCABCABCABCABC' FROM 2 REPEAT 3); -> returns 10

POSITION ('A' IN 'ABCABCABCABCABC' REPEAT -2); -> returns 10
POSITION ('BC' IN 'ABCABCABCABCABC' FROM 2 REPEAT -3); -> returns 5
```

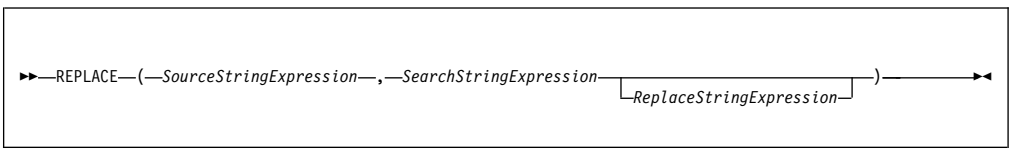
A list of the ESQL string manipulation functions that you can use.

REPLACE function:

REPLACE is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and replaces parts of a string with supplied substrings.

Syntax



REPLACE returns a string consisting of the source string, with each occurrence of the search string replaced by the replace string. The parameter strings can be of the CHARACTER, BLOB, or BIT data types, but all three must be of the same type.

If any parameter is NULL, the result is NULL.

The search process is single pass from the left and disregards characters that have already been matched.

If you do not specify the replace string expression, the replace string uses the default value of an empty string, and the behavior of the function is to delete all occurrences of the search string from the result.

The following examples give the results shown:

```
REPLACE('ABCDABCDABCDA', 'A', 'AA')
-- RESULT = AABCDAABCDAABCDAA
```

The above example shows that replacement is single pass. Each occurrence of A is replaced by AA but these are not then expanded further.

```
REPLACE('AAAABCDEFGHAAAABCDEFGH', 'AA', 'A')
-- RESULT = AABCDEFGHAABCDEFGH
```

This example shows that after characters are matched, they are not considered further. Each occurrence of AA is replaced by A. The resulting AA pairs are not matched.

```
REPLACE('AAAAABCDEFGHAAAABCDEFGH', 'AA', 'XYZ')
 -- RESULT = XYZXYZABCDEFGHXYZXYZBCDEFGH
```

This last example shows that matching is from the left. The first four As are matched as two pairs and replaced. The fifth A is not matched.

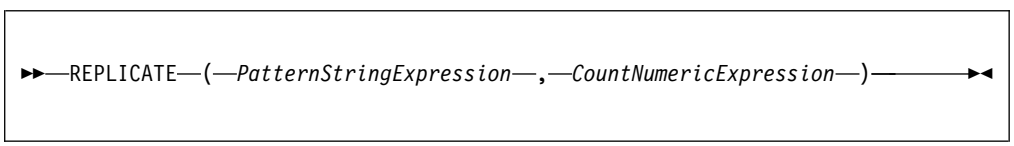
REPLICATE function:

REPLICATE is a string manipulation function that manipulates all data types (BIT, BLOB, and CHARACTER) and returns a string made up of multiple copies of a supplied string.

Syntax



REPLICATE returns a string consisting of the pattern string given by *PatternStringExpression* repeated the number of times given by *CountNumericExpression*.

The pattern string can be of the CHARACTER, BLOB, or BIT datatype and the count must be of type INTEGER. The result is of the same data type as the pattern string.

If the count is negative or zero, a zero length string is returned. If either parameter is NULL, the result is NULL.

The count is limited to 32*1024*1024 to protect the broker from erroneous programs. If this limit is exceeded, an exception condition is issued.

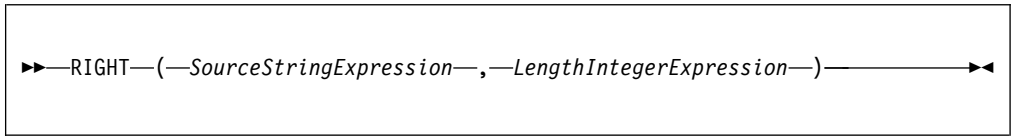
RIGHT function:

RIGHT is a string manipulation function that manipulates all data types (BIT, BLOB, and CHARACTER), and truncates a string.

Syntax



RIGHT returns a string consisting of the source string truncated to the length given by the length expression. The truncation discards the initial characters of the source string.

The source string can be of the CHARACTER, BLOB, or BIT data type and the length must be of type INTEGER.

If the length is negative or zero, a zero length string is returned. If either parameter is NULL, the result is NULL

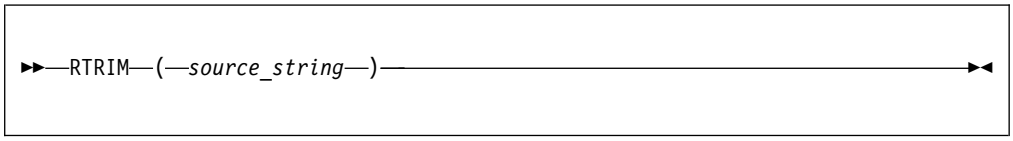
RTRIM function:

RTRIM is a string manipulation function that manipulates all data types (BIT, BLOB, and CHARACTER), and removes trailing singletons from a string.

Syntax



RTRIM returns a string value of the same data type and content as *source_string* but with any trailing default singletons removed. The term *singleton* refers to a single part (BIT, BLOB, or CHARACTER) within a string of that type.

The RTRIM function is equivalent to TRIM(TRAILING FROM *source_string*).

If the parameter is NULL, the result is NULL.

The default singleton depends on the data type of *source_string*:

Data type of source string	Default singleton
Character	' ' (space)
BLOB	X'00'
Bit	B'0'

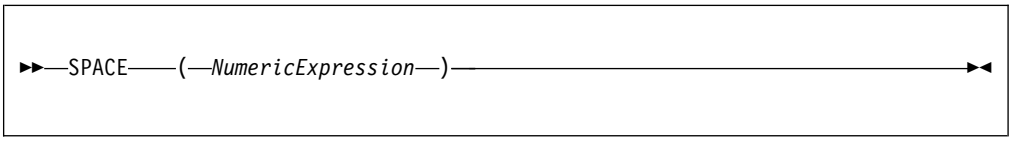
SPACE function:

SPACE is a string manipulation function that manipulates all data types (BIT, BLOB, and CHARACTER), and creates a string consisting of a defined number of blank spaces.

Syntax



SPACE returns a character string consisting of the number of blank spaces given by *NumericExpression*. The parameter must be of type INTEGER; the result is of type CHARACTER.

If the parameter is negative or zero, a zero length character string is returned. If the parameter is NULL, the result is NULL.

The string is limited to 32*1024*1024 to protect the broker from erroneous programs. If this limit is exceeded, an exception condition is issued.

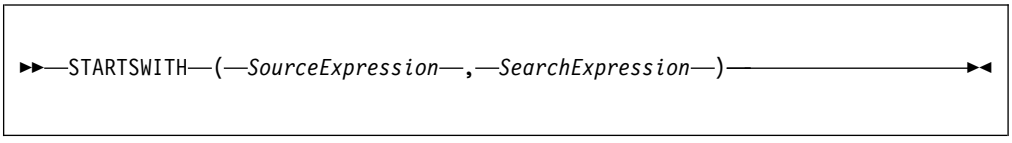
STARTSWITH function:

STARTSWITH is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and returns a Boolean value to indicate whether one string begins with another.

Syntax



STARTSWITH returns TRUE if *SourceExpression* begins with *SearchExpression*, otherwise it returns FALSE.

The parameter strings for both *SearchExpression* and *SourceExpression* can be of the CHARACTER, BLOB, or BIT data type, but must be of the same data type.

If any parameter is NULL, the result is NULL.

Examples

```
STARTSWITH('Hello World!', 'Hello');
```

returns TRUE.

```
STARTSWITH('Hello World!', 'World');
```

returns FALSE.

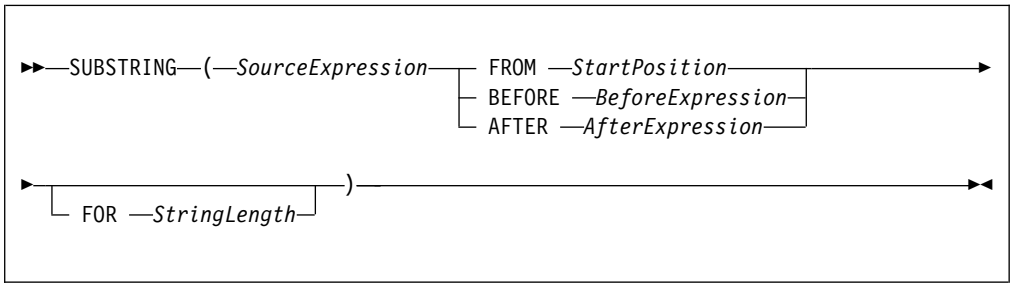
SUBSTRING function:

SUBSTRING is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and extracts characters from a string to create another string.

Syntax



Parameters must be of the following types:

- *SourceExpression*, *BeforeExpression*, and *AfterExpression* can be BIT, BLOB, or CHARACTER.
- *StartPosition* and *StringLength* can be INTEGER only.

StartPosition

If you specify *StartPosition*, SUBSTRING returns a new string of the same type as *SourceExpression* containing one contiguous sequence of characters that are

extracted from *SourceExpression*, as specified by *StartPosition* and *StringLength*. If you do not specify *StringLength*, the sequence runs from *StartPosition* until the end of *SourceExpression*. The *StartPosition* can be negative, and together, the *StartPosition* and *StringLength* define a range. The result is the overlap between this range and the *SourceExpression*; the *StringLength* cannot be less than the *StartPosition*.

BeforeExpression

If you specify *BeforeExpression*, SUBSTRING returns a new string of the same type as *SourceExpression* containing one contiguous sequence of characters that are extracted from *StringLength* characters before the first occurrence of *BeforeExpression* within *SourceExpression*, up to (but not including) the first character of the first occurrence of *BeforeExpression*. If you do not specify *StringLength*, the sequence of characters is taken from the beginning of *SourceExpression* up to (but not including) the first character of the first occurrence of *BeforeExpression*. If the *BeforeExpression* string does not occur in *SourceExpression*, an empty (zero length) string is returned.

The *BeforeExpression* string must be of the same data type as *SourceExpression*.

AfterExpression

If you specify *AfterExpression*, SUBSTRING returns a new string of the same type as *SourceExpression*, containing one contiguous sequence of characters that are extracted from *SourceExpression*, beginning with the first character after the end of the first occurrence of *AfterExpression* until the end of *SourceExpression* (or *StringLength* characters, if specified). If the *AfterExpression* string does not occur in *SourceExpression*, an empty (zero length) string is returned.

The *AfterExpression* string must be of the same data type as *SourceExpression*.

If any parameter is NULL, the result is NULL. This is not a zero length string.

Examples:

```
SUBSTRING('Hello World!' FROM 7 FOR 4)
```

returns `'Worl'`.

```
SUBSTRING('Hello World!' BEFORE 'World');
```

returns `'Hello '`.

```
SUBSTRING('Hello World!' BEFORE 'World' FOR 3);
```

returns `'lo '`.

```
SUBSTRING('Hello World!' BEFORE 'e');
```

returns `'H'`.

```
SUBSTRING('Hello World!' AFTER 'World');
```

returns `'!'`.

```
SUBSTRING('Hello World!' AFTER 'W' FOR 2);
```

returns `'or'`.

```
SUBSTRING('Hello World!' AFTER 'P');
```

returns `''`.

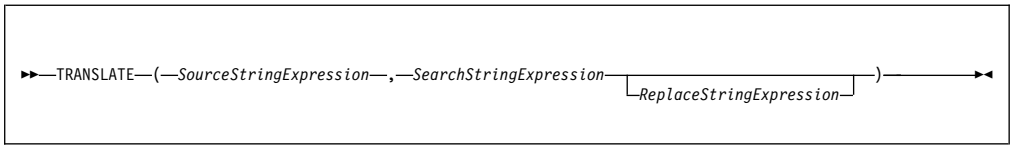
TRANSLATE function:

TRANSLATE is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and replaces specified characters in a string.

Syntax



TRANSLATE returns a string consisting of the source string, with each occurrence of any character that occurs in the search string being replaced by the corresponding character from the replace string.

The parameter strings can be of the CHARACTER, BLOB, or BIT data type but all three must be of the same type. If any parameter is NULL, the result is NULL.

If the replace string is shorter than the search string, there are characters in the search string for which there is no corresponding character in the replace string. This is treated as an instruction to delete these characters and any occurrences of these characters in the source string are absent from the returned string

If the replace string expression is not specified, the replace string is assumed to be an empty string, and the function deletes all occurrences of any characters in the search string from the result.

Related concepts:

"ESQL overview" on page 2371

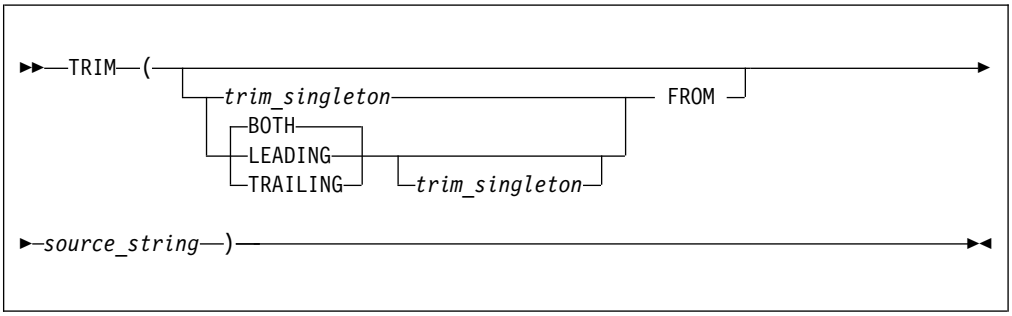
TRIM function:

TRIM is a string manipulation function that manipulates all string data types (BIT, BLOB, and CHARACTER), and removes trailing and leading singletons from a string.

Syntax



TRIM returns a new string of the same type as *source_string*, in which the leading, trailing, or both leading and trailing singletons have been removed. The term *singleton* refers to a single part (BIT, BYTE, or CHARACTER) within a string of that type.

The singleton can contain a list of multiple characters to be trimmed from the source string.

If *trim_singleton* is not specified, a default singleton is assumed. The default singleton depends on the data type of *source_string*:

Character	**' ' (space)**
BLOB	X'00'
Bit	B'0'

If any parameter is NULL, the result is NULL.

It is often unnecessary to strip trailing blanks from character strings before comparison, because the rules of character string comparison mean that trailing blanks are not significant.

The following examples illustrate the behavior of the TRIM function:

```
TRIM(TRAILING 'b' FROM 'aaabBb')
```

returns `'aaabB'`.

```
TRIM('  a  ')
```

returns 'a'.

```
TRIM(LEADING FROM '  a  ')
```

returns 'a '.

```
TRIM('b' FROM 'bbbaaabbb')
```

returns 'aaa'.

An example of using a multiple character singleton is:

```
DECLARE input1 CHARACTER 'testmgktest';
SET OutputRoot.XMLNSC.Top.Out1 = TRIM( 'ste' FROM input1);
```

The preceding code produces the output message:

```
<Top><Out1>mgk</Out1></Top>
```

An example of using a multiple character singleton to remove leading and trailing white space characters is:

```
DECLARE whiteSpace CONSTANT CHARACTER CAST( X'090D0A20' AS CHAR CCSID 1208);
 /* tab, cr, lf, space */
DECLARE input2 CHARACTER 'smith';

SET input2 = whiteSpace || input2 || whiteSpace;
SET OutputRoot.XMLNSC.Top.Out2 = TRIM( whiteSpace FROM input2);
```

The preceding code produces the output message:

```
<Top><Out2>smith</Out2></Top>
```

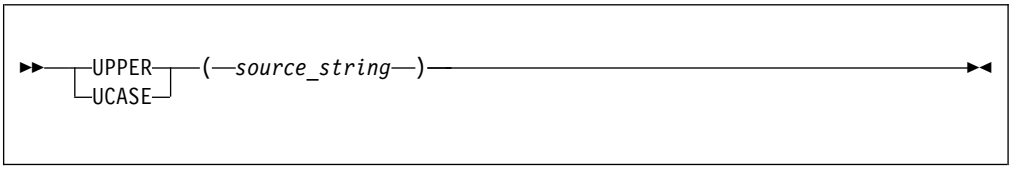
UPPER and UCASE functions:

UPPER and UCASE are equivalent string manipulation functions that manipulate CHARACTER string data and convert lowercase characters in a string to uppercase.

Syntax



UPPER and UCASE both return a new character string, which is identical to *source_string*, except that all lowercase letters are replaced with the corresponding uppercase letters.

For example:

```
UPPER('ABCD')
```

returns `'ABCD'`.

```
UCASE('abc123')
```

returns `'ABC123'`.

Converting characters from different code pages to uppercase

If you are using certain code pages, characters with no uppercase equivalent in your code page might be converted when you use the UPPER or UCASE function. This conversion happens because the bit stream is converted to a Unicode message tree by the message parser. Even though characters might have no uppercase equivalent in the source code page, they can still have an uppercase equivalent in the Unicode code page, and are converted by the UPPER or UCASE function. When the bit stream is converted back to the original code page, these characters cannot be converted back, and a substitution character is inserted into the output message for each character. The substitution character inserted depends on the original code page. For example, conversion to an EBCDIC code page inserts an X'3F' byte and conversion to a Japanese code page inserts an X'7F' byte.

A solution to this problem is to use the TRANSLATE function to convert selected characters to uppercase, instead of using the UPPER or UCASE function. Any characters that have no uppercase equivalent in the code page are excluded from the conversion.

In the following example, the input message is in code page 284, and the `InputRoot.XML.MSG.APPDATA` element contains characters that do not have an uppercase equivalent in code page 284, but do have uppercase equivalents in the Unicode code page. The TRANSLATE function is used to convert only the lowercase characters 'a' to 'z' to their equivalent uppercase characters. Any other characters in `InputRoot.XML.MSG.APPDATA` are excluded from the conversion.

```
DECLARE char1 CHAR;
SET char1 = TRANSLATE(InputRoot.XML.MSG.APPDATA,'abcdefghijklmnopqrstuvwxyz','ABCDEFGHIJKLMNOPQRSTUVWXYZ');
SET OutputRoot.MQMD.CodedCharSetId = 284;
SET OutputRoot.XML.TEST.translated = char1;
```

You can use ESQL statements to manipulate message trees, update databases, or interact with nodes.

"ESQL functions" on page 5168
The following types of function are available.

ASBITSTREAM function:

The ASBITSTREAM field function generates a bit stream for the subtree of a given field according to the rules of the parser that owns the field.

The ASBITSTREAM field function uses parameters supplied by the caller for:

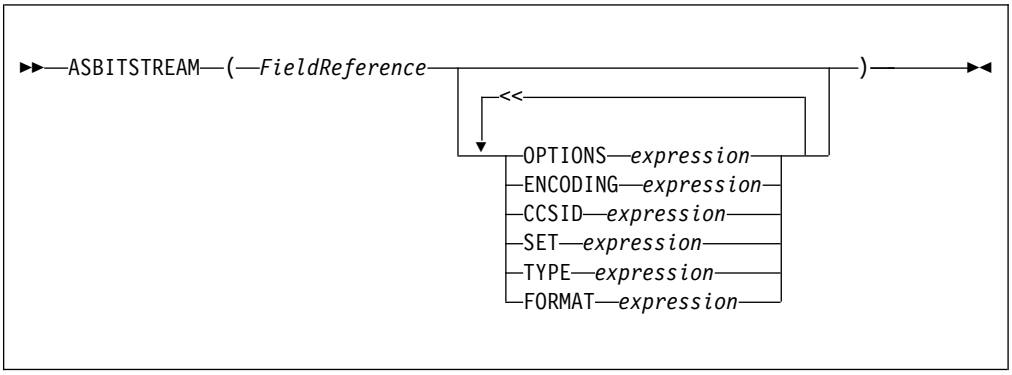
- Encoding

- CCSID
- Message set
- Message type
- Message format
- Options

The ASBITSTREAM function removes the limitation of the existing BITSTREAM function, which can be used only on a tree produced by a parser that belongs to an input node.

The BITSTREAM function is retained only for compatibility with earlier versions.

Syntax



Note that each clause can occur once only.

ASBITSTREAM returns a value of type BLOB that contains a bitstream representation of the field that is pointed to by *FieldReference* and its children.

The algorithm for doing this varies from parser to parser, and according to the options specified. All parsers support the following modes:

- RootBitStream, in which the algorithm that generates the bit stream is the same as the algorithm that is used by an output node. In this mode, a meaningful result is obtained only if the field pointed to is at the head of a subtree with an appropriate structure.
- EmbeddedBitStream, in which not only is the algorithm that generates the bit stream the same as the algorithm used by an output node, but also the
  - Encoding
  - CCSID
  - Message set
  - Message type
  - Message format

  are determined, if not explicitly specified, in the same way as the output node. That is, they are determined by searching the previous siblings of *FieldReference* on the assumption that they represent headers.

  In this way, the algorithm for determining these properties is essentially the same as that used for the BITSTREAM function.

Some parsers also support another mode, FolderBitStream, which generates a meaningful bit stream for any subtree, provided that the field that is pointed to represents a folder.

In all cases, the bit stream obtained can be given to a CREATE statement with a PARSE clause, using the same DOMAIN and OPTIONS to reproduce the original subtree.

When the function is called, any clause expressions are evaluated. An exception is thrown if any of the expressions do not result in a value of the appropriate type.

If any parameter is NULL the result is NULL.

Clause	Type	Default value
OPTIONS	Integer	RootBitStream & ValidateNone
ENCODING	Integer	0
CCSID	Integer	0
SET	Character	Zero length string
TYPE	Character	Zero length string
FORMAT	Character	Zero length string

For details of the syntax of the TYPE clause, refer to "Specifying namespaces in the Message Type property" on page 1208.

Although the OPTIONS clause accepts any expression that returns a value of type integer, it is only meaningful to generate option values from the list of supplied constants, using the BITOR function if more than one option is required.

The generated value becomes an integer and can be saved in a variable, passed as a parameter to a function, or used directly in an ASBITSTREAM call. The list of globally-defined constants is:

```
Validate master options...
ValidateContentAndValue
ValidateValue    -- Can be used with ValidateContent
ValidateContent  -- Can be used with ValidateValue
ValidateNone

Validate failure action options...
ValidateException
ValidateExceptionList
ValidateLocalError
ValidateUserTrace
```

Note:

1. For full details of the validation options, refer to "Validation properties" on page 4169.

C and Java equivalent APIs

Note that equivalent options are not available on:

- The Java plugin node API MBElement methods **createElementAsLastChildFromBitstream()** and **toBitstream()**
- The C plugin node API methods **cniCreateElementAsLastChildFromBitstream()** and **cniElementAsBitstream**.

Only one option from each group can be specified, with the exception of ValidateValue and ValidateContent, which can be used together to obtain the content and value validation. If you do not specify an option within a group, the option in bold is used.

The ENCODING clause accepts any expression that returns a value of type integer. However, it is only meaningful to generate encoding values from the list of supplied constants:

```
0
MQENC_INTEGER_NORMAL
MQENC_INTEGER_REVERSED
MQENC_DECIMAL_NORMAL
MQENC_DECIMAL_REVERSED
MQENC_FLOAT_IEEE_NORMAL
MQENC_FLOAT_IEEE_REVERSED
MQENC_FLOAT_S390
```

`0` uses the queue manager's encoding.

The values that are used for the CCSID clause follow the normal numbering system. For example, 1200 = UCS-2, 1208 = UTF-8.

In addition the special values 0 and -1 are supported:

- `0` uses the queue manager's CCSID
- `-1` uses the CCSID's as determined by the parser itself. This value is reserved.

For absent clauses, the given default values are used. Use the CCSID and encoding default values, because they take their values from the queue manager's encoding and CCSID settings.

Similarly, use the default values for each of the message set, type, and format options, because many parsers do not require message set, type, or format information; any valid value is sufficient.

When any expressions have been evaluated, the appropriate bit stream is generated.

Note: Because this function has a large number of clauses, an alternative syntax is supported in which the parameters are supplied as a comma-separated list rather than by named clauses. In this case, the expressions must be in the following order:

```
ENCODING -> CCSID -> SET -> TYPE -> FORMAT -> OPTIONS
```

The list can be truncated at any point and you can use an empty expression for any clauses for which you do not supply a value.

Examples

```
DECLARE options INTEGER BITOR(FolderBitStream, ValidateContent,
                              ValidateValue);
SET result = ASBITSTREAM(cursor OPTIONS options CCSID 1208);
SET Result = ASBITSTREAM(Environment.Variables.MQRFH2.Data,,1208
                         ,,,,options);
```

ESQL provides functions that support field operations.

"BITSTREAM function (deprecated)"
The BITSTREAM field function returns a value that represents the bit stream that is described by the given field and its children. Its use is deprecated; use the newer ASBITSTREAM function instead.

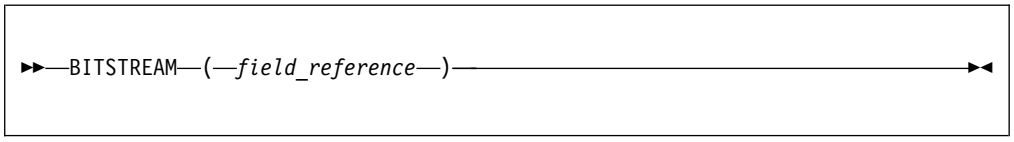
"Supported code pages" on page 4176
Application messages must conform to supported code pages.

BITSTREAM function (deprecated):

The BITSTREAM field function returns a value that represents the bit stream that is described by the given field and its children. Its use is deprecated; use the newer ASBITSTREAM function instead.

The BITSTREAM function can be used only on a tree produced by a parser belonging to an input node. The ASBITSTREAM function does not suffer from this limitation.

Syntax



The BITSTREAM function returns a value of type BLOB that represents the bit stream that is described by the given field and its children. For incoming messages, the appropriate portion of the incoming bit stream is used. For messages that are constructed by Compute nodes, the following algorithm is used to establish the ENCODING, CCSID, message set, message type, and message format:

- If the addressed field has a previous sibling, and this sibling is the root of a subtree that belongs to a parser capable of providing an ENCODING and CCSID, these values are obtained and used to generate the requested bit stream. Otherwise, the broker's default ENCODING and CCSID (that is, those of its queue manager) are used.
- Similarly, if the addressed field has a previous sibling, and this sibling is the root of a subtree that belongs to a parser capable of providing a message set, message type, and message format, these values are obtained and used to generate the requested bit stream. Otherwise, zero length strings are used.

This function is typically used for message warehouse scenarios, where the bit stream of a message needs to be stored in a database. The function returns the bit stream of the physical portion of the incoming message, identified by the parameter. In some cases, it does not return the bit stream that represents the actual field identified. For example, the following two calls return the same value:

```
BITSTREAM(Root.MQMD);
BITSTREAM(Root.MQMD.UserIdentifier);
```

because they lie in the same portion of the message.

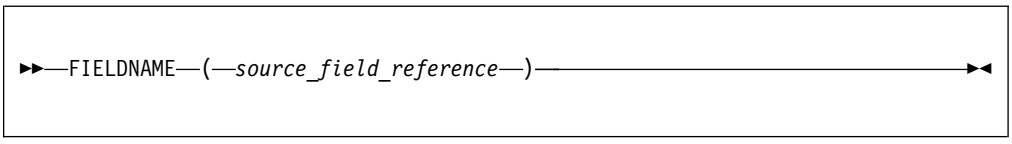
ESQL provides functions that support field operations.

"ASBITSTREAM function" on page 5224
The ASBITSTREAM field function generates a bit stream for the subtree of a given field according to the rules of the parser that owns the field.

FIELDNAME function:
The FIELDNAME field function returns the name of a given field.

Syntax



FIELDNAME returns the name of the field identified by *source_field_reference* as a character value. If the parameter identifies a nonexistent field, NULL is returned.

For example:

- `FIELDNAME(InputRoot.XMLNS)` returns XMLNS.

- `FIELDNAME(InputBody)` returns the name of the last child of InputRoot, which could be XMLNS.
- `FIELDNAME(InputRoot.*[<])` returns the name of the last child of InputRoot, which could be XMLNS.

This function does not show any namespace information; this must be obtained by a separate call to the "FIELDNAMESPACE function."

Whereas the following ESQL sets X to "F1":

```
SET X=FIELDNAME(InputBody.*[<]);
```

The following ESQL sets Y to null:

```
SET Y=FIELDNAME(InputBody.F1.*[<]);
```

However, the following ESQL sets Z to the (expected) child of F1:

```
SET Z=FIELDNAME(InputBody.*[<].*[<]);
```

This is because F1 belongs to a namespace and needs to be explicitly referenced by, for example:

```
DECLARE ns NAMESPACE 'urn:nid:xxxxxx';

SET Y=FIELDNAME(InputBody.ns:F1.*[<]);
```

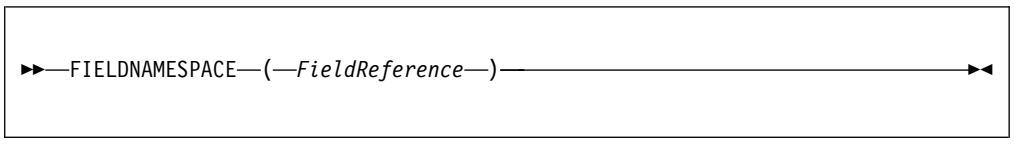
ESQL provides functions that support field operations.

FIELDNAMESPACE function:
The FIELDNAMESPACE field function returns the namespace of a given field.

Syntax



FIELDNAMESPACE takes a field reference as a parameter and returns a value of type CHARACTER containing the namespace of the addressed field. If the parameter identifies a nonexistent field, NULL is returned.

Related concepts:

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

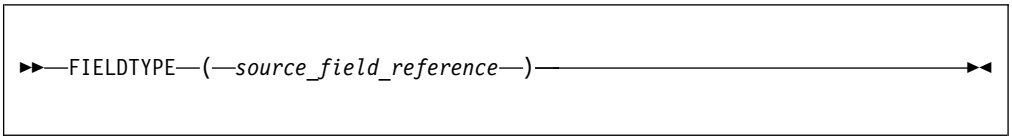
"ESQL field functions" on page 5224
ESQL provides functions that support field operations.

FIELDTYPE function:

The FIELDTYPE field function returns the type of a given field.

Syntax



FIELDTYPE returns an integer representing the type of the field identified by *source_field_reference*; this is the type of the field, not the data type of the field that the parameter identifies. If the parameter identifies a nonexistent entity, NULL is returned.

The mapping of integer values to field types is not published, and might change from release to release. Compare the results of the FIELDTYPE function with named field types.

For example:

```
IF FIELDTYPE(source_field_reference) = NameValue
 THEN ...
```

The named field types that you can use in this context are listed in this section. You must use these types with the capitalization shown.

The following types are domain-independent:

- *Name*
- *Value*
- *NameValue*
- *MQRFH2.BitStream*
- *MQRFH2.Field*
- *MQRFH2C.Field*

The *XML.** types are applicable to the XML, XMLNS, JMSMap, and JMSStream domains, except for *XML.NamespaceDecl*, which is specific to the XML domain.

- *XML.AsisElementContent*
- *XML.Attribute*

- *XML.AttributeDef*
- *XML.AttributeDefDefaultType*
- *XML.AttributeDefType*
- *XML.AttributeDefValue*
- *XML.AttributeList*
- *XML.BitStream*
- *XML.CDataSection*
- *XML.Comment*
- *XML.Content*
- *XML.DocTypeCommentt*
- *XML.DocTypeDecl*
- *XML.DocTypePI*
- *XML.DocTypeWhiteSpace*
- *XML.Element*
- *XML.ElementDef*
- *XML.Encoding*
- *XML.EntityDecl*
- *XML.EntityDeclValue*
- *XML.EntityReferenceEnd*
- *XML.EntityReferenceStart*
- *XML.EntityValue*
- *XML.ExternalEntityDecl*
- *XML.ExternalParameterEntityDecl*
- *XML.ExtSubset*
- *XML.IntSubset*
- *XML.NamespaceDecl*
- *XML.NotationDecl*
- *XML.NotationReference*
- *XML.Opaque*
- *XML.ParameterEntityDecl*
- *XML.ParserRoot*
- *XML.ProcessingInstruction*
- *XML.PublicId*
- *XML.RequestedDomain*
- *XML.Standalone*
- *XML.SystemId*
- *XML.UnparsedEntityDecl*
- *XML.Version*
- *XML.WhiteSpace*
- *XML.XmlDecl*

The *XMLNSC.** types are applicable to the XMLNSC domain. The same constants can also be prefixed with *SOAP.** for use in the SOAP domain.

- *XMLNSC.AnyCData*
- *XMLNSC.AnyHybrid*

- *XMLNSC.AnyPCData*
- *XMLNSC.AnyValue*
- *XMLNSC.AsisElementContent*
- *XMLNSC.Attribute*
- *XMLNSC.base64Binary*
- *XMLNSC.BitStream*
- *XMLNSC.CDataField*
- *XMLNSC.CDataValue*
- *XMLNSC.Comment*
- *XMLNSC.DocumentType*
- *XMLNSC.DoubleAttribute*
- *XMLNSC.DoubleEntityDefinition*
- *XMLNSC.DoubleNamespaceDecl*
- *XMLNSC.Element*
- *XMLNSC.EntityDefinition*
- *XMLNSC.EntityReference*
- *XMLNSC.Field*
- *XMLNSC.Folder*
- *XMLNSC.gDay*
- *XMLNSC.gMonth*
- *XMLNSC.gMonthDay*
- *XMLNSC.gYear*
- *XMLNSC.gYearMonth*
- *XMLNSC.HybridField*
- *XMLNSC.HybridValue*
- *XMLNSC.NamespaceDecl*
- *XMLNSC.Opaque*
- *XMLNSC.PCDataField*
- *XMLNSC.PCDataValue*
- *XMLNSC.ProcessingInstruction*
- *XMLNSC.SingleAttribute*
- *XMLNSC.SingleEntityDefinition*
- *XMLNSC.SingleNamespaceDecl*
- *XMLNSC.Value*
- *XMLNSC.XmlDeclaration*

You can also use this function to determine whether a field in a message exists. To do this, use the form:

```
FIELDTYPE(SomeFieldReference) IS NULL
```

If the field exists, an integer value is returned to the function that indicates the field type (for example, string). When this is compared to NULL, the result is FALSE. If the field does not exist, NULL is returned and therefore the result is TRUE. For example:

```
IF FIELDTYPE(InputRoot.XMLNS.Message1.Name)
    IS NULL THEN
// Name field does not exist, take error
action....
```

```
... more ESQL ...
ELSE
// Name field does exist, continue....
... more ESQL ...
END IF
```

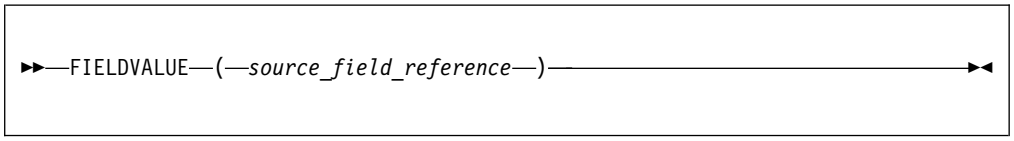
The names of the XML and MRM parser constants, together with their corresponding values, and a link to the XMLNSC constants.

"XMLNSC: Using field types" on page 1094
The XMLNSC parser sets the field type on every syntax element that it creates.

FIELDVALUE function:
The FIELDVALUE field function returns the scalar value of a given field.

Syntax



FIELDVALUE returns the scalar value of the field identified by *source_field_reference*. If it identifies a non-existent field, NULL is returned.

For example, consider the following XML input message:

```
<Data>
   <Qty Unit="Gallons">1234</Qty>
</Data>
```

The ESQL statement

```
SET OutputRoot.XML.Data.Quantity =
    FIELDVALUE(InputRoot.XML.Data.Qty);
```

gives the result:

```
<Data><Quantity>1234</Quantity></Data>
```

whereas this ESQL statement (without the FIELDVALUE function):

```
SET OutputRoot.XML.Data.Quantity =
    InputRoot.XML.Data.Qty;
```

causes a tree copy, with the result:

```
<Data><Quantity Unit="Gallons">1234</Quantity></Data>
```

because the field `Qty` is not a leaf field.

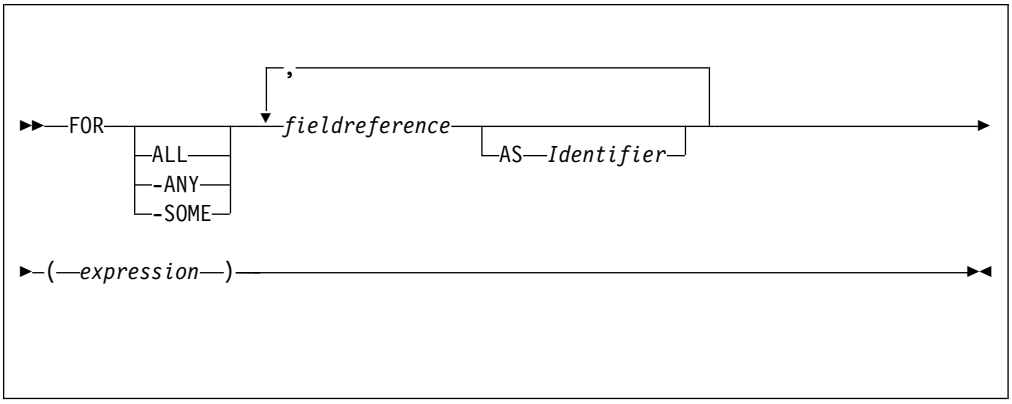
"ESQL field functions" on page 5224
ESQL provides functions that support field operations.

FOR function:

The FOR field function evaluates an expression and assigns a resulting value of TRUE, FALSE, or UNKNOWN.

Syntax



FOR enables you to write an expression that iterates over all instances of a repeating field. For each instance it processes a boolean expression and collates the results.

For example:

```
FOR ALL Body.Invoice.Purchases."Item"[] AS I (I.Quantity <= 50)
```

Note:

1. With the quantified predicate , the first thing to note is the [] on the end of the field reference after the FOR ALL. The square brackets define iteration over all instances of the `Item` field.

In some cases, this syntax appears unnecessary, because you can get that information from the context, but it is done for consistency with other pieces of syntax.

2. The ASclause associates the name `I` in the field reference with the current instance of the repeating field. This is similar to the concept of iterator classes used in some object oriented languages such as C++. The expression in parentheses is a predicate that is evaluated for each instance of the `Item` field.

If you specify the **ALL** keyword, the function iterates over all instances of the field Item inside `Body.Invoice.Purchases` and evaluates the predicate `I.Quantity <= 50`. If the predicate evaluates to:

- TRUE (if the field is empty, or for all instances of `Item`) return TRUE.
- FALSE (for any instance of `Item`) return FALSE.
- Anything else, return UNKNOWN.

The **ANY** and **SOME** keywords are equivalent. If you use either, the function iterates over all instances of the field Item inside `Body.Invoice.Purchases` and evaluates the predicate `I.Quantity <= 50`. If the predicate evaluates to:

- FALSE (if the field is empty, or for all instances of `Item`) return FALSE.
- TRUE (for any instance of `Item`) return TRUE.
- Anything else, return UNKNOWN.

To further illustrate this, the following examples are based on the message described in "Example message" on page 5311. In the following filter expression:

```
FOR ANY Body.Invoice.Purchases."Item"[] AS I (I.Title = 'The XML Companion')
```

the sub-predicate evaluates to TRUE. However, this next expression returns FALSE:

```
FOR ANY Body.Invoice.Purchases."Item"[] AS I (I.Title = 'C Primer')
```

because the C Primer is not included on this invoice. If in this instance some of the items in the invoice do not include a book title field, the sub-predicate returns UNKNOWN, and the quantified predicate returns the value UNKNOWN.

Take great care to deal with the possibility of null values appearing. Write this filter with an explicit check on the existence of the field, as follows:

```
FOR ANY Body.Invoice.Purchases."Item"[] AS I (I.Book IS NOT NULL AND
I.Book.Title = 'C Primer')
```

The IS NOT NULL predicate ensures that, if an `Item` field does not contain a `Book`, a FALSE value is returned from the sub-predicate.

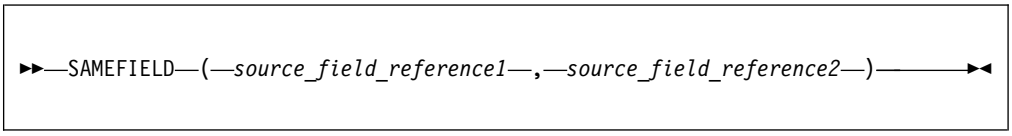
"MOVE statement" on page 5145
The MOVE statement changes the field to which the *Target* reference variable points.

SAMEFIELD function:
The SAMEFIELD field function tells you whether two field references point to the same target.

Syntax



SAMEFIELD returns a BOOLEAN value indicating whether two field references point to the same target. If they do, SAMEFIELD returns TRUE; otherwise SAMEFIELD returns FALSE.

For example:

```
DECLARE ref1 REFERENCE TO OutputRoot.XMLNS.Invoice.Purchases.Item[1];
MOVE ref1 NEXTSIBLING;
SET Result = SAMEFIELD(ref1,OutputRoot.XMLNS.Invoice.Purchases.Item[2]);
```

`Result` is `TRUE`.

ESQL list functions:

ESQL provides several functions to work with lists.

"CARDINALITY function"

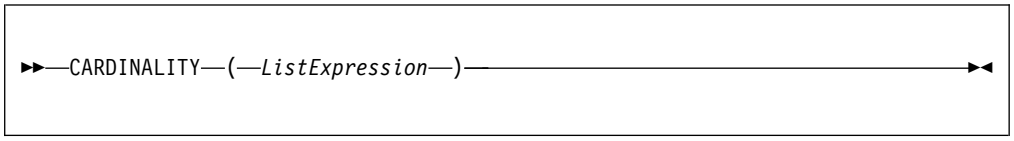
"EXISTS function" on page 5239

"SINGULAR function" on page 5241

"THE function" on page 5242

CARDINALITY function:
The CARDINALITY function returns the number of elements in a list.

Syntax



CARDINALITY returns an integer value giving the number of elements in the list specified by *ListExpression*.

ListExpression is any expression that returns a list. All the following, for example, return a list:
- A LIST constructor
- A field reference with the [] array indicator
- Some SELECT expressions (not all return a list)

A common use of this function is to determine the number of fields in a list before iterating over them.

Examples

```
-- Determine the number of F1 fields in the message.
-- Note that the [ ] are required
DECLARE CountF1 INT CARDINALITY(OutputRoot.XMLNS.Data.Source.F1[]);

-- Determine the number of fields called F1 with the value 'F12' in the message.
-- Again note that the [ ] are required
DECLARE CountF1F12 INT
  CARDINALITY(SELECT F.* FROM OutputRoot.XMLNS.Data.Source.F1[] AS F
              where F = 'F12');

-- Use the value returned by CARDINALITY to refer to a specific element
-- in a list or array:
-- Array indices start at 1, so this example refers to the third-from-last
-- instance of the Item field
Body.Invoice.Item[CARDINALITY(Body.Invoice.Item[]) - 2].Quantity
```

The SINGULAR function returns a Boolean value that indicates whether a list contains exactly one element.

"THE function" on page 5242
The THE function returns the first element of a list.

"Syntax diagrams" on page 3677

"ESQL list functions" on page 5238
ESQL provides several functions to work with lists.

EXISTS function:

The EXISTS function returns a Boolean value to indicate whether a list contains at least one element (that is, whether the list exists).

Syntax

If the list specified by *ListExpression* contains one or more elements, EXISTS returns TRUE. If the list contains no elements, EXISTS returns FALSE.

ListExpression is any expression that returns a list. All the following expressions, for example, return a list:
- A LIST constructor
- A field reference with the [] array indicator
- Some SELECT expressions (not all return a list)

If you want to know only whether a list contains at least one elements or none, EXISTS executes more quickly than an expression involving the CARDINALITY function (for example, `CARDINALITY(ListExpression ) <> 0`).

A typical use of this function is to determine whether a field exists.

Examples

```
-- Determine whether the F1 array exists in the message. Note that the [ ]
-- are required
DECLARE Field1Exists BOOLEAN EXISTS(OutputRoot.XMLNS.Data.Source.F1[]);
-- Determine whether the F1 array contains an element with the value 'F12'.
-- Again note that the [ ] are required
DECLARE Field1F12Exists BOOLEAN
  EXISTS(SELECT F.* FROM OutputRoot.XMLNS.Data.Source.F1[] AS F where F = 'F12');
```

The THE function returns the first element of a list.

"Syntax diagrams" on page 3677

"ESQL list functions" on page 5238
ESQL provides several functions to work with lists.

SINGULAR function:

The SINGULAR function returns a Boolean value that indicates whether a list contains exactly one element.

Syntax

If the list specified by *ListExpression* contains exactly one element, SINGULAR returns TRUE. If the list contains more or fewer elements, SINGULAR returns FALSE.

ListExpression is an expression that returns a list. All the following expressions, for example, return a list:
- A LIST constructor
- A field reference with the [] array indicator
- Some SELECT expressions (not all return a list)

If you want to know only whether a list contains just one element or some other number, SINGULAR executes more quickly than an expression involving the CARDINALITY function (for example, `CARDINALITY(ListExpression ) = 1`).

A typical use of this function is to determine whether a field is unique.

Examples

```
-- Determine whether there is just one F1 field in the message.
-- Note that the [ ] are required
DECLARE Field1Unique BOOLEAN SINGULAR(OutputRoot.XMLNS.Data.Source.F1[]);

-- Determine whether there is just one field called F1 with the value 'F12'
-- in the message. Again note that the [ ] are required
DECLARE Field1F12Unique BOOLEAN
  SINGULAR(SELECT F.* FROM OutputRoot.XMLNS.Data.Source.F1[] AS F where F = 'F12');
```

Complex ESQL functions:
This topic lists the complex ESQL functions and covers the following:

"CASE function" on page 5243

"CAST function" on page 5245

"SELECT function" on page 5260

"ROW constructor function" on page 5267

"LIST constructor function" on page 5269

"ROW and LIST combined" on page 5270

"ROW and LIST comparisons" on page 5271

"Supported casts" on page 5273

"Implicit casts" on page 5282

"Implicit CASTs for comparisons" on page 5282

"Implicit CASTs for arithmetic operations" on page 5285

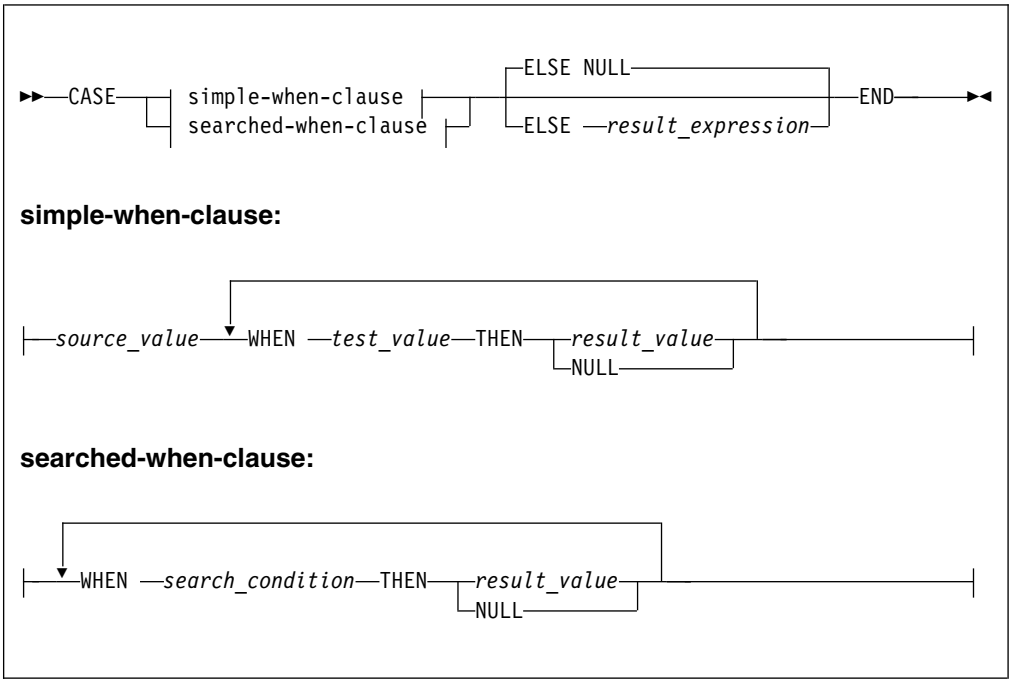
"Implicit CASTs for assignment" on page 5287

"Data types of values from external databases" on page 5288

CASE function:

CASE is a complex function that has two forms; the simple-when form and the searched-when form. In either form CASE returns a result, the value of which controls the path of subsequent processing.

Syntax



In the simple-when form, *source_value* is compared with each *test_value* until a match is found. The result of the CASE function is the value of the corresponding *result_value*. The data type of *source_value* must therefore be comparable to the data type of each *test_value*.

The CASE function must have at least one WHEN clause. The ELSE expression is optional. The default ELSE expression is NULL. A CASE expression is delimited by END. The test values do not have to be literal values.

The searched-when form is similar, but has the additional flexibility of allowing a number of different values to be tested.

The following example shows a CASE function with a simple WHEN clause. In this example, the CASE can be determined only by one variable that is specified next to the CASE keyword.

```
DECLARE CurrentMonth CHAR;
 DECLARE MonthText CHAR;
 SET CurrentMonth = SUBSTRING(InputBody.Invoice.InvoiceDate FROM 6 FOR 2);

 SET MonthText =
  CASE CurrentMonth
     WHEN '01' THEN 'January'
     WHEN '02' THEN 'February'
     WHEN '03' THEN 'March'
     WHEN '04' THEN 'April'
     WHEN '05' THEN 'May'
     WHEN '06' THEN 'June'
     ELSE 'Second half of year'
  END;
```

The following example shows a CASE function with a searched-when-clause. This example is still determined by one variable CurrentMonth:

```
DECLARE CurrentMonth CHAR;
 DECLARE MonthText CHAR;
 SET CurrentMonth = SUBSTRING(InputBody.Invoice.InvoiceDate FROM 6 FOR 2);

 SET MonthText =
  CASE
     WHEN Month = '01' THEN 'January'
     WHEN Month = '02' THEN 'February'
     WHEN Month = '03' THEN 'March'
     WHEN Month = '04' THEN 'April'
     WHEN Month = '05' THEN 'May'
     WHEN Month = '06' THEN 'June'
     ELSE 'Second half of year'
  END;
```

In a searched-when-clause, different variables can be used in the WHEN clauses to determine the result. This is demonstrated in the following example of the searched-when-clause:

```
DECLARE CurrentMonth CHAR;
 DECLARE CurrentYear CHAR;
 DECLARE MonthText CHAR;
 SET CurrentMonth = SUBSTRING(InputBody.Invoice.InvoiceDate FROM 6 FOR 2);
 SET CurrentYear = SUBSTRING(InputBody.Invoice.InvoiceDate FROM 1 FOR 4);

 SET MonthText =
   CASE
     WHEN CurrentMonth = '01' THEN 'January'
     WHEN CurrentMonth = '02' THEN 'February'
     WHEN CurrentMonth = '03' THEN 'March'
     WHEN CurrentYear = '2000' THEN 'A month in the Year 2000'
     WHEN CurrentYear = '2001' THEN 'A month in the Year 2001'
     ELSE 'Not first three months of any year or a month in the Year 2000 or 2001'
   END;
```

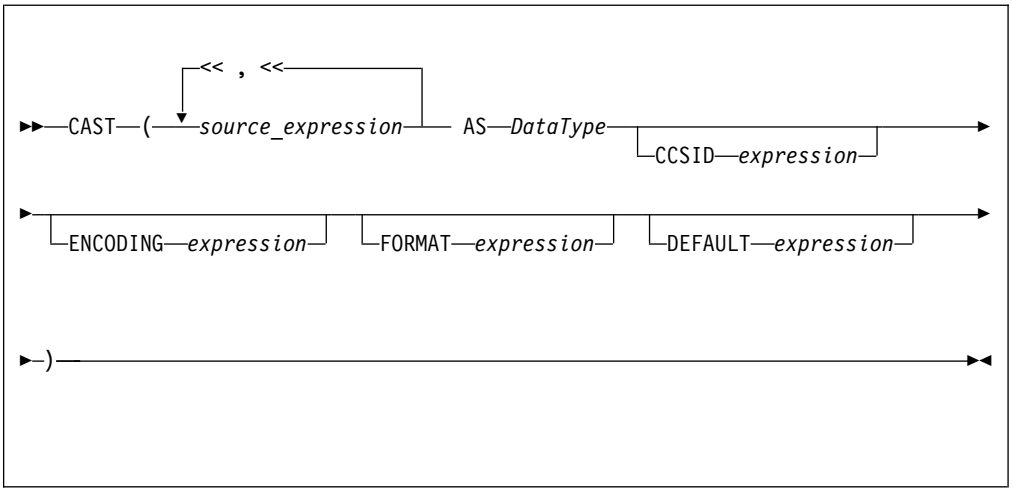
"MOVE statement" on page 5145
The MOVE statement changes the field to which the *Target* reference variable points.

CAST function:
CAST is a complex function that transforms one or more values from one data type into another.

Syntax



In practice, you cannot specify all of the above parameters at the same time. For example, **CCSID** and **ENCODING** parameters take effect only on string-to-string conversions, while **FORMAT** applies only to string-numeric and string-datetime conversions (in either direction).

Not all conversions are supported; see "Supported casts" on page 5273 for a list of supported conversions.

Parameters:
Source expression

CAST returns its first parameter (**source_expression**), which can contain more than one value, as the data type that is specified by its second parameter (**DataType**). In all cases, if the source expression is NULL, the result is NULL. If the evaluated source expression is not compatible with the target data type, or if the source expression is of the wrong format, a runtime error is generated.

CCSID

The **CCSID** parameter is used only for conversions to or from one of the string data types. Use the **CCSID** parameter to specify the code page of the source or target string.

The **CCSID** parameter can be any expression that evaluates to a value of type INT. The expression is interpreted according to normal WebSphere Message Broker rules for CCSIDs. See "Supported code pages" on page 4176 for a list of valid values.

DataType

The **DataType** parameter is the data type into which the source value is transformed. The possible values are:

- String types:
  - BIT
  - BLOB
  - CHARACTER
- Numeric types:
  - DECIMAL
  - FLOAT
  - INTEGER
- Date/Time types:
  - DATE
  - GMTTIME
  - GMTTIMESTAMP
  - INTERVAL
  - TIME
  - TIMESTAMP
- Boolean:
  - BOOLEAN

Ensure that you specify a valid ESQL interval subtype after a Date/Time type of INTERVAL. For valid ESQL interval subtypes, see "ESQL INTERVAL data type" on page 5027. For example commands that show how to specify a valid ESQL interval subtype, see examples 12, 13, and 14 later in this section.

DEFAULT

The **DEFAULT** parameter provides a method of avoiding exceptions being thrown from CAST statements by providing a last-resort value to return.

The **DEFAULT** parameter must be a valid ESQL expression that returns the same data type as that specified on the **DataType** parameter, otherwise an exception is thrown.

The **CCSID**, **ENCODING**, and **FORMAT** parameters are not applied to the result of the **DEFAULT** parameter; the expression must, therefore, be of the correct **CCSID**, **ENCODING**, and **FORMAT**.

ENCODING

Use the **ENCODING** parameter to specify the encoding for certain conversions. The **ENCODING** value can be any expression that evaluates to a value of type INT, and is interpreted according to normal WebSphere Message Broker rules for encoding. Valid values are:

- MQENC_NATIVE (0x00000222L)
- MQENC_INTEGER_NORMAL (0x00000001L)
- MQENC_INTEGER_REVERSED (0x00000002L)
- MQENC_DECIMAL_NORMAL (0x00000010L)

- MQENC_DECIMAL_REVERSED (0x00000020L)
- MQENC_FLOAT_IEEE_NORMAL (0x00000100L)
- MQENC_FLOAT_IEEE_REVERSED (0x00000200L)
- MQENC_FLOAT_S390 (0x00000300L)

FORMAT

Use the **FORMAT** parameter for conversions between string data types and numeric or date/time data types. For conversions *from* string types, **FORMAT** defines how the source string should be parsed to fill the target data type. For conversions *to* string types, it defines how the data in the source expression is formatted in the target string.

FORMAT takes different types of expression for date/time and numeric conversions. However, the same **FORMAT** expression can be used irrespective of whether the conversion is to a string or from a string.

You can specify a **FORMAT** parameter when casting:

- From any of the string data types (BIT, BLOB, or CHARACTER) to:
  - DECIMAL
  - FLOAT
  - INTEGER
  - DATE
  - GMTTIMESTAMP
  - TIMESTAMP
  - GMTTIME
  - TIME
- To any of the string data types (BIT, BLOB, or CHARACTER) from any of the numeric and date/time data types in the previous list.

Specifying **FORMAT** for an unsupported combination of source and target data types causes error message BIP3205 to be issued.

For more information about conversion to and from numeric data types, see "Formatting and parsing numbers as strings" on page 5250. For more information about conversion to and from date/time data types, see "Formatting and parsing dateTimes as strings" on page 5253.

The **FORMAT** parameter is equivalent to those used in many other products, such as ICU and Microsoft Excel.

Examples:

Example 1. Formatted CAST from DECIMAL to CHARACTER

```
DECLARE source DECIMAL 31415.92653589;
DECLARE target CHARACTER;
DECLARE pattern CHARACTER '#,##0.00';
SET target = CAST(source AS CHARACTER FORMAT pattern);
-- target is now '31,415.93'
```

Example 2. Formatted CAST from DATE to CHARACTER

```
DECLARE now CHARACTER;
SET now = CAST(CURRENT_TIMESTAMP AS CHARACTER FORMAT 'yyyyMMdd-HHmmss');
-- target is now '20041007-111656' (in this instance at least)
```

Example 3. Formatted CAST from CHARACTER to DATE

```
DECLARE source CHARACTER '01-02-03';
DECLARE target DATE;
DECLARE pattern CHARACTER 'dd-MM-yy';
SET target = CAST(source AS DATE FORMAT pattern);
-- target now contains Year=2003, Month=02, Day=01
```

Example 4. Formatted CAST from CHARACTER to TIMESTAMP

```
DECLARE source CHARACTER '12 Jan 03, 3:45pm';
DECLARE target TIMESTAMP;
DECLARE pattern CHARACTER 'dd MMM yy, h:mma';
SET target = CAST(source AS TIMESTAMP FORMAT pattern);
-- target now contains Year=2003, Month=01, Day=03, Hour=15, Minute=45,
                       Seconds=58
-- (seconds taken from CURRENT_TIME since not present in input)
```

Example 5. Formatted CAST from DECIMAL to CHARACTER, with negative pattern

```
DECLARE source DECIMAL -54231.122;
DECLARE target CHARACTER;
DECLARE pattern CHARACTER '#,##0.00;(#,##0.00)';
SET target = CAST(source AS CHARACTER FORMAT pattern);
-- target is now '£(54,231.12)'
```

Example 6. Formatted CAST from CHARACTER to TIME

```
DECLARE source CHARACTER '16:18:30';
DECLARE target TIME;
DECLARE pattern CHARACTER 'hh:mm:ss';
SET target = CAST(source AS TIME FORMAT pattern);
-- target now contains  Hour=16, Minute=18, Seconds=30
```

Example 7. CASTs from the numeric types to DATE

```
CAST(7, 6, 5 AS DATE);
CAST(7.4e0, 6.5e0, 5.6e0 AS DATE);
CAST(7.6, 6.51, 5.4 AS DATE);
```

Example 8. CASTs from the numeric types to TIME

```
CAST(9, 8, 7 AS TIME);
CAST(9.4e0, 8.6e0, 7.1234567e0 AS TIME);
CAST(9.6, 8.4, 7.7654321 AS TIME);
```

Example 9. CASTs to TIMESTAMP

```
CAST(DATE '0001-02-03', TIME '04:05:06' AS TIMESTAMP);
CAST(2, 3, 4, 5, 6, 7.8 AS TIMESTAMP);
```

Example 10. CASTs to GMTTIMESTAMP

```
CAST(DATE '0002-03-04', GMTTIME '05:06:07' AS GMTTIMESTAMP);
CAST(3, 4, 5, 6, 7, 8 AS GMTTIMESTAMP);
CAST(3.1e0, 4.2e0, 5.3e0, 6.4e0, 7.5e0, 8.6789012e0 AS GMTTIMESTAMP);
CAST(3.2, 4.3, 5.4, 6.5, 7.6, 8.7890135 AS GMTTIMESTAMP);
```

Example 11. CASTs to INTERVAL from INTEGER

```
CAST(1234 AS INTERVAL YEAR);
CAST(32, 10 AS INTERVAL YEAR   TO MONTH );
CAST(33, 11 AS INTERVAL DAY    TO HOUR  );
CAST(34, 12 AS INTERVAL HOUR   TO MINUTE);
CAST(35, 13 AS INTERVAL MINUTE TO SECOND);
CAST(36, 14, 10  AS INTERVAL DAY  TO MINUTE);
CAST(37, 15, 11  AS INTERVAL HOUR TO SECOND);
CAST(38, 16, 12, 10 AS INTERVAL DAY TO SECOND);
```

Example 12. CASTs to INTERVAL from FLOAT

```
CAST(2345.67e0   AS INTERVAL YEAR  );
CAST(3456.78e1   AS INTERVAL MONTH );
CAST(4567.89e2   AS INTERVAL DAY   );
CAST(5678.90e3   AS INTERVAL HOUR  );
CAST(6789.01e4   AS INTERVAL MINUTE);
CAST(7890.12e5   AS INTERVAL SECOND);
CAST(7890.1234e0 AS INTERVAL SECOND);
```

Example 13. CASTs to INTERVAL from DECIMAL

```
CAST(2345.67   AS INTERVAL YEAR  );
CAST(34567.8   AS INTERVAL MONTH );
CAST(456789    AS INTERVAL DAY   );
CAST(5678900   AS INTERVAL HOUR  );
CAST(67890100  AS INTERVAL MINUTE);
CAST(789012000 AS INTERVAL SECOND);
CAST(7890.1234 AS INTERVAL SECOND);
```

Example 14. CASTs to FLOAT from INTERVAL

```
CAST(INTERVAL '1234' YEAR   AS FLOAT);
CAST(INTERVAL '2345' MONTH  AS FLOAT);
CAST(INTERVAL '3456' DAY    AS FLOAT);
CAST(INTERVAL '4567' HOUR   AS FLOAT);
CAST(INTERVAL '5678' MINUTE AS FLOAT);
CAST(INTERVAL '6789.01' SECOND AS FLOAT);
```

Example 15. CASTs DECIMAL from INTERVAL

```
CAST(INTERVAL '1234' YEAR   AS DECIMAL);
CAST(INTERVAL '2345' MONTH  AS DECIMAL);
CAST(INTERVAL '3456' DAY    AS DECIMAL);
CAST(INTERVAL '4567' HOUR   AS DECIMAL);
CAST(INTERVAL '5678' MINUTE AS DECIMAL);
CAST(INTERVAL '6789.01' SECOND AS DECIMAL);
```

Example 16. A ternary cast that fails and results in the substitution of a default value

```
CAST(7, 6, 32 AS DATE DEFAULT DATE '1947-10-24');
```

Example 17. A sexternary cast that fails and results in the substitution of a default value

```
CAST(2, 3, 4, 24, 6, 7.8 AS TIMESTAMP DEFAULT TIMESTAMP '1947-10-24 07:08:09');
```

Example 18. A ternary cast that fails and throws an exception

```
BEGIN
  DECLARE EXIT HANDLER FOR SQLSTATE LIKE '%' BEGIN
    SET OutputRoot.XMLNS.Data.Date.FromIntegersInvalidCast = 'Exception thrown';
    END;

  DECLARE Dummy CHARACTER CAST(7, 6, 32 AS DATE);
  END;
```

Example 19. A sexternary cast that fails and throws an exception

```
BEGIN
  DECLARE EXIT HANDLER FOR SQLSTATE LIKE '%' BEGIN
    SET OutputRoot.XMLNS.Data.Timestamp.FromIntegersInvalidCast = 'Exception thrown';
    END;

  DECLARE Dummy CHARACTER CAST(2, 3, 4, 24, 6, 7.8 AS TIMESTAMP);
  END;
```

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

Related tasks:

"Developing ESQL" on page 2370
Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

"Casting data from message fields" on page 2474
You can use the CAST function to transform the data type of one value to match the data type of the other. For example, you can use the CAST function when you process generic XML messages. All fields in an XML message have character values, so if you want to perform arithmetic calculations or datetime comparisons, for example, you must convert the string value of the field into a value of the appropriate type using CAST.

Formatting and parsing numbers as strings:

For conversions between string data types and numeric data types, you can supply, on the FORMAT parameter of the CAST function, an optional formatting expression.

For conversions *from* string types, the formatting expression defines how the source string should be parsed to fill the target data type.

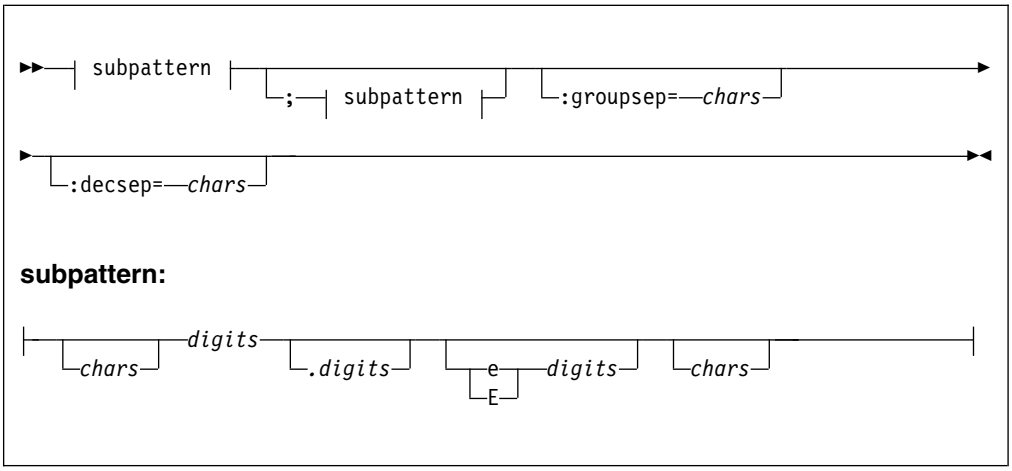
For conversions *to* string types, the formatting expression defines how the data in the source expression is to be formatted in the target string.

You can specify a FORMAT expression for the following numeric conversions (Specifying a FORMAT expression for date/time conversions is described in "Formatting and parsing dateTimes as strings" on page 5253).

- From any of the string data types (BIT, BLOB, or CHARACTER) to:
  - DECIMAL
  - FLOAT
  - INTEGER
- To any of the string data types (BIT, BLOB, or CHARACTER) from any of the numeric data types that are in the previous list.

The formatting expression consists of three parts:
1. A `subpattern` that defines positive numbers.
2. An optional `subpattern` that defines negative numbers. (If only one `subpattern` is defined, negative numbers use the positive pattern, prefixed with a minus sign.)
3. The optional parameters `groupsep` and `decsep`.

Syntax



Parameters:
chars

A sequence of zero or more characters. All characters can be used, *except* the special characters that are listed under "subpattern" on page 5252.

decsep

One or more characters to be used as the separator between the whole and decimal parts of a number (the decimal separator). The default decimal separator is a period (.).

digits

A sequence of one or more of the numeric tokens (0 # - + , .) that are listed under "subpattern" on page 5252.

groupsep

One or more characters to be used as the separator between clusters of integers, to make large numbers more readable (the grouping separator). The default grouping separator is nothing (that is, there is no grouping of digits or separation of groups).

Grouping is commonly done in thousands, but it can be redefined by either the pattern or the locale. There are two grouping sizes:

The primary grouping size
Used for the least significant integer digits.

The secondary grouping size
Used for all other integer digits.

In most cases, the primary and secondary grouping sizes are the same, but they can be different. For example, if the pattern used is `#,##,##0`, the primary grouping size is 3 and the secondary is 2. The number 123456789 would become the string “12,34,56,789”.

If multiple grouping separators are used (as in the previous example), the rightmost separator defines the primary size, and the penultimate rightmost separator defines the secondary size.

subpattern

The subpattern consists of:
1. An optional prefix (*chars*)
2. A mandatory pattern representing a whole number
3. An optional pattern representing decimal places
4. An optional pattern representing an exponent (the power by which the preceding number is raised)
5. An optional suffix (*chars*)

Parts 2, 3, and 4 of the subpattern are defined by the tokens in the following table.

Token	Represents
0	Any digit, including a leading zero.
#	Any digit, excluding a leading zero. (See the explanation of the difference between 0 and # that follows this table.)
.	Decimal separator.
+	Prefix of positive numbers.
-	Prefix of negative numbers.
,	Grouping separator.
E/e	Separates the number from the exponent.
;	Subpattern boundary.
'	Quotation mark, applied to special characters. If a quotation mark is needed in output, it must be doubled (').
*	Padding specifier. The character following the asterisk is used to pad the number to fit the length of the format pattern.

The # and 0 characters are used for digit substitution, the difference between them being that a # character is removed if there is no number to replace it with. For example, 10 formatted by the pattern `#,##0.00` gives “10.00”, but formatted by `0,000.00` gives “0,010.00”.

To specify padding characters, use an asterisk. When an asterisk is placed in either of the two *chars* regions (the prefix and suffix), the character immediately following it is used to pad the output. Padding can be specified only once. For example, a pattern of `*x#,###,##0.00` applied to 1234 gives “xxx1,234.00”. But applied to 1234567, it gives “1,234,567.00”.

Examples of formatting patterns:
The following table shows formatting patterns and the strings that are generated from sample numeric input.

Pattern	Input number	Output string
`+###,##0.00;-###,###,##0.00:groupsep='':decsep=,`	123456789.123	“+123'456'789,12”
`##0.00`	1000000	“1000000.00”
`##0.00`	3.14159265	“3.14”

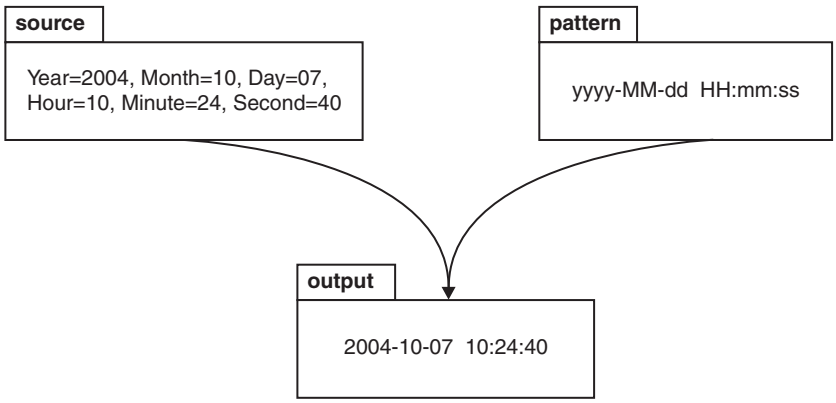
Formatting and parsing dateTimes as strings:

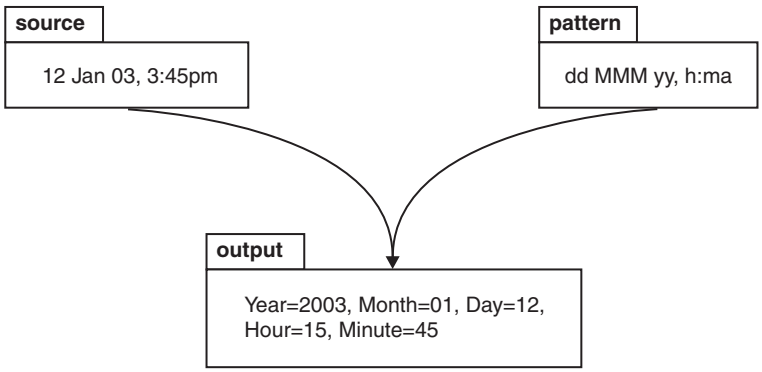
This section gives information on how you can specify the dateTime format using a string of pattern letters.

When you convert a date or time into a string, a format pattern must be applied that directs the conversion. Apply the format pattern to convert a date or time into a string, or to parse a string into a date or time.

During the conversion (for example, of a dateTime into a string), a pattern or a set of tokens is replaced with the equivalent source. The following diagram shows how a pattern is used to format a dateTime source to produce a character string output.



When a string is parsed (for example, when converting the string to a dateTime), the pattern or set of tokens is used to determine which part of the target dateTime is represented by which part of the string. The following diagram shows how this is done.



Syntax

The expression pattern is defined by:

Where:

symbol
is a character in the set **adDeEFGhHIkKmMsSTUwWyYzZ**.

string is a sequence of characters enclosed in single quotation marks. If a single quotation mark is required within the string, use two single quotation marks ('').

Characters for formatting a dateTime as a string

The following table lists the characters that you can use in a pattern for formatting or parsing strings in relation to a dateTime. The table is followed by some notes that explain more about some of the examples in the table.

Symbol	Meaning	Presentation	Examples
a	am or pm marker	Text	Input am, AM, pm, PM. Output AM or PM
d	day in month (1-31)	Number	1, 20
dd	day in month (01-31)	Number	01, 31
D	day in year (1-366)	Number	3, 80, 100
DD	day in year (01-366)	Number	03, 80, 366
DDD	day in year (001-366)	Number	003
e	day in week (1-7)[1]	Number	2
EEE	day in week[1]	Text	Tue
EEEE	day in week[1]	Text	Tuesday

Symbol	Meaning	Presentation	Examples
F	day of week in month (1-5)[2]	Number	2
G	Era	Text	BC or AD
h	hour in am or pm (1-12)	Number	6
hh	hour in am or pm (01-12)	Number	06
H	hour of day in 24 hour form (0-23)[3]	Number	7
HH	hour of day in 24 hour form (00-23)[3]	Number	07
I	ISO8601 Date/Time (up to yyyy-MM-dd'T'HH:mm:ss.SSSZZZ)[4]	Text	2006-10-07T12:06:56.568+01:00
IU	ISO8601 Date/Time (similar to I, but ZZZ with output "Z" if the time zone is +00:00)[4]	Text	2006-10-07T12:06:56.568+01:00, 2003-12 -15T15:42:12.000Z
k	hour of day in 24 hour form (1-24)[3]	Number	8
kk	hour of day in 24 hour form (01-24)[3]	Number	08
K	hour in am or pm (0-11)	Number	9
KK	hour in am or pm (00-11)	Number	09
m	minute	Number	4
mm	minute	Number	04
M	numeric month	Number	5, 12
MM	numeric month	Number	05, 12
MMM	named month	Text	Jan, Feb
MMMM	named month	Text	January, February
s	seconds[10]	Number	5
ss	seconds[10]	Number	05
S	decisecond[5]	Number	7
SS	centisecond[5]	Number	70
SSS	millisecond[5]	Number	700
SSSS	0.0001 second[5]	Number	7000
SSSSS	0.00001 second[5]	Number	70000
SSSSSS	0.000001 second[5]	Number	700000
T	ISO8601 Time (up to HH:mm:ss.SSSZZZ)[4]	Text	12:06:56.568+01:00
TU	ISO8601 Time (similar to T, but a time zone of +00:00 is replaced with 'Z')[4]	Text	12:06:56.568+01:00, 15:42:12.000Z
w	week in year[6]	Number	7, 53
ww	week in year[6]	Number	07, 53
W	week in month[7]	Number	2
yy	year[8]	Number	06

Symbol	Meaning	Presentation	Examples
yyyy	year[8]	Number	2006
YY	year: use with week in year only[6]	Number	06
YYYY	year: use with week in year only[6]	Number	2006
zzz	time zone (abbreviated name)[9]	Text	EST
zzzz	time zone (full name)	Text	Eastern Standard Time
Z	time zone (+/-n)	Text	+3
ZZ	time zone (+/-nn)	Text	+03
ZZZ	time zone (+/-nn:nn)	Text	+03:00
ZZZU	time zone (as ZZZ, "+00:00" is replaced by "Z")	Text	+03:00, Z
ZZZZ	time zone (GMT+/-nn:nn)	Text	GMT+03:00
ZZZZZ	time zone (as ZZZ, but no colon) (+/-nnnn)	Text	+0300
'	escape for text		'User text'
''	(two single quotation marks) single quotation mark within escaped text		'o''clock'

The presentation of the dateTime object depends on what symbols you specify.

- **Text**. If you specify four or more of the symbols, the full form is presented. If you specify less than four symbols, the short or abbreviated form, if it exists, is presented. For example, `EEEE` produces `Monday`, `EEE` produces `Mon`.
- **Number**. The number of characters for a numeric dateTime component must be within the bounds of the corresponding formatting symbols. Repeat the symbol to specify the minimum number of digits that are required. The maximum number of digits allowed is the upper bound for a particular symbol. For example, `day in month` has an upper bound of 31; therefore, a format string of `d` allows the values 2 or 21 to be parsed but disallows the values 32 and 210. On output, numbers are padded with zeros to the specified length. A year is a special case; see note 8 in the following list. Fractional seconds are also special case; see note 5 in the following list.
- Any characters in the pattern that are not in the ranges of ['a'..'z'] and ['A'..'Z'] are treated as quoted text. For example, characters like colon (:), comma (,), period (.), the number sign (hash or pound, #), the at sign (@), and space appear in the resulting time text even if they are not enclosed within single quotes.
- You can create formatting strings that produce unpredictable results; therefore, you must use these symbols with care. For example, if you specify `dMyyyy`, you cannot distinguish between day, month, and year. `dMyyyy` tells the broker that a minimum of one character represents the day, a minimum of one character represents the month, and four characters represent the year. Therefore, `3111999` can be interpreted as either 3/11/1999 or 31/1/1999.

Notes: The following notes apply to the table above.

1. You can specify the following values in the `day in week` field:
   - 1 - Sunday

- 2 - Monday
- 3 - Tuesday
- 4 - Wednesday
- 5 - Thursday
- 6 - Friday
- 7 - Saturday

2. 12th July 2006 is the second Wednesday in July and can be expressed as `2006 July Wednesday 2` using the format string `yyyy MMMM EEEE F`. Note that this format does not represent the Wednesday in week 2 of July 2006, which is 5th July 2006; the format string for this is `yyyy MMMM EEEE W`.
3. 24-hour fields might result in an ambiguous time, if specified with a conflicting am/pm field.
4. See "ISO8601, I and T DateTime tokens" on page 5258.
5. Fractional seconds are represented by uppercase S. The length must implicitly match the number of format symbols on input. The format string `ss SSS` or `ss.SSS`, for example, represents seconds and milliseconds. However, the format string `ss.sss` represents a repeated field (of seconds); the value after the period (.) is taken as a seconds field, not as fractional seconds. The output is truncated to the specified length.
6. In ESQL, the first day of the year is assumed to be in the first week; therefore, January 1 is always in week 1. As a result, dates that are specified relative to one year might be in a different year. For example, "Monday week 1 2005" parsed using `"EEEE' week 'w' 'YYYY"` gives a date of 2004-12-27, because the Monday of the first week in 2005 is a date in 2004.

   If you use the `y` symbol, the adjustment is not done and unpredictable results might occur for dates around the end of the year. For example, if the string "2005 01 Monday" is formatted:

   - Monday of week 1 in 2005 using format string `"YYYY ww EEEE"` is correctly interpreted as 27th December 2004
   - Monday of week 1 in 2005 using format string `"yyyy ww EEEE"` is incorrectly interpreted as 27th December 2005
7. The first and last week in a month might include days from neighboring months. For example, Monday 31st July 2006 can be expressed as *Monday in week one of August 2006*, which is `2006 08 1 Monday` using format string `yyyy MM W EEEE`.
8. Year is handled as a special case.
   - On output, if the count of `y` is 2, the year is truncated to 2 digits. For example, if `yyyy` produces `1997`, `yy` produces `97`.
   - On input, for 2 digit years the `century window` is fixed to 53. For example, an input date of 52 results in a year value of 2052, whereas an input date of 53 gives an output year of 1953, and 97 gives 1997.
9. Using the `zzz` option can have ambiguous results. For example, `BST` can be interpreted as `Bangladesh Standard Time` or `British Summer Time`. For compatibility reasons, WebSphere Message Broker uses the former interpretation.

   To avoid these problems, use the `zzzz` option with a well-defined name; for example, Europe/London, Asia/Dhaka, or America/Los_Angeles.
10. Seconds `s` & `ss`, must be in the range 0-59. If you need to construct a TIMESTAMP representing the time during a leap second, where the value being created or cast uses the value 60 for seconds, you must handle this case

within your ESQL code. The CURRENT_ datetime functions (for example, CURRENT_TIME) within the product never produce a time where the seconds value falls outside of the 0-59 range.

ISO8601, I and T DateTime tokens

If your dateTime values comply with the ISO8601:2000 'Representation of dates and times' standard, consider using the formatting symbols I and T, which match the following subset of the ISO8601 standard.

- The restricted profile as proposed by the W3C at http://www.w3.org/TR/NOTE-datetime
- Truncated representations of calendar dates, as specified in section 5.2.1.3 of ISO8601:2000
  - Basic format (subsections c, e, and f)
  - Extended format (subsections a, b, and d)

Use the formatting symbols I and T only on their own:

- The I formatting symbol matches any dateTime string that conforms to the supported subset.
- The T formatting symbol matches any dateTime string that conforms to the supported subset that consists of a time portion only.

The following table shows how the output form relates to the logical data type.

Logical model data type	ESQL data type	Output form
xsd:dateTime	TIMESTAMP or GMTTIMESTAMP	yyyy-MM-dd'T'HH:mm:ss.SSSZZZ
xsd:date	DATE	yyyy-MM-dd
xsd:gYear	INTERVAL	yyyy
xsd:gYearMonth	INTERVAL	yyyy-MM
xsd:gMonth	INTERVAL	--MM
xsd:gmonthDay	INTERVAL	--MM-dd
xsd:gDay	INTERVAL	---dd
xsd:time	TIME / GMTTIME	'T'HH:mm:ss.SSSZZZ

Note:

- On input, both I and T accept both '+00:00' and 'Z' to indicate a zero time difference from Coordinated Universal Time (UTC), but on output they always generate '+00:00'. If you want 'Z' to always be generated on output, use the IU or TU formatting symbols instead.
- ZZZ always writes '+00:00' to indicate a zero time difference from Coordinated Universal Time (UTC). If you want 'Z' to always be generated on output, use ZZZU instead.

Using the input UTC format on output

An element or attribute of logical type xsd:dateTime or xsd:time that contains a dateTime as a string can specify Coordinated Universal Time (UTC) by using either the Z symbol or time zone +00:00. On input, the MRM parser remembers the UTC format of such elements and attributes. On output, you can specify whether Z or +00:00 is displayed by using the `Default DateTime Format` property of the element or attribute. Alternatively, you can preserve the input UTC format by selecting the

message set property `Use input UTC format on output`. If this property is selected, the UTC format is preserved in the output message and overrides the format that is implied by the dateTime format property.

Understanding daylight saving time and the CAST function

When the broker is running in a time zone other than GMT, it calculates the daylight saving time (DST) offset on times that are supplied to it by the CAST function. For CAST to calculate the offset correctly, the time passed into CAST must have a time zone associated with it, as a Z parameter. If no time zone is associated with the value passed, the time is converted into GMT time; it is not treated as a local time stamp.

Also, when you use CAST to cast a string to a time value, the DST offset is calculated using the current system date. To cast a string to a time variable and calculate DST for a specific date, you must also specify the date.

For example, if timeValue='10:00:00', the following code, run on a broker that is in the Central Daylight Time zone, converts the time to GMT, because no time zone identifier is specified:

```
DECLARE castTime TIME;
SET castTime = CAST (timeValue AS TIME FORMAT timePattern)
```

The time is not converted into GMT again if the castTime variable is used in any subsequent code, for example

```
CAST(castDate, castTime AS GMTTIMESTAMP);
```

Examples

The following table shows a few examples of dateTime formats.

Format pattern	Result
"yyyy.MM.dd 'at' HH:mm:ss ZZZ"	2006.07.10 at 15:08:56 -05:00
"EEE, MMM d, "yy"	Wed, July 10, '06
"h:mm a"	8:08 PM
"hh o"clock a, ZZZZ"	09 o'clock AM, GMT+09:00
"K:mm a, ZZZ"	9:34 AM, -05:00
"yyyy.MMMMM.dd hh:mm aaa"	1996.July.10 12:08 PM

Use within an MRM domain

In MRM it is possible to define an element that has the logical type of dateTime.

When a dateTime element is parsed, a field is created in the message tree that has the ESQL datatype of CURRENT_TIME or CURRENT_TIMESTAMP. However, the CURRENT_TIME and CURRENT_TIMESTAMP data types do not have the functionality to store timezone information, and the MRM does not adjust the time according to the input timezone and the timezone of the broker.

Although the CURRENT_TIME and CURRENT_TIMESTAMP data types cannot store timezone information, the MRM stores this information as part of the

underlying field. This means that if the field is copied between message trees, the timezone information is copied with it, allowing this information to be preserved on output.

Note that the information is preserved only if the field is copied to a field of the same name.

However, if any new field is derived from the original field, the new field does not have the timezone information. This means that if such a field is cast as a character, the new field assumes the timezone of the broker, but its value is not adjusted for any difference between the input timezone and the timezone of the broker.

For example, an input dateTime element containing `2009-02-20T06:08:07-08:00` could be copied from the input message tree to the output message tree and appear in an output message in exactly the same format. However, if the element is cast as character, using format `IU`, by a broker running GMT the result would be `2009-02-20T06:08:07.000Z`.

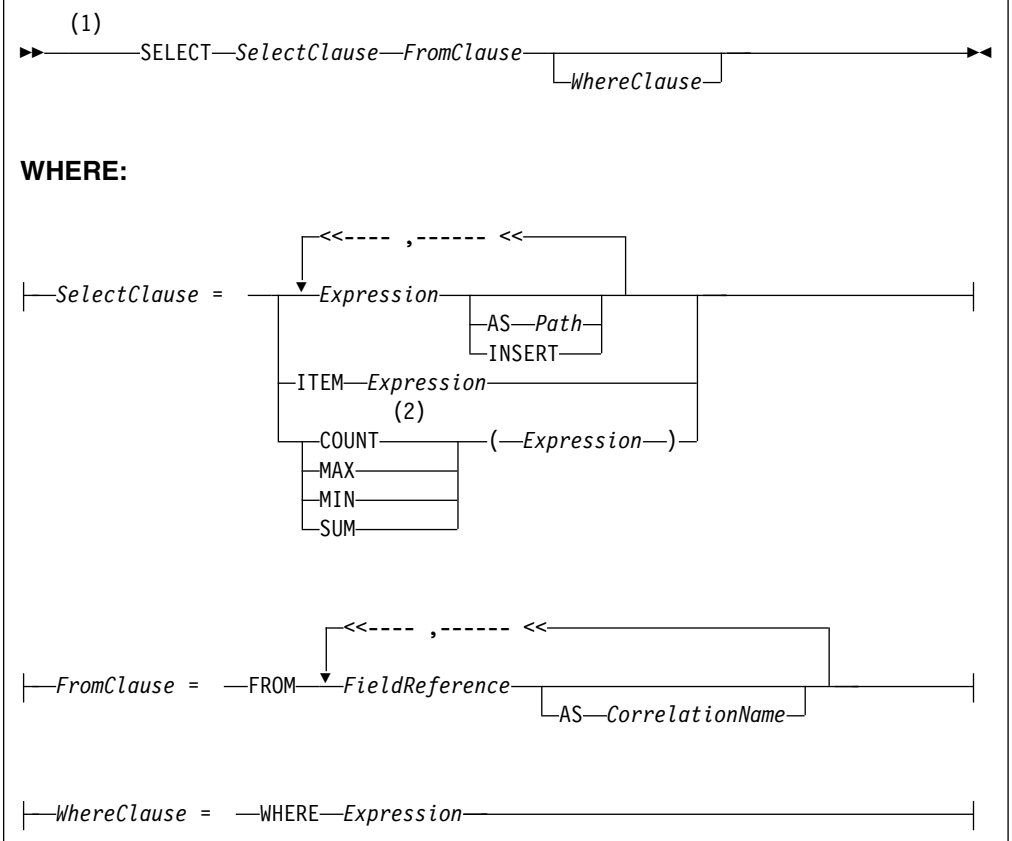
SELECT function:

The SELECT function combines, filters, and transforms complex message and database data.

Syntax



Notes:

1 You no longer require the enclosing parentheses in SELECT expressions. This does not prevent you using parentheses but, if they are present, they are merely normal, expression-scoping, parentheses.

2 For the COUNT parameter only, you can specify the value of the following *Expression* as a single star (*).

Usage

The SELECT function is the usual and most efficient way of transforming messages. You can use SELECT to:

- Comprehensively reformat messages
- Access database tables
- Make an output array that is a subset of an input array
- Make an output array that contains only the values of an input array
- Count the number of entries in an array
- Select the minimum or maximum value from a number of entries in an array
- Sum the values in an array

Introduction to SELECT

The SELECT function considers a message tree (or sub-tree) to consist of a number of rows and columns, rather like a database table. A *FieldReference* in a FROM clause identifies a field in a message tree. The identified field is regarded in the following ways:
- The identified field is regarded as a row in a table.
- The field's siblings are regarded as other rows of the same table.
- The field's children are regarded as the table's columns.

Note: The *FieldReference* in a FROM clause can also be a table reference that refers directly to a real database table.

The return value of the SELECT function is typically another message tree that contains rows whose structure and content is determined by the *SelectClause*. The number of rows in the result is the sum of all the rows pointed to by all the field references and table references in the FROM clause, filtered by the WHERE clause; only those fields for which the WHERE clause evaluates to TRUE are included.

The return value of the SELECT function can also be scalar (see "ITEM selections" on page 5264).

You can specify the *SelectClause* in several ways; see:
- "Simple selections"
- "INSERT selections" on page 5264
- "ITEM selections" on page 5264
- "Column function selections" on page 5264

If you have created a message flow that contains one of the following nodes, and the ESQL that is associated with this node includes a SELECT function and a database reference, you must specify a value for the `Data source` property of the relevant node:
- Compute
- Database
- Filter

Simple selections

To understand the SELECT function in more detail, first consider the following simple case:
- The *SelectClause* consists of a number of expressions, each with an AS *Path* clause.
- The FROM clause contains a single *FieldReference* and an AS *CorrelationName* clause.

The SELECT function creates a local, reference, correlation variable, whose name is given by the AS *CorrelationName* clause, and then steps, in turn, through each row of the list of rows derived from the FROM clause. For each row:
1. The correlation variable is set to point to the current row.
2. The WHERE clause (if present) is evaluated. If it evaluates to FALSE or unknown (null), nothing is added to the result tree and processing proceeds to the next row of the input. Otherwise processing proceeds to the next step.
3. A new member is added to the result list.

4. The SELECT clause expressions are evaluated and assigned to fields named as dictated by the AS *Path* clause. These fields are child fields of the new member of the result list.

Typically, both the *SelectClause* and the WHERE clause expressions use the correlation variable to access column values (that is, fields in the input message tree) and thus to build a new message tree containing data from the input message. The correlation variable is referred to by the name specified in the AS *CorrelationName* clause or, if an AS clause is not specified, by the final name in the FROM *FieldReference* (that is, the name after the last dot).

Note that:

- Despite the analogy with a table, you are not restricted to accessing or creating messages with a flat, table-like, structure; you can access and build trees with arbitrarily deep folder structures.
- You are not restricted to a column being a single value; a column can be a repeating list value or a structure.

These concepts are best understood by reference to the examples.

If the field reference is a *TableReference*, the operation is very similar. In this case, the input is a real database table and is thus restricted to the flat structures supported by databases. The result tree is still not so restricted, however.

If the FROM clause contains more than one field reference, the rightmost reference steps through each of its rows for each row in the next-to-rightmost reference, and so on. The total number of rows in the result is thus the product of the number of rows in each table. Such selects are known as *joins* and commonly use a WHERE clause that excludes most of these rows from the result. Joins are commonly used to add database data to messages.

The AS *Path* clause is optional. If it is unspecified, the broker generates a default name according to the following rules:

1. If the *SelectClause* expression is a reference to a field or a cast of a reference to a field, the name of the field is used.
2. Otherwise the broker uses the default names Column1, Column2, and so on.

Examples

The following example performs a SELECT on the table Parts in the schema Shop in the database DSN1. Because no WHERE clause exists, all rows are selected. Because the select clause expressions (for example, P.PartNumber) contain no AS clauses, the fields in the result adopt the same names:

```
SET PartsTable.Part[] = SELECT
  P.PartNumber,
  P.Description,
  P.Price
 FROM Database.DSN1.Shop.Parts AS P;
```

If the target of the SET statement (PartsTable) is a variable of type ROW, after the statement is executed PartsTable will have, as children of its root element, a field called Part for each row in the table. Each of the Part fields will have child fields called PartNumber, Description, and Price. The child fields will have values dictated by the contents of the table. (PartsTable could also be a reference into a message tree).

The next example performs a similar SELECT. This case differs from the last in that the SELECT is performed on the message tree produced by the first example (rather than on a real database table). The result is assigned into a subfolder of OutputRoot:

```
SET OutputRoot.XMLNS.Data.TableData.Part[] = SELECT
  P.PartNumber,
  P.Description,
  P.Price
 FROM PartsTable.Part[] AS P;
```

INSERT selections

The INSERT clause is an alternative to the AS clause. It assigns the result of the *SelectClause* expression (which must be a row) to the current new row itself, rather than to a child of it. The effect of this is to merge the row result of the expression into the row being generated by the SELECT. This differs from the AS clause, in that the AS clause always generates at least one child element before adding a result, whereas INSERT generates none. INSERT is useful when inserting data from other SELECT operations, because it allows the data to be merged without extra folders.

ITEM selections

The *SelectClause* can consist of the keyword ITEM and a single expression. The effect of this is to make the results nameless. That is, the result is a list of values of the type returned by the expression, rather than a row. This option has several uses:

- In conjunction with a scalar expression and the THE function, it can be used to create a SELECT query that returns a single scalar value (for example, the price of a particular item from a table).
- In conjunction with a CASE expression and ROW constructors, it can be used to create a SELECT query that creates or handles messages in which the structure of some rows (that is, repeats in the message) is different from others. This is useful for handling messages that have a repeating structure but in which the repeats do not all have the same structure.
- In conjunction with a ROW constructor, it can be used to create a SELECT query that collapses levels of repetition in the input message.

Column function selections

The *SelectClause* can consist of one of the functions COUNT, MAX, MIN, and SUM operating on an expression. These functions are known as column functions. They return a single scalar value (not a list) giving the count, maximum, minimum, or sum of the values that *Expression* evaluated to in stepping through the rows of the FROM clause. If *Expression* evaluates to NULL for a particular row, the value is ignored, so that the function returns the count, maximum, minimum, or sum of the remaining rows.

For the COUNT function only, *Expression* can consist of a single star (*). This form counts the rows regardless of null values.

To make the result a useful reflection of the input message, *Expression* typically includes the correlation variable.

Typically, *Expression* evaluates to the same data type for each row. In these cases, the result of the MAX, MIN, and SUM functions are of the same data type as the

operands. The returned values are not required to be all of the same type however, and if they are not, the normal rules of arithmetic apply. For example, if a field in a repeated message structure contains integer values for some rows and float values for others, the sum follows the normal rules for addition. The sum is of type float because the operation is equivalent to adding a number of integer and float values.

The result of the COUNT function is always an integer.

Differences between message and database selections

FROM expressions in which a correlation variable represents a row in a message behave slightly differently from those in which the correlation variable represents a row in a real database table.

In the message case, a path involving a star (*) has the normal meaning; it ignores the field's name and finds the first field that matches the other criteria (if any).

In the database case a star (*) has, for historical reasons, the special meaning of all fields. This special meaning requires advance knowledge of the definition of the database table and is supported only when querying the default database (that is, the database pointed to by the node's `data source` attribute). For example, the following queries return column name and value pairs only when querying the default database:

```
SELECT * FROM Database.Datasource.SchemaName.Table As A
SELECT A.* FROM Database.Datasource.SchemaName.Table As A
SELECT A FROM Database.Datasource.SchemaName.Table AS A
```

Specifying the SELECT expressions

SelectClause
SelectClause expressions can use any of the broker's operators and functions in any combination. They can refer to the tables' columns, message fields, correlation names declared by containing SELECTs, and to any other declared variables or constants that are in scope.

AS *Path*
An AS *Path* expression is a relative path (that is, there is no correlation name) but is otherwise unrestricted in any way. For example, it can contain:

- Indexes (for example, A.B.C[i])
- Field-type specifiers (for example, A.B.(XML.Attribute)C)
- Multipart paths (for example, A.B.C)
- Name expressions (for example, A.B.{var})

Any expressions in these paths can also use any of the broker's operators and functions in any combination. The expressions can refer to the tables' columns, message fields, correlation names declared by containing SELECTs, and any declared variables or constants.

FROM clause
FROM clause expressions can contain multiple database references, multiple message references, or a mixture of the two. You can join tables with tables, messages with messages, or tables with messages.

FROM clause *FieldReference*s can contain expressions of any kind (for example, `Database.{DataSource}.{Schema}.Table1`).

You can calculate a field, data source, schema, or table name at run time.

WHERE clause

The WHERE clause expression can use any of the broker's operators and functions in any combination. It can refer to table columns, message fields, and any declared variables or constants.

However, be aware that the broker treats the WHERE clause expression by examining the expression and deciding whether the whole expression can be evaluated by the database. If it can, it is given to the database. In order to be evaluated by the database, it must use only those functions and operators supported by the database.

The WHERE clause can, however, refer to message fields, correlation names declared by containing SELECT functions, and to any other declared variables or constants within scope.

If the whole expression cannot be evaluated by the database, the broker looks for top-level AND operators and examines each sub-expression separately. It then attempts to give the database those sub-expressions that it can evaluate, leaving the broker to evaluate the rest. You need to be aware of this situation for two reasons:

1. Apparently trivial changes to WHERE clause expressions can have large effects on performance. You can determine how much of the expression was given to the database by examining a user trace.
2. Some databases' functions exhibit subtle differences of behavior from those of the broker.

Relation to the THE function

You can use the function THE (which returns the first element of a list) in conjunction with SELECT to produce a non-list result. This is useful, for example, when a SELECT query is required to return no more than one item. It is particularly useful in conjunction with ITEM (see "ITEM selections" on page 5264).

Differences from the SQL standard

ESQL SELECT differs from database SQL SELECT in the following ways:

- ESQL can produce tree-structured result data
- ESQL can accept arrays in SELECT clauses
- ESQL has the THE function and the ITEM and INSERT parameters
- ESQL has no SELECT ALL function in this release
- ESQL has no ORDER BY function in this release
- ESQL has no SELECT DISTINCT function in this release
- ESQL has no GROUP BY or HAVING parameters in this release
- ESQL has no AVG column function in this release

Restrictions

The following restrictions apply to the current release:

- When a SELECT command operates on more than one database table, all the tables must be in the same database instance. (That is, the *TableReference*s must not specify different data source names.)
- If the FROM clause refers to both messages and tables, the tables must precede the messages in the list.

- Using dynamic DSN, SCHEMA and TABLE names with 'SELECT *' statements is not supported. If you use a schema, table or datasource name as a variable (dynamic variables) in 'SELECT *' queries, the variables are not resolved to the correct set of schema or table names.
- The WHERE clause of a SELECT statement cannot itself contain a SELECT statement that relies on results returned from the original SELECT if either SELECT statement is from database tables.

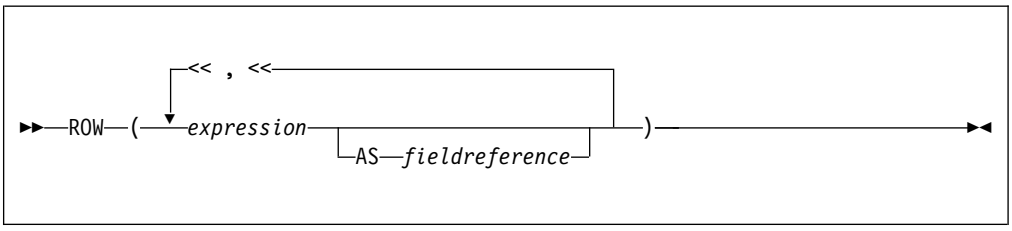
ROW constructor function:
ROW constructor is a complex function used to explicitly generate rows of values that can be assigned to fields in an output message.

Syntax



A ROW consists of a sequence of named values. When assigned to a field reference it creates that sequence of named values as child fields of the referenced field. A ROW cannot be assigned to an array field reference.

Examples:

Example 1

```
SET OutputRoot.XMLNS.Data = ROW('granary' AS bread,
                        'riesling' AS wine,
                        'stilton' AS cheese);
```

produces:

```
<Data>
   <bread>granary</bread>
   <wine>riesling</wine>
   <cheese>stilton</cheese>
</Data>
```

Example 2

Given the following XML input message body:

```
<Proof>
   <beer>5</beer>
   <wine>12</wine>
   <gin>40</gin>
</Proof>
```

the following ESQL:

```
SET OutputRoot.XMLNS.Data = ROW(InputBody.Proof.beer,
                      InputBody.Proof.wine AS vin,
                        (InputBody.Proof.gin * 2) AS special);
```

produces the following result:

```
<Data>
   <beer>5</beer>
   <vin>12</vin>
   <special>80</special>
</Data>
```

Because the values in this case are derived from field references that already have names, it is not necessary to explicitly provide a name for each element of the row, but you might choose to do so.

"LIST constructor function" on page 5269

"ROW and LIST combined" on page 5270

"ROW and LIST comparisons" on page 5271
You can compare ROWs and LISTs against other ROWs and LISTs.

LIST constructor function:
The LIST constructor complex function is used to explicitly generate lists of values that can be assigned to fields in an output message.

Syntax

A LIST consists of a sequence of unnamed values. When assigned to an array field reference (indicated by [] suffixed to the last element of the reference), each value is assigned in sequence to an element of the array. A LIST cannot be assigned to a non-array field reference.

Examples:
Example 1

Given the following XML message input body:

```
<Car>
   <size>big</size>
   <color>red</color>
</Car>
```

The following ESQL:

```
SET OutputRoot.XMLNS.Data.Result[] = LIST{InputBody.Car.colour,
                                                    'green',
                                                    'blue'};
```

produces the following results:

```
<Data>
   <Result>red</Result>
   <Result>green</Result>
   <Result>blue</Result>
</Data>
```

In the case of a LIST, there is no explicit name associated with each value. The values are assigned in sequence to elements of the message field array specified as the target of the assignment. Curly braces rather than parentheses are used to surround the LIST items.

Example 2

Given the following XML input message body:

```
<Data>
   <Field>Keats</Field>
   <Field>Shelley</Field>
   <Field>Wordsworth</Field>
   <Field>Tennyson</Field>
   <Field>Byron</Field>
</Data>
```

the following ESQL:

```
-- Copy the entire input message to the output message,
-- including the XML message field array as above
SET OutputRoot = InputRoot;
SET OutputRoot.XMLNS.Data.Field[] = LIST{'Henri','McGough','Patten'};
```

Produces the following output:

```
<Data>
   <Field>Henri</Field>
   <Field>McGough</Field>
   <Field>Patten</Field>
</Data>
```

The previous members of the `Data.Field[]` array have been discarded. Assigning a new list of values to an already existing message field array removes all the elements in the existing array before the new ones are assigned.

Related reference:

"Complex ESQL functions" on page 5242

"ROW constructor function" on page 5267

"ROW and LIST combined"

"ROW and LIST comparisons" on page 5271
You can compare ROWs and LISTs against other ROWs and LISTs.

ROW and LIST combined:
ROW and LIST combined form a complex function.

A ROW might validly be an element in a LIST. For example:

```
SET OutputRoot.XMLNS.Data.Country[] =
         LIST{ROW('UK' AS name,'pound' AS currency),
              ROW('US' AS name, 'dollar' AS currency),
                                'default'};
```

produces the following result:

```
<Data>
   <Country>
      <name>UK</name>
      <currency>pound</currency>
   </Country>
   <Country>
      <name>US</name>
      <currency>dollar</currency>
   </Country>
   <Country>default</Country>
</Data>
```

ROW and non-ROW values can be freely mixed within a LIST.

A LIST cannot be a member of a ROW. Only named scalar values can be members of a ROW.

"ROW constructor function" on page 5267

"LIST constructor function" on page 5269

"ROW and LIST comparisons"
You can compare ROWs and LISTs against other ROWs and LISTs.

ROW and LIST comparisons:

You can compare ROWs and LISTs against other ROWs and LISTs.

Examples:
Example 1

```
IF ROW(InputBody.Data.*[1],InputBody.Data.*[2]) =
                ROW('Raf' AS Name,'25' AS Age) THEN ...
IF LIST{InputBody.Data.Name, InputBody.Data.Age} = LIST{'Raf','25'} THEN ...
```

With the following XML input message body both the IF expressions in both the above statements evaluate to TRUE:

```
<Data>
   <Name>Raf</Name>
   <Age>25</Age>
</Data>
```

In the comparison between ROWs, both the name and the value of each element are compared; in the comparison between LISTs only the value of each element is compared. In both cases, the cardinality and sequential order of the LIST or ROW operands being compared must be equal in order for the two operands to be equal. Therefore, the following examples are false because either the sequential order or the cardinality of the operands being compared do not match:

```
ROW('alpha' AS A, 'beta' AS B) =
             ROW('alpha' AS A, 'beta' AS B, 'delta' AS D)
ROW('alpha' AS A, 'beta' AS B) =
             ROW('beta' AS B,'alpha' AS A)
LIST{1,2,3} = LIST{1,2,3,4}
LIST{3,2,1} = LIST{1,2,3}
```

Example 2

Consider the following ESQL:

```
IF InputBody.Places =
   ROW('Ken' AS first, 'Bob' AS second, 'Kate' AS third) THEN ...
```

With the following XML input message body, the above IF expression evaluates to TRUE:

```
<Places>
   <first>Ken</first>
   <second>Bob</second>
   <third>Kate</third>
</Places>
```

The presence of an explicitly-constructed ROW as one of the operands to the comparison operator results in the other operand also being treated as a ROW.

Contrast this with a comparison such as:

```
IF InputBody.Lottery.FirstDraw = InputBody.Lottery.SecondDraw THEN ...
```

which compares the value of the FirstDraw and SecondDraw fields, not the names and values of each of FirstDraw and SecondDraw's child fields constructed as a ROW. Thus an XML input message body such as:

```
<Lottery>
   <FirstDraw>wednesday
      <ball1>32</ball1>
      <ball2>12</ball2>
   </FirstDraw>
   <SecondDraw>saturday
      <ball1>32</ball1>
      <ball2>12</ball2>
   </SecondDraw>
</Lottery>
```

would not result in the above IF expression being evaluated as TRUE, because the values wednesday and saturday are being compared, not the names and values of the ball fields.

Example 3

Consider the following ESQL:

```
IF InputBody.Cities.City[] = LIST{'Athens','Sparta','Thebes'} THEN ...
```

With the following XML input message body, the IF expression evaluates to TRUE:

```
<Cities>
 <City>Athens</City>
 <City>Sparta</City>
 <City>Thebes</City>
</Cities>
```

Two message field arrays can be compared together in this way, for example:

```
IF InputBody.Cities.Mediaeval.City[] =
                    InputBody.Cities.Modern.City[] THEN ...

IF InputBody.Cities.Mediaeval.*[] = InputBody.Cities.Modern.*[] THEN ...

IF InputBody.Cities.Mediaeval.(XML.Element)[] =
                    InputBody.Cities.Modern.(XML.Element)[] THEN ...
```

With the following XML input message body, the IF expression of the first and third of the statements above evaluates to TRUE:

```
<Cities>
   <Mediaeval>1350
      <City>London</City>
      <City>Paris</City>
   </Mediaeval>
   <Modern>1990
      <City>London</City>
      <City>Paris</City>
   </Modern>
</Cities>
```

However the IF expression of the second statement evaluates to FALSE, because the *[] indicates that all the children of Mediaeval and Modern are to be compared, not just the (XML.Element)s. In this case the values 1350 and 1990, which form nameless children of Mediaeval and Modern, are compared as well as the values of the City tags.

The IF expression of the third statement above evaluates to TRUE with an XML input message body such as:

```
<Cities>
   <Mediaeval>1350
      <Location>London</Location>
      <Location>Paris</Location>
   </Mediaeval>
   <Modern>1990
      <City>London</City>
      <City>Paris</City>
   </Modern>
</Cities>
```

LISTs are composed of unnamed values. It is the values of the child fields of Mediaeval and Modern that are compared, not their names.

Supported casts:
This topic lists the CASTs that are supported between combinations of data-types.

A CAST is not supported between every combination of data-types. Those that are supported are listed in the following table, along with the effect of the CAST.

When casting, there can be a one-to-one or a many-to-one mapping between the source data-type and the target data-type. An example of a one-to-one mapping is where the source data-type is a single integer and the target data-type a single float. An example of a many-to-one mapping is where the source data consists of three integers that are converted to a single date. Table 265 lists the supported one-to-one casts. Table 266 on page 5280 lists the supported many-to-one casts.

See "ESQL data types" on page 2373 for information about `precision`, `scale`, and `interval qualifier`.

Table 265. Supported casts: one-to-one mappings of source to target data-type

Source data-type	Target data-type	Effect
BIT	BIT	The result is the same as the input.
BIT	BLOB	The bit array is converted to a byte array with a maximum of 2^{63} elements. An error is reported if the source is not of a suitable length to produce a BLOB (that is a multiple of 8).
BIT	CHARACTER	The result is a string conforming to the definition of a bit string literal whose interpreted value is the same as the source value. The resulting string has the form B'bbbbbb' (where b is either 0 or 1). If you specify either a CCSID or ENCODING clause, the bit array is assumed to be characters in the specified CCSID and encoding, and is code-page converted into the character return value. If you specify only a CCSID, big endian encoding is assumed. If you specify only an encoding, a CCSID of 1208 is assumed. This function reports conversion errors if the code page or encoding are unknown, the data supplied is not an integral number of characters of the code page, or the data contains characters that are not valid in the given code page.
BIT	INTEGER	The bit array has a maximum of 2^{63} elements and is converted to an integer. An error is reported if the source is not of the correct length to match an integer.
BLOB	BIT	The given byte array is converted to a bit array with a maximum of 2^{63} elements.
BLOB	BLOB	The result is the same as the input.
BLOB	CHARACTER	The result is a string conforming to the definition of a binary string literal whose interpreted value is the same as the source value. The resulting string has the form X'hhhh' (where h is any hexadecimal character). If you specify either a CCSID or ENCODING clause, the byte array is assumed to be characters in the specified CCSID and encoding, and is code-page converted into the character return value. If you specify only a CCSID, big endian encoding is assumed. If you specify only an encoding, a CCSID of 1208 is assumed. This function reports conversion errors if the code page or encoding are unknown, the data supplied is not an integral number of characters of the code page, or the data contains characters that are not valid in the given code page.

Table 265. Supported casts: one-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect
BLOB	INTEGER	The byte array has a maximum of 2^{63} elements and is converted to an integer. An error is reported if the source is not of the correct length to match an integer.
BOOLEAN	BOOLEAN	The result is the same as the input.
BOOLEAN	CHARACTER	If the source value is TRUE, the result is the character string TRUE. If the source value is FALSE, the result is the character string FALSE. Because the UNKNOWN Boolean value is the same as the NULL value for Booleans, the result is NULL if the source value is UNKNOWN.
CHARACTER	BIT	The character string must conform to the rules for a bit string literal or for the contents of the bit string literal. That is, the character string can be of the form B'bbbbbbb' or bbbbbb (where b' can be either 0 or 1). If you specify either a CCSID or ENCODING clause, the character string is converted into the specified CCSID and encoding and placed without further conversion into the bit array return value. If you specify only a CCSID, big endian encoding is assumed. If you specify only an encoding, a CCSID of 1208 is assumed. This function reports conversion errors if the code page or encoding are unknown or the data contains Unicode characters that cannot be converted to the given code page.
CHARACTER	BLOB	This cast can work in two ways: 1. If you specify either a CCSID or ENCODING clause, the whole string is written out in the code page or encoding that you requested. For example, the string "Cat" in CCSID 850 becomes the three-byte array in hexadecimal, 43,61,74. 2. If you specify neither the CCSID nor ENCODING clause, the string must itself contain two-character hexadecimal digits of the form X'hhhhhh' or hhhhhh (where h can be any hexadecimal characters). In this case, the input string "436174" becomes the same three-byte binary array (43,61,74). Note that an error is generated if the input string is not of the correct format. If you specify only a CCSID, big endian encoding is assumed. If you specify only an encoding, a CCSID of 1208 is assumed. This function reports conversion errors if the code page or encoding are unknown or the data contains Unicode characters that cannot be converted to the given code page.
CHARACTER	BOOLEAN	The character string is interpreted in the same way as a Boolean literal. That is, the character string must be one of the strings TRUE, FALSE, or UNKNOWN (in any case combination).
CHARACTER	CHARACTER	The result is the same as the input.
CHARACTER	DATE	If a FORMAT clause is not specified, the character string must conform to the rules for a date literal or the date string. That is, the character string can be either DATE '2002-10-05' or 2002-10-05. See also “Formatting and parsing dateTimes as strings” on page 5253.

Table 265. Supported casts: one-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect
CHARACTER	DECIMAL	The character string is interpreted in the same way as an exact numeric literal to form a temporary decimal result with a `scale` and `precision` defined by the format of the string. This is converted into a decimal of the specified `precision` and `scale`, with a runtime error being generated if the conversion results in loss of significant digits. If you do not specify the `precision` and `scale`, the `precision` and `scale` of the result are the minimum necessary to hold the given value. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing numbers as strings" on page 5250.
CHARACTER	FLOAT	The character string is interpreted in the same way as a floating point literal. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing numbers as strings" on page 5250.
CHARACTER	GMTTIME	The character string must conform to the rules for a GMT time literal or the time string. That is, the character string can be either GMTTIME '09:24:15' or 09:24:15. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.
CHARACTER	GMTTIMESTAMP	The character string must conform to the rules for a GMT timestamp literal or the timestamp string. That is, the character string can be either GMTTIMESTAMP '2002-10-05 09:24:15' or 2002-10-05 09:24:15. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.
CHARACTER	INTEGER	The character string is interpreted in the same way as an integer literal. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing numbers as strings" on page 5250.
CHARACTER	INTERVAL	The character string must conform to the rules for an interval literal with the same `interval qualifier` as specified in the CAST function, or it must conform to the rules for an interval string that apply for the specified `interval qualifier`.
CHARACTER	TIME	The character string must conform to the rules for a time literal or for the time string. That is, the character string can be either TIME '09:24:15' or 09:24:15. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.
CHARACTER	TIMESTAMP	The character string must conform to the rules for a timestamp literal or for the timestamp string. That is, the character string can be either TIMESTAMP '2002-10-05 09:24:15' or 2002-10-05 09:24:15. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.

Table 265. Supported casts: one-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect

DATE	CHARACTER	The result is a string conforming to the definition of a date literal, whose interpreted value is the same as the source date value.
		
		For example:
		`CAST(DATE '2002-10-05' AS CHARACTER)`
		
		returns
		`DATE '2002-10-05'`
		
		The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.

DATE	DATE	The result is the same as the input.
DATE	GMTTIMESTAMP	The result is a value whose date fields are taken from the source date value, and whose time fields are taken from the current GMT time.
DATE	TIMESTAMP	The result is a value whose date fields are taken from the source date value, and whose time fields are taken from the current time.
DECIMAL	CHARACTER	The result is the shortest character string that conforms to the definition of an exact numeric literal and whose interpreted value is the value of the decimal. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing numbers as strings" on page 5250.
DECIMAL	DECIMAL	The value is converted to the specified `precision` and `scale`, with a runtime error being generated if the conversion results in loss of significant digits. If you do not specify the `precision` and `scale`, the value, `precision` and `scale` are preserved; it is a NOOP (no operation).
DECIMAL	FLOAT	The number is converted, with rounding if necessary.
DECIMAL	INTEGER	The value is rounded and converted into an integer, with a runtime error being generated if the conversion results in loss of significant digits.
DECIMAL	INTERVAL	If the `interval qualifier` specified has only one field, the result is an interval with that qualifier with the field equal to the value of the exact numeric. Otherwise a runtime error is generated.
FLOAT	CHARACTER	The result is the shortest character string that conforms to the definition of an approximate numeric literal and whose mantissa consists of a single digit that is not 0, followed by a period and an unsigned integer, and whose interpreted value is the value of the float. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing numbers as strings" on page 5250. When you CAST a FLOAT to a DECIMAL or CHARACTER, either implicitly or explicitly, the FLOAT can be rounded to a maximum precision of 15 digits.
FLOAT	FLOAT	The result is the same as the input.

Table 265. Supported casts: one-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect
FLOAT	DECIMAL	The value is rounded and converted into a decimal of the specified `precision` and `scale`, with a runtime error being generated if the conversion results in loss of significant digits. If you do not specify the `precision` and `scale`, the `precision` and `scale` of the result are the minimum necessary to hold the given value. When you CAST a FLOAT to a DECIMAL or CHARACTER, either implicitly or explicitly, the FLOAT can be rounded to a maximum precision of 15 digits.
FLOAT	INTEGER	The value is rounded and converted into an integer, with a runtime error being generated if the conversion results in loss of significant digits.
FLOAT	INTERVAL	If the specified `interval qualifier` has only one field, the result is an interval with that qualifier with the field equal to the value of the numeric. Otherwise a runtime error is generated.
GMTTIME	CHARACTER	The result is a string conforming to the definition of a GMTTIME literal whose interpreted value is the same as the source value. The resulting string has the form GMTTIME 'hh:mm:ss'. The behavior changes if the FORMAT clause is specified. See also “Formatting and parsing dateTimes as strings” on page 5253.
GMTTIME	GMTTIME	The result is the same as the input.
GMTTIME	TIME	The resulting value is the source value plus the local time zone displacement (as returned by LOCAL_TIMEZONE). The hours field is calculated modulo 24.
GMTTIME	GMTTIMESTAMP	The result is a value whose date fields are taken from the current date, and whose time fields are taken from the source GMT time.
GMTTIME	TIMESTAMP	The result is a value whose date fields are taken from the current date, and whose time fields are taken from the source GMT time, plus the local time zone displacement (as returned by LOCAL_TIMEZONE).
GMTTIMESTAMP	CHARACTER	The result is a string conforming to the definition of a GMTTIMESTAMP literal whose interpreted value is the same as the source value. The resulting string has the form GMTTIMESTAMP 'yyyy-mm-dd hh:mm:ss'. The behavior changes if the FORMAT clause is specified. See also “Formatting and parsing dateTimes as strings” on page 5253.
GMTTIMESTAMP	DATE	The result is a value whose fields consist of the date fields of the source GMTTIMESTAMP value.
GMTTIMESTAMP	GMTTIME	The result is a value whose fields consist of the time fields of the source GMTTIMESTAMP value.
GMTTIMESTAMP	TIME	The result is a value whose time fields are taken from the source GMTTIMESTAMP value, plus the local time zone displacement (as returned by LOCAL_TIMEZONE). The hours field is calculated modulo 24.
GMTTIMESTAMP	GMTTIMESTAMP	The result is the same as the input.
GMTTIMESTAMP	TIMESTAMP	The resulting value is source value plus the local time zone displacement (as returned by LOCAL_TIMEZONE).
INTEGER	BIT	The given integer is converted to a bit array with a maximum of 2^{63} elements.

Table 265. Supported casts: one-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect
INTEGER	BLOB	The given integer is converted to a byte array with a maximum of 2^{63} elements.
INTEGER	CHARACTER	The result is the shortest character string that conforms to the definition of an exact numeric literal and whose interpreted value is the value of the integer. The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing numbers as strings" on page 5250.
INTEGER	FLOAT	The number is converted, with rounding if necessary.
INTEGER	INTEGER	The result is the same as the input.
INTEGER	DECIMAL	The value is converted into a decimal of the specified `precision` and `scale`, with a runtime error being generated if the conversion results in loss of significant digits. If you do not specify the `precision` and `scale`, the `precision` and `scale` of the result are the minimum necessary to hold the given value.
INTEGER	INTERVAL	If the `interval qualifier` specified has only one field, the result is an interval with that qualifier with the field equal to the value of the exact numeric. Otherwise a runtime error is generated.

INTERVAL	CHARACTER	The result is a string conforming to the definition of an INTERVAL literal, whose interpreted value is the same as the source interval value.
		
		For example:
		`CAST(INTERVAL '4' YEARS AS CHARACTER)`
		
		returns
		`INTERVAL '4' YEARS`

INTERVAL	DECIMAL	If the interval value has a qualifier that has only one field, the result is a decimal of the specified `precision` and `scale` with that value, with a runtime error being generated if the conversion results in loss of significant digits. If the interval has a qualifier with more than one field, such as YEAR TO MONTH, a runtime error is generated. If you do not specify the `precision` and `scale`, the `precision` and `scale` of the result are the minimum necessary to hold the given value.
INTERVAL	FLOAT	If the interval value has a qualifier that has only one field, the result is a float with that value. If the interval has a qualifier with more than one field, such as YEAR TO MONTH, a runtime error is generated.
INTERVAL	INTEGER	If the interval value has a qualifier that has only one field, the result is an integer with that value. If the interval has a qualifier with more than one field, such as YEAR TO MONTH, a runtime error is generated.
INTERVAL	INTERVAL	The result is the same as the input. Year-month intervals can be converted only to year-month intervals, and day-second intervals only to day-second intervals. The source interval is converted into a scalar in units of the least significant field of the target `interval qualifier`. This value is normalized into an interval with the target `interval qualifier`. For example, to convert an interval that has the qualifier MINUTE TO SECOND into an interval with the qualifier DAY TO HOUR, the source value is converted into a scalar in units of hours, and this value is normalized into an interval with qualifier DAY TO HOUR.

Table 265. Supported casts: one-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect

TIME	CHARACTER	The result is a string conforming to the definition of a TIME literal, whose interpreted value is the same as the source time value.
		For example:
		`CAST(TIME '09:24:15' AS CHARACTER)`
		returns
		`TIME '09:24:15'`
		The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.

TIME	GMTTIME	The result value is the source value minus the local time zone displacement (as returned by LOCAL_TIMEZONE). The hours field is calculated modulo 24.
TIME	GMTTIMESTAMP	The result is a value whose date fields are taken from the current date, and whose time fields are taken from the source GMT time, minus the local time zone displacement (as returned by LOCAL_TIMEZONE).
TIME	TIME	The result is the same as the input.
TIME	TIMESTAMP	The result is a value whose date fields are taken from the current date, and whose time fields are taken from the source time value.

TIMESTAMP	CHARACTER	The result is a string conforming to the definition of a TIMESTAMP literal, whose interpreted value is the same as the source timestamp value.
		For example:
		`CAST(TIMESTAMP '2002-10-05 09:24:15' AS CHARACTER)`
		returns
		`TIMESTAMP '2002-10-05 09:24:15'`
		The behavior changes if the FORMAT clause is specified. See also "Formatting and parsing dateTimes as strings" on page 5253.

TIMESTAMP	DATE	The result is a value whose fields consist of the date fields of the source timestamp value.
TIMESTAMP	GMTTIME	The result is a value whose time fields are taken from the source TIMESTAMP value, minus the local time zone displacement (as returned by LOCAL_TIMEZONE). The hours field is calculated modulo 24.
TIMESTAMP	GMTTIMESTAMP	The resulting value is the source value minus the local time zone displacement (as returned by LOCAL_TIMEZONE).
TIMESTAMP	TIME	The result is a value whose fields consist of the time fields of the source timestamp value.
TIMESTAMP	TIMESTAMP	The result is the same as the input.

Table 266. Supported casts: many-to-one mappings of source to target data-type

Source data-type	Target data-type	Effect
Numeric, Numeric, Numeric	DATE	Creates a DATE value from the numerics in the order year, month, and day. Non-integer values are rounded.
Numeric, Numeric, Numeric	TIME	Creates a TIME value from the numerics in the order hours, minutes, and seconds. Non-integer values for hours and minutes are rounded.

Table 266. Supported casts: many-to-one mappings of source to target data-type (continued)

Source data-type	Target data-type	Effect
Numeric, Numeric, Numeric	GMTIME	Creates a GMTTIME value from the numerics in the order of hours, minutes, and seconds. Non-integer values for hours and minutes are rounded.
Numeric, Numeric, Numeric, Numeric, Numeric, Numeric	TIMESTAMP	Creates a TIMESTAMP value from the numerics in the order years, months, days, hours, minutes, and seconds. Non-integer values for years, months, days, hours, and minutes are rounded.
Numeric, Numeric, Numeric, Numeric, Numeric, Numeric	GMTTIMESTAMP	Creates a GMTIMESTAMP value from the numerics in the order years, months, days, hours, minutes, and seconds. Non-integer values for years, months, days, hours, and minutes are rounded.
DATE, TIME	TIMESTAMP	The result is a TIMESTAMP value with the given DATE and TIME.
DATE, GMTTIME	GMTIMESTAMP	The result is a GMTTIMESTAMP value with the given DATE and GMTTIME.
Numeric, Numeric	INTERVAL YEAR TO MONTH	The result is an INTERVAL with the first source as years and the second as months. Non-integer values are rounded.
Numeric, Numeric	INTERVAL HOUR TO MINUTE	The result is an INTERVAL with the first source as hours and the second as minutes. Non-integer values are rounded.
Numeric, Numeric, Numeric	INTERVAL HOUR TO SECOND	The result is an INTERVAL with the sources as hours, minutes, and seconds, respectively. Non-integer values for hours and minutes are rounded.
Numeric, Numeric	INTERVAL MINUTE TO SECOND	The result is an INTERVAL with the sources as minutes and seconds, respectively. Non-integer values for minutes are rounded.
Numeric, Numeric	INTERVAL DAY TO HOUR	The result is an INTERVAL with the sources as days and hours, respectively. Non-integer values are rounded.
Numeric, Numeric, Numeric	INTERVAL DAY TO MINUTE	The result is an INTERVAL with the sources as days, hours, and minutes, respectively. Non-integer values are rounded.
Numeric, Numeric, Numeric, Numeric	INTERVAL DAY TO SECOND	The result is an INTERVAL with the sources as days, hours, minutes, and seconds, respectively. Non-integer values for days, hours, and minutes are rounded.
Numeric	INTERVAL YEAR	The result is an INTERVAL with the source as years, rounded if necessary.
Numeric	INTERVAL MONTH	The result is an INTERVAL with the source as months, rounded if necessary.
Numeric	INTERVAL DAY	The result is an INTERVAL with the source as days, rounded if necessary.
Numeric	INTERVAL HOUR	The result is an INTERVAL with the source as hours, rounded if necessary.
Numeric	INTERVAL MINUTE	The result is an INTERVAL with the source as minutes, rounded if necessary.
Numeric	INTERVAL SECOND	The result is an INTERVAL with the source as seconds.

Related concepts:

"ESQL overview" on page 2371
Extended Structured Query Language (ESQL) is a programming language defined by WebSphere Message Broker to define and manipulate data within a message flow.

"ESQL data types" on page 2373
A data type defines the characteristics of an item of data, and determines how that data is processed. ESQL supports six data types, listed later in this section. Data that is retrieved from databases, received in a self-defining message, or defined in a message model (using MRM data types), is mapped to one of these basic ESQL types when it is processed in ESQL expressions.

"Data types of values from external databases" on page 5288
How database data types are implicitly cast to ESQL data types.

"Supported code pages" on page 4176
Application messages must conform to supported code pages.

Implicit casts:
This topic discusses implicit casts.

It is not always necessary to cast values between types. Some casts are done implicitly. For example, numbers are implicitly cast between the three numeric types for the purposes of comparison and arithmetic. Character strings are also implicitly cast to other data types for the purposes of comparison.

There are three situations in which a data value of one type is cast to another type implicitly. The behavior and restrictions of the implicit cast are the same as described for the explicit cast function, except where noted in the following topics.

Related concepts:

"ESQL overview" on page 2371

"Implicit CASTs for comparisons"
The standard SQL comparison operators>, <,>=, <=, =, <> are supported for comparing two values in ESQL.

"Implicit CASTs for arithmetic operations" on page 5285

"Implicit CASTs for assignment" on page 5287

Implicit CASTs for comparisons:

The standard SQL comparison operators>, <,>=, <=, =, <> are supported for comparing two values in ESQL.

When the data types of the two values are not the same, one of them can be implicitly cast to the type of the other to allow the comparison to proceed. In the following table, the vertical axis represents the left hand operand, the horizontal axis represents the right hand operand.

L means that the right hand operand is cast to the type of the left hand operand before comparison; R means the opposite; X means that no implicit casting takes place; a blank means that comparison between the values of the two data types is not supported.

	ukn	**bln**	**int**	**float**	**dec**	**char**	**time**	**gtm**	**date**	**ts**	**gts**	**ivl**	**blob**	**bit**
ukn														
bln		X				L								
int			X	R	R	L								
float			L	X	L	L								
dec			L	R	X	L								
chr		R	R	R	R	X	R	R	R	R	R	R[1]	R	R
tm						L	X	L						
gtm						L	R	X						
dt						L			X	R[2]	R[2]			
ts						L			L[2]	X	L			
gts						L			L[2]	R	X			
ivl						L[1]						X		
blb						L							X	
bit						L								X

Notes:

1. When casting from a character string to an interval, the character string must be of the format INTERVAL '<values>' <qualifier>. The format <values>, which is allowede for an explicit CAST, is not allowed here because no qualifier external to the string is supplied.
2. When casting from a DATE to a TIMESTAMP or GMTTIMESTAMP, the time portion of the TIMESTAMP is set to all zero values (00:00:00). This is different from the behavior of the explicit cast, which sets the time portion to the current time.

Numeric types:
The comparison operators operate on all three numeric types.

Character strings:
You cannot define an alternative collation order that, for example, collates upper and lowercase characters equally.

When comparing character strings, trailing blanks are not significant, so the comparison `'hello' = 'hello '` returns true.

Datetime values:
Datetime values are compared in accordance with the natural rules of the Gregorian calendar and clock.

You can compare the time zone you are working in with the GMT time zone. The GMT time zone is converted into a local time zone based on the difference between your local time zone and the GMT time specified. When you compare your local time with the GMT time, the comparison is based on the difference at a given time on a given date.

Conversion is always based on the value of LOCAL_TIMEZONE. This is because GMT timestamps are converted to local timestamps only if it can be done unambiguously. Converting a local timestamp to a GMT timestamp has difficulties around the daylight saving cut-over time, and converting between times and GMT times (without date information) has to be done based on the LOCAL_TIMEZONE value, because you cannot specify which time zone difference to use otherwise.

Booleans:
Boolean values can be compared using all the normal comparison operators. The TRUE value is defined to be greater than the FALSE value. Comparing either value to the UNKNOWN Boolean value (which is equivalent to NULL) returns an UNKNOWN result.

Intervals:
Intervals are compared by converting the two interval values into intermediate representations, so that both intervals have the same interval qualifier. Year-month intervals can be compared only with other year-month intervals, and day-second intervals can be compared only with other day-second intervals.

For example, if an interval in minutes, such as `INTERVAL '120' MINUTE` is compared with an interval in days to seconds, such as `INTERVAL '0 02:01:00'`, the two intervals are first converted into values that have consistent interval qualifiers, which can be compared. So, in this example, the first value is converted into an interval in days to seconds, which gives `INTERVAL '0 02:00:00'`, which can be compared with the second value.

Comparing character strings with other types:
If a character string is compared with a value of another type, the broker attempts to cast the character string into a value of the same data type as the other value.

For example, you can write an expression:

```
'1234'> 4567
```

The character string on the left is converted into an integer before the comparison takes place. This behavior reduces some of the need for explicit CAST operators when comparing values derived from a generic XML message with literal values. (For details of explicit casts that are supported, see “Supported casts” on page 5273.) It is this facility that allows you to write the following expression:

```
Body.Trade.Quantity> 5000
```

In this example, the field reference on the left evaluates to the character string '1000' and, because this is being compared to an integer, that character string is converted into an integer before the comparison takes place.

You must still check whether the price field that you want interpreted as a decimal is greater than a given threshold. Make sure that the literal you compare it to is a decimal value and not an integer.

Consider the following example:

```
Body.Trade.Price> 100
```

This comparison does not return the required or expected result, because the `Price` field is converted into an integer, and that conversion fails because the character string contains a decimal point. However, the following expression succeeds:

```
Body.Trade.Price> 100.00
```

"Implicit CASTs for arithmetic operations"

"Implicit CASTs for assignment" on page 5287

Implicit CASTs for arithmetic operations:
This topic lists the implicit CASTs available for arithmetic operations.

Normally the arithmetic operators (+, -, *, and /) operate on operands of the same data type, and return a value of the same data type as the operands. Cases where it is acceptable for the operands to be of different data types, or where the data type of the resulting value is different from the type of the operands, are shown in the following table.

The following table lists the implicit CASTs for arithmetic operation.

Left operand data type	Right operand data type	Supported operators	Result data type
INTEGER	FLOAT	+, -, *, /	FLOAT[1]
INTEGER	DECIMAL	+, -, *, /	DECIMAL[1]
INTEGER	INTERVAL	*	INTERVAL[4]
FLOAT	INTEGER	+, -, *, /	FLOAT[1]
FLOAT	DECIMAL	+, -, *, /	FLOAT[1]
FLOAT	INTERVAL	*	INTERVAL[4]
DECIMAL	INTEGER	+, -, *, /	DECIMAL[1]
DECIMAL	FLOAT	+, -, *, /	FLOAT[1]
DECIMAL	INTERVAL	*	INTERVAL[4]
TIME	TIME	-	INTERVAL[2]
TIME	GMTTIME	-	INTERVAL[2]
TIME	INTERVAL	+, -	TIME[3]
GMTTIME	TIME	-	INTERVAL[2]
GMTTIME	GMTTIME	-	INTERVAL[2]
GMTTIME	INTERVAL	+, -	GMTTIME[3]

Left operand data type	Right operand data type	Supported operators	Result data type
DATE	DATE	-	INTERVAL[2]
DATE	INTERVAL	+, -	DATE[3]
TIMESTAMP	TIMESTAMP	-	INTERVAL[2]
TIMESTAMP	GMTTIMESTAMP	-	INTERVAL[2]
TIMESTAMP	INTERVAL	+, -	TIMESTAMP[3]
GMTTIMESTAMP	TIMESTAMP	-	INTERVAL[2]
GMTTIMESTAMP	GMTTIMESTAMP	-	INTERVAL[2]
GMTTIMESTAMP	INTERVAL	+, -	GMTTIMESTAMP[3]
INTERVAL	INTEGER	*, /	INTERVAL[4]
INTERVAL	FLOAT	*, /	INTERVAL[4]
INTERVAL	DECIMAL	*, /	INTERVAL[4]
INTERVAL	TIME	+	TIME[3]
INTERVAL	GMTTIME	+	GMTTIME[3]
INTERVAL	DATE	+	DATE[3]
INTERVAL	TIMESTAMP	+	TIMESTAMP[3]
INTERVAL	GMTTIMESTAMP	+	GMTTIMESTAMP[3]

Notes:

1. The operand that does not match the data type of the result is cast to the data type of the result before the operation proceeds. For example, if the left operand to an addition operator is an INTEGER, and the right operand is a FLOAT, the left operand is cast to a FLOAT before the addition operation is performed.
2. Subtracting a (GMT)TIME value from a (GMT)TIME value, a DATE value from a DATE value, or a (GMT)TIMESTAMP value from a (GMT)TIMESTAMP value, results in an INTERVAL value representing the time interval between the two operands.
3. Adding or subtracting an INTERVAL from a (GMT)TIME, DATE or (GMT)TIMESTAMP value results in a new value of the data type of the non-INTERVAL operand, representing the point in time represented by the original non-INTERVAL, plus or minus the length of time represented by the INTERVAL.
4. Multiplying or dividing an INTERVAL by an INTEGER, FLOAT, or DECIMAL value results in a new INTERVAL representing the length of time represented by the original, multiplied or divided by the factor represented by the non-INTERVAL operand. For example, an INTERVAL value of 2 hours 16 minutes multiplied by a FLOAT value of 2.5 results in a new INTERVAL value of 5 hours 40 minutes. The intermediate calculations involved in multiplying or dividing the original INTERVAL are carried out in the data type of the non-INTERVAL, but the individual fields of the INTERVAL (such as HOUR, YEAR, and so on) are always integral, so some rounding errors might occur.

"Implicit CASTs for comparisons" on page 5282
The standard SQL comparison operators>, <,>=, <=, =, <> are supported for comparing two values in ESQL.

"Implicit CASTs for assignment"

Implicit CASTs for assignment:
Values can be assigned to one of three entities.

A message field (or equivalent in an exception or destination list)
Support for implicit conversion between the WebSphere Message Broker data types and the message (in its bitstream form) depends on the appropriate parser. For example, the XML parser casts everything as character strings before inserting them into the WebSphere MQ message.

A field in a database table

WebSphere Message Broker converts each of its data types into a suitable standard SQL C data type, as detailed in the following table. Conversion between this standard SQL C data type, and the data types supported by each DBMS, depends on the DBMS. Consult your DBMS documentation for more details.

The following table lists the available conversions from WebSphere Message Broker to SQL data types

WebSphere Message Broker data type	SQL data type
NULL, or unknown or invalid value	SQL_NULL_DATA
BOOLEAN	SQL_C_BIT
INTEGER	SQL_C_LONG
FLOAT	SQL_C_DOUBLE
DECIMAL	SQL_C_CHAR[1]
CHARACTER	SQL_C_CHAR
TIME	SQL_C_TIME
GMTTIME	SQL_C_TIME
DATE	SQL_C_DATE
TIMESTAMP	SQL_C_TIMESTAMP
GMTTIMESTAMP	SQL_C_DATE
INTERVAL	Not supported[2]
BLOB	SQL_C_BINARY
BIT	Not supported[2]

Notes:

1. For convenience, DECIMAL values are passed to the DBMS in character form.
2. There is no suitable standard SQL C data type for INTERVAL or BIT. Cast these to another data type, such as CHARACTER, if you need to assign them to a database field.

A scalar variable
When assigning to a scalar variable, if the data type of the value being assigned and that of the target variable data type are different, an implicit cast is attempted with the same restrictions and behavior as specified for the explicit CAST function. The only exception is when the data type of the variable is INTERVAL or DECIMAL.

In both these cases, the value being assigned is first cast to a CHARACTER value, and an attempt is made to cast the CHARACTER value to an INTERVAL or DECIMAL. This is because INTERVAL requires a qualifier and DECIMAL requires a precision and scale. These must be specified in the explicit cast, but must be obtained from the character string when implicitly casting. Therefore, a further restriction is that when implicitly casting to an INTERVAL variable, the character string must be of the form INTERVAL '<values>' <qualifier>. The shortened <values> form that is acceptable for the explicit cast is not acceptable here.

"Implicit CASTs for arithmetic operations" on page 5285

Data types of values from external databases:

How database data types are implicitly cast to ESQL data types.

The ESQL data type of message fields depends on the type of the message (for example, XML), and the parser that is used to parse it. The ESQL data type of the value returned by a database column reference depends on the data type of the column in the database.

The following table shows how the various built-in database data types are cast to ESQL data types, when they are accessed by message flows that are running in a broker.

The versions that are supported for the database products shown in this table are listed in "Supported databases" on page 3591.

DB2	SQL Server and Sybase	Oracle	Informix	ESQL data type
N/A	BIT	N/A	N/A	BOOLEAN
SMALLINT, INTEGER, BIGINT	INT, SMALLINT, TINYINT	N/A	INT, SMALLINT	INTEGER
REAL, DOUBLE	FLOAT, REAL	NUMBER()[1]	FLOAT, SMALLFLOAT, DOUBLE	FLOAT
DECIMAL	DECIMAL, NUMERIC, MONEY, SMALLMONEY	NUMBER(P)[1], NUMBER(P,S)[1]	DECIMAL, MONEY	DECIMAL

DB2	SQL Server and Sybase	Oracle	Informix	ESQL data type
CHAR, VARCHAR, CLOB, GRAPHIC, VARGRAPHIC[2]	CHAR, VARCHAR, TEXT	CHAR, VARCHAR2, ROWID, UROWID, LONG, CLOB	CHAR, VARCHAR, CHAR VARYING	CHARACTER
TIME	N/A	N/A	N/A	TIME
N/A	N/A	N/A	N/A	GMTTIME
DATE	N/A	N/A	DATE	DATE
TIMESTAMP	DATETIME, SMALLDATETIME, TIMESTAMP	DATE	DATETIME	TIMESTAMP
N/A	N/A	N/A	N/A	GMTTIMESTAMP
N/A	N/A	N/A	INTERVAL	INTERVAL
BLOB	BINARY, VARBINARY, IMAGE, UNIQUEIDENTIFIER	RAW LONG, RAW BLOB	N/A	BLOB
N/A	N/A	N/A	N/A	BIT
XML	N/A	• Up to Version 7.0.0.2: CHAR • At Version 7.0.0.3 onwards: XML	N/A	BLOB

The table shows all data types that are supported for each database.

If an Oracle database column with NUMBER data type is defined with an explicit precision (P) and scale (S), it is cast to an ESQL DECIMAL value; otherwise it is cast to a FLOAT. For example, an ESQL statement like this:

```
SET OutputRoot.xxx[]
 = (SELECT T.department FROM Database.personnel AS T);
```

where `Database.personnel` resolves to a TINYINT column in an SQL Server database table, results in a list of ESQL INTEGER values being assigned to `OutputRoot.xxx`.

By contrast, an identical query, where `Database.personnel` resolves to a NUMBER() column in an Oracle database, results in a list of ESQL FLOAT values being assigned to `OutputRoot.xxx`.

Note, that data types of stored procedure parameters are cast using the definition of that external procedure in the “CREATE PROCEDURE statement” on page 5103.

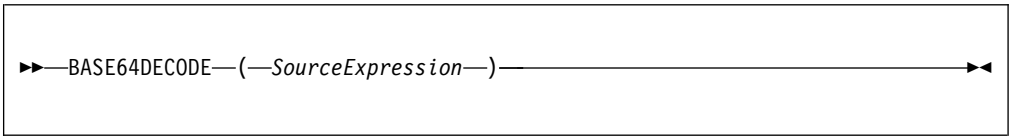
The following types of function are available.

BASE64DECODE function:

BASE64DECODE is a function that manipulates CHARACTER strings that are base64-encoded, and returns a BLOB string that contains the base64-decoded version of the source string.

Syntax



BASE64DECODE returns a BLOB string containing a base64-decoded representation of the source string. The source string can only be of the CHARACTER data type. If *SourceExpression* is NULL, the result is NULL. If the source string does not contain valid base64 data, SQSTATE 'S22018' exception is produced.

Examples

For examples of usage see the BASE64ENCODE function.

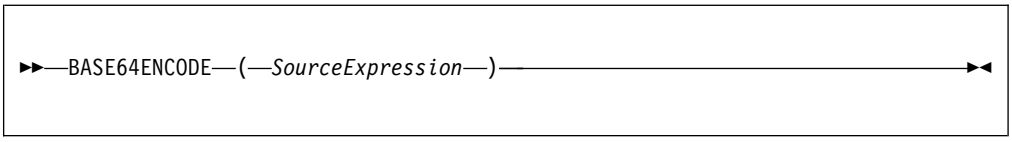
ESQL provides additional functions that support miscellaneous operations.

BASE64ENCODE function:

BASE64ENCODE is a function that manipulates all string data types (BIT, BLOB, and CHARACTER).

BASE64ENCODE returns a CHARACTER string that contains the base64-encoded version of the source string.

Syntax



BASE64ENCODE returns a CHARACTER string containing a base64 representation of the source string. The source string can be a string of the CHARACTER, BLOB, or BIT data type. If *SourceExpression* is NULL, the result is NULL.

If *SourceExpression* is of CHARACTER type, it is first converted to the UTF-8 code page before encoding as base64.
If *SourceExpression* is of BLOB type, it is encoded as base64 directly, without any prior changes.

If *SourceExpression* is of BIT type, it is first CAST to BLOB before encoding as base64 and so its length must be a multiple of 8.

Examples

The base64 encoding of a BLOB source string and subsequent decoding back to BLOB is shown by the following example:

```
DECLARE original BLOB X'48656c6c6f';
DECLARE encoded CHARACTER BASE64ENCODE(original);
DECLARE decoded BLOB BASE64DECODE(encoded);
```

The base64 encoding of a CHARACTER source string that is first automatically converted to UTF-8 and later decoded is shown by the following example:

```
DECLARE original CHARACTER 'Hello World!';
DECLARE encoded CHARACTER BASE64ENCODE(original);
DECLARE decoded BLOB BASE64DECODE(encoded);
DECLARE decoded2 CHARACTER CAST(decoded AS CHARACTER CCSID 1208);
```

The base64 encoding of a BIT source string that is first automatically converted to a BLOB and later decoded is shown by the following example:

```
DECLARE original BIT B'0010001001000001';
DECLARE encoded CHARACTER BASE64ENCODE(original);
DECLARE decoded BLOB BASE64DECODE(encoded);
DECLARE decoded2 BIT CAST(decoded AS BIT);
```

Encoding from a CHARACTER source string to a BLOB and back to CHARACTER again in a code page other than UTF-8 is shown by the following example:

```
DECLARE original CHARACTER 'Hello World!';
DECLARE originalBlob BLOB CAST(original AS BLOB CCSID 819);
DECLARE encoded CHARACTER BASE64ENCODE(originalBlob);
DECLARE decoded BLOB BASE64DECODE(encoded);
DECLARE decoded2 CHARACTER CAST(decoded AS CHARACTER CCSID 819);
```

ESQL provides additional functions that support miscellaneous operations.

CHANGEIDENTIFIERTIMEOUT function:

The CHANGEIDENTIFIERTIMEOUT function changes the timeout value associated with the reply identifier of a SOAPInput node or the request identifier of an HTTPInput node. The function returns a Boolean value to indicate the success or otherwise of the change.

Syntax

The function returns TRUE if the given identifier is valid and the timeout was adjusted to the new value without the new value causing the identifier to timeout. It returns FALSE if the identifier passed to the function is invalid or, after the timeout adjustment, the identifier has expired. Note that if the function is passed an identifier that has already expired, the function always return FALSE. Note that for HTTPInput nodes, the function only processes identifiers that are associated with the embedded execution group listener.

The *IdentifierExpression* parameter is a BLOB expression that must resolve to a valid reply identifier (for a SOAPInput node) or request identifier (for an HTTPInput node). An identifier is unique to an individual message, therefore only the message associated with the identifier will be affected by this function.

The *TimeoutExpression* parameter is an INTEGER expression that represents a certain number of seconds to be added to or subtracted from the identifier's timeout value. Specifying a positive value will cause the timeout to be increased by the chosen amount, whilst specifying a negative value will cause the timeout to be decreased by the chosen amount. Passing a value of 0 allows an identifier to be tested for validity without changing it, because FALSE is returned if the identifier is invalid or has expired, whereas TRUE is returned if the identifier is valid and has not timed out.

If either parameter is NULL, the result is NULL.

Examples

The following example shows how to reduce the timeout of the specified SOAP reply identifier by 5 seconds. It returns TRUE if the identifier is valid and has not expired after changing the timeout duration:

```
ChangeIdentifierTimeout(
  LocalEnvironment.Destination.SOAP.Reply.ReplyIdentifier, -5);
```

The following example shows how to increase the timeout on the specified identifier by 30 seconds. It returns TRUE if the identifier is valid and has not expired after changing the timeout duration:

```
ChangeIdentifierTimeout(myReplyIdentifier, 30);
```

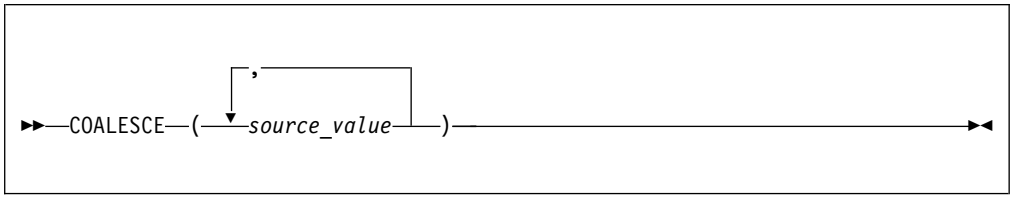
ESQL provides additional functions that support miscellaneous operations.

COALESCE function:
COALESCE is a miscellaneous function that lets you provide default values for fields.

Syntax



The COALESCE function evaluates its parameters in order and returns the first one that is not NULL. The result is NULL if, and only if, all the arguments are NULL. The parameters can be of any scalar type, but they need not all be of the same type.

Use the COALESCE function to provide a default value for a field, which might not exist in a message. For example, the expression:

```
COALESCE(Body.Salary, 0)
```

returns the value of the Salary field in the message if it exists, or 0 (zero) if that field does not exist.

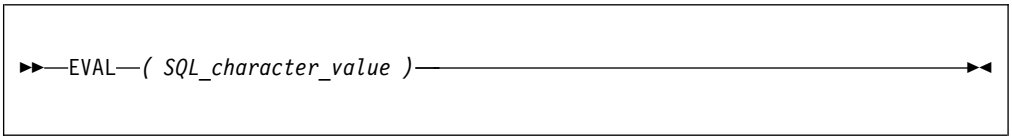
"Miscellaneous ESQL functions" on page 5290
ESQL provides additional functions that support miscellaneous operations.

EVAL function:

The EVAL function takes a character value and interprets that value as an ESQL expression that returns a value.

For details of the EVAL statement, see "EVAL statement" on page 5131.

Syntax



EVAL takes one parameter in the form of an expression, evaluates this expression, and casts the resulting value to a character string if it is not one already. The expression that is passed to EVAL must therefore be able to be represented as a character string.

User defined functions cannot be defined within an EVAL function but EVAL can be used to call a user-defined function that is in scope where the EVAL function is used.

If you use the EVAL function to call out to a user-defined function that is not called from anywhere else in the ESQL for a given node, you need to add the following code to your ESQL, to ensure that the user-defined function being called is included when the code is compiled:

```
IF (FALSE) THEN CALL function(<parameters>) INTO Environment.temp; END IF;
```

Note, that in the preceding example, you must replace `function()` with the name of the function in question.

In the following examples, A and B are integer scalar variables, and scalarVar1 and OperatorAsString are character string scalar variables.

The following examples are valid uses of EVAL:

- `SET OutputRoot.XMLNS.Data.Result = EVAL(A+B);`

  The expression A+B is acceptable because, although it returns an integer value, integer values are representable as character strings, and the necessary cast is performed before EVAL continues with its second stage of evaluation.
- `SET OutputRoot.XMLNS.Data.Result  = EVAL('A' ||  operatorAsString || 'B');`
- `EVAL('SET ' || scalarVar1 || ' = 2;');`

  The semicolon included at the end of the final string literal is necessary, because if EVAL is being used in place of an ESQL statement, its first stage evaluation must return a string that represents a valid ESQL statement, including the terminating semicolon.

The real power of EVAL is that it allows you to dynamically construct ESQL statements or expressions. In the second and third examples above, the value of scalarVar1 or operatorAsString can be set according to the value of an incoming message field, or other dynamic value, allowing you to effectively control what ESQL is executed without requiring a potentially lengthy IF-THEN ladder.

However, consider the performance implications in using EVAL. Dynamic construction and execution of statements or expressions is necessarily more time-consuming than simply executing pre-constructed ones. If performance is vital, you might prefer to write more specific, but faster, ESQL.

The following are not valid uses of EVAL:

- `SET EVAL(scalarVar1) = 2;`

  In this example, EVAL is being used to replace a field reference, not an expression.
- `SET OutputRoot.XMLNS.Data.Result[] = EVAL((SELECT T.x FROM Database.y AS T));`

  In this example, the `(SELECT T.x FROM Database.y)` passed to EVAL returns a list, which is not representable as a character string.

The following example is acceptable because `(SELECT T.x FROM Database.y AS T)` is a character string literal, not an expression in itself, and therefore is representable as a character string.

```
SET OutputRoot.XMLNS.Data.Result[]
 = EVAL('(SELECT T.x FROM Database.y AS T)');
```

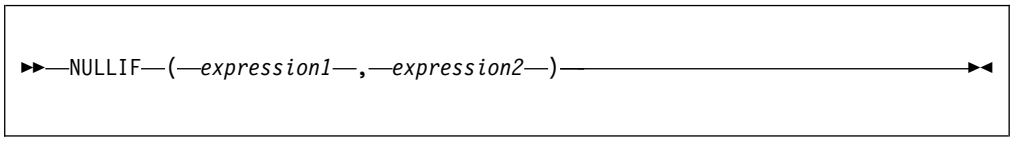
"EVAL statement" on page 5131
The EVAL statement takes a character value, interprets it as an SQL statement, and processes that statement.

NULLIF function:
NULLIF is a miscellaneous function that returns a NULL value if the arguments are equal.

Syntax



The NULLIF function returns a NULL value if the arguments are equal; otherwise, it returns the value of the first argument. The arguments must be comparable. The result of using `NULLIF(e1,e2)` is the same as using the expression:

```
CASE WHEN e1=e2 THEN NULL ELSE e1 END
```

When `e1=e2` evaluates to unknown (because one or both of the arguments is NULL), NULLIF returns the value of the first argument.

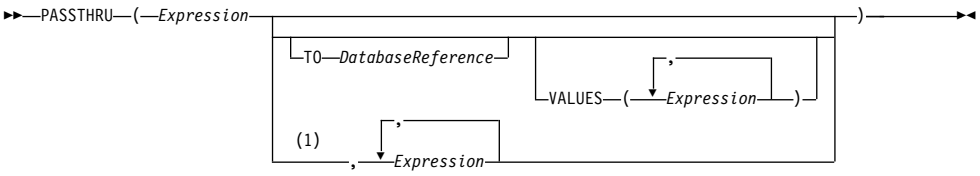
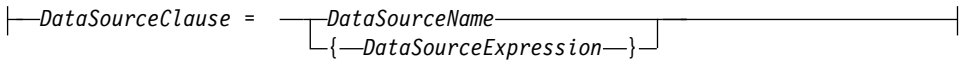
PASSTHRU function:

The PASSTHRU function evaluates an expression and executes the resulting character string as a database statement, returning a result set.

Syntax



WHERE:



Notes:

1 The lower half of the main syntax diagram describes syntax retained for backward compatability.

The PASSTHRU function is similar to the PASSTHRU statement, which is described in "PASSTHRU statement" on page 5147.

Usage

The main use of the PASSTHRU function is to issue complex SELECTs, not currently supported by the broker, to databases. (Examples of complex SELECTs not currently supported by the broker are those containing GROUP BY or HAVING clauses.)

The first expression is evaluated and the resulting character string is passed to the database pointed to by *DatabaseReference* (in the TO clause) for execution. If the TO clause is not specified, the database pointed to by the node's `data source` attribute is used.

Use question marks (?) in the database string to denote parameters. The parameter values are supplied by the VALUES clause.

If the VALUES clause is specified, its expressions are evaluated and passed to the database as parameters; (that is, the expressions' values are substituted for the question marks in the database statement).

If only one VALUE expression exists, the result might or might not be a list. If it is a list, the list's scalar values are substituted sequentially for the question marks. If it is not a list, the single scalar value is substituted for the (single) question mark in the database statement. If more than one VALUE expression exists, none of the expressions evaluate to a list; their scalar values are substituted sequentially for the question marks instead.

Because the database statement is constructed by the user program, it is not essential to use parameter markers (that is, the question marks) or the VALUES clause, because the whole of the database statement could be supplied, as a literal string, by the program. However, use parameter markers whenever possible because this reduces the number of different statements that need to be prepared and stored in the database and the broker.

Database reference

A database reference is a special instance of the field references that is used to refer to message trees. It consists of the word **Database** followed by the name of a data source (that is, the name of a database instance).

You can specify the data source name directly or by an expression enclosed in braces ({...}). A directly-specified data source name is subject to name substitution. That is, if the name used has been declared to be a known name, the value of the declared name is used rather than the name itself (see "DECLARE statement" on page 5117).

If you have created a message flow that contains one of the following nodes, and the ESQL that is associated with this node includes a PASSTHRU statement and a database reference, you must specify a value for the `Data source` property of the relevant node:
- Compute
- Database
- Filter

Handling errors

It is possible for errors to occur during PASSTHRU operations. For example, the database might not be operational or the statement might be invalid. In these cases, an exception is thrown (unless the node has its `Throw exception on database error` property cleared). These exceptions set appropriate SQL code, state, native error, and error text values and can be dealt with by error handlers (see the DECLARE HANDLER statement).

For further information about handling database errors, see "Capturing database state" on page 2512.

Example

The following example performs a SELECT on table `Table1` in schema `Schema1` in database DSN1, passing two parameters to the WHERE clause and asking for the result set to be ordered in ascending name order. The result set is assigned to the `SelectResult` folder:

```
SET OutputRoot.XML.Data.SelectResult.Row[] =
  PASSTHRU('SELECT R.* FROM Schema1.Table1 AS R WHERE R.Name = ? OR R.Name =
           ? ORDER BY Name'
   TO Database.DSN1
   VALUES ('Name1', 'Name4'));
```

The above example assigns the result set to the `OutputRoot` message body tree that is owned by the Generic XML parser, which allows self-defining messages.

If assigning the result set into a message tree owned by one of the MRM parsers, and the result set structure exactly matches the MRM message definition, the result set can be assigned directly into the `OutputRoot` message body tree.

If the result set structure does not exactly match the MRM message definition, you must first assign the result set into a ROW data type, or an Environment tree that does not have any parsers associated with it. The required data can then be assigned to `OutputRoot` to build a message tree that conforms to the message definition.

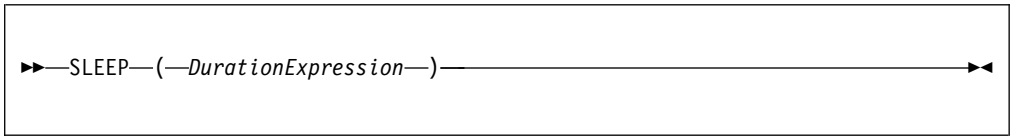
SLEEP function:

The SLEEP function delays the execution of a message flow instance for a defined period of time, and returns a Boolean value to indicate whether the sleep completed without interruption.

Syntax



The SLEEP function returns TRUE if the sleep is completed for the specified duration without interruption, otherwise it returns FALSE.

The *DurationExpression* parameter specifies the number of milliseconds to sleep. It must be of INTEGER data type. If *DurationExpression* is NULL, the function returns NULL immediately without sleeping.

SLEEP cannot be called from inside an ATOMIC block because this would block other instances from having access to the shared resource. If such a call is attempted, FALSE is returned immediately.

The SLEEP function is automatically interrupted and returns FALSE, if a configuration or redeploy message for the flow arrives while the flow is sleeping.

Example

In the following example, SLEEP is called for 1000, if it is not interrupted for reconfiguration:

```
DECLARE returnValue BOOLEAN
SET returnValue = SLEEP(1000); /* attempt to sleep for one second */
```

Customize processing implemented by the Compute, Database, DatabaseInput, and Filter nodes in your message flows by coding ESQL.

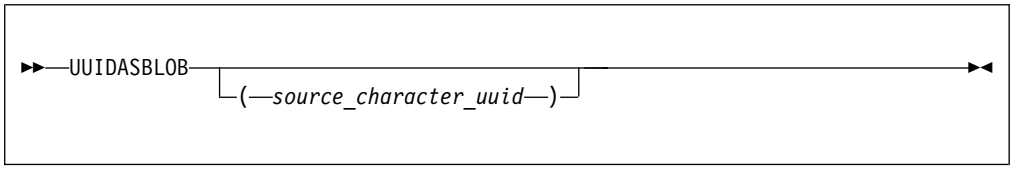
Related reference:

"Syntax diagrams" on page 3677

"Miscellaneous ESQL functions" on page 5290
ESQL provides additional functions that support miscellaneous operations.

UUIDASBLOB function:
UUIDASBLOB is a miscellaneous function that returns universally unique identifiers (UUIDs) as BLOBs.

Syntax



If (*source_character_uuid*) is not specified, UUIDASBLOB creates a new UUID and returns it as a BLOB.

If (*source_character_uuid*) is specified, UUIDASBLOB converts an existing character UUID in the form `ddddddddd_dddd_dddd_dddd_dddddddddddd` to the BLOB form. An exception is thrown if the parameter is not of the expected form.

The result is NULL if a NULL parameter is supplied.

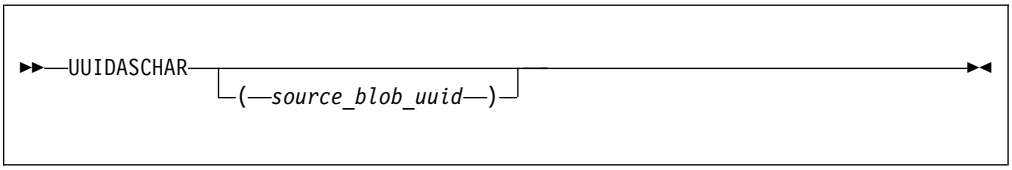
ESQL provides additional functions that support miscellaneous operations.

UUIDASCHAR function:
UUIDASCHAR is a miscellaneous function that returns universally unique identifiers (UUIDs) as CHARACTER values.

Syntax



If (*source_blob_uuid*) is not specified, UUIDASCHAR creates a new UUID and returns it as a CHARACTER value.

If (*source_blob_uuid*) is specified, UUIDASCHAR converts an existing BLOB UUID to the character form.

The result is NULL if a NULL parameter is supplied.

ESQL constants:

Use these constants to make or parse a bit stream.

ESQL constants in the Mapping node	Corresponding ESQL constants
$esql:RootBitStream	RootBitStream
$esql:FolderBitStream	FolderBitStream
$esql:ValidateContentAndValue	ValidateContentAndValue
$esql:ValidateValue	ValidateValue
$esql:ValidateContent	ValidateContent
$esql:ValidateNone	ValidateNone
$esql:ValidateException	ValidateException
$esql:ValidateExceptionList	ValidateExceptionList
$esql:ValidateLocalError	ValidateLocalError
$esql:ValidateUserTrace	ValidateUserTrace
$esql:ParseComplete	ParseComplete
$esql:ParseImmediate	ParseImmediate
$esql:ParseOnDemand	ParseOnDemand

Related tasks:
"Setting the value of a target element to an ESQL constant" on page 2260
There are two ways to set the value of a target element to an ESQL constant, depending on whether the target element has an entry in the Map Script column of the Message Mapping editor Spreadsheet pane.

Broker properties that are accessible from ESQL and Java:

You can access broker, message flow, and node properties from ESQL and Java.

The following table shows the properties that are available to ESQL and Java code by using the CMP interface.

The Java code, where applicable, is shown in the third column of the table.

Note that the `BrokerProxy`, `ExecutionGroupProxy`, `MessageFlowProxy`, and `LocalBrokerUtilities` classes are all part of the CMP interface (`ConfigManagerProxy.jar`). This JAR needs to be referenced from your Java project in your WebSphere Message Broker Toolkit, but it does not need to be deployed to the broker.

For a complete overview of broker properties, see "Broker properties" on page 1144.

Table 267. General broker properties.

Note: The only broker-defined properties that can be used in a Trace node are those in the "General broker properties" group. For example, you could specify the `Pattern` setting of a Trace node as:

```
#### Start Trace Input Message
  Time: ${CURRENT_TIMESTAMP}
  Broker: ${BrokerName}  Version: ${BrokerVersion}  Platform: ${Family}
  ProcessID: ${ProcessId}  BrokerUserId: ${BrokerUserId}
  ExecutionGroupLabel: ${ExecutionGroupLabel}
  Transaction: ${Transaction}
  Root Tree: ${Root}
#### End Trace Input Message
```

ESQL Property name	Java access method	Description
BrokerName (Character)	Accessible through: 1. `MbNode.getBroker()` 2. `MbBroker.getName()`	The name of the broker.
BrokerUserId (Character)	Use `System.getProperty("user.name");` to get the name of the user ID under which the broker was started.	The user ID under which the broker is running (that is, the user ID specified by the **-i** flag on the **mqsicreatebroker** command on Windows, or the user ID that started the broker by using the **mqsistart** command on Linux and UNIX systems).

BrokerVersion (Character)	Use
	
	`BrokerProxy b = BrokerProxy.getLocalInstance();`
	`int v = b.getBrokerVersion();`
		The 4-character version number of the broker (see "BrokerVersion" on page 5305).

ExecutionGroupLabel (Character)	Use
	
	`ExecutionGroupProxy eg = ExecutionGroupProxy.getLocalInstance();`
	`eg.getName();`
		The label of the execution group (a human-readable name).

ExecutionGroupName (Character)	Use
	
	`ExecutionGroupProxy eg = ExecutionGroupProxy.getLocalInstance();`
	`eg.getUUID();`
		The name of the execution group (typically a UUID identifier).

Family (Character)	Use `System.getProperty("os.name")` to return the operating system name from Java.	The generic name of the software platform that the broker is running on (`'WINDOWS'`, `'UNIX'`, or `'ZOS'`).

ProcessId (Integer)	Use
	
	`ExecutionGroupProxy eg = ExecutionGroupProxy.getLocalInstance();`
	`String processId =`
	`eg.getRuntimeProperty(AttributeConstants.EG_THIS_PROCESSID_PROPERTY);`
		The process identifier (PID) of the execution group.

QueueManagerName (Character)		The name of the WebSphere MQ queue manager to which the broker is connected.
WorkPath (Character)	To return any non-default workpath in Java, use: `String wp = LocalBrokerUtilities.getLocalBrokerWorkpath(brokerName);`	(Optional) The directory in which working files for this broker are stored.

Table 268. Flow properties

ESQL Property name	Java access method	Description

AdditionalInstances (Integer)	Use
	
	`ExecutionGroupProxy eg = ExecutionGroupProxy.getLocalInstance();`
	`MessageFlowProxy mf = eg.getMessageFlowByName("mf1");`
	`int i = mf.getAdditionalInstances();`
		The number of additional threads that the broker can use to service the message flow.

CommitCount (Integer)	Use
	
	`ExecutionGroupProxy eg = ExecutionGroupProxy.getLocalInstance();`
	`MessageFlowProxy mf = eg.getMessageFlowByName("mf1");`
	`int i = mf.getCommitCount();`
		The number of input messages that are processed by the message flow before a syncpoint is taken.

CommitInterval (Integer)	Use
	
	`ExecutionGroupProxy eg = ExecutionGroupProxy.getLocalInstance();`
	`MessageFlowProxy mf = eg.getMessageFlowByName("mf1");`
	`int i = mf.getCommitInterval();`
		The time interval at which a commit is taken when the `CommitCount` property is greater than 1 (that is, when the message flow is batching messages), but the number of messages processed has not reached the value of the `CommitCount` property.

CoordinatedTransaction (Boolean)	Not possible	Whether the message flow is processed as a global transaction, coordinated by WebSphere MQ.
MessageFlowLabel (Character)	Not possible	The name of the flow.

Table 269. Node properies

ESQL Property name	Java access method	Description
DataSource (Character)	Not possible	The ODBC Data Source Name (DSN) of the database in which the user tables are created.
DataSourceUserId (Character)	Not possible	The user ID that the broker uses to access the database user tables.
MessageOptions (Integer 64-bit)[1]	Not possible	The bit stream and validation options in force.
NodeLabel (Character)	Not applicable	The name of the node.
NodeType (Character)	Not applicable	The type of node (Compute, Database, or Filter).
ThrowExceptionOnDatabaseError (Boolean)[1]	Not possible	Whether the broker generates an exception when a database error is detected.
TransactionType (Character)[1]	Not possible	The type of transaction (Automatic or Commit) used to access a database from this node.
TreatWarningsAsErrors (Boolean)[1]	Not possible	Whether database warning messages are treated as errors, and cause the output message to be propagated to the failure terminal.

Notes:
1. Not applicable for the DatabaseInput node.

BrokerVersion

The BrokerVersion property contains a 4-character code that indicates the version of the broker. The code is based on the IBM Version/Release/Modification/Fix pack (VRMF) product-numbering system. The VRMF code works like this:

V The Version number. A Version is a separate IBM licensed program that usually has significant new code or new function. Each version has its own license, terms, and conditions.

R The Release number. A Release is a distribution of new function and authorized program analysis report (APAR) fixes for an existing product.

M The Modification number. A Modification is new function added to an existing product, and is delivered separately from an announced Version or Release.

F The Fix pack number. Fix packs contain defect and APAR fixes. They do not contain new function.

A fix pack is cumulative: that is, it contains all the fixes shipped in previous maintenance to the release, including previous fix packs. It can be applied on top of any previously-shipped maintenance to bring the system up to the current fix pack level.

Special characters, case sensitivity, and comments in ESQL:

When you work with ESQL, it is useful to know about the special characters that are available, whether ESQL syntax is case sensitive, and how to handle comments.

- "Special characters" on page 5306
- "Case sensitivity of ESQL syntax" on page 5306
- "Comments" on page 5306

Special characters

Symbol	Name	Usage
;	semicolon	End of ESQL statement
.	period	Field reference separator or decimal point
=	equals	Comparison or assignment
>	greater than	Comparison
<	less than	Comparison
[]	square brackets	Array subscript
'	single quotation mark	Delimit string, date-time, and decimal literals Note, that to escape a single quotation mark inside a string literal, you must use two single quotation marks.
||	double vertical bar	Concatenation
()	parentheses	Expression delimiter
"	quotation mark	Identifier delimiter
*	asterisk	Any name or multiply
+	plus	Arithmetic add
-	minus	Arithmetic subtract, date separator, or negation
/	forward slash	Arithmetic divide
_	underscore	LIKE single wildcard
%	percent	LIKE multiple wildcard
\	backslash	LIKE escape character
:	colon	Name space and Time literal separator
,	comma	List separator
<>	less than greater than	Not equals
--	double minus	ESQL single line comment
/* */	slash asterisk asterisk slash	ESQL multiline comment
?	question mark	Substitution variable in PASSTHRU
<=	less than or equal	Comparison
>=	greater than or equal	Comparison
/*!{ }!*/	executable comment	Bypass tools check

Case sensitivity of ESQL syntax

The case of ESQL statements is:

- Case sensitive in field reference literals
- Not case sensitive in ESQL language words

Comments

ESQL has two types of comment: single line and multiple line. A single line comment starts with the characters -- and ends at the end of the line.

In arithmetic expressions you must take care not to initiate a line comment accidentally. For example, consider the expression:

```
1 - -2
```

Removing all white space from the expression results in:

```
1--2
```

which is interpreted as the number 1, followed by a line comment.

A multiple line comment starts with /* anywhere in ESQL and ends with */.

ESQL reserved keywords:

The keywords listed are reserved in uppercase, lowercase, or mixed case.

You cannot use these keywords for variable names. However, you *can* use reserved keywords as names in a field reference.

The following list shows all ESQL reserved keywords:

- ALL
- ASYMMETRIC
- BOTH
- CASE
- DISTINCT
- FROM
- ITEM
- LEADING
- NOT
- SYMMETRIC
- TRAILING
- WHEN

Use the PHPCompute node to route and transform an incoming message, using the PHP scripting language.

"PHP data types" on page 5323
PHP data types are supported by WebSphere Message Broker.

MbsElement:

The MbsElement class represents a single parsed element in a message (or other logical tree).

The MbsElement class provides the API methods shown in the following table (parameters in square brackets are optional):

Method	Description
Constructor()	Instantiates a new MbsElement object.
object **getValue**()	Returns the value of the current element.
void **setValue**(*object $value*)	Sets the value of the current element.
int **getType**()	Returns the specific type of the current element. For a full list of type values, see "PHP constants for type values" on page 5343.
void **setType**(*int $type*)	Sets the specific type of the current element. For a full list of type values, see "PHP constants for type values" on page 5343.

Method	Description
object **xpath**(*string $expression [, array $namespace]*)	Evaluates the XPath expression with the current element as the context node. It returns the result as either a string, double, boolean, or a nodeset as an array of MbsElement objects. The optional **namespace** parameter is an associative array with namespace prefixes as the keys and namespace URIs as the values.
string **getName**()	Returns the name of the current element.
void **setName**(*string $name*)	Sets the name of the current element.
string **getNamespace**()	Returns the namespace URI of the current element.
void **setNamespace**(*$namespace*)	Sets the namespace URI of the current element.
MbsElement **getParent**()	Returns the parent of the current element.
MbsElement **getChild**(*string $name [, int $occurrence]*)	Returns the first child of the current element whose name is given by the first parameter. The n^{th} occurrence of that child can be returned by specifying the second optional parameter.
array **getChildren**(*[string $namespace]*)	Returns all the child elements n of the current element as an array of MbsElements. If the **namespace** parameter is specified, the array contains only the child elements with that namespace URI.
MbsElement **getFirstChild**()	Returns the first child of the current element.
MbsElement **getLastChild**()	Returns the last child of the current element.
MbsElement **getNextSibling**()	Returns the next sibling of the current element.
MbsElement **getPreviousSibling**()	Returns the previous sibling of the current element.
MbsElement **getAttribute**(*string $name*)	Returns the attribute of the current element given by the **name** parameter.
MbsElement **addAttribute**(*string $name, object $value [, string $namespace]*)	Adds an attribute to the current element.
MbsElement **addElement**(*string $name, object $value [, string $namespace [, int $type [, int $position]]]*)	Creates an element as last child (by default) of the current element. The optional **type** parameter is the parser-specific type of the new node (which defaults to XML element type for XML parsers). The optional **position** parameter can be one of the following values: • *MB_FIRST_CHILD* • *MB_LAST_CHILD* • *MB_NEXT_SIBLING* • *MB_PREVIOUS_SIBLING*
MbsElement **detach**()	Detaches the current element from the tree.
void **detachAllChildren**()	Detaches all child elements of the current element.

Method	Description
string **asBitstream**(*[array $options]*)	Serializes the element tree to produce a bit stream. When using the MRM parser (and other parsers), the *options* array must be populated with the following key/value pairs: `array ('set' => '<MessageSet>', 'type' => '<MessageType>', 'format' => '<MessageFormat>', 'encoding' => '<encoding>', 'ccsid' => '<ccsid>')`
void **addElementFromBitstream**(*string $bitstream [, array $options]*)	Creates an element tree from the supplied bit stream. Without *options* supplied, the bit stream is parsed by using the parser of the current element and attached as its last child (no domain element is created in this case). If *options* is supplied, it must contain the key/value pair `'domain' => '<parserDomain>'` plus any of the additional options for the MRM parser (see **asBitstream**()). In this case, a parser element is created at the head of the new subtree and attached as the last child of the current element.

You can create elements in PHP to build subtrees. The following example shows a PHP function that generates and returns part of an output tree:

```
function transformItem($input) {
      $item = new MbsElement;
      $item->Desc = $input->Description;
      $item->Cost = $input->Price->getValue() * 1.6;
      $item->Qty = $input->Quantity;

      return $item;
   }
```

You can copy this subtree into an output message by using the following code:

```
$output_assembly->XMLNSC->doc->item = transformItem($input_sub_tree);
```

where *$input_sub_tree* is a reference to a part of the input message.

Related concepts:

"Accessing elements in the message tree from a PHPCompute node" on page 2692
Access the contents of a message, for reading or writing, by using the structure and arrangement of the elements in the tree that the parser creates from the input bit stream.

MbsElementIterator:

The MbsElementIterator implements the SPL RecursiveIterator.

The MbsElementIterator class provides the API methods shown in the following table:

Method	Description
mixed current()	Returns the current element as an MbsElementIterator object, or NULL on failure.
object getChildren()	Returns an MbsElementIterator object containing child elements of the current MbsElementIterator element.
bool hasChildren()	Returns TRUE if the current MbsElementIterator element has child elements; otherwise returns FALSE.
mixed key()	Returns the name of the current element, or FALSE on failure.
void next()	Moves the MbsElementIterator to the next element.
void rewind()	Rewinds the MbsElementIterator to the first element.
bool valid()	Checks whether the current element is valid after calls to rewind() or next(). It returns TRUE if the current element is valid; otherwise returns FALSE.

The MbsMessage class represents one of the logical trees that make up the message assembly.

"MbsMessageAssembly" on page 5319
The MbsMessageAssembly class represents the message assembly that is propagated between nodes in a message flow.

"PHPCompute node" on page 4639
Use the PHPCompute node to route and transform an incoming message, using the PHP scripting language.

MbsMessage:

The MbsMessage class represents one of the logical trees that make up the message assembly.

The MbsMessage class provides the API methods shown in the following table. The parameters in square brackets are optional:

Method	Description
Constructor([*MbsMessage $msg*])	Instantiates a new message object, which is a copy of the **msg** parameter (optional). If no parameter is supplied, a new empty message is created.
int getType()	Returns the specific type of the root element.
array xpath(*string $expression [, array $namespace]*)	Evaluates the XPath expression by using the last child of root (body element) as the context node. It returns the result as either a string, double, boolean, or a nodeset as an array of MbsElement objects. The optional **namespace** parameter is an associative array with namespace prefixes as the keys and namespace URIs as the values.

Method	Description
MbsElement getChild(*string $name [, int $occurrence]*)	Returns the first child of the root element whose name is given by the first parameter. The nth occurrence of that child can be returned by specifying the second optional parameter.
array getChildren(*[string $namespace]*)	Returns all the child elements of the root element as an array of MbsElements. If the **namespace** parameter is specified, the array contains only the child elements with that namespace URI.
MbsElement getFirstChild()	Returns the first child of the root element.
MbsElement getLastChild()	Returns the last child of the root element.
MbsElement addElement(*string $name, object $value [, string $namespace [, int $type [, int $position]]]*)	Creates an element as last child (by default) of the root element. The optional **type** parameter is the parser-specific type of the new node, which defaults to XML element type for XML parsers. The optional **position** parameter can be one of the following values: • *MB_FIRST_CHILD* • *MB_LAST_CHILD* • *MB_NEXT_SIBLING* • *MB_PREVIOUS_SIBLING*
MbsElement addDomainElement(*string $domainName*)	Creates a domain element.
void detachAllChildren()	Detaches all child elements of the root element.
string asBitstream(*[array $options]*)	Serializes the element tree to produce a bit stream. When using the MRM parser (and other parsers), the *options* array must be populated with the following key/value pairs: `array ('set' => '<MessageSet>', 'type' => '<MessageType>', 'format' => '<MessageFormat>', 'encoding' => '<encoding>', 'ccsid' => '<ccsid>')`
void addElementFromBitstream(*string $bitstream [, array $options]*)	Creates an element tree from the supplied bit stream. Without *options* supplied, the bit stream is parsed by the parser of the root element and attached as its last child (no domain element is created in this case). If *options* is supplied, it must contain the key/value pair `'domain' => '<parserDomain>'` plus any of the additional options for the MRM parser (see **asBitstream**()). In this case, a parser element is created at the head of the new subtree and attached as the last child of the root element.

The MbsBlob class supports the ESQL BLOB type.

"PHPCompute node" on page 4639
Use the PHPCompute node to route and transform an incoming message, using the PHP scripting language.

MbsMessageAssembly:

The MbsMessageAssembly class represents the message assembly that is propagated between nodes in a message flow.

The message assembly comprises four individual trees:

- Message
- LocalEnvironment
- GlobalEnvironment
- ExceptionList

If *assembly* is an instance of MbsMessageAssembly, you can access the four component trees by using the following code:

```
MbsMessage message = $assembly[MB_MESSAGE];
MbsMessage local_env = $assembly[MB_LOCAL_ENVIRONMENT];
MbsMessage global_env = $assembly[MB_GLOBAL_ENVIRONMENT];
MbsMessage ex_list = $assembly[MB_EXCEPTION_LIST];
```

The MbsMessageAssembly class provides the API methods shown in the following table. Parameters in square brackets are optional:

Method	Description
Constructor(*MbsMessageAssembly $assembly, MbsMessage $msg [, MbsMessage $local_env [, MbsMessage $exception_list]]*)	Instantiates a new message assembly object based on the specified template assembly. The message for the assembly is replaced by the message passed in on the **msg** parameter. The other logical trees can also be replaced if their associated parameter is provided. If the associated parameter is not provided, the tree from the template assembly is used.
int getType()	Returns the specific type of the root element of the message tree.
array xpath(*string $expression [, array $namespace]*)	Evaluates the XPath expression with the last child of root (body element) as the context node. It returns the result as either a string, double, boolean, or a nodeset as an array of MbsElement objects. The optional **namespace** parameter is an associative array with namespace prefixes as the keys and namespace URIs as the values.
MbsElement getChild(*string $name [, int $occurrence]*)	Returns the first child of the root element of the message tree whose name is given by the first parameter. The n^{th} occurrence of that child can be returned by specifying the second optional parameter.
array getChildren(*[string $namespace]*)	Returns all the child elements of the root element of the message tree as an array of MbsElements. If the **namespace** parameter is specified, the array contains only the child elements with that namespace URI.
MbsElement getFirstChild()	Returns the first child of the root element of the message tree.
MbsElement getLastChild()	Returns the last child of the root element of the message tree.
MbsElement addElement(*string $name, object $value [, string $namespace [, int $type [, int $position]]]*)	Creates an element as last child (by default) of the root element of the message tree. The optional **type** parameter is the parser-specific type of the new node (defaults to XML element type for XML parsers). The optional **position** parameter can be one of the following values: • *MB_FIRST_CHILD* • *MB_LAST_CHILD* • *MB_NEXT_SIBLING* • *MB_PREVIOUS_SIBLING*
MbsElement addDomainElement(*string $domainName*)	Creates a domain element.
void detachAllChildren()	Detaches all child elements of the root element of the message tree.

Method	Description
string asBitstream(*[array $options]*)	Serializes the element tree to produce a bit stream. When using the MRM parser (and other parsers), the *options* array must be populated with the following key/value pairs: `array ('set' => '<MessageSet>', 'type' => '<MessageType>', 'format' => '<MessageFormat>', 'encoding' => '<encoding>', 'ccsid' => '<ccsid>')`
void addElementFromBitstream(*string $bitstream [, array $options]*)	Creates an element tree from the supplied bit stream. Without *options* supplied, the bit stream is parsed by the parser of the root element of the message tree and attached as its last child (no domain element is created in this case). If *options* is supplied, it must contain the key/value pair `'domain' => '<parserDomain>'` plus any of the additional options for the MRM parser (see **asBitstream**()). In this case, a parser element is created at the head of the new subtree and attached as the last child of the root element of the message tree.
void propagate(*string $terminalName*)	Propagates the message assembly to the output terminal given by the parameter **terminalName**.
void routeToLabel(*string $labelName*)	Routes the message assembly to the Label node given by the parameter **labelName**.

MbsBlob:

The MbsBlob class supports the ESQL BLOB type.

The MbsBlob class provides the API methods shown in the following table:

Method	Description
Constructor(*[string $blob]*)	Instantiates a new BLOB object from the string parameter (or an empty BLOB if no parameter is supplied).
string getValue()	Returns the value of the current element.
void setValue(*[string $value]*)	Sets the value of the current element.

PHP data types:

PHP data types are supported by WebSphere Message Broker.

The following table shows the mappings between the ESQL and PHP data types:

ESQL type	PHP type
INTEGER, INT	• int - for integers in the range -2147483648 - 2147483647 • float - for integers outside the range -2147483648 - 2147483647
FLOAT	float
DECIMAL	Java BigDecimal
CHARACTER, CHAR	string
BLOB	MbsBlob
DATE	Java com.ibm.broker.plugin.MbDate
TIME, GMTIME	Java com.ibm.broker.plugin.MbTime
TIMESTAMP, GMTIMESTAMP	Java com.ibm.broker.plugin.MbTimestamp
INTERVAL	Not supported
BOOLEAN	Boolean
REFERENCE	MbsElement

Some of the PHP types are mapped onto Java data types; for example, BigDecimal and MbTimestamp. You can manipulate these values by using the Java bridge. For more information, see “Calling Java from PHP” on page 2716.

No 64-bit integer type exists in PHP, therefore large values are represented as a float. You can use the Java bridge to manipulate Java types. The INTERVAL ESQL type is not represented in the Java API for the broker.

PHP processes the values stored in a string data type as single-byte strings. However, PHP has a multibyte string extension that enables the manipulation of multibyte strings in a PHP string variable. This PHP extension is included with the PHPCompute node.

For more information about PHP extensions, see the PHP: Hypertext Preprocessor website.

The following multibyte functions are provided with the PHPCompute node:

Function	Description
mb_convert_encoding	Converts the character encoding of a string.
mb_decode_mimeheader	Decodes the encoded string in a MIME header.
mb_encode_mimeheader	Encodes a string with MIME header encoding.
mb_ereg	Runs the regular expression match with multibyte support.
mb_ereg_replace	Replaces the regular expression with multibyte support.
mb_internal_encoding	Sets or gets the internal character encoding.
mb_regex_encoding	Returns the current encoding for a multibyte regex as a string.

Function	Description
mb_regex_set_options	Sets the default options (specified by the **options** parameter) for multibyte regex functions.
mb_split	Splits a multibyte string and returns the result as an array.
mb_stripos	Finds the position of the first occurrence of a string within another. This function is not case sensitive.
mb_stristr	Finds the first occurrence of a string within another. This function is not case sensitive.
mb_strlen	Gets the length of a string.
mb_strpos	Finds the position of the first occurrence of a string in a string.
mb_strrchr	Finds the last occurrence of a character in a string within another string.
mb_strrichr	Finds the last occurrence of a character in a string within another string. This function is not case sensitive.
mb_strripos	Finds the position of the last occurrence of a string within another string. This function is not case sensitive.
mb_strrpos	Finds the position of the last occurrence of a string within a string.
mb_strstr	Finds the first occurrence of a string within another.
mb_strtolower	Makes a string lowercase.
mb_strtoupper	Makes a string uppercase.
mb_substitute_character	Sets or gets a substitution character.
mb_substr	Gets part of a string.
mb_substr_count	Counts the number of substring occurrences.

"PHP API" on page 5313
The WebSphere Message Broker PHP API provides classes to represent the message, the message assembly, and the element tree.

"PHP data types" on page 5323
PHP data types are supported by WebSphere Message Broker.

Differences between WebSphere Message Broker PHP and PHP.net:

Some differences exist between PHP.net and the implementation of PHP that is provided by WebSphere Message Broker.

The differences for each function are shown in the following tables.

Table 270. MySQL functions

Function	Differences
mysql_fetch_field	Checks for a distinction between types that are returned from TINYTEXT and VARCHAR. One is a blob, the other is a string. This implementation returns both as VARCHAR, therefore it is not possible to distinguish between them. The call returns the maximum length that is defined in the database, not the maximum length that is used. For example, (`VARCHAR[50] xyz = abc`) gives *3* on PHP.net, and *50* on WebSphere Message Broker PHP.

Table 271. String functions

Function	Differences
crypt	Not available on Windows.
html_entity_decode	Results in a warning if the specified character set hint is not equal to UTF8.
htmlentities	Results in a warning if the specified character set hint is not equal to UTF8.
htmlspecialchars	Results in a warning if the specified character set hint is not equal to UTF8.

Table 272. Session handling functions

Function	Differences
Session handling functions	The INI option support session.use_trans_sid is not supported.

Table 273. File system functions

Function	Differences
All file system functions	Safe mode is not supported.
clearstatcache	No statcache exists, therefore this function has no effect.
flock	You cannot use flock(, LOCK_EX) to obtain an exclusive lock on a file that is opened as read-only, unless you also have write permissions for the file; this does not mean that you must open the file in write mode, just that you have permission to do so. If you do not have write permissions and False is returned indicating that no lock has been obtained, a warning is generated.
fopen	The PHP.net runtime issues a "No such file or directory" message when an invalid mode is used within fopen, whereas WebSphere Message Broker PHP issues a message saying that it is an invalid mode.
fseek	When you use fopen and file modes with the "t" option under Windows (Windows translation), fseek does not operate in the same way as the runtime PHP.net runtime.

Table 273. File system functions (continued)

Function	Differences
realpath	The realpath() function does not detect changes to file names that were previously symbolic links because of the canonical file name cache in Java. To replicate the behavior in PHP, you can start the JVM with `Dsun.io.useCanonCaches=false`

Table 274. BCMath Arbitrary Precision Mathematics functions

Function	Differences
All BCMath Arbitrary Precision Mathematics functions	WebSphere Message Broker PHP raises an E_WARNING, whereas PHP.net writes a warning to STDERR.
bcmul	WebSphere Message Broker PHP does not truncate trailing zeros.
bcpow	WebSphere Message Broker PHP does not truncate trailing zeros.
bcpowmod	WebSphere Message Broker PHP does not support trailing zeros when a scale other than 0 is used.

Table 275. Network functions

Function	Differences
fsockopen	The errno output argument is not supported. The errstr argument is not supported. Encrypted streams (SSL and TLS) are not available.

Table 276. Array functions

Function	Differences
All array functions	When sorting array entries that have equal weight under the sorting algorithm in use, the resulting sorted array might have entries in a different order to that produced by the sorting algorithms used by PHP.net. For example, a SORT_NUMERIC sort of the values "a","b","c".

Table 277. Multibyte string functions

Function	Differences
All multibyte string functions	If you specify the correct encoding for character data and if the character data is correct, the mb_* functions operate in the same way as MBString. No guarantee exists that the output is the same as MBString if the character data is not valid or if you do not specify the correct encoding. For example, mb_substr, if you pass in str and define it as UTF-32 when it is really ASCII or UTF-8, you do not get the same result as PHP.net.

Table 277. Multibyte string functions (continued)

Function	Differences
mb_convert_encoding	Does not support an array or string containing multiple encodings, or *auto* being passed as the from_encoding value. A PHP warning is generated in these cases.

Table 278. Program execution functions

Function	Differences
All program execution functions	WebSphere Message Broker PHP does not support Safe mode.
proc_open	WebSphere Message Broker PHP does not support the additional options that are specified by the optional sixth parameter.
proc_terminate	WebSphere Message Broker PHP does not support the sending of signals to the child process, as specified by the optional second parameter.
proc_get_status	This function is not supported by WebSphere Message Broker PHP.

Table 279. Error handling and logging functions

Function	Differences
error_log	Does not support message_type of 1 (email). A warning is issued and function returns *false*.

Table 280. Stream functions

Function	Differences
stream_get_meta_data	The unread bytes field (used buffer size) in return is not always the same for file streams, because the file stream implementation does not use buffers.
stream_context_create	Support for stream contexts is limited; the HTTP stream type supports only header, method, timeout, and content options.

"PHP API" on page 5313
The WebSphere Message Broker PHP API provides classes to represent the message, the message assembly, and the element tree.

"PHP data types" on page 5323
PHP data types are supported by WebSphere Message Broker.

PHP constants for type values:

You can use type values to create syntax elements in your message tree.

The following tables detail PHP constants for type variables and their corresponding XMLNSC constants:
- "Common field types"
- "XMLNSC field types"
- "JSON field types" on page 5344

Common field types

Use the following common field type constants to create syntax elements in the message tree.

Construct	PHP Field Type constant	Field Type constant
A name element	MB_TYPE_NAME	Name
A name value element	MB_TYPE_NAME_VALUE	NameValue
A value element	MB_TYPE_VALUE	Value

XMLNSC field types

Use the following XMLNSC field type constants to create syntax elements in the message tree.

Construct	PHP Field Type constant	Field Type constant
Simple element	MB_XMLNSC_FIELD MB_XMLNSC_CDATA_FIELD	XMLNSC.Field XMLNSC.CDataField
Attribute	MB_XMLNSC_SINGLE_ATTRIBUTE MB_XMLNSC_ATTRIBUTE	XMLNSC.SingleAttribute XMLNSC.Attribute
Mixed content	MB_XMLNSC_VALUE MB_XMLNSC_CDATA_VALUE	XMLNSC.Value XMLNSC.CDataValue
Namespace declaration	MB_XMLNSC_NAMESPACE_DECL	XMLNSC.NamespaceDecl
Complex element	MB_XMLNSC_FOLDER	XMLNSC.Folder
Inline DTD	MB_XMLNSC_DOCUMENT_TYPE	XMLNSC.DocumentType
XML declaration	MB_XMLNSC_XML_DECLARATION	XMLNSC.XmlDeclaration
Entity reference	MB_XMLNSC_ENTITY_REFERENCE	XMLNSC.EntityReference
Entity definition	MB_XMLNSC_SINGLE_ENTITY MB_XMLNSC_ENTITY	XMLNSC.SingleEntityDefinition XMLNSC.EntityDefinition

Construct	PHP Field Type constant	Field Type constant
Comment	MB_XMLNSC_COMMENT	XMLNSC.Comment
Processing instruction	MB_XMLNSC_PROCESSING_INSTRUCTION	XMLNSC.ProcessingInstruction
BLOB type element to be written directly to the bit stream	MB_XMLNSC_BITSTREAM	XMLNSC.BitStream

JSON field types

Use the following JSON field type constants to create syntax elements in the message tree.

Construct	PHP Field Type constant	Field Type constant
JSON array	MB_JSON_ARRAY	JSON.ARRAY

Use the Broker Archive editor to create and manage broker archive (BAR) files.

User-defined patterns

View the reference information in this section to modify user-defined patterns by using the Java API and the PHP API. Use these APIs to write code that modifies a pattern instance when a pattern instance is generated by a pattern user.

APIs

To find information about APIs, see the following topics:

- "Java API for user-defined patterns" on page 5345
- "PHP API for user-defined patterns" on page 5345

Related concepts:

"Patterns" on page 1310
A *pattern* is a reusable solution that encapsulates a tested approach to solving a common architecture, design, or deployment task in a particular context.

"User-defined patterns" on page 1334
A *user-defined pattern* extends the function of WebSphere Message Broker so that you are able to create patterns that you can reuse within your organization.

"Modifying pattern instances by using Java or PHP" on page 1364
Use Java or PHP code to modify pattern instances when the pattern user generates an instance of a user-defined pattern. For example, you can use Java or PHP code to modify the structure of a message flow based on the values of pattern parameters.

Related tasks:

"Extending a user-defined pattern" on page 1340
Extend a user-defined pattern to customize its behavior so that it is easier to use or to provide guidance to pattern users.

Java API for user-defined patterns

Use the Java API to write Java code to modify user-defined pattern instances.

To view the Javadoc for the Java API, see Java API.

For the Java user-defined node API, which applies to user-defined nodes and to Java code that is called by JavaCompute nodes, see Java user-defined extensions API.

Related concepts:

"Modifying pattern instances by using Java or PHP" on page 1364
Use Java or PHP code to modify pattern instances when the pattern user generates an instance of a user-defined pattern. For example, you can use Java or PHP code to modify the structure of a message flow based on the values of pattern parameters.

PHP API for user-defined patterns

Use the PHP API to write PHP code to develop user-defined pattern applications.

PHP API

For information about the mb_pattern_run_template function, see "mb_pattern_run_template."

For information about the variables available in the _MB superglobal, see "_MB superglobal variables" on page 5347.

For information about the PHP extensions supported by WebSphere Message Broker, see "PHP extensions" on page 5348.

Related concepts:

"Patterns" on page 1310
A *pattern* is a reusable solution that encapsulates a tested approach to solving a common architecture, design, or deployment task in a particular context.

"User-defined patterns" on page 1334
A *user-defined pattern* extends the function of WebSphere Message Broker so that you are able to create patterns that you can reuse within your organization.

"Modifying pattern instances by using Java or PHP" on page 1364
Use Java or PHP code to modify pattern instances when the pattern user generates an instance of a user-defined pattern. For example, you can use Java or PHP code to modify the structure of a message flow based on the values of pattern parameters.

Related tasks:

"Extending a user-defined pattern" on page 1340
Extend a user-defined pattern to customize its behavior so that it is easier to use or to provide guidance to pattern users.

mb_pattern_run_template:

Use the mb_pattern_run_template function to run a PHP script from within another script in user-defined patterns.

The following example shows how the mb_pattern_run_template function is called:

```
mb_pattern_run_template(string $project_name, string template_path, string
$output_path);
```

The arguments taken by mb_pattern_run_template are shown in the following table.

Argument	Description
project_name	The name of the pattern instance project to which the output from the template is written. You can include the pattern instance name if you are not using an exemplar project.For example, if the pattern includes an exemplar project called *project1*, and the pattern user creates an instance called *instance1*, the *project_name* is *project1* (although the actual project name created is *instance1_project1*). However, if the pattern is not an exemplar project, you can specify the prefix for that project: *instance1_project1*.
template_path	The relative path from this PHP script to the template PHP script that you want to run. For example, if the template script is called `example.esql.php` and it is in the same directory, *template_path* is `example.esql.php`. If the template script is in a subdirectory, `testdirectory`, of the directory where the current script is located, *template_path* is `testdirectory/example.esql.php`.
output_path	The relative path in the project to where the output from the template script is written. This path is relative to the root directory of the pattern instance project specified by *project_name*. The path must exist. For example, if the output file is called `example.esql` and is written to the root directory of the pattern instance project, *output_path* is `example.esql`. If the file is written to a subdirectory, `outputdirectory`, of the pattern instance project, *output_path* is `outputdirectory/example.esql`

Related tasks:

"Modifying pattern instances by using PHP" on page 1389
Add PHP code to a code plug-in project to modify a pattern instance when the pattern instance is generated by a pattern user.

"Examples of PHP API code" on page 1390
Use the following examples of PHP API code for common tasks to help you write your own PHP code to modify pattern instances.

"Testing PHP API code" on page 1394
After writing PHP code to modify pattern instances, test the code to check that it works correctly.

Related reference:

"_MB superglobal variables"
The PHP API for user-defined patterns contains four variables within the _MB superglobal. You can use these variables in PHP scripts that are used to modify instances of user-defined patterns.

"PHP extensions" on page 5348
WebSphere Message Broker supports a set of PHP extensions.

"Differences between WebSphere Message Broker PHP and PHP.net" on page 5363
Some differences exist between PHP.net and the implementation of PHP that is provided by WebSphere Message Broker.

_MB superglobal variables:

The PHP API for user-defined patterns contains four variables within the _MB superglobal. You can use these variables in PHP scripts that are used to modify instances of user-defined patterns.

The _MB superglobal for the PHP API for user-defined patterns contains the variables shown in the following table.

Variable	Description

PATTERN_INSTANCE_MANAGER	Includes methods to log messages and get access to message flows. For more information about the methods available in PATTERN_INSTANCE_MANAGER, see "Java API for user-defined patterns" on page 5345. The following example shows you how to access PATTERN_INSTANCE_MANAGER methods:
	`<?php`
	`  $pim = $_MB["PATTERN_INSTANCE_MANAGER"];`
	`  $flow = $pim->getMessageFlow("Transform", "mqsi/Tra`
	`  $node = $flow->getNodeByName("MQInput");`
	`?>`

PP	Returns an array that is populated with the pattern parameters. The following example shows you how to print the value of the parameter *pp2*:
	`<?php`
	`  var_dump($_MB['PP']['pp2']);`
	`?>`

PATTERN_INSTANCE_NAME	Returns the name of the current pattern instance that is being generated.
WORKSPACE_ROOT	Returns the full path to the current workspace location.

Related tasks:

"Modifying pattern instances by using PHP" on page 1389
Add PHP code to a code plug-in project to modify a pattern instance when the pattern instance is generated by a pattern user.

"Differences between WebSphere Message Broker PHP and PHP.net" on page 5363
Some differences exist between PHP.net and the implementation of PHP that is provided by WebSphere Message Broker.

Differences between WebSphere Message Broker PHP and PHP.net:

Some differences exist between PHP.net and the implementation of PHP that is provided by WebSphere Message Broker.

The differences for each function are shown in the following tables.

Table 281. MySQL functions

Function	Differences
mysql_fetch_field	Checks for a distinction between types that are returned from TINYTEXT and VARCHAR. One is a blob, the other is a string. This implementation returns both as VARCHAR, therefore it is not possible to distinguish between them. The call returns the maximum length that is defined in the database, not the maximum length that is used. For example, (`VARCHAR[50] xyz = abc`) gives *3* on PHP.net, and *50* on WebSphere Message Broker PHP.

Table 282. String functions

Function	Differences
crypt	Not available on Windows.
html_entity_decode	Results in a warning if the specified character set hint is not equal to UTF8.
htmlentities	Results in a warning if the specified character set hint is not equal to UTF8.
htmlspecialchars	Results in a warning if the specified character set hint is not equal to UTF8.

Table 283. Session handling functions

Function	Differences
Session handling functions	The INI option support session.use_trans_sid is not supported.

Table 284. File system functions

Function	Differences
All file system functions	Safe mode is not supported.
clearstatcache	No statcache exists, therefore this function has no effect.
flock	You cannot use flock(, LOCK_EX) to obtain an exclusive lock on a file that is opened as read-only, unless you also have write permissions for the file; this does not mean that you must open the file in write mode, just that you have permission to do so. If you do not have write permissions and False is returned indicating that no lock has been obtained, a warning is generated.

Table 284. File system functions (continued)

Function	Differences
fopen	The PHP.net runtime issues a "No such file or directory" message when an invalid mode is used within fopen, whereas WebSphere Message Broker PHP issues a message saying that it is an invalid mode.
fseek	When you use fopen and file modes with the "t" option under Windows (Windows translation), fseek does not operate in the same way as the runtime PHP.net runtime.
realpath	The realpath() function does not detect changes to file names that were previously symbolic links because of the canonical file name cache in Java. To replicate the behavior in PHP, you can start the JVM with `Dsun.io.useCanonCaches=false`

Table 285. BCMath Arbitrary Precision Mathematics functions

Function	Differences
All BCMath Arbitrary Precision Mathematics functions	WebSphere Message Broker PHP raises an E_WARNING, whereas PHP.net writes a warning to STDERR.
bcmul	WebSphere Message Broker PHP does not truncate trailing zeros.
bcpow	WebSphere Message Broker PHP does not truncate trailing zeros.
bcpowmod	WebSphere Message Broker PHP does not support trailing zeros when a scale other than 0 is used.

Table 286. Network functions

Function	Differences
fsockopen	The errno output argument is not supported. The errstr argument is not supported. Encrypted streams (SSL and TLS) are not available.

Table 287. Array functions

Function	Differences
All array functions	When sorting array entries that have equal weight under the sorting algorithm in use, the resulting sorted array might have entries in a different order to that produced by the sorting algorithms used by PHP.net. For example, a SORT_NUMERIC sort of the values "a","b","c".

Table 288. Multibyte string functions

Function	Differences
All multibyte string functions	If you specify the correct encoding for character data and if the character data is correct, the mb_* functions operate in the same way as MBString. No guarantee exists that the output is the same as MBString if the character data is not valid or if you do not specify the correct encoding. For example, mb_substr, if you pass in str and define it as UTF-32 when it is really ASCII or UTF-8, you do not get the same result as PHP.net.
mb_convert_encoding	Does not support an array or string containing multiple encodings, or *auto* being passed as the from_encoding value. A PHP warning is generated in these cases.

Table 289. Program execution functions

Function	Differences
All program execution functions	WebSphere Message Broker PHP does not support Safe mode.
proc_open	WebSphere Message Broker PHP does not support the additional options that are specified by the optional sixth parameter.
proc_terminate	WebSphere Message Broker PHP does not support the sending of signals to the child process, as specified by the optional second parameter.
proc_get_status	This function is not supported by WebSphere Message Broker PHP.

Table 290. Error handling and logging functions

Function	Differences
error_log	Does not support message_type of 1 (email). A warning is issued and function returns *false*.

Table 291. Stream functions

Function	Differences
stream_get_meta_data	The unread bytes field (used buffer size) in return is not always the same for file streams, because the file stream implementation does not use buffers.
stream_context_create	Support for stream contexts is limited; the HTTP stream type supports only header, method, timeout, and content options.

"Message Set Editor and Message Definition Editor preferences"
While looking at a large message set that contains a number of message definition files that have different namespaces, or multiple message definition files that have the same namespace, you might want to view the information in alternative ways to make it easier for you to visualize the structure of the message set. If you double-click the global construct, you open the message definition file in which the global construct is defined.

"Validation of the message model" on page 5369
You can customize some of the warning messages that are generated by message set validation. Use the Message Set Validation Preference page to do this.

"XML Schema Importer" on page 5370
Preferences for the message set XML Schema Importer.

"Message set properties" on page 5371
Message sets have properties that you can set to define their characteristics and the way in which they are processed.

Message Set Editor and Message Definition Editor preferences:

While looking at a large message set that contains a number of message definition files that have different namespaces, or multiple message definition files that have the same namespace, you might want to view the information in alternative ways

to make it easier for you to visualize the structure of the message set. If you double-click the global construct, you open the message definition file in which the global construct is defined.

Message set editor settings

Property	Type	Meaning
Group by namespace and then by collections	Button	Selecting this view groups the global constructs by namespace then by collection (for example, Messages, Types, Groups, or Elements and Attributes). Using this view you can visualize all of the constructs that belong to each of the defined namespaces.
Group by collections and then by namespace	Button	Selecting this view groups the global constructs by collection (for example, Messages, Types, Groups, or Elements and Attributes) then by namespace. Using this view you can visualize which global construct in the message set is defined in which namespace.

Message definition editor settings

Property	Type	Meaning
Show base complex types	Check box	Where your complex type is based on another complex type that is derived by an extension, selecting this will display the base complex type in the outline view.
Prefix for created messages	String	This property allows you to specify a prefix to precede the name of the initial complex type in the name of the created message. This prefix applies only to messages created from C or COBOL files. The default value is `msg_`. Note, however, that no prefix is applied when a message is created from a C file, and the selected preprocessing option is SAP ALE IDoc or SAP File IDoc.

Tab Extensions

Click **Tab Extensions** to display check boxes that allow you to determine what tabs are enabled for the Message Set Editor, the Message Definition Editor, and the Message Category Editor. All these check boxes are always selected and cannot be cleared.

Editor	Tab Extensions
Message Set Editor	Properties
Message Definition Editor	Overview Properties
Message Category Editor	Properties

A control is provided that allows you to choose the order in which the tab extensions for each of the editors are displayed.

"Validation of the message model"
You can customize some of the warning messages that are generated by message set validation. Use the Message Set Validation Preference page to do this.

"XML Schema Importer" on page 5370
Preferences for the message set XML Schema Importer.

Validation of the message model:

You can customize some of the warning messages that are generated by message set validation. Use the Message Set Validation Preference page to do this.

Any warning or error that falls into a category from the following list can be customized according to the relevant category. The customization can affect both severity and priority.

The severity can be one of the following values:

- Error
- Warning
- Info
- Ignore

If the severity is not *Ignore*, the priority can be one of the following values:

- High
- Normal
- Low

If the severity is *Ignore*, you cannot change the priority.

Message set validation settings

The categories that you can customize are described in the following list:

- Use of deprecated constructs
- Messages with abstract global elements
- Facet runtime validation differences
- Type/Element substitution runtime validation differences
- Mixed content runtime validation differences
- Wildcard runtime validation differences
- Unique Particle Attribution checks

- Tagged/Delimited String group content
- Zero Custom Wire Format length count
- Zero Tagged/Delimited String Format length count
- Empty Tagged/Delimited String Format tag
- List or Union with Custom Wire Format
- List or Union with Tagged/Delimited String Format
- Unbounded max occurs with Custom Wire Format
- Unbounded max occurs with Tagged/Delimited String Format

While looking at a large message set that contains a number of message definition files that have different namespaces, or multiple message definition files that have the same namespace, you might want to view the information in alternative ways to make it easier for you to visualize the structure of the message set. If you double-click the global construct, you open the message definition file in which the global construct is defined.

"XML Schema Importer"
Preferences for the message set XML Schema Importer.

XML Schema Importer:

Preferences for the message set XML Schema Importer.

You can customize the following categories that affect the way in which an XML Schema is imported into a message set that does not support namespaces.

Category	Modify	Reject	Accept
Import	Converts Import to Include	Import fails if it sees an Import	Not applicable
Redefine	Removes the Redefine statements	Import fails if it sees a Redefine	Redefine imported (gives task list error)
List	Changes type base to xsd:string	Import fails if it sees a List	List imported

Category	Modify	Reject	Accept
Union	Changes type base to xsd:string	Import fails if it sees a Union	Union imported
Abstract Complex Type	Sets abstract to false	Import fails if it sees an Abstract Complex Type	Abstract Complex Type imported
Abstract Element	Sets abstract to false	Import fails if it sees an Abstract Element	Abstract Element imported

Message set properties

Message sets have properties that you can set to define their characteristics and the way in which they are processed.

General message set properties

The following table defines the properties that you can set to customize the message set.

Property	Type	Meaning
Default message domain and Supported message domains	String and check boxes	The message parser name must match the *Message Domain* property of any input node that processes messages from the message set, or the <Msd> element value of any MQRFH2 header that precedes a message from the message set. Choose a value from the list offered for the *Default Message Domain* property, and select check boxes (from *Supported Message Domains*) to choose other domains. You can select as many of these check boxes as you want. Use the message parser name when you write ESQL field references for messages in the message set; for example, `InputRoot.MRM.Document`. The Mapping editor and the content assist feature of the ESQL editor use the message parser name when they generate ESQL field references. You can choose from the following names: • XMLNSC (the default if you select **Finish** from page two of the New Message Set wizard). Choose this domain if you want to model XML messages. You can deploy the message set to brokers if you want, because the XMLNSC parser optionally uses the message set at run time. • MRM. Choose this domain for binary or text messages. You can also use this domain for XML messages. You must deploy the message set to the brokers that receive these messages. The deploy action creates a runtime dictionary against which the MRM parser checks the received message. • SOAP. Choose this domain for SOAP Web Services. • DataObject. Choose this domain for data from WebSphere Adapters. • XMLNS. You might need to choose this domain for some kinds of XML messages. You do not have to deploy the message set to brokers, because the XMLNS parser does not use the message set at run time. • JMSMap. Choose this domain if you want to model a JMS MapMessage message. You do not have to deploy the message set to brokers, because this parser does not use the message set at run time. • JMSStream. Choose this domain if you want to model a JMS StreamMessage message. You do not have to deploy the message set to brokers, because this parser does not use the message set at run time. • MIME. Choose this domain if you want to model a MIME message. You do not have to deploy the message set to brokers, because the MIME parser does not use the message set at run time. • JSON. Choose this domain if you want to model a JSON message. You do not have to deploy the message set to brokers, because the JSON parser does not use the message set at run time. • XML. This domain is deprecated. Use the XMLNSC domain instead. • IDOC. This domain is deprecated. Use the MRM domain instead.
Use namespaces	Check box	Select this property if you want to use namespaces within the message set. Namespaces provide a method of avoiding naming conflicts where different document definitions have elements of the same name. For further information see Namespaces. By default, this check box is selected. Using namespaces affects how elements are created in the logical message tree. Each element in the message tree has both a name and a namespace, so an ESQL or Java reference to one of these elements has to specify both name and namespace. Therefore, using namespaces has an effect on the ESQL or the Java that you write. Always select this property if you want to use the message set to model XML messages.

MRM domain

Property	Type	Meaning
Default wire format	String	(Optional) Specify the default wire format used, only if you select MRM as the default message domain, or MRM is selected in the list of supported message domains. The default value is <no default specified>. If you do not select MRM, either as the default message domain or as one of the supported message domains, the Default Wire Format property is unavailable.
Message set ID	String	This property is a unique identifier that is automatically generated for you when you create the message set. You cannot change this property.
Message set alias	String	Specify an alternative unique value that identifies the message set. This property is only required if you are using the Message Identity technique to identify embedded messages. Using this technique, the embedded messages are defined in this message set but the parent message is defined in a different message set, and the bit stream does not contain the actual message set name or identifier.
Message type prefix	String	This property is used when you define multipart messages, specifically when using the Message Path technique to identify embedded messages. The value that you specify is used as an absolute or relative path to the innermost message from the outermost, and is used as a prefix to the value of the *Message Type* property that is specified for the outermost message (specified either in the MQRFH2 header of the message, or in the input node of the message flow). If you set a value, it must be in the form id1/id2/.../idnu where id1 is the identifier of the outermost message, id2 is the identifier of the next element or message, and idn is the identifier of the innermost message. The default value is blank (not set). The following table, describing the use of the message set property *Message Type Prefix*, shows how this value is combined with the *Message Type* property of an input message.
Broker will treat Length facet as MaxLength	Check box	Select this property if you want the COBOL importer to create a maxLength facet, rather than a length facet, for a fixed length string element. By default, this check box is selected.

Use of the *Message type prefix* property

The following table shows the implications of using the property *Message type prefix*. The message type or message prefix can describe either elements or messages.

Message Type property example	Message type prefix not set	Message type prefix set
Simple Message Type:`msg_type`	Results in the simple Message Type:`msg_type`	Results in the path Message Type: `/msg_prefix_1/.../msg_prefix_n/msg_type`
Path Message Type:`msg_type_1/.../msg_type_m`	Results in the path Message Type:`/msg_type_1/.../msg_type_m`	Results in the combined path Message Type: `/msg_prefix_1.../msg_prefix_n /msg_type_1/.../msg_type_m`

Message Type property example	Message type prefix not set	Message type prefix set
Simple absolute Message Type:/msg_type	Results in the simple Message Type:msg_type	Results in the simple Message Type:msg_type An error is raised if Message Type Prefix is set to any value other than msg_type.
Path absolute Message Type:/msg_type_1/.../msg_type_m	Results in the path Message Type:/msg_type_1/.../msg_type_m	Results in the path Message Type:/msg_type_1/.../msg_type_m An error is raised if all identifiers in Message Type Prefix do not match the corresponding identifiers in the resulting path.

If you are using MRM or IDOC domains, in addition to the main message set properties, you can update message set properties that are specific to each of the physical formats. The following reference topics describe these properties.

Related concepts:

"Parsers" on page 1072
A parser is a program that interprets the physical bit stream of an incoming message, and creates an internal logical representation of the message in a tree structure. The parser also regenerates a bit stream for an outgoing message from the internal message tree representation.

"XMLNSC parser" on page 1090
The XMLNSC parser is a flexible, general-purpose XML parser that offers high performance XML parsing and optional XML Schema validation.

"XMLNS parser" on page 1104
The XMLNS parser is a flexible, general-purpose XML parser.

"XML parser" on page 1110
The XML domain is very similar to the XMLNS domain, but the XML domain has no support for XML namespaces or opaque parsing.

"MRM parser and domain" on page 1111
You can use the MRM domain to parse and write a wide range of message formats.

"Which XML parser should you use?" on page 1080
If your messages are general-purpose XML documents, you can use one of the dedicated XML domains (XMLNSC or XMLNS) to parse the message, or you can use the MRM domain to parse the message.

"JMS parsers and domains" on page 1116
The JMSMap and JMSStream domains can be used for modeling messages that are produced by the implementations of the Java Messaging Service standard.

"SOAP parser and domain" on page 1082
You can use the SOAP parser to create a common WSDL-based logical tree format for working with Web services, independent of the physical bitstream format.

"Multipart messages" on page 1191
A *multipart message* contains one or more other messages within its structure. The contained message is sometimes referred to as an *embedded message*.

"Identifying an embedded message by using a Message Identity" on page 1193
You can identify an embedded message by using the Message Identity. This technique is used by the MRM domain, and replaces the use of the Message Key.

"Identifying an embedded message by using a Message Path" on page 1196
The Message Path technique for identifying embedded messages is useful when the multipart message contains no information about the identity of an embedded message.

"Message set projects" on page 1161
A *message set project* is a specialized container in which you create and maintain all the resources associated with one message set.

"Message sets overview" on page 1162
A message set is a container for grouping messages and associated message resources (elements, types, groups).

"Physical formats in the MRM domain" on page 1211
Each message definition file within a message set describes both the *logical structure* of your messages, and the *physical formats* that describe the precise appearance of your message bit stream during transmission.

"Namespaces in the message model" on page 1201
Use namespaces to qualify message model object names.

Related tasks:

"Accessing embedded messages in the MRM domain" on page 2594
If you have defined a multipart message, you have at least one message embedded within another. Within the overall complex type that represents the outer messages, you can model the inner message in two ways.

"Working with a message set project" on page 2838
Creating and deleting a message set.

"Working with a message set" on page 2840
Complete a variety of tasks that are involved in working with a message set.

Related reference:

"Custom Wire Format message set properties"
The tables define the properties that you can set for a Custom Wire Format message set.

"XML Wire Format message set properties" on page 5400
The following tables define the properties for the XML Wire Format for the message set.

"TDS Format message set properties" on page 5381
The following tables show the properties that you can set for a TDS format message set.

"Documentation properties for all message set objects" on page 5413
Use the documentation property of an object to add information that describes the function of the object.

Custom Wire Format message set properties:

The tables define the properties that you can set for a Custom Wire Format message set.

Some of the message set properties (marked with an asterisk (*)) are relevant only if the message being processed is ***not*** using WebSphere MQ as the transport protocol.

If the transport protocol is WebSphere MQ, values are derived from the message headers (for example, MQMD), and the message set properties, if set, are ignored.

Binary representation of boolean values

Property	Type	Meaning
Boolean True Value	String	Enter up to eight hexadecimal digits. Do not include the hexadecimal indicator (0x) preceding this number. Each digit is a half byte. The maximum length is 4 bytes. You must enter an even number of digits (a whole number of bytes). This value must be different from, but the same length as, the `Boolean False Value`. The default value is 00000001.
Boolean False Value	String	Enter up to eight hexadecimal digits. Do not include the hexadecimal indicator (0x) preceding this number. Each digit is a half byte. The maximum length is 4 bytes. You must enter an even number of digits (a whole number of bytes). This value must be different from, but the same length as, the `Boolean True Value`. The default value is 00000000.
Boolean Null Value	String	Enter up to eight hexadecimal digits. Do not include the hexadecimal indicator (0x) preceding this number. Each digit is a half byte. The maximum length is 4 bytes. You must enter an even number of digits (a whole number of bytes). This value can be the same as either `Boolean True Value` or `Boolean False Value`, or different. The default value is 00000000.

Output settings

Use these settings when messages are being produced.

Property	Type	Meaning
Byte Alignment Pad	String	If the xsd:element Custom Wire Format properties `Byte Alignment`, `Leading Skip Count`, and `Trailing Skip Count` cause bytes to be skipped in the bit stream when the message is serialized, this property supplies the character to be used in the skipped positions. Set this character in one of the following ways: • Select SPACE, NUL, or 0 (the default) from the list of values shown. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a decimal character code in the form YY where YY is a decimal value. • Enter a hexadecimal character code in the form 0xYY where YY is a hexadecimal value. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal format.
Policy for Missing Elements	Enumerated	This property determines the action that is taken by the broker when fields are missing from the message tree when the message is serialized (for output): • Use *Default Value* (the default). If a *Default Value* exists for the element, write it; otherwise, throw an exception. • Use *Null Value*. If the *Nillable* property of the element is selected, and an *Encoding Null Value* is specified for the element, write the *Encoding Null Value* according to the rules that are defined by the *Encoding Null* property; otherwise, throw an exception.

Property	Type	Meaning
Truncate fixed length strings	Check box	This property applies only to output strings. If this check box is selected, and the element or attribute is a fixed length string (that is, the logical type is xsd:string and the physical type is Fixed Length String) that is longer than either the length that is specified in the model or the length reference, the string is truncated to this length. No exception is raised on output, unless validation (see "Validating messages" on page 1478) is active. The end from which data is truncated is determined by the value of the *Justification* property. If the value of the *Justification* property is Left justify, data is truncated from the right; if the value of the *Justification* property is Right justify, data is truncated from the left. However, if the value of the *Justification* property is Not applicable, truncation does not occur and an exception occurs if the string is too long. If this check box is cleared, an exception occurs if the element or attribute is a fixed length string (that is, the logical type is xsd:string and the physical type is Fixed Length String) that is longer than either the length that is specified in the model, or the length reference. This behavior occurs in releases of the WebSphere Message Broker earlier than Version 6.1. By default, this check box is cleared.

Binary representation of decimal values

Property	Type	Meaning
Packed Decimal Positive Code	Enumerated	Select, from the list, the positive sign that is used for packed decimal numbers. The default value is `C`, which indicates that `0x0C` is used as the positive sign; this value is used in most systems. You can also select `F`, which indicates that `0x0F` is used as the positive sign; this value is used in some systems.

Datetime settings

Property	Type	Meaning
Derive default dateTime format from logical type	Button	Select this option if you want the default dateTime format to be determined by the logical type of the element or attribute. You can override this property for an element or attribute within a complex type.
Use default dateTime format	Button and String	Select this option if you want to specify a default dateTime format that is fixed for all elements or attributes of logical type dateTime, date, time, gYear, gYearMonth, gMonth, gMonthDay, and gDay. You can override this property for an element or attribute within a complex type. For more information, see "DateTime formats" on page 6310.
Start of century for 2-digit years	Integer	This property determines how 2-digit years are interpreted. Specify the two digits that start a 100-year window that contains the current year. For example, if you specify 89, and the current year is 2002, all 2-digit dates are interpreted as being in the range 1989 - 2088.

Property	Type	Meaning
Days in First Week of Year	Enumerated	Specify the number of days of the new year that must fall within the first week. The start of a year typically falls in the middle of a week. If the number of days in that week is less than the value specified here, the week is considered to be the last week of the previous year; therefore, week 1 starts some days into the new year. Otherwise, it is considered to be the first week of the new year; in this case, week 1 starts some days before the new year. Select Use Broker Locale, which causes the broker to get the information from the underlying platform, or select a number from the list that is displayed.
First Day Of Week	Enumerated	Specify the day on which each new week starts. Select Use Broker Locale, which causes the broker to get the information from the underlying platform, or select a value from the list that is displayed.

Property	Type	Meaning
Strict DateTime Checking	Check box	Select this option if you want to restrict dateTimes to a valid dateTime format. If `Strict DateTime Checking` is selected, receiving an incorrect dateTime causes an error. **Strict dateTime checking** Examples of strict dateTime checking are: • DateTimes are restricted to valid dateTimes only. When you use this option, a date such as the 35th March is not processed as 4th April, and 10:79 is not processed as 11:19. Receiving an out-of-band dateTime, such as these examples, causes an error to occur. • The number of characters for a numeric dateTime component must be within the bounds of the corresponding formatting symbols. Repeat the symbol to specify the minimum number of digits that you require. The maximum number of digits that is permitted becomes the upper bound for a particular symbol. For example, day in month has an upper bound of 31; therefore, a format string of 'd' allows the values 2 and 21 to be parsed, but does not allow the values 32 and 210. On output, numbers are padded with zeros to the specified length. A year is a special case; see the message set property `Start of century for 2 digit years`. For fractional seconds, the length must implicitly match the number of format symbols on input. The output is rounded to the specified length. • White space is not skipped over. The white space in the input string must correspond with the same number and position of white space in the formatting string. • If data remains that is not parsed in the input string after all the symbols in the formatting string have been matched, an error occurs. **Lenient dateTime checking** Examples of lenient dateTime checking are: • The parser converts out-of-band dateTime values to the appropriate in-band value. For example, a date of 2005-05-32 is converted to 2005-06-01. • Output of dateTimes always adheres to the symbol count. For example, a formatting string of yyyy-MM-dd (where '-' is the field separator) allows one or more characters to be parsed against MM and dd. Therefore, dates that are not valid - for example, 2005-1-123 and 2005-011-12 - can be entered. The first value of 2005-1-123 is output as the date 2005-05-03, and the second value of 2005-011-12 is output as the date 2005-11-12. • The number of the timezone formatting symbol Z is applicable only to the output dateTime format. • White space is skipped over.
Time Zone	Enumerated	The value that you set for this property is used if the value that you specified for the `Default DateTime Format` property does not include Time Zone information. The initial value is Use Broker Locale, which causes the broker to get the information from the underlying platform. You can change this property by selecting from the list of values.
Daylight Saving Time	Check box	Select this option if the area in the `Time Zone` property observes daylight saving time. If it does not observe daylight saving time, do not select this option. For example, if an area is selected in `Time Zone` and this option is not selected, the value passed represents the time zone without the daylight saving time.

Property	Type	Meaning
Use input UTC format on output	Check box	This property applies to elements and attributes of logical type xsd:dateTime or xsd:time that contain a dateTime as a string and that have a dateTime format of I, IU, T, or TU, or that include ZZZ or ZZZU. Such elements and attributes can specify Coordinated Universal Time (UTC) by using either the Z character or timezone +00:00 in the value. On input, the MRM parser remembers the way that UTC was specified. If this property is selected, and the element or attribute is copied to an output message, the UTC format is preserved into the output message and overrides the format that is implied by the dateTime format property. If this property is cleared, or if the element or attribute was not copied from an input message, the UTC format in the output message is controlled solely by the dateTime format property.

Character and numeric encoding for non-WebSphere MQ messages

Use these settings only for messages with no MQMD.

Property	Type	Meaning
Default CCSID*	Integer	Enter a numeric value for the default Coded Character Set Identifier. The default is 500. If the input message is a WebSphere MQ message, the equivalent attribute that is set for the queue manager is used, and this property is ignored.
Default Byte Order*	Enumerated	Select either Big Endian (the default) or Little Endian from the list to specify the byte order of numbers that are represented as binary integers. In C, this is equivalent to data type short or long. In COBOL, this is equivalent to a PIC 9, COMP, COMP-4, COMP-5, or BINARY data type. Your choice must match the encoding with which messages are created. Typically, Big Endian is the correct option for messages that are created on UNIX or z/OS; Little Endian is the correct option for messages that are created on Windows. Do not use this property if the message is received across the WebSphere MQ transport protocol; in this case, the property is deduced from the MQMD of the message, or from the encoding of the broker queue manager.
Default Packed Decimal Byte Order*	Enumerated	Select Big Endian (the default) or Little Endian from the displayed list to specify the byte order of numbers that are represented as packed decimal. In COBOL, this is equivalent to PIC 9 COMP-3 data type. There is no equivalent data type in C. Your choice must match the encoding with which messages are created. Typically, Big Endian is the correct option for messages that are created on UNIX or z/OS; Little Endian is the correct option for messages that are created on Windows.
Default Float Format*	Enumerated	Select one of S390 (the default), IEEE, or Reverse IEEE from the displayed list to specify the byte order of numbers in the message that are represented as floating point.

Related concepts:

"Physical formats in the MRM domain" on page 1211
Each message definition file within a message set describes both the *logical structure* of your messages, and the *physical formats* that describe the precise

appearance of your message bit stream during transmission.

"MRM Custom Wire Format" on page 1214
Custom Wire Format (CWF) is the physical representation of a message that is composed of a number of fixed-format data structures or elements, which are not separated by delimiters.

"MRM Custom wire format: Relationship to the logical model" on page 1219
Some restrictions exist in relation to the logical model for messages that are defined by using the CWF.

Related tasks:

"Working with physical formats" on page 2847
If you are using the MRM domain to parse and write your messages, when you are developing your message model you might want to add one or more physical format layers to a message set, then configure the properties of these physical formats.

Related reference:

"Message model reference information" on page 5366
Reference information in this section can help you develop and configure message models.

"Message set properties" on page 5371
Message sets have properties that you can set to define their characteristics and the way in which they are processed.

"XML Wire Format message set properties" on page 5400
The following tables define the properties for the XML Wire Format for the message set.

"TDS Format message set properties"
The following tables show the properties that you can set for a TDS format message set.

TDS Format message set properties:

The following tables show the properties that you can set for a TDS format message set.

See "Default TDS message set properties" on page 5394 for the default settings of these properties for each of the industry standards.

Messaging Standard

Property	Type	Meaning
Messaging Standard	Enumerated	Specify the standard to be used for this wire format. Select one of the following values: • User Defined Text - for text data not based on a standard • SWIFT • ACORD AL3 • EDIFACT • X12 • TLOG • HL7 • CSV - Comma Separated Values • User Defined Mixed - for mixed text and binary data If you are defining your own tagged/delimited messages, or are using a standard that is not included in the list of values shown, select either User Defined Text, if all your data is text, or User Defined Mixed, if not all your data is text. The value that you select for this property determines the default values of some of the other properties. The default is User Defined Text.

Data element separation settings

Property	Type	Meaning
Group Indicator	String	Specify the default value of a special character or string that precedes the data that belongs to a group or complex type within the bit stream.
Group Terminator	String	Specify the default value of a special character or string that terminates data that belongs to a group or a complex type within the bit stream.
Delimiter	String	Specify the default value of a special character or string that specifies the delimiter that is used between data elements. This property applies only to the delimited `Data Element Separation` methods (Tagged Delimited, All Elements Delimited, and Variable Length Elements Delimited).
Suppress Absent Element Delimiters	Enumerated	Use this property to select whether you want delimiters to be suppressed for elements that are missing within a message. Select from: • End Of Type. Use this option to suppress the delimiter when an element is missing. For example, if the model has been defined to have up to three elements and only two are present, the last delimiter can be omitted from the message. • Never. Use this option to ensure that even if optional elements are not present, all delimiters are written out. This option must be used when the same delimiter is used to delimit parent objects and child objects. For example, if an optional child element is missing and all the delimiters are the same, message processing applications cannot tell where the child elements in a message ends and where the next parent element starts.

Property	Type	Meaning
Tag Data Separator	String	Specify the default value of a special character or string that separates the tag from the data. If you set the property `Tag Data Separator`, the `Length of Tag` property is ignored. This property applies only to the tagged `Data Element Separation` methods (Tagged Delimited, Tagged Fixed Length, and Tagged Encoded Length).
Length of Tag	Integer	Specify the default length of a tag value. When the message is parsed, this property allows tags to be extracted from the bit stream. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, the `Length of Tag` property is ignored. This property applies only to the tagged `Data Element Separation` methods (Tagged Delimited, Tagged Fixed Length, and Tagged Encoded Length).

Note: Any value that you set for a group or complex type property overrides the value that you set for the corresponding message set property.

Character data settings

Property	Type	Meaning
Default CCSID	Integer	CCSID (Coded Character Set Identification) specifies the mapping between character codes and symbols. You must specify a code set that is supported by WebSphere Message Broker. This property stores the default CCSID for the message bit stream, but this value can be overridden when the message is processed (for example, by the CCSID in the header of a WebSphere MQ input message).

Property	Type	Meaning
Trim on input	Enumerated	This property applies only to elements and attributes with a physical type of Text. This property specifies whether a simple element or attribute value is to be trimmed when it is parsed. The property does not apply to a simple element, or attribute, with a logical type of Boolean or Binary. All trimming is applied to element or attribute values before the conversion of the value to its logical type. This property does not apply when writing elements or attributes. This property only applies to a simple element, or attribute, that is contained within a complex type or group that has the `Justification` property set to Left Justify or Right Justify, and that satisfies one of the following conditions: • The `Data Element Separation` property is set to Fixed Length, Fixed Length AL3, Tagged Fixed Length, Use Data Pattern, or Tagged Encoded Length. • The `Data Element Separation` property is set to Variable Length Elements Delimited, and the element or attribute has a value set for its model length or length reference. • The `Data Element Separation` property is set to Tagged Delimited or All Elements Delimited, and the `Observe Element Length` property is set. The element or attribute has a model length or length reference value set. This property can be set to one of the following values: • No Trim. No characters are trimmed from the element or attribute value. • Leading White Spaces. White space characters are trimmed from the left of the element or attribute value. • Trailing White Spaces. White space characters are trimmed from the right of the element or attribute value. • Trim Both. White space characters are trimmed from both the left and the right of the element or attribute value. • Trim Padding Chars. Padding characters are trimmed from the element or attribute value. The padding character is set by the `Padding Character` property of the element or attribute. If the `Justification` property of the element or attribute is set to Left Justify, the padding characters are trimmed from the right. If the `Justification` property of the element or attribute is set to Right Justify, the padding characters are trimmed from the left. If the `Justification` property of the element or attribute is set to Not Applicable, no trimming takes place. White space characters include control characters that are in the range from U+0000 to U+001f and from U+007f to U+009f. You might need to use this property if you have data input that is mapped to a numeric simple type. For example, if the input data has leading spaces, you can set this property to Leading White Spaces to avoid data conversion problems when you process these fields.

Property	Type	Meaning
Truncate on output	Check box	This property applies only to output strings that have a physical type of Text. The property applies to elements or attributes that have a logical type of xsd:string and that are contained within a structure with a `Data Element Separation` of Fixed Length, Fixed Length AL3, Tagged Fixed Length, Use Data Pattern, or Variable Length Elements Delimited where a length has been specified. If this check box is selected, and the element or attribute has a length that is longer than the length that is specified in the model or the length reference, the string is truncated to this length. No exception is raised on output, unless validation (see "Validating messages" on page 1478) is active. The end from which data is truncated is determined by the value of the Justification property. If the value of the Justification property is Left justify, data is truncated from the right; if the value of the Justification property is Right justify, data is truncated from the left. However, if the value of the Justification property is Not applicable, truncation does not occur and an exception occurs if the string is too long. If this check box is cleared, an exception occurs if the element or attribute is a fixed length string (that is, the physical type is Text and a length has been specified) that is longer than either the length that is specified in the model or the length reference. This behavior occurs in releases of the WebSphere Message Broker earlier than Version 6.1.
Escape Character	Button and String	Specify the escape character that is used to allow special reserved characters (such as delimiters) to be included as part of data. You must specify a single character only, or a mnemonic that represents a single character. Escape characters apply only in variable length fields. Escape characters, on parsing, always escape the next character, and are always removed. Escape characters, on writing, are inserted in front of all the characters that are listed in `Reserved Characters`. You can specify either an escape character or a quote character, but not both, for a given message set.
Quote Character	Button and String	Specify the quote character that is used to allow special reserved characters (such as delimiters) to be included as part of data. You must specify a single character only, or a mnemonic that represents a single character. Quote characters apply only to variable length fields. Quote characters, on parsing, must be present at both the start and the end of the data, and are always removed. Quote characters, on writing, are added to both the start and end of the data, if the data contains any character that is listed in the `Reserved Characters` property. You can specify either an `Escape Character` or a `Quote Character`, but not both, for a given message set.

Property	Type	Meaning
Reserved Characters	String	Specify any special reserved characters. Either these reserve characters must be preceded by the `Escape Character`, or the data field that contains them must be delimited by a pair of `Quote Characters`, if they are to be included as part of the data. The `Escape Character`, `Quote Character`, delimiters, and group indicators must be included in this list. If the set of reserved characters is to be updated dynamically (in the case of EDIFACT and X12 when reserved characters, such as delimiters, are specified in service strings), you must use the supplied mnemonics to specify characters in this list. If you have specified `Reserved Characters`, an `Escape Character` or a `Quote Character` must also be specified. Reserved characters apply only in variable length fields. Reserved characters are not used when parsing.

Numeric settings

Property	Type	Meaning
Decimal Point	String	Specify the character that is used to separate the whole part of a number from its fraction.
Packed decimal positive code	String	Controls the positive sign that is used for packed decimal fields. Valid values are `C` or `F`.Specify the character that is used to separate the whole part of a number from its fraction.
Strict Numeric Checking	Check box	Use this property in conjunction with the `Messaging Standard` property, the `Virtual Decimal Point` property and the `Precision` property of an element. Using this property allows you to apply stricter rules for the checking of numbers. The rules for `Strict Numeric Checking` are: • If the `Precision` property of an element is set to All Significant Digits , a decimal separator is present only if the value has a fractional part. • If the `Precision` property of an element is set to Explicit Decimal Point, the decimal separator must always be present, even if the fractional part is missing. • If the `Precision` property of an element is set to Exponential Notation, the incoming value must be in exponential notation. Exponential notation is only allowed for floating numbers. • If the `Precision` property of an element is set to a specific value, the specific number of digits after the decimal separator must be present. • All values must contain at least one digit in the integer part of the number. • If a `Virtual Decimal Point` of an element has been set, the number must not have a decimal point. • Except for EDIFACT, the decimal separator can be only the specified value, and '.' is not permitted. For EDIFACT, both '.' and the specified separator are permitted. In this case, the decimal separator must be specified as ',' and the code permits '.' to be used. • Except for exponential functions, only digits 0-9, the decimal separator, the positive sign, and the negative sign are permitted. For exponential functions the characters 'e' and 'E' are also permitted. Padding characters are permitted only if they are in a position to be stripped from the number.

Property	Type	Meaning
Derive sign from logical type	Check box	If this property is selected, an unset TDS `Signed` property attempts to derive its value from the simple type of the element (integer and decimal simple logical types only). For these logical types it applies only to the Integer, External Decimal, and Packed Decimal physical types.
Default byte order	Enumerated	Controls the byte order of numbers that are represented as binary integers for messages with no MQMD. Valid values are Big Endian or Little Endian. This property stores the default byte order for numbers that are represented as binary integers for messages with no MQMD, but this value can be overridden when the message is processed.
Default packed decimal byte order	Enumerated	Controls the byte order of numbers that are represented as packed decimal for messages with no MQMD. Valid values are Big Endian or Little Endian. This property stores the default byte order of numbers that are represented as packed decimal for messages with no MQMD, but this value can be overridden when the message is processed.
Default float format	Enumerated	Controls the format of numbers that are represented as float for messages with no MQMD. Valid values are S390, IEEE, or Reverse IEEE. This property stores the default format of numbers that are represented as float for messages with no MQMD, but this value can be overridden when the message is processed.

Representation of boolean values

Property	Type	Meaning
Text boolean true value	String	Specifies the character that represents the text Boolean true value.
Text boolean false value	String	Specifies the character that represents the text Boolean false value.
Text boolean null value	String	Specifies the character that represents the text Boolean null value.
Binary boolean true value	String	Specifies a hexadecimal value that represents the binary Boolean true value.
Binary boolean false value	String	Specifies a hexadecimal value that represents the binary Boolean false value.
Binary boolean null value	String	Specifies a hexadecimal value that represents the binary Boolean null value.

Datetime settings

Property	Type	Meaning
Derive default dateTime format from logical type	Button	Select this option if you want the default dateTime format to be determined by the logical type of the element or attribute. You can override this property for an element or attribute within a complex type.

Property	Type	Meaning
Use default dateTime format	Button and String	Select this option if you want to specify a default dateTime format that is fixed for all elements or attributes of logical type dateTime, date, time, gYear, gYearMonth, gMonth, gMonthDay, and gDay. You can override this property for an element or attribute within a complex type. For more information, see "DateTime formats" on page 6310.
Start of century for 2-digit years	Integer	This property determines how 2-digit years are interpreted. Specify the two digits that start a 100-year window that contains the current year. For example, if you specify 89, and the current year is 2002, all 2-digit dates are interpreted as being in the range 1989 - 2088.
Days in First Week of Year	Enumerated	Specify the number of days of the new year that must fall within the first week. The start of a year typically falls in the middle of a week. If the number of days in that week is less than the value specified here, the week is considered to be the last week of the previous year; therefore, week 1 starts some days into the new year. Otherwise, it is considered to be the first week of the new year; in this case, week 1 starts some days before the new year. Select Use Broker Locale, which causes the broker to get the information from the underlying platform, or select a number from the list that is displayed.
First Day Of Week	Enumerated	Specify the day on which each new week starts. Select Use Broker Locale, which causes the broker to get the information from the underlying platform, or select a value from the list that is displayed.

Property	Type	Meaning
Strict DateTime Checking	Check box	Select this option if you want to restrict dateTimes to a valid dateTime format. If `Strict DateTime Checking` is selected, receiving an incorrect dateTime causes an error. **Strict dateTime checking** Examples of strict dateTime checking are: • DateTimes are restricted to valid dateTimes only. When you use this option, a date such as the 35th March is not processed as 4th April, and 10:79 is not processed as 11:19. Receiving an out-of-band dateTime, such as these examples, causes an error to occur. • The number of characters for a numeric dateTime component must be within the bounds of the corresponding formatting symbols. Repeat the symbol to specify the minimum number of digits that you require. The maximum number of digits that is permitted becomes the upper bound for a particular symbol. For example, day in month has an upper bound of 31; therefore, a format string of 'd' allows the values 2 and 21 to be parsed, but does not allow the values 32 and 210. On output, numbers are padded with zeros to the specified length. A year is a special case; see the message set property `Start of century for 2 digit years`. For fractional seconds, the length must implicitly match the number of format symbols on input. The output is rounded to the specified length. • White space is not skipped over. The white space in the input string must correspond with the same number and position of white space in the formatting string. • If data remains that is not parsed in the input string after all the symbols in the formatting string have been matched, an error occurs. **Lenient dateTime checking** Examples of lenient dateTime checking are: • The parser converts out-of-band dateTime values to the appropriate in-band value. For example, a date of 2005-05-32 is converted to 2005-06-01. • Output of dateTimes always adheres to the symbol count. For example, a formatting string of yyyy-MM-dd (where '-' is the field separator) allows one or more characters to be parsed against MM and dd. Therefore, dates that are not valid - for example, 2005-1-123 and 2005-011-12 - can be entered. The first value of 2005-1-123 is output as the date 2005-05-03, and the second value of 2005-011-12 is output as the date 2005-11-12. • The number of the timezone formatting symbol Z is applicable only to the output dateTime format. • White space is skipped over.
Time Zone	Enumerated	The value that you set for this property is used if the value that you specified for the `Default DateTime Format` property does not include Time Zone information. The initial value is Use Broker Locale, which causes the broker to get the information from the underlying platform. You can change this property by selecting from the list of values.
Daylight Saving Time	Check box	Select this option if the area in the `Time Zone` property observes daylight saving time. If it does not observe daylight saving time, do not select this option. For example, if an area is selected in `Time Zone` and this option is not selected, the value passed represents the time zone without the daylight saving time.

Property	Type	Meaning
Use input UTC format on output	Check box	This property applies to elements and attributes of logical type xsd:dateTime or xsd:time that have a dateTime format of I, IU, T, or TU, or that include ZZZ or ZZZU. Such elements and attributes can specify Coordinated Universal Time (UTC) by using either the Z character or timezone +00:00 in the value. On input, the MRM parser remembers the way that UTC was specified. If this property is selected, and the element or attribute is copied to an output message, the UTC format is preserved into the output message and overrides the format that is implied by the dateTime format property. If this property is cleared, or the element or attribute was not copied from an input message, the UTC format in the output message is controlled solely by the dateTime format property.

General settings

Property	Type	Meaning
Output policy for missing elements	Enumerated	Controls whether the default value or null value is used on output for missing elements. Valid values are UseDefaultValue or UseNullValue.
Derive default length from logical type	Check box	If this property is selected, an unset TDS `Length` property attempts to derive its default value from the simple type of the element (string, binary, integer, and decimal simple logical types only). For these logical types, it applies only to the Binary, Text, Integer, External Decimal, and Packed Decimal physical types.

Use the documentation property of an object to add information that describes the function of the object.

TDS Mnemonics:

The Tagged/Delimited String Format (TDS) uses mnemonics for a number of properties for a message set, complex type, or both.

These TDS mnemonics and their associated properties are listed in the following table.

Mnemonic string	Meaning	Default value	Associated property
<EDIFACT_CS>	Component separator in EDIFACT	:	Message set and complex type or group, `Delimiter`
<EDIFACT_DEC_NOTATION>	Decimal notation in EDIFACT	.	Message set, `Decimal Point`
<EDIFACT_DS>	Data element separator in EDIFACT	+	Message set and complex type or group, `Delimiter`
<EDIFACT_ESC_CHAR>	Escape character in EDIFACT	?	Message set, `Escape Character`
<EDIFACT_GROUP_TERM>	Tag terminator in EDIFACT	'	Message set, `Group Terminator`
<EDIFACT_TAGDATA_SEP>	Tag data separator in EDIFACT This is overridden with the same value as that which overrides <EDIFACT_DS>	+	Message set and complex type or group, `Tag Data Separator`
<HL7_CS>	Component separator in HL7	^	Message set and complex type or group, `Delimiter`
<HL7_FS>	Data element separator in HL7	|	Message set and complex type or group, `Delimiter`
<HL7_RS>	Repeating element delimiter in HL7	~	Local element and element reference, `Repeating Element Delimiter`
<HL7_SCS>	Sub-component separator in HL7	&	Message set and complex type or group, `Delimiter`
<X12_CS>	Component separator for X12	:	Message set and complex type or group, `Delimiter`
<X12_DS>	Data element separator for X12	*	Message set and complex type or group, `Delimiter`

Mnemonic string	Meaning	Default value	Associated property
<X12_ERS>	Element repetition separator for X12	{	Local element and element reference, `Repeating Element Delimiter`
<X12_GROUP_TERM>	Tag terminator in X12	!	Message set level, `Group Terminator`

Mnemonics for control characters are shown in the following table.

Mnemonic	Hex value	Unicode	Description
<ACK>	X'06'	<U+0006>	Acknowledge
<BEL>	X'07'	<U+0007>	Bell
<BS>	X'08'	<U+0008>	Backspace
<CAN>	X'18'	<U+0018>	Cancel
<CR>	X'0D'	<U+000D>	Carriage Return
<DC1>	X'11'	<U+0011>	Device Control One
<DC2>	X'12'	<U+0012>	Device Control Two
<DC3>	X'13'	<U+0013>	Device Control Three
<DC4>	X'14'	<U+0014>	Device Control Four
<DLE>	X'10'	<U+0010>	Data Link Escape
<EM>	X'19'	<U+0019>	End of Medium
<ENQ>	X'05'	<U+0005>	Inquiry
<EOT>	X'04'	<U+0004>	End of Transmission
<ESC>	X'1B'	<U+001B>	Escape
<ETB>	X'17'	<U+0017>	End of Transmission Block
<ETX>	X'03'	<U+0003>	End of Text
<FF>	X'0C'	<U+000C>	Form Feed
<FS>	X'1C'	<U+001C>	File Separator
<GS>	X'1D'	<U+001D>	Group Separator
<GT>	X'3E'	<U+003E>	Greater Than
<HT>	X'09'	<U+0009>	Horizontal Tabulation
<LF>	X'0A'	<U+000A>	Line Feed
<LT>	X'3C'	<U+003C>	Less Than
<NAK>	X'15'	<U+0015>	Negative Acknowledge
<NUL>	X'00'	<U+0000>	Null-
<RS>	X'1E'	<U+001E>	Record Separator
<SI>	X'0F'	<U+000F>	Locking Shift Zero (Shift In)
<SO>	X'0E'	<U+000E>	Locking Shift One (Shift Out)
<SOH>	X'01'	<U+0001>	Start of Heading
<SP>	X'20'	<U+0020>	Space
<STX>	X'02'	<U+0002>	Start of Text
<SUB>	X'1A'	<U+001A>	Substitute

Mnemonic	Hex value	Unicode	Description
<SYN>	X'16'	<U+0016>	Synchronous Idle
<US>	X'1F'	<U+001F>	Unit Separator
<VT>	X'0B'	<U+000B>	Vertical Tabulation

These mnemonics were created for characters that cannot be entered into the message editor.

You can enter a mnemonic in the form `<U+NNNN>`, where `NNNN` are hexadecimal digits. None of the characters in this structure are case-sensitive. Do not enclose spaces inside the angle brackets. These numbers represent a Unicode character, not a character in the code page of the input message.

You can enter a mnemonic in the form `<0xNN>`, where `NN` are hexadecimal digits. None of the characters in this structure are case-sensitive. Do not enclose spaces inside the angle brackets. These numbers represent a raw hexadecimal byte value, not a character in the code page of the input message.

If a mnemonic is of the form `<0xNN>`, it is applied directly to the input data, and no code page conversion takes place. Otherwise, a mnemonic is applied to the data after the data has been converted into Unicode from the code page of the input data.

The following tables show the properties that you can set for a TDS format message set.

"TDS Mnemonics" on page 5391
The Tagged/Delimited String Format (TDS) uses mnemonics for a number of properties for a message set, complex type, or both.

XML Wire Format message set properties:

The following tables define the properties for the XML Wire Format for the message set.

Namespace settings

Property	Type	Meaning
Namespace URI	String	Enter the name of the namespace that you are using for the associated prefix.
Prefix	String	Enter the prefix to associate the element and attribute names that you use it with to the namespace name.

Namespace schema locations

Property	Type	Meaning
Namespace URI	String	Enter the namespace name that identifies which namespace you are using.
Schema location	String	Enter the location of the schema for the associated namespace name that is used to validate objects within the namespace.

XML declaration

Property	Type	Meaning
Suppress XML Declaration	Check box	Select the check box to suppress the XML declaration. If selected, the declaration (for example, `<?xml version='1.0'>`) is suppressed. By default, the check box is cleared.
XML Version	Enumerated type	This controls the value of the version in the generated XML declaration. The default is 1.0. If you set `Suppress XML Declaration` to Yes, this property is ignored.

Property	Type	Meaning
XML Encoding	Enumerated type	This controls whether an encoding attribute is written in the generated XML declaration. If Null is selected, no encoding attribute is written in the XML declaration of the output XML document. If As document text is selected, an encoding attribute is generated that is consistent with the text in the XML document. The default is Null. If the `Suppress XML Declaration` check box is selected, this property is ignored.
Standalone Document	Enumerated type	Select `Yes`, `No`, or `Null` from the list of values. If you select `Null`, no standalone declaration is present in the XML declaration. If you select `Yes` or `No`, the declaration `standalone = "yes"` or `standalone = "no"` is added to the XML declaration when the output message is written. The default value is `Null`. The setting of this property does not determine whether an external DTD subset is loaded; external DTD subsets are never loaded in this release. If the `Suppress XML Declaration` check box is selected, this property is ignored.
Output Namespace Declaration	Enumerated type	The *`Output Namespace Declaration`* property controls where the namespace declarations are placed in the output XML document. Select from: • `At start of document`. Declarations for all of the entries in the *`Namespace schema locations`* table above are output as attributes of the message in the output XML document. The disadvantage of this option is that, in some cases, unnecessary declarations might be output. • `As required`. Declarations are output only when required by an element or attribute that is in that namespace. The disadvantage of this option is that the same namespace declaration might need to be output more than once in the output XML document. The default option is `At start of document`. This property is active only if namespaces are enabled for this message set.

XML document type settings

Property	Type	Meaning
Suppress DOCTYPE	Check box	If you select the check box, the DOCTYPE (DTD) declaration is suppressed. By default, the check box is selected.
DOCTYPE System ID	String	Specify the System ID for DOCTYPE external DTD subset (if DOCTYPE is present). This is typically set to the name of the generated (or imported) DTD for a message set. If *`Suppress DOCTYPE`* is set, this property is ignored and cannot be changed (the field is disabled). The default value is `www.mrmnames.net/`, followed by the message set identifier.
DOCTYPE Public ID	String	Specify the Public ID for DOCTYPE external DTD subset (if DOCTYPE is present, and System ID is specified). If *`Suppress DOCTYPE`* is set, this property is ignored and cannot be changed (the field is disabled). The default value is the message set identifier.

Property	Type	Meaning
DOCTYPE Text	String	Use this property to add additional DTD declarations. It is not parsed by the XML parser and, therefore, it might not be valid XML. You can include ENTITY definitions or internal DTD declarations. It is a string (up to 32 KB) in which new line and tab characters are replaced by `\n` and `\t` respectively. The content is *not* parsed, and appears in the output message. If there is an in-line DTD, the content of this property takes precedence. If you have set *`Suppress DOCTYPE`*, this property is ignored and cannot be changed (the field is disabled). For more information, see "MRM XML: In-line DTDs and the DOCTYPE text property" on page 5407. The default value is empty (not set).

XML representation of Boolean values

Property	Type	Meaning
Boolean True Value	String	Specify the string that is used to encode and recognize BOOLEAN true values. When an XML document is parsed, the string `1` is always accepted as true for a BOOLEAN element. Enter a string of up to 254 characters. The default is `true`. `1` is also valid.
Boolean False Value	String	Specify the string that is used to encode and recognize BOOLEAN false values. When an XML document is parsed, the string `0` is always accepted as false for a BOOLEAN element. Enter a string of up to 254 characters. The default is `false`. `0` is also valid.

XML representation of null values

Property	Type	Meaning
Encoding Numeric Null	Enumerated type	Specify the null encoding for numeric XML elements. This provides a method of assigning a logical null meaning to such elements. You must select one of the following values from the list shown: • `NULLEmpty`. If the element value is the empty string, the element is null. This is the default value. • `NULLValue`. If the element value matches that provided by associated property *`Encoding Numeric Null Value`*, the element is null. • `NULLXMLSchema`. If the element contains an *`xsi:nil`* attribute that evaluates to true, the element is null. • `NULLValueAttribute`. This option is valid only for elements that have XML Wire Format property *`Render`* set to either `XMLElementAttrVal` or `XMLElementAttrIDVal`. See "XML Null handling options" on page 6258 for details. • `NULLAttribute` (deprecated). If the element contains an attribute with a name that matches that provided by associated property *`Encoding Numeric Null Value`*, and the attribute evaluates to true, the element is null. • `NULLElement` (deprecated). If the element contains a child element with a name that matches that provided by associated property *`Encoding Numeric Null Value`*, the element is null. See "XML Null handling options" on page 6258 for full details.

Property	Type	Meaning
Encoding Numeric Null Value	String	Specify the value to qualify the *Encoding Numeric Null* property, if you have set that to NULLValue, NULLAttribute, or NULLElement. Refer to "XML Null handling options" on page 6258 for further information.
Encoding Non-Numeric Null	Enumerated type	Specify the null encoding for non-numeric XML elements. This provides a method of assigning a logical null meaning to such elements. The options are identical to those available for property *Encoding Numeric Null*.
Encoding Non-Numeric Null Value	String	Specify the value to qualify the *Encoding Non-Numeric Null* property. Refer to "XML Null handling options" on page 6258 for further information.

DateTime settings

Property	Type	Meaning
Derive default dateTime format from logical type	Button	Select this option if you want the default dateTime format to be determined by the logical type of the element or attribute. You can override this property for an element or attribute within a complex type.
Use default dateTime format	Button and String	Select this option if you want to specify a default dateTime format that is fixed for all elements or attributes of logical type dateTime, date, time, gYear, gYearMonth, gMonth, gMonthDay, and gDay. You can override this property for an element or attribute within a complex type. For more information, see "DateTime formats" on page 6310.
Start of century for 2-digit years	Integer	This property determines how 2-digit years are interpreted. Specify the two digits that start a 100-year window that contains the current year. For example, if you specify 89, and the current year is 2002, all 2-digit dates are interpreted as being in the range 1989 - 2088.
Days in First Week of Year	Enumerated	Specify the number of days of the new year that must fall within the first week. The start of a year typically falls in the middle of a week. If the number of days in that week is less than the value specified here, the week is considered to be the last week of the previous year; therefore, week 1 starts some days into the new year. Otherwise, it is considered to be the first week of the new year; in this case, week 1 starts some days before the new year. Select Use Broker Locale, which causes the broker to get the information from the underlying platform, or select a number from the list that is displayed.
First Day Of Week	Enumerated	Specify the day on which each new week starts. Select Use Broker Locale, which causes the broker to get the information from the underlying platform, or select a value from the list that is displayed.

Property	Type	Meaning
Strict DateTime Checking	Check box	Select this option if you want to restrict dateTimes to a valid dateTime format. If `Strict DateTime Checking` is selected, receiving an incorrect dateTime causes an error. **Strict dateTime checking** Examples of strict dateTime checking are: • DateTimes are restricted to valid dateTimes only. When you use this option, a date such as the 35th March is not processed as 4th April, and 10:79 is not processed as 11:19. Receiving an out-of-band dateTime, such as these examples, causes an error to occur. • The number of characters for a numeric dateTime component must be within the bounds of the corresponding formatting symbols. Repeat the symbol to specify the minimum number of digits that you require. The maximum number of digits that is permitted becomes the upper bound for a particular symbol. For example, day in month has an upper bound of 31; therefore, a format string of 'd' allows the values 2 and 21 to be parsed, but does not allow the values 32 and 210. On output, numbers are padded with zeros to the specified length. A year is a special case; see the message set property `Start of century for 2 digit years`. For fractional seconds, the length must implicitly match the number of format symbols on input. The output is rounded to the specified length. • White space is not skipped over. The white space in the input string must correspond with the same number and position of white space in the formatting string. • If data remains that is not parsed in the input string after all the symbols in the formatting string have been matched, an error occurs. **Lenient dateTime checking** Examples of lenient dateTime checking are: • The parser converts out-of-band dateTime values to the appropriate in-band value. For example, a date of 2005-05-32 is converted to 2005-06-01. • Output of dateTimes always adheres to the symbol count. For example, a formatting string of yyyy-MM-dd (where '-' is the field separator) allows one or more characters to be parsed against MM and dd. Therefore, dates that are not valid - for example, 2005-1-123 and 2005-011-12 - can be entered. The first value of 2005-1-123 is output as the date 2005-05-03, and the second value of 2005-011-12 is output as the date 2005-11-12. • The number of the timezone formatting symbol Z is applicable only to the output dateTime format. • White space is skipped over.
Time Zone	Enumerated	The value that you set for this property is used if the value that you specified for the `Default DateTime Format` property does not include Time Zone information. The initial value is Use Broker Locale, which causes the broker to get the information from the underlying platform. You can change this property by selecting from the list of values.
Daylight Saving Time	Check box	Select this option if the area in the `Time Zone` property observes daylight saving time. If it does not observe daylight saving time, do not select this option. For example, if an area is selected in `Time Zone` and this option is not selected, the value passed represents the time zone without the daylight saving time.

Property	Type	Meaning
Use input UTC format on output	Check box	This property applies to elements and attributes of logical type xsd:dateTime or xsd:time that have a dateTime format of I, IU, T, or TU, or that include ZZZ or ZZZU. Such elements and attributes can specify Coordinated Universal Time (UTC) by using either the Z character or timezone +00:00 in the value. On input, the MRM parser remembers the way that UTC was specified. If this property is selected, and the element or attribute is copied to an output message, the UTC format is preserved into the output message and overrides the format that is implied by the dateTime format property. If this property is cleared, or the element or attribute was not copied from an input message, the UTC format in the output message is controlled solely by the dateTime format property.

xsi:type settings

Property	Type	Meaning
Output policy for xsi:type attributes	Enumerated type	When writing XML documents, use this property to specify the circumstances under which the xsi:type attribute of elements is produced as output. **Never** Do not produce xsi:type attributes for elements, even if xsi:type attributes appear in the message tree. **When present** Produce xsi:type attributes for elements only when xsi:type attributes appear in the message tree. This value is the default value. **Always (Simple elements only)** Ensure that all simple elements are produced with an xsi:type attribute. If a simple element already has an xsi:type attribute in the message tree, it is used; otherwise, an xsi:type attribute is generated by using the rules in the following table. **Always (All elements)** Ensure that all elements are produced with an xsi:type attribute if possible to do so. If an element already has an xsi:type attribute in the message tree, it is used; otherwise, an xsi:type attribute is generated by using the rules in the following table. **Follow SOAP Encoding rules** Follow the same behavior as for Always (Simple elements only). Additionally, produce a SOAP encoding-style attribute in the root tag of all messages.

If an xsi:type attribute needs to be produced as output, but does not appear in the message tree, the value is generated as described in the following table.

Element type	Value generated when element is defined in model	Value generated when element is self-defining
Simple type	If the type is global or is a built-in type, use it. If the type is local, use the global or built-in type from which it is derived.	Use the built-in type which best matches the data type of the element in the message tree.

Element type	Value generated when element is defined in model	Value generated when element is self-defining
Complex type with simple content	If the type is global use it. If the type is local, use the global or built-in type from which it is derived.	Use the built-in type which best matches the data type of the element in the message tree.
Complex type with complex content	If the type is global use it. If the type is local, no xsi:type attribute is produced.	No xsi:type attribute is produced.

Deprecated

Note: The following properties are used to control behavior of the MRM parser; they should not be changed from their default settings. These properties will be withdrawn in a future release.

Property	Type	Meaning
Root Tag Name	String	Specify the name of the message set root tag. You can leave this property blank, in which case no wrapper tags are used for messages (that is, the message tag is the root of the document). The name can be followed by a space and additional text for attribute/value pairs to appear with the root tag. The default value is blank.
Suppress Timestamp Comment	Check box	If selected, the timestamp comment string in the XML output is suppressed. If not selected, the comment is *not* suppressed, and a comment of the form `<!--MRM Generated XML Output on: Tue Apr 23 09:34:42 2002-->` is included in the output message. The default is for the check box to be selected.
Enable Versioning Support	Check box	If this is selected, versioning support is enabled. This property specifies whether XML namespace definitions are coded for the root tag in the message, together with namespace qualifiers for any elements that do not belong to the default namespace. These namespace definitions are used to represent the message set dependency information, which is used to support the exchange of messages between applications that are based on different customizations of the same message set. The default is for the check box to be selected, for compatibility with MRM XML messages in earlier releases. If you did *not* use MRM XML messages in earlier releases, you should ensure that this check box is not selected.

The tables define the properties that you can set for a Custom Wire Format message set.

"MRM XML: In-line DTDs and the DOCTYPE text property"
You can include in-line DTDs in your messages, and you can specify additional information by setting the property *DOCTYPE Text*. The parser takes certain actions when constructing an output message.

"TDS Format message set properties" on page 5381
The following tables show the properties that you can set for a TDS format message set.

"Documentation properties for all message set objects" on page 5413
Use the documentation property of an object to add information that describes the function of the object.

MRM XML: In-line DTDs and the DOCTYPE text property:

You can include in-line DTDs in your messages, and you can specify additional information by setting the property *DOCTYPE Text*. The parser takes certain actions when constructing an output message.

1. If the output message has to be regenerated, for example if you configure a Compute node to create an output message by coding ESQL statements like `SET OutputRoot.MRM.Field1 = xxx`:
   - If you have set the property *Suppress DOCTYPE* for the message set in which you have defined this message to `Yes`, both DOCTYPE information (specified in the *DOCTYPE Text* property for the message set or message) and in-line DTD are excluded from the output message.
   - If you have set the property *Suppress DOCTYPE* for the message set in which you have defined this message to `No`.
     - The in-line DTD is preserved if possible.
     - Otherwise, if the message is self-defining, the message set *DOCTYPE Text* property information is included in the output message.
     - Otherwise (the message is *not* self-defining), the message level *DOCTYPE Text* property information is included in the output message.
2. If the output message does not have to be regenerated, the parser generates an output message that is a direct copy of the input message. This occurs if you have configured a Compute node in the message flow to copy the message using `SET OutputRoot = InputRoot` (explicitly, or by checking the *Copy entire message* check box), and you do not modify the message in any way in this or

any other node. In this case the in-line DTD is retained in the output message but any information that you specify in the *DOCTYPE Text* property for the message set or message is not included.

"XML Wire Format message set properties" on page 5400
The following tables define the properties for the XML Wire Format for the message set.

Documentation properties for a message set:

Use the documentation property of a message set to add information that enhances the understanding of the function of the message set.

Property	Type	Meaning
Version	String	Use this field to enter a version for the message set. The version of the message set is then displayed in the Eclipse properties view. You can set a default value for this field in the message set preferences.
Documentation	String	You use the documentation property of a message set to add information that enhances the understanding of the function of the message set. This field requires a string value ; you can use any standard alphanumeric characters. You can also use this field to define a keyword and its value that is displayed for the deployed message set in the properties view of Eclipse. An example is: `$MQSI Author=Fred MQSI$` When the properties of the deployed message set are displayed, a row is added to the display showing "Author" as the property name and "Fred" as its value.

Message definition file properties

The properties of a message definition file.

Namespace

Property	Type	Meaning
Prefix	String	The namespace prefix for the target namespace of this file. This field cannot be changed after the message definition file has been created.
Target Namespace	String	The target namespace for the message definition file. All global objects created within the file will have this namespace by default. This field cannot be changed after the message definition file has been created.

Default namespaces for local objects

Property	Type	Meaning
Elements	String	The default namespace for all local elements within this message definition file.
Attributes	String	The default namespace for all local attributes within this message definition file.

Property	Type	Meaning
Default block	String and Enumerated type	The default value for the block attribute for all complex types and elements within this message definition file.

Property	Type	Meaning
Default final	String and Enumerated type	The default value for the final attribute for all complex types and elements within this message definition file.

Property	Type	Meaning
Use xml.xsd schema	Check box	Select this check box if you need to use the xml.xsd schema. When you select this check box, the http://www.w3.org/2001/xml.xsd schema is imported and you can use any of the constructs in that schema.

Note: The full text that describes this check box is *Use http://www.w3.org/2001/xml.xsd schema*.

Message category properties

A message category provides a way of grouping your messages.

The following table describes the properties that are associated with a message category:

Property	Type	Meaning
Category Kind	Enumerated type	This property describes the purpose of the message category. Choose from the following values: • `wsdl`. This value is the default. Choose this value if the message category is to participate in the generation of WSDL documents. When the WSDL document is generated, the name of the message category provides the name for the <wsdl:operation> element that is generated for eligible messages in the message category. **Note:** Message categories are no longer necessary for the generation of WSDL documents; they were necessary in Version 6.0. • `other`. This value ndicates that the category represents a generic grouping of messages as an aid to organizing them in your workspace.

Property	Type	Meaning
Category Usage	Enumerated type	Use this property to describe the operation type for a WSDL operation. Choose from the following values: • `wsdl:request-response`. This is the default if Category Kind is `wsdl`. • `wsdl:solicit-response`. • `wsdl:one-way`. • `wsdl:notification`. • `empty string`. This is the default if Category Kind is `other`.
Documentation	String	Use this property to add information to enhance the understanding of an object's function. This property is a string field; any standard alphanumeric characters can be used. If Category Kind is `wsdl`, the value of the field is included in any generated WSDL as the wsdl:documentation child of the operation element in the WSDL portType. If Category Kind is `other`, the value of the field merely documents the Message Category within your workspace.

"Message category member properties"
This describes the properties that are associated with a message category member.

Message category member properties:

This describes the properties that are associated with a message category member.

Property	Type	Meaning
Role Name	String	If Category Kind is wsdl, the value of the property becomes the WSDL message part name and must be unique within the category. It always defaults to the message name. If Category Kind is other, the value of the property has no particular significance.

Property	Type	Meaning
Role Type	Enumerated type	This property determines the role that the message plays in the message category. Select from: • `wsdl:input` • `wsdl:output` • `wsdl:return` • `wsdl:fault` • `empty string` If Category Kind is wsdl, the default value is wsdl:input. This property dictates the role within a WSDL operation. The value wsdl:return implies wsdl:output, but for rpc-style WSDL generation it also identifies the message part that is used as the return value and in this instance can be omitted from the parameterOrder attribute. No more than one message can have Role Type of wsdl:return. If Category Kind is other, the value defaults to an empty string and this property has no role in the message category.
Role Usage	Enumerated type	This property determines the role that the message plays in the SOAP binding. Select from: • `soap:body` • `soap:header` • `soap:fault` • `soap:headerfault` • `empty string` If Category Kind is wsdl, this property defaults to soap:body and dictates the SOAP-binding child of the WSDL input, output, or fault element. If Category Kind is other, this property is deactivated.
Documentation	String	This is a string property; any standard alphanumeric characters can be used. If Category Kind is wsdl, the value of the property is included in any generated WSDL as the wsdl:documentation child of the WSDL input, output, or fault element under the WSDL portType. If Category Kind is other, the value merely documents the Message Category within your workspace.

"Message category properties" on page 5413
A message category provides a way of grouping your messages.

Message model object properties

Access property information by property kind, or by object.

There are two ways of accessing the reference information for the properties of message model objects. The following topics allow you to access the property information by property kind:

- "Logical properties for message model objects"
- "Physical properties for message model objects" on page 5455
- "Documentation properties for all message set objects" on page 5413

Alternatively, you can access the property information by object, starting from:

- "Message model object properties by object" on page 5536

Deprecated objects are dealt with separately. For further information, see "Deprecated message model object properties" on page 6069

Attribute reference logical properties:

The logical properties of an attribute reference.

Property	Type	Meaning
Reference Name	Enumerated type	The `Reference Name` is the name of the object that this object is referring to. The objects available to reference can be selected from the list.

Property	Type	Meaning
Usage	Enumerated type	Use this property with the `Value` property found in an attribute object. The default value for the `Usage` property is optional. Select from the following options: • optional. – If the `Value` property is set to default, and no data has been entered in the `Value` property, the attribute can appear once and can have any value. – If the `Value` property is set to default, the attribute can appear once. If it does not appear, its value is the data that has been entered in the `Value` property. If it does appear, it is the value given. – Where the `Value` property is set to fixed, the attribute can appear once. If it does appear, its value must match the data that has been entered in the `Value` property. If it does not appear, its value is the data that has been entered in the `Value` property. • prohibited. The attribute must not appear. • required. – If the `Value` property is set to default, and no data has been entered in the `Value` property, the attribute must appear once and can have any value. – If the `Value` property is set to fixed, the attribute must appear once, and it must match the data that has been entered in the `Value` property.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Complex type logical properties:

The logical properties of a complex type include properties that describe content and substitution settings.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.
Base Type	Enumerated type	You can use this property to select a type (simple or complex) that is used as the starting point to define a new complex type that is derived by restriction or extension.
Derived By	Enumerated type	If this property is active, select one of the following options: • restriction. If a complex type is derived by restriction, the content model of the complex type is a subset of the base type. • extension. If the complex type is derived by extension, the content model of the complex type is the content model of the base type plus the content model specified in the type derivation. Derivation by list or union is not supported.

Content

The following table shows the valid settings for `Composition` and `Content Validation`. These properties are located on the group which defines the content of this type. They can be edited only if the `Local group` button is selected. If the `Global group` button is selected, these properties are taken from the global group identified by the `Group name` field.

Valid children in a complex type that depend on both `Composition` and `Content Validation` are shown in "MRM content validation" on page 5422.

Property	Type	Meaning
Local Group	Button	Select this property if the content of your complex type is a local group.

Property	Type	Meaning
Composition	Enumerated type	Define the order, and the number of occurrences, of the elements and groups in your messages. Composition does not affect the attributes in a complex type. Select one of the following options: • Empty • sequence. If you select this option, you can define members that are elements or groups. These members, if present, must appear in the specified order in the message. They can repeat, and the same element or group can appear more than once. • choice. If you select this option, you can define members that are elements or groups. Exactly one of the defined members must be present in the message, and can repeat. Use this option if you want to model C unions and COBOL REDEFINES in a Custom Wire Format, or an XML DTD element that uses choice in an XML Wire Format, or a SWIFT field that has more than one option. • all. If you select this option, you can define members that are elements; groups are not allowed. The elements in an all group can appear in any order. Each element can appear once, or not at all. An all group can be used only at the top level of a complex type; it cannot be a member of another group within a type. • unorderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements can appear in any order in the message. • orderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements must appear in the specified order in the message. • message. This option is supported only by the MRM domain.If you select this option, you can define only messages as members. Each member can repeat, but the same message cannot appear twice in the list of members. Like choice, only one of the defined members can be present in a message. Unlike choice, when writing a message, if the complex type or group has more than one member, the bit stream is not padded to the length of the longest member. Use this option to model multipart messages, which are used in some industry standards; for example, SWIFT. For more information, see the section on multipart messages in “Multipart messages” on page 1191.

Property	Type	Meaning
Content Validation	Enumerated type	`Content Validation` is used only by the MRM domain. If validation is enabled in your message flow, `Content Validation` specifies the strictness of the MRM validation for members of a complex type or group. See "MRM content validation" on page 5422 for further details. Select from the following options: • Closed. The complex type can only contain the child elements that you have added to it. • Open Defined. The complex type can contain any valid element defined within the message set. • Open. The complex type can contain any valid element, not just those that you have added to this complex type. See "Combinations of Composition and Content Validation" on page 5612 for further details of these options.
Group Reference	Button	Select this option if the content of your complex type is a reference to a group object
Group Name	Enumerated type	The `Group Name` is the name of the group that this complex type refers to. The groups available to be referenced can be selected from the drop down list.
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`.
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences.
Mixed	Check box	Select this option when the complex type has mixed content, and contains character data and sub-elements.

Substitution settings

Property	Type	Meaning
Final	Multiple selection enumerated type	The final attribute on a complex type controls whether other types can be derived from it. Valid values are extension/restriction/all. You can select from one or more of the following: • Empty • `restriction`. Prohibit type substitution by elements whose types are restrictions of the head element's type. • `extension`. Prohibit type substitution by elements whose types are extensions of the head element's type. • `#all`. Prohibit substitution by any method. To select more than one, you must type the selection into the property field.

Property	Type	Meaning
Block	Multiple selection enumerated type	The block attribute on a complex type restricts the types of substitutions which are allowed for elements based on that type. In the WebSphere Message Broker its effect is the same as if the block attribute were copied from the complex type onto every element based on the complex type. You can select from one or more of the following: • Empty • `restriction`. Prohibit type substitution by elements whose types are restrictions of the head element's type. • `extension`. Prohibit type substitution by elements whose types are extensions of the head element's type. • `#all`. Prohibit substitution by any method. To select more than one, you must type the selection into the property field.
Abstract	Check box	If selected, no elements based on this type can appear in the message.

"Logical properties for message model objects" on page 5416
Logical property information is available for certain objects.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

MRM content validation:

`Content Validation` is applied when the domain is MRM and validation is enabled. The `Content Validation` property specifies how strictly the MRM parser validates the members of a complex type or group.

The first of the following two tables shows the valid settings for `Content Validation` if `Composition` is set to `Message`. The second table shows the valid settings for `Content Validation` if `Composition` is not set to `Message`.

Content Validation options if Composition is set to Message

Option	Meaning
Open	When a message is parsed, this complex type or group can contain any message, not just those that you have defined in this message set. You can use this option for sparse messages (see "Self-defining elements and messages" on page 1198 for a definition of sparse messages).
Closed	When a message is parsed, this complex type or group can only contain the messages that are members of this complex type or group. This is always the case for messages represented in CWF format.
Open Defined	When a message is parsed, this complex type or group can contain any message defined within the message set.

Content Validation options if Composition is not set to Message

Option	Meaning
Open	When a message is parsed, this complex type or group can contain any elements and not just those that you have defined in this message set (see "Self-defining elements and messages" on page 1198 for a definition of sparse messages).
Closed	When a message is parsed, this complex type or group can only contain the elements that are members of this complex type or group.
Open Defined	When a message is parsed, this complex type or group can contain any element that you have defined within the message set.

When you are using `Content Validation` set to `open` or `open defined`, you cannot specify the precise position where the content that is not modeled is permitted to occur. If you want to do this, you should consider using a wildcard element as an alternative. Wildcard elements can appear only within a complex type or group with `Composition` of `sequence` and `Content Validation` of `closed`.

Related concepts:

"The message model" on page 1160
The message model consists of the following components.

Related tasks:

"Complex type logical properties" on page 5419
The logical properties of a complex type include properties that describe content and substitution settings.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Element reference logical properties:

The logical properties of an element reference include properties that specify the number of occurrences of the element reference.

Property	Type	Meaning
Reference Name	Enumerated type	The `Reference Name` is the name of the object that this object is referring to. The objects available to reference can be selected from the list.

Occurrences

Property	Type	Meaning
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`.

Property	Type	Meaning
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences.

The Min Occurs and Max Occurs properties are used in conjunction with an element's Value properties. The following table summarizes how an element reference can be constrained.

Min Occurs	Max Occurs	Fixed	Default	Notes
1	1			The element must appear once, and can have any value.
1	1	Delta		The element must appear once, and it must match the data that has been entered in the `Value` property. In this example, the element must contain the text Delta.
2	-1	Delta		The element must appear twice or more, and it must match the data that has been entered in the `Value` property. In this example, at least two elements must contain the text Delta.
0	1			The element is optional, can appear once, and can have any value.
0	1	Delta		The element is optional, and can appear once. If it does appear, its value must match the data that has been entered in the `Value` property. If it does not appear, its value is the data that has been entered in the `Value` property.
0	1		Delta	The element is optional, and can appear once. If it does not appear, its value is the data that has been entered in the `Value` property. If it does appear, it must be the value given in the element.
0	2		Delta	The element is optional and can appear once, twice, or not at all. If the element does not appear, it is not provided. If the element appears and it is empty, it set to the data held in the `Value` property, else it is the value given in the element.
0	0			The element is prohibited, and must not appear.

Related concepts:

"The message model" on page 1160

Logical property information is available for certain objects.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Global attribute logical properties:

The logical properties of a global attribute.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Type	Enumerated type	The Type property constrains the type of data that can be present in the object. Select from the following options: • `int` • `string` • `Boolean` • `hexBinary` • `dateTime` • `date` • `time` • `decimal` • `float` • `(More...)` • `(New Simple Type)` • `(New Complex Type)` If you select (More...), the Type Selection wizard starts. In this wizard, you can select any of the available types. If you select (New Simple Type), the New Simple Type wizard starts. In this wizard, you can create an Anonymous simple type that is based on an existing type. This type can be created locally or globally. If you select (New Complex Type), the New Complex Type wizard starts. In this wizard, you can create an Anonymous complex type, which can be derived from an existing base type. This type can be created locally or globally. For further information about these types, and examples of their use, see the XML Schema Part 0: Primer. This document is available on the World Wide Web Consortium (W3C) Web site.
Namespace	Enumerated type	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. If <no target namespace> is displayed, a namespace has not been set for this object. If the property is inactive, the message set has not been configured to support namespaces. Where the property is active, namespaces that are available for selection are displayed in the drop-down list.

Value

The *Value* properties are used with the *Usage* property in an Attribute Reference or a Local Attribute.

Property	Type	Meaning
Default	Button and String	This property provides the default value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, default values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if they have default values. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the default value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for default values **Other domains** No support for default values.
Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.

Property	Type	Meaning
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

The logical properties of a global element.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • `-` the hyphen • `_` the underscore • `.` the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.
Type	Enumerated type	The Type property constrains the type of data that can be present in the object. Select from the following options: • `int` • `string` • `Boolean` • `hexBinary` • `dateTime` • `date` • `time` • `decimal` • `float` • `(More...)` • `(New Simple Type)` • `(New Complex Type)` If you select (More...), the Type Selection wizard starts. In this wizard, you can select any of the available types. If you select (New Simple Type), the New Simple Type wizard starts. In this wizard, you can create an Anonymous simple type that is based on an existing type. This type can be created locally or globally. If you select (New Complex Type), the New Complex Type wizard starts. In this wizard, you can create an Anonymous complex type, which can be derived from an existing base type. This type can be created locally or globally. For further information about these types, and examples of their use, see the XML Schema Part 0: Primer. This document is available on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Namespace	Enumerated type	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. If <no target namespace> is displayed, a namespace has not been set for this object. If the property is inactive, the message set has not been configured to support namespaces. Where the property is active, namespaces that are available for selection are displayed in the drop-down list.

Value

Property	Type	Meaning
Default	Button and String	This property provides the default value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, default values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if they have default values. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the default value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for default values **Other domains** No support for default values.

Property	Type	Meaning
Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.
Nillable	Check box	Select this option if you want the element to be able to be defined as null. A null value is distinct from being empty, when the element contains no data.
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

Substitution settings

Substitution Groups provide a means by which one element may be substituted for another in a message. The element which can be substituted is called the 'head' element, and the substitution group is the list of elements that may be used in its place. An element can be in at most one substitution group.

Property	Type	Meaning
Final	Enumerated type	Limit the set of elements that can belong to its substitution group. • Empty • restriction. Prohibit element substitution by elements whose types are restrictions of the type of the head element. • extension. Prohibit element substitution by elements whose types are extensions of the type of the head element. • #all. Prohibit substitution by all methods.
Block	Enumerated type	Limit the set of elements that can be substituted for this element in a message. • Empty • restriction. Prohibit element substitution by elements whose types are restrictions of the type of the head element • extension. Prohibit element substitution by elements whose types are extensions of the type of the head element • substitution. Prohibit element substitution by members of the element's substitution group. • #all. Prohibit substitution by all methods.
Substitution Group	Enumerated type	Specify the name of a 'head' element. Setting this property indicates that this element is a member of the substitution group for the head element.
Abstract	Check box	Select this option if you do not want the element to appear in the message, but require one of the members of its substitution group to appear in its place.

The following objects have properties that can be viewed or set.

Global group logical properties:

The logical properties of a global group.

Valid children in a global group that depend on both **Composition** and **Content Validation** are shown in "MRM content validation" on page 5422.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Composition	Enumerated type	Define the order, and the number of occurrences, of the elements and groups in your messages. Composition does not affect the attributes in a complex type. Select from the following options: • Empty • sequence. If you select this option, you can define members that are elements or groups. These members, if present, must appear in the specified order in the message. They can repeat, and the same element or group can appear more than once. • choice. If you select this option, you can define members that are elements or groups. Exactly one of the defined members must be present in the message, and can repeat. Use this option if you want to model C unions and COBOL REDEFINES in a Custom Wire Format, or an XML DTD element that uses choice in an XML Wire Format, or a SWIFT field that has more than one option. • all. If you select this option, you can define members that are elements; groups are not allowed. The elements in an all group can appear in any order. Each element can appear once, or not at all. An all group can be used only at the top level of a complex type; it cannot be a member of another group within a type. • unorderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements can appear in any order in the message. • orderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements must appear in the specified order in the message. • message. This option is supported only by the MRM domain. If you select this option, you can define only messages as members. Each member can repeat, but the same message cannot appear twice in the list of members. Like choice, only one of the defined members can be present in a message. Unlike choice, when writing a message, if the complex type or group has more than one member, the bit stream is not padded to the length of the longest member. Use this option to model multipart messages, which are used in some industry standards; for example, SWIFT. For more information, see the section on multipart messages in “Multipart messages” on page 1191.

Property	Type	Meaning
Content Validation	Enumerated type	`Content Validation` is used only by the MRM domain. If validation is enabled in your message flow, `Content Validation` specifies the strictness of the MRM validation for members of a complex type or group. See "MRM content validation" on page 5422 for further details. Select from the following options: • Closed. The complex type can only contain the child elements that you have added to it. • Open Defined. The complex type can contain any valid element defined within the message set. • Open. The complex type can contain any valid element, not just those that you have added to this complex type. See "Combinations of Composition and Content Validation" on page 5612 for further details of these options.

The following objects have properties that can be viewed or set.

Group reference logical properties:

The logical properties of a group reference include properties that specify the number of occurrences of the group reference.

Property	Type	Meaning
Reference Name	Enumerated type	The `Reference Name` is the name of the object that this object is referring to. The objects available to reference can be selected from the list.

Occurrence properties

Property	Type	Meaning
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`.

Property	Type	Meaning
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences.

The following objects have properties that can be viewed or set.

Local attribute logical properties:

The logical properties of a local attribute.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Type	Enumerated type	The Type property constrains the type of data that can be present in the object. Select from the following options: • `int` • `string` • `Boolean` • `hexBinary` • `dateTime` • `date` • `time` • `decimal` • `float` • `(More...)` • `(New Simple Type)` • `(New Complex Type)` If you select (More...), the Type Selection wizard starts. In this wizard, you can select any of the available types. If you select (New Simple Type), the New Simple Type wizard starts. In this wizard, you can create an Anonymous simple type that is based on an existing type. This type can be created locally or globally. If you select (New Complex Type), the New Complex Type wizard starts. In this wizard, you can create an Anonymous complex type, which can be derived from an existing base type. This type can be created locally or globally. For further information about these types, and examples of their use, see the XML Schema Part 0: Primer. This document is available on the World Wide Web Consortium (W3C) Web site.
Namespace	Enumerated type	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. If <no target namespace> is displayed, a namespace has not been set for this object. If the property is inactive, the message set has not been configured to support namespaces. Where the property is active, namespaces that are available for selection are displayed in the drop-down list.

Value

The *Value* properties are used in conjunction with the *Usage* property in an Attribute Reference or a Local Attribute.

Property	Type	Meaning
Default	Button and String	This property provides the default value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, default values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if they have default values. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the default value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for default values **Other domains** No support for default values.
Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.

Property	Type	Meaning
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

Usage properties

Property	Type	Meaning
Usage	Enumerated type	Use this property with the `Value` property found in an attribute object. The default value for the `Usage` property is optional. Select from the following options: • optional. – If the `Value` property is set to default, and no data has been entered in the `Value` property, the attribute can appear once and can have any value. – If the `Value` property is set to default, the attribute can appear once. If it does not appear, its value is the data that has been entered in the `Value` property. If it does appear, it is the value given. – Where the `Value` property is set to fixed, the attribute can appear once. If it does appear, its value must match the data that has been entered in the `Value` property. If it does not appear, its value is the data that has been entered in the `Value` property. • prohibited. The attribute must not appear. • required. – If the `Value` property is set to default, and no data has been entered in the `Value` property, the attribute must appear once and can have any value. – If the `Value` property is set to fixed, the attribute must appear once, and it must match the data that has been entered in the `Value` property.

Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.

Property	Type	Meaning
Nillable	Check box	Select this option if you want the element to be able to be defined as null. A null value is distinct from being empty, when the element contains no data.
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

Substitution settings

Substitution Groups provide a means by which one element may be substituted for another in a message. The element which can be substituted is called the 'head' element, and the substitution group is the list of elements that may be used in its place. An element can be in at most one substitution group.

Property	Type	Meaning
Final	Enumerated type	Limit the set of elements that can belong to its substitution group. • Empty • restriction. Prohibit element substitution by elements whose types are restrictions of the type of the head element. • extension. Prohibit element substitution by elements whose types are extensions of the type of the head element. • #all. Prohibit substitution by all methods.
Block	Enumerated type	Limit the set of elements that can be substituted for this element in a message. • Empty • restriction. Prohibit element substitution by elements whose types are restrictions of the type of the head element • extension. Prohibit element substitution by elements whose types are extensions of the type of the head element • substitution. Prohibit element substitution by members of the element's substitution group. • #all. Prohibit substitution by all methods.
Substitution Group	Enumerated type	Specify the name of a 'head' element. Setting this property indicates that this element is a member of the substitution group for the head element.

Property	Type	Meaning
Abstract	Check box	Select this option if you do not want the element to appear in the message, but require one of the members of its substitution group to appear in its place.

Message logical properties:

This section describes the logical properties of a message.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.
Message Alias	String	Specify an alternative unique value that identifies the message. This property is only required if you are using the MRM domain and the Message Identity technique to identify embedded messages, and the bit stream does not contain the actual message name.

The following objects have properties that can be viewed or set.

Simple type logical properties:

The logical properties of a simple type.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.
Base Type	Enumerated type	This property only applies to a simple type restriction. You can use this property to select a base type that is used as the starting point to define a new simple type that is derived by setting additional value constraints.
Item Type	Enumerated type	This property only applies to a simple type list. You can use this property to select the type that is used as the item type of the list.
Variety	Enumerated type	This property displays the variety of the simple type you have selected, either atomic, list, or union.

A simple type can also have "Simple type logical value constraints."

Logical property information is available for certain objects.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Simple type logical value constraints:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Wildcard attribute logical properties:

The logical properties of a wildcard attribute.

Property	Type	Meaning
Namespace	String	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. This field is initially blank.

Property	Type	Meaning
Process Content	Enumerated type	If a message contains an attribute that corresponds to a wildcard in the message model, `Process Content` defines how the attribute is validated. Select one of the following options: • strict. The parser can match only against attributes declared in the specified namespace. • lax. The parser attempts to match against attributes declared in all accessible namespaces. If the specified namespace cannot be found, an error is not generated. • skip. If you select skip, the parser does not perform validation on the attribute.

Related concepts:

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Wildcard element logical properties:

The logical properties of a wildcard element include properties that specify the number of occurrences of the wildcard element.

Property	Type	Meaning
Namespace	String	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. This field is initially blank.

Property	Type	Meaning
Process Content	Enumerated type	If a message contains an element that corresponds to a wildcard in the message model, `Process Content` defines how the element is validated. Select one of the following options: • strict. The parser can match only against elements declared in the specified namespace. • lax. The parser attempts to match against elements declared in any accessible namespace. If the specified namespace cannot be found, an error is not generated. • skip. If you select skip the parser does not perform validation on the element.

Occurrences

Property	Type	Meaning
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`. This property is ignored by brokers that are earlier than WebSphere Message Broker Version 6.0.
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences. This property is ignored by brokers that are earlier than WebSphere Message Broker Version 6.0.

Group reference CWF properties:

The CWF properties of a group reference.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

Local group CWF properties:

The CWF properties of a local group are described in the following tables.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`

Property	Type	Meaning
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *`Repeat Reference`* is specified, it overrides any setting for the *`Max Occurs`* logical property when parsing and writing the message, but not for validation of the message.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Element reference XML properties:

The properties, and their permissible values, vary according to the type of object.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float

Type of object	Properties
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Message XML properties:

The following tables describe the XML properties of a message.

Namespace schema locations

This property is only active if namespaces have been enabled.

Property	Type	Meaning
Namespace URI	String	A unique string, usually in the form of a URL that identifies the schema. If namespaces have not been enabled, this property displays `<no target namespace>`. This property overrides the same property at the message set level.
Schema location	String	Enter the location of the schema for the associated namespace name to be used to validate objects in the namespace.

XML declarations

Property	Type	Meaning
Output Namespace Declaration	Enumerated type	The `Output Namespace Declaration` property controls where the namespace declarations are placed in the output XML document. Select from: • `At start of document`. Declarations for all of the entries in the `Namespace schema locations` table above are produced as attributes of the message in the output XML document. The disadvantage of this option is that in some cases unnecessary declarations might be produced. • `As required`. Declarations are produced only when required by an element or attribute that is in that namespace. The disadvantage of this option is that the same namespace declaration might need to be produced more than once in the output XML document. The default option is `At start of document`. This property is active only if namespaces are enabled for this message set.

XML document type settings

Property	Type	Meaning
DOCTYPE System ID	String	Specify the System ID for DOCTYPE external DTD subset. It overrides the equivalent message set property setting for this particular message. If the message set property `Suppress DOCTYPE` is set to `Yes`, this parameter is ignored and cannot be changed (the field is disabled). The default value is the value that you specified for the `DOCTYPE System ID` property for the message set.
DOCTYPE Public ID	String	Specify the Public ID for DOCTYPE external DTD subset. It overrides the equivalent message set property setting for this particular message. If the message set property `Suppress DOCTYPE` is set to `Yes`, this parameter is ignored and cannot be changed (the field is disabled) . The default value is the value that you specified for the `DOCTYPE Public ID` property for the message set.
DOCTYPE Text	String	Enter optional additional text to include within the DOCTYPE. It overrides the message set property for this particular message. If the message set property `Suppress DOCTYPE` is set to `Yes`, this parameter is ignored and cannot be changed (the field is disabled). For more information, see "MRM XML: In-line DTDs and the DOCTYPE text property" on page 5407. The default value is the value that you specified for the `DOCTYPE Text` property for the message set.

Property	Type	Meaning
Root Tag Name	String	Specify the name of the root tag for a message bit stream XML document. It overrides the message set property set for this message. The default value is the value that you specified for the `Root Tag Name` property for the message set. **Note:** This property is deprecated. Do not change its value from its default setting.

Field identification

A number of the following properties will only become active depending on the value that `Render` property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (for output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their `XML Name` property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in `ID Attribute Name` and a value as specified in `ID Attribute Value`. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set `XML Name`, `ID Attribute Name`, `ID Attribute Value` to the same values: – You must also set `Value Attribute Name` to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *`Render`* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *`ID Attribute`*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *`Render`* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.

Attribute reference TDS properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Complex type TDS properties:

The TDS properties of a complex type.

Field Identification

If the complex type is based on a global group, the TDS properties listed are located in the global group. If so, any changes to these properties are applied to the global group, and affect all references to the group (including any other complex types which are based on it).

Property	Type	Meaning
Data Element Separation	Enumerated type	Select one of the following values to specify the method that is used to separate the data elements within the type. • `Tagged Delimited`. This value indicates that all elements within the complex type are identified by a tag, and, if a value is specified in the optional `Delimiter` property, are separated by that value. You must set the `Tag` property for all child elements of simple type, and you can set the `Delimiter` property to a non-empty value. See "Global element TDS properties" on page 5513. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Fixed Length`. This value indicates that each element is identified by a tag, and the data has a fixed length. There are no delimiters. You must set the `Tag` property for each of the child elements of this complex type, and each child element must have a `Length` or `Length Reference` property assigned to it. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Encoded Length`. This value indicates that all elements within the complex type are separated by a tag, and a length field follows each tag. There are no delimiters. The tag can be fixed length, as set by the `Length of Tag` property, or variable length delimited by the `Tag Data Separator` property. You must also set the `Length Of Encoded Length` property so that the parser knows the size of the length field, and set the `Extra Chars in Encoded Length` property. This property tells the parser what to subtract from the value in the `Length Of Encoded Length` property to get the actual length of the data that follows the length field. This method provides a more flexible way of handling ACORD AL3 standard messages than using the `Fixed Length AL3` value, by allowing different parts of the messages to be at different versions of the ACORD AL3 standard. • `All Elements Delimited`. This value indicates that all elements within the complex type are separated by a delimiter. You must set a value in the `Delimiter` property. • `Variable Length Elements Delimited`. This value indicates that some of the elements within the complex type might be of variable length. Variable length elements must be delimited by the value specified in the `Delimiter` property. • `Use Data Pattern`. This value indicates that the parser determines the elements by matching the data with the regular expression that is set in the `Data Pattern` property of the element or type member. See "Message definition file properties" on page 5409. • `Fixed Length`. This value indicates that all elements within the complex type are fixed length. The next data element is accessed by adding the value of the `Length` property to the offset. See "Global element TDS properties" on page 5513. If you set the `Data Element Separation` property of a complex type to `Fixed Length`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length`. Each child element must have a `Length` or `Length Reference` property assigned to it. • `Fixed Length AL3`. This value has a similar meaning to the separation type `Fixed Length`, but also indicates to the parser that a number of predefined rules regarding missing optional elements, encoded lengths, and versioning, must be applied. If you set the `Data Element Separation` property of a complex type to `Fixed Length AL3`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length AL3`. • `Undefined`. This value is set automatically if you set the `Type Composition` property of a complex type to `Message`, and you cannot change it to any other value. Do not set the `Type Composition` property to `Empty`, `Choice`, `Unordered Set`, `Ordered Set`, `Sequence`, or `Simple Unordered Set`. If you do, you cannot check in the type.

Property	Type	Meaning
Group Indicator	String	Specify the value of a special character, or string, that precedes the data that belongs to a group, or a complex type, within the bit stream.
Group Terminator	String	Specify the value of a special character, or string, that terminates the data that belongs to a group, or a complex type, within the bit stream.
Delimiter	String	Specify the value of a special character, or string, that specifies the delimiter that is used between data elements. This property applies only to the delimited `Data Element Separation` methods (`Tagged Delimited`, `All Elements Delimited`, and `Variable Length Elements Delimited`).
Suppress Absent Element Delimiters	Enumerated type	Use this property to select whether you want delimiters to be suppressed for elements that are missing within a message. Select from: • `End Of Type`. Use this option to suppress the delimiter when an element is missing. For example, if the model has been defined to have up to three elements and only two are present, the last delimiter can be omitted from the message. • `Never`. Use this option to ensure that even if optional elements are not present, all delimiters are written out. Use this option when the same delimiter is used to delimit parent and child objects. For example, if an optional child element is missing, message processing applications cannot tell where the child elements in a message end and the next parent element starts, if the delimiters are all the same.
Observe Element Length	Check box	This property is applicable when `Data Element Separation` is `All Elements Delimited` or `Tagged Delimited`. Select this check box if the `Length` property of child simple elements is significant when parsing and writing. • During parsing, an exception is thrown if the length of the extracted data exceeds the specified length. Otherwise, the data is trimmed according to the `Justification` and `Padding Character` properties of the child element. • During writing, an exception is thrown if the data to write exceeds the specified length. Otherwise, the data is padded according to the `Justification` and `Padding Character` properties of the child element. Clear this check box to ignore the `Length` property when parsing and writing. The default value depends on the setting of the `Messaging Standard` property (at the message set level) and the `Data Element Separation` property. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is `TLOG`, the check box is selected. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is other than `TLOG`, the check box is cleared. • If `Data Element Separation` is `Tagged Delimited`, the check box is cleared. For all other data element separation methods, the check box is disabled and does not influence the behavior of the TDS parser.
Tag Data Separator	Button and String	Specify the value of a special character or string that separates the Tag from the data. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides `Length of Tag`. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).

Property	Type	Meaning
Length of Tag	Button and Integer	Specify the length of a tag value. When the message is parsed, this property allows tags to be extracted from the bit stream if the `Tag Data Separator` property is not set. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides this value. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).
Length of Encoded Length	Integer	Specifies the number of characters (not bytes) after a tag that are used for the length field. Enter a value from 0 to 2147483647. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`; it is not valid otherwise. The actual number of data characters that are parsed depends on the value of the `Extra Chars in Encoded Length` property.
Extra Chars in Encoded Length	Integer	(Only valid if the `Data Element Separation` method is set to `Tagged Encoded Length`.) Specifies the number of extra characters included in the value found in the length field. (For example, the value in the length might include the size of the length field itself as well as the size of the data field, or it might be the total size of the tag, length, and data fields.) Enter a value from 0 to 2147483647. The parser subtracts this number from the number found in the length field to get the number of data characters that follow the length field. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`, and the actual number of data characters is less than the value found in the length field.

The following objects have properties that can be viewed or set.

Global group TDS properties:

The TDS properties of a global group.

Field Identification

Property	Type	Meaning
Data Element Separation	Enumerated type	Select one of the following values to specify the method that is used to separate the data elements within the type. • `Tagged Delimited`. This value indicates that all elements within the complex type are identified by a tag, and, if a value is specified in the optional `Delimiter` property, are separated by that value. You must set the `Tag` property for all child elements of simple type, and you can set the `Delimiter` property to a non-empty value. See "Global element TDS properties" on page 5513. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Fixed Length`. This value indicates that each element is identified by a tag, and the data has a fixed length. There are no delimiters. You must set the `Tag` property for each of the child elements of this complex type, and each child element must have a `Length` or `Length Reference` property assigned to it. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Encoded Length`. This value indicates that all elements within the complex type are separated by a tag, and a length field follows each tag. There are no delimiters. The tag can be fixed length, as set by the `Length of Tag` property, or variable length delimited by the `Tag Data Separator` property. You must also set the `Length Of Encoded Length` property so that the parser knows the size of the length field, and set the `Extra Chars in Encoded Length` property. This property tells the parser what to subtract from the value in the `Length Of Encoded Length` property to get the actual length of the data that follows the length field. This method provides a more flexible way of handling ACORD AL3 standard messages than using the `Fixed Length AL3` value, by allowing different parts of the messages to be at different versions of the ACORD AL3 standard. • `All Elements Delimited`. This value indicates that all elements within the complex type are separated by a delimiter. You must set a value in the `Delimiter` property. • `Variable Length Elements Delimited`. This value indicates that some of the elements within the complex type might be of variable length. Variable length elements must be delimited by the value specified in the `Delimiter` property. • `Use Data Pattern`. This value indicates that the parser determines the elements by matching the data with the regular expression that is set in the `Data Pattern` property of the element or type member. See "Message definition file properties" on page 5409. • `Fixed Length`. This value indicates that all elements within the complex type are fixed length. The next data element is accessed by adding the value of the `Length` property to the offset. See "Global element TDS properties" on page 5513. If you set the `Data Element Separation` property of a complex type to `Fixed Length`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length`. Each child element must have a `Length` or `Length Reference` property assigned to it. • `Fixed Length AL3`. This value has a similar meaning to the separation type `Fixed Length`, but also indicates to the parser that a number of predefined rules regarding missing optional elements, encoded lengths, and versioning, must be applied. If you set the `Data Element Separation` property of a complex type to `Fixed Length AL3`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length AL3`. • `Undefined`. This value is set automatically if you set the `Type Composition` property of a complex type to `Message`, and you cannot change it to any other value. Do not set the `Type Composition` property to `Empty`, `Choice`, `Unordered Set`, `Ordered Set`, `Sequence`, or `Simple Unordered Set`. If you do, you cannot check in the type.

Property	Type	Meaning
Group Indicator	String	Specify the value of a special character, or string, that precedes the data that belongs to a group, or a complex type, within the bit stream.
Group Terminator	String	Specify the value of a special character, or string, that terminates the data that belongs to a group, or a complex type, within the bit stream.
Delimiter	String	Specify the value of a special character, or string, that specifies the delimiter that is used between data elements. This property applies only to the delimited `Data Element Separation` methods (`Tagged Delimited`, `All Elements Delimited`, and `Variable Length Elements Delimited`).
Suppress Absent Element Delimiters	Enumerated type	Use this property to select whether you want delimiters to be suppressed for elements that are missing within a message. Select from: • `End Of Type`. Use this option to suppress the delimiter when an element is missing. For example, if the model has been defined to have up to three elements and only two are present, the last delimiter can be omitted from the message. • `Never`. Use this option to ensure that even if optional elements are not present, all delimiters are written out. Use this option when the same delimiter is used to delimit parent and child objects. For example, if an optional child element is missing, message processing applications cannot tell where the child elements in a message end and the next parent element starts, if the delimiters are all the same.
Observe Element Length	Check box	This property is applicable when `Data Element Separation` is `All Elements Delimited` or `Tagged Delimited`. Select this check box if the `Length` property of child simple elements is significant when parsing and writing. • During parsing, an exception is thrown if the length of the extracted data exceeds the specified length. Otherwise, the data is trimmed according to the `Justification` and `Padding Character` properties of the child element. • During writing, an exception is thrown if the data to write exceeds the specified length. Otherwise, the data is padded according to the `Justification` and `Padding Character` properties of the child element. Clear this check box to ignore the `Length` property when parsing and writing. The default value depends on the setting of the `Messaging Standard` property (at the message set level) and the `Data Element Separation` property. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is `TLOG`, the check box is selected. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is other than `TLOG`, the check box is cleared. • If `Data Element Separation` is `Tagged Delimited`, the check box is cleared. For all other data element separation methods, the check box is disabled and does not influence the behavior of the TDS parser.
Tag Data Separator	Button and String	Specify the value of a special character or string that separates the Tag from the data. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides `Length of Tag`. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).

Property	Type	Meaning
Length of Tag	Button and Integer	Specify the length of a tag value. When the message is parsed, this property allows tags to be extracted from the bit stream if the `Tag Data Separator` property is not set. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides this value. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).
Length of Encoded Length	Integer	Specifies the number of characters (not bytes) after a tag that are used for the length field. Enter a value from 0 to 2147483647. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`; it is not valid otherwise. The actual number of data characters that are parsed depends on the value of the `Extra Chars in Encoded Length` property.
Extra Chars in Encoded Length	Integer	(Only valid if the `Data Element Separation` method is set to `Tagged Encoded Length`.) Specifies the number of extra characters included in the value found in the length field. (For example, the value in the length might include the size of the length field itself as well as the size of the data field, or it might be the total size of the tag, length, and data fields.) Enter a value from 0 to 2147483647. The parser subtracts this number from the number found in the length field to get the number of data characters that follow the length field. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`, and the actual number of data characters is less than the value found in the length field.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Group reference TDS properties:

The following tables describe the TDS properties of a group reference.

Field identification

Property	Type	Meaning
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Occurrences

Property	Type	Meaning
Repeating Element Delimiter	String	Specify the delimiter to use between repeating elements. This delimiter is used only when the element repeats and the `Data Element Separation` property of the parent group or complex type is set to `All Elements Delimited` or `Variable Length Elements Delimited`. A default value is provided if the previous conditions are true; if the messaging standard is HL7, the mnemonic <HL7_RS> is used; if the messaging standard is not HL7, and the maximum number of repeats is fixed, the delimiter of the parent group or complex type is used. If none of the previous conditions are true, a default is not applied.
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, no integer objects exist before this one in the message structure. If a `Repeat Reference` is specified, it overrides any setting for the `Max Occurs` logical property when parsing and writing the message, but not for validating the message.

Field Identification

Property	Type	Meaning
Data Element Separation	Enumerated type	Select one of the following values to specify the method that is used to separate the data elements within the type. • `Tagged Delimited`. This value indicates that all elements within the complex type are identified by a tag, and, if a value is specified in the optional `Delimiter` property, are separated by that value. You must set the `Tag` property for all child elements of simple type, and you can set the `Delimiter` property to a non-empty value. See "Global element TDS properties" on page 5513. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Fixed Length`. This value indicates that each element is identified by a tag, and the data has a fixed length. There are no delimiters. You must set the `Tag` property for each of the child elements of this complex type, and each child element must have a `Length` or `Length Reference` property assigned to it. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Encoded Length`. This value indicates that all elements within the complex type are separated by a tag, and a length field follows each tag. There are no delimiters. The tag can be fixed length, as set by the `Length of Tag` property, or variable length delimited by the `Tag Data Separator` property. You must also set the `Length Of Encoded Length` property so that the parser knows the size of the length field, and set the `Extra Chars in Encoded Length` property. This property tells the parser what to subtract from the value in the `Length Of Encoded Length` property to get the actual length of the data that follows the length field. This method provides a more flexible way of handling ACORD AL3 standard messages than using the `Fixed Length AL3` value, by allowing different parts of the messages to be at different versions of the ACORD AL3 standard. • `All Elements Delimited`. This value indicates that all elements within the complex type are separated by a delimiter. You must set a value in the `Delimiter` property. • `Variable Length Elements Delimited`. This value indicates that some of the elements within the complex type might be of variable length. Variable length elements must be delimited by the value specified in the `Delimiter` property. • `Use Data Pattern`. This value indicates that the parser determines the elements by matching the data with the regular expression that is set in the `Data Pattern` property of the element or type member. See "Message definition file properties" on page 5409. • `Fixed Length`. This value indicates that all elements within the complex type are fixed length. The next data element is accessed by adding the value of the `Length` property to the offset. See "Global element TDS properties" on page 5513. If you set the `Data Element Separation` property of a complex type to `Fixed Length`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length`. Each child element must have a `Length` or `Length Reference` property assigned to it. • `Fixed Length AL3`. This value has a similar meaning to the separation type `Fixed Length`, but also indicates to the parser that a number of predefined rules regarding missing optional elements, encoded lengths, and versioning, must be applied. If you set the `Data Element Separation` property of a complex type to `Fixed Length AL3`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length AL3`. • `Undefined`. This value is set automatically if you set the `Type Composition` property of a complex type to `Message`, and you cannot change it to any other value. Do not set the `Type Composition` property to `Empty`, `Choice`, `Unordered Set`, `Ordered Set`, `Sequence`, or `Simple Unordered Set`. If you do, you cannot check in the type.

Property	Type	Meaning
Group Indicator	String	Specify the value of a special character, or string, that precedes the data that belongs to a group, or a complex type, within the bit stream.
Group Terminator	String	Specify the value of a special character, or string, that terminates the data that belongs to a group, or a complex type, within the bit stream.
Delimiter	String	Specify the value of a special character, or string, that specifies the delimiter that is used between data elements. This property applies only to the delimited `Data Element Separation` methods (`Tagged Delimited`, `All Elements Delimited`, and `Variable Length Elements Delimited`).
Suppress Absent Element Delimiters	Enumerated type	Use this property to select whether you want delimiters to be suppressed for elements that are missing within a message. Select from: • `End Of Type`. Use this option to suppress the delimiter when an element is missing. For example, if the model has been defined to have up to three elements and only two are present, the last delimiter can be omitted from the message. • `Never`. Use this option to ensure that even if optional elements are not present, all delimiters are written out. Use this option when the same delimiter is used to delimit parent and child objects. For example, if an optional child element is missing, message processing applications cannot tell where the child elements in a message end and the next parent element starts, if the delimiters are all the same.
Observe Element Length	Check box	This property is applicable when `Data Element Separation` is `All Elements Delimited` or `Tagged Delimited`. Select this check box if the `Length` property of child simple elements is significant when parsing and writing. • During parsing, an exception is thrown if the length of the extracted data exceeds the specified length. Otherwise, the data is trimmed according to the `Justification` and `Padding Character` properties of the child element. • During writing, an exception is thrown if the data to write exceeds the specified length. Otherwise, the data is padded according to the `Justification` and `Padding Character` properties of the child element. Clear this check box to ignore the `Length` property when parsing and writing. The default value depends on the setting of the `Messaging Standard` property (at the message set level) and the `Data Element Separation` property. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is `TLOG`, the check box is selected. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is other than `TLOG`, the check box is cleared. • If `Data Element Separation` is `Tagged Delimited`, the check box is cleared. For all other data element separation methods, the check box is disabled and does not influence the behavior of the TDS parser.
Tag Data Separator	Button and String	Specify the value of a special character or string that separates the Tag from the data. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides `Length of Tag`. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).

Property	Type	Meaning
Length of Tag	Button and Integer	Specify the length of a tag value. When the message is parsed, this property allows tags to be extracted from the bit stream if the `Tag Data Separator` property is not set. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides this value. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).
Length of Encoded Length	Integer	Specifies the number of characters (not bytes) after a tag that are used for the length field. Enter a value from 0 to 2147483647. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`; it is not valid otherwise. The actual number of data characters that are parsed depends on the value of the `Extra Chars in Encoded Length` property.
Extra Chars in Encoded Length	Integer	(Only valid if the `Data Element Separation` method is set to `Tagged Encoded Length`.) Specifies the number of extra characters included in the value found in the length field. (For example, the value in the length might include the size of the length field itself as well as the size of the data field, or it might be the total size of the tag, length, and data fields.) Enter a value from 0 to 2147483647. The parser subtracts this number from the number found in the length field to get the number of data characters that follow the length field. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`, and the actual number of data characters is less than the value found in the length field.

Field Identification

Property	Type	Meaning
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see “Regular expression syntax” on page 6304.

Occurrences

Property	Type	Meaning
Repeating Element Delimiter	String	Specify the delimiter to use between repeating elements. This delimiter is used only when the element repeats and the `Data Element Separation` property of the parent group or complex type is set to `All Elements Delimited` or `Variable Length Elements Delimited`. A default value is provided if the previous conditions are true; if the messaging standard is HL7, the mnemonic <HL7_RS> is used; if the messaging standard is not HL7, and the maximum number of repeats is fixed, the delimiter of the parent group or complex type is used. If none of the previous conditions are true, a default is not applied.

Property	Type	Meaning
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, no integer objects exist before this one in the message structure. If a `Repeat Reference` is specified, it overrides any setting for the `Max Occurs` logical property when parsing and writing the message, but not for validating the message.

The following objects have properties that can be viewed or set.

Message TDS properties:

Message TDS properties.

Property	Type	Meaning
Message Key	String	Specify an alternative unique value that identifies the message in the bit stream. This property is required if the message is embedded within another message. **Note:** From Version 6.0 onwards, the use of `Message Key` has been deprecated for identifying an embedded message. You now have the option of identifying an embedded message by Message Identity, using the `Message Alias` logical property.

Related concepts:

“Message model object properties by object” on page 5536
The following objects have properties that can be viewed or set.

White space characters in TDS:

White space characters are defined as ASCII characters (hexadecimal) 'X'09 to 'X'0D and EBCDIC characters 'X'05, 'X'0B, 'X'0C, 'X'0D, 'X'25, and 'X'40.

You can specify these characters in your message model using TDS mnemonics if they are important to your processing, for example, to use as group terminators or delimiting characters. See “TDS Mnemonics” on page 5391 for further information.

If both the following conditions are met, white space after the end of a group and preceding the tag of the next element is ignored:

- TDS messaging standard property is "X12" or "EDIFACT"
- TDS data element separation in force for the structure is one of the following types:
  - Tagged delimiter
  - Tagged fixed length
  - Tagged encoded length

The following bit stream is accepted:

```
Tag<data>!<Any white space character>Tag
```

where:

- `!` is the group terminator
- `<Any white space character>` is one of the ASCII or EBCDIC characters listed previously

The following X12 ASCII message successfully parses:

```
ST*856*777777%<SPC><SPC><SPC><HEX 09>BSN*00*7654321*940920*10000%
```

The sequence

```
<SPC><SPC><SPC><HEX 09>
```

is ignored by the parser.

The following objects have properties that can be viewed or set.

Attribute reference CWF properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

Custom Wire Format (CWF) is the physical representation of a message that is composed of a number of fixed-format data structures or elements, which are not separated by delimiters.

"MRM Custom wire format: Relationship to the logical model" on page 1219
Some restrictions exist in relation to the logical model for messages that are defined by using the CWF.

Related tasks:

"Working with physical formats" on page 2847
If you are using the MRM domain to parse and write your messages, when you are developing your message model you might want to add one or more physical format layers to a message set, then configure the properties of these physical formats.

"Configuring physical properties" on page 2912
Working with the physical properties of message model objects.

CWF properties for attribute reference and local attribute binary types:

CWF properties for attribute reference and local attribute binary types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- Binary schema types: base64Binary, hexBinary

Physical representation

Property	Type	Meaning
Length	Button and Integer	If you have selected the length to be defined by *Length*, enter the number of length units for the element. The minimum value that you can specify is 1. The maximum value that you can specify is 2147483647. The default value is empty (not set).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *Length Reference*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if *Length Reference* is set. If the check box is selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object only. If the check box is selected, the *Length Units* property of the sibling integer object must be the same as that of the current object.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. The length is given in bytes. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`* or *`Length Reference`* property. The default is `Bytes`.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.

Property	Type	Meaning
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

CWF properties for attribute reference and local attribute dateTime types:

CWF properties for attribute reference and local attribute dateTime types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Fixed Length String`. The element's length is determined by other length properties as follows. • `Length Encoded String 1`. The first byte of the element contains the length of the string following the length byte in length units. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The element's first 2 bytes contain the length of the string following the two length bytes in length units. The maximum length of a `Length Encoded String 2` element is 65535 length units. The two length bytes are in the format of the WebSphere MQ queue manager Encoding. • `Null Terminated String`. The string ends with the hexadecimal NULL character, `X'00'`. • `Packed Decimal`. The dateTime is coded as a Packed Decimal number. It is valid only if the *`DateTime Format`* property represents numeric-only data. • `Binary`. The dateTime is encoded as a binary sequence of bytes. If you select this option, the range of symbols that you can specify for the Format String property is less than the range of symbols you can specify if you select a string option (see "DateTime formats" on page 6310 for details). • `Time Seconds`. This value supports C time_t and Java Date and Time objects. It is valid only if the *`DateTime Format`* property represents numeric-only data. • `Time Milliseconds`. This value supports C time_t and Java Date and Time objects. It is valid only if the *`DateTime Format`* property represents numeric-only data. The default value is `fixed length string`.
DateTime Format	String	Specify a template for date and time. The default dateTime format is dependent on the logical type of the object. For information about the defaults for the dateTime format according to the logical type, see "DateTime defaults by logical type" on page 6320. See "DateTime formats" on page 6310 for details of date and time formats.
Length	Button and Integer	If you have selected a *`Physical Type`* of `Fixed Length String`, `Packed Decimal`, or `Binary`, and have selected the length to be defined by *`Length`*, enter the number of length units for the element. The minimum value that you can specify is 1 for all three physical types. The maximum value that you can specify is `256` for `Fixed Length String`, `10` for `Packed Decimal`, and `2147483647` for `Binary`. The default value is 0 (zero).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *`Length Reference`*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see "Reordering objects" on page 2900.

Property	Type	Meaning
Inclusive Length Reference	Check box	This property is applicable only if *Length Reference* is set. If the check box is selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object only. If the check box is selected, the *Length Units* property of the sibling integer object must be the same as that of the current object.
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • Bytes. The length is given in bytes. • Characters. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • Character Units. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to Characters. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the Length property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • End of Bitstream. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *Length Count* or *Length Reference* property. The default is Bytes.
Justification	Enumerated type	If you have set the *Physical Type* property to Fixed Length String, select Left Justify (the default value) or Right Justify from the list. If you have selected another value for *Physical Type*, this property is inactive.

Property	Type	Meaning
Padding Character	String	If you have set the *Physical Type* property to `Fixed Length String`, and the *Justification* property is either `Left Justify` or `Right Justify`, this property is applicable. When writing an output message, use the padding character to fill out the remaining character positions when the string length is less than the length implied by the *Length* or *Length Reference* property. Whether the string is padded from the left or the right is governed by the *Justification* property. When parsing an input message, the padding character is trimmed from the end of the string. Whether the string is trimmed from the left or the right is governed by the *Justification* property. Specify this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the displayed list. • Enter a character between quotation marks; for example, `"c"` or `'c'`, where c is any alphanumeric character. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, it is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed. This property is applicable only if the *Physical type* property is `Packed Decimal`. By default, this check box is cleared, which indicates that the value is not signed.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

CWF properties for attribute reference and local attribute decimal types:

CWF properties for attribute reference and local attribute decimal types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- Decimal schema types: decimal, integer, negativeInteger, nonNegativeInteger, nonPositiveInteger, positiveInteger, unsignedLong

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Integer`. This equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. Equates to the COMP-3 data type in COBOL. • `External Decimal`. Equates to the data type PIC 9 USAGE DISPLAY in COBOL. The representation of numeric elements can be affected by the Encoding and CodedCharSetId attributes that are set for the WebSphere MQ queue manager: • Elements that have *`Physical Type`* set to `Integer` and `Packed Decimal` are represented in the appropriate WebSphere MQ Encoding value. • Elements that have *`Physical Type`* set to `External Decimal` are represented in the WebSphere MQ CodedCharSetId value.
Length	Integer	Enter the number of bytes to specify the element length: • If you set the *`Physical Type`* to `Integer`, select `1`, `2`, or `4` (the default) from the displayed list. • If you set the *`Physical Type`* to `Packed Decimal`, enter a value between 1 and 10. • If you set the *`Physical Type`* to `Extended Decimal`, enter a value between 1 and 256. (Numbers greater than the maximum COBOL PICTURE clause of 18 are assumed to be 18.)

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`*. The default is `Bytes`.
Justification	Enumerated type	If you have set the *`Physical Type`* property to `External Decimal`, select `Left Justify` or `Right Justify` (the default value) from the list. If you have selected another value for *`Physical Type`*, this property is inactive.

Property	Type	Meaning
Padding Character	String	The padding character is used to fill out the remaining character positions when the string length is less than the specified string size. If you have set the *Physical Type* property to Extended Decimal, and the *Justification* property is either Left Justify or Right Justify, specify this character in one of the following ways: • Select NUL, '0', or SPACE from the displayed list. • Enter a character between quotation marks; for example, "c" or 'c', where c is any alphanumeric character. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form 0xYY, where YY is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, this is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Select (the default) or clear this property. This property is used with *Sign Orientation*.

Property	Type	Meaning
Sign EBCDIC Custom Overpunched	Check box	If the *Physical Type* is set to External Decimal and the *Signed EBCDIC Custom* property is set, this indicates that the Sign EBCDIC Custom Overpunched representation is to be used within an ASCII environment. If this check box is not selected (the default), the Sign ASCII representation is used. The setting of the *Sign EBCDIC Custom Overpunched* check box is appropriate only if the *Sign Orientation* property is set to Leading or Trailing (indicating that the element/attribute has an embedded sign representation). The check box is not available if the element/attribute is unsigned (for example, if the *Signed* check box is not set).
Sign Orientation	Enumerated type	If you have set *Physical Type* to External Decimal and you have selected *Signed*, choose from the following options that represent the COBOL options for displaying numeric data: • Leading Overpunched. This option sets a bit in the first byte if the number is negative. No setting is made if the number is positive. For example, the ASCII hexadecimal representation of the number 22 is x'3232'. Using this option, the number +22 would be x'3232' and the number -22 would be x'7232'. The default value. • Leading Separate. This option sets the first byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. • Trailing Overpunched. This option sets a bit in the last byte if the number is negative. No setting is made if the number is positive. Using this option, the number +22 would be x'3232' and the number -22 would be x'3272'. • Trailing Separate. This option sets the last byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. If you have set *Physical Type* to any other value, the value Not Applicable is set for you.
Virtual Decimal Point	Integer	Specify the number of places to the left (for a positive value) or right (for a negative value) that a decimal point is to be moved from its assumed position. For example, a decimal element containing 1234 with a Virtual Decimal value of 3 is 1.234, equivalent to 'V' or 'P' in a COBOL picture clause. There is no C equivalent

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • 1 Bytes. The default value. • 2 Bytes • 4 Bytes • 8 Bytes • 16 Bytes
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.

Property	Type	Meaning
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

CWF properties for attribute reference and local attribute float types:

CWF properties for attribute reference and local attribute float types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- Float schema types: double, float

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Integer`. This equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Float`. This equates to the data type FLOAT or DOUBLE in C or the COMP-1 or COMP-2 data type in COBOL and is the default value. • `Packed Decimal`. Equates to the COMP-3 data type in COBOL. • `External Decimal`. Equates to the data type PIC 9 USAGE DISPLAY in COBOL. The representation of numeric elements can be affected by the Encoding and CodedCharSetId attributes that are set for the WebSphere MQ queue manager: • Elements that have *`Physical Type`* set to `Integer`, `Packed Decimal`, and `Float` are represented in the appropriate WebSphere MQ Encoding value. • Elements that have *`Physical Type`* set to `External Decimal` are represented in the WebSphere MQ CodedCharSetId value.
Length	Integer	Enter the number of bytes to specify the element length: • If you set the *`Physical Type`* to `Float`, select a value from the displayed list. The default value is `8`. • If you set the *`Physical Type`* to `Integer`, select `1`, `2`, or `4` (the default) from the displayed list. • If you set the *`Physical Type`* to `Packed Decimal`, enter a value between 1 and 10. • If you set the *`Physical Type`* to `Extended Decimal`, enter a value between 1 and 256. (Numbers greater than the maximum COBOL PICTURE clause of 18 are assumed to be 18.)

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`*. The default is `Bytes`.
Justification	Enumerated type	If you have set the *`Physical Type`* property to `External Decimal`, select `Left Justify` or `Right Justify` (the default value) from the list. If you have selected another value for *`Physical Type`*, this property is inactive.

Property	Type	Meaning
Padding Character	String	The padding character is used to fill out the remaining character positions when the string length is less than the specified string size. If you have set the *Physical Type* property to Extended Decimal, and the *Justification* property is either Left Justify or Right Justify, specify this character in one of the following ways: • Select NUL, '0', or SPACE from the displayed list. • Enter a character between quotation marks; for example, "c" or 'c', where c is any alphanumeric character. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form 0xYY, where YY is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, this is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Select or clear (unsigned, the default) this property. If you have set *Physical Type* to Float, this is selected. This property is used with *Sign Orientation*.

Property	Type	Meaning
Sign EBCDIC Custom Overpunched	Check box	If the *Physical Type* is set to External Decimal and the *Signed EBCDIC Custom* property is set, this indicates that the Sign EBCDIC Custom Overpunched representation is to be used within an ASCII environment. If this check box is not selected (the default), the Sign ASCII representation is used. The setting of the *Sign EBCDIC Custom Overpunched* check box is appropriate only if the *Sign Orientation* property is set to Leading or Trailing (indicating that the element/attribute has an embedded sign representation). The check box is not available if the element/attribute is unsigned (for example, if the *Signed* check box is not set).
Sign Orientation	Enumerated type	If you have set *Physical Type* to External Decimal and you have selected *Signed*, choose from the following options that represent the COBOL options for displaying numeric data: • Leading Overpunched. This option sets a bit in the first byte if the number is negative. No setting is made if the number is positive. For example, the ASCII hexadecimal representation of the number 22 is x'3232'. Using this option, the number +22 would be x'3232' and the number -22 would be x'7232'. The default value. • Leading Separate. This option sets the first byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. • Trailing Overpunched. This option sets a bit in the last byte if the number is negative. No setting is made if the number is positive. Using this option, the number +22 would be x'3232' and the number -22 would be x'3272'. • Trailing Separate. This option sets the last byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. If you have set *Physical Type* to any other value, the value Not Applicable is set for you.
Virtual Decimal Point	Integer	Specify the number of places to the left (for a positive value) or right (for a negative value) that a decimal point is to be moved from its assumed position. For example, a float element containing 1234 with a Virtual Decimal value of 3 is 1.234. This property is not applicable if you have set *Physical Type* to Float.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • 1 Bytes. The default value. • 2 Bytes • 4 Bytes • 8 Bytes • 16 Bytes
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.

Property	Type	Meaning
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Integer`. This equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. Equates to the COMP-3 data type in COBOL. • `External Decimal`. Equates to the data type PIC 9 USAGE DISPLAY in COBOL. The representation of numeric elements can be affected by the Encoding and CodedCharSetId attributes that are set for the WebSphere MQ queue manager: • Elements that have *`Physical Type`* set to `Integer` and `Packed Decimal` are represented in the appropriate WebSphere MQ Encoding value. • Elements that have *`Physical Type`* set to `External Decimal` are represented in the WebSphere MQ CodedCharSetId value.
Length	Integer	Enter the number of bytes to specify the element length: • If you set the *`Physical Type`* to `Integer`, select `1`, `2`, or `4` (the default) from the displayed list. • If you have set *`Physical Type`* to `Packed Decimal`, enter a value between 1 and 6. • If you have set *`Physical Type`* to `Extended Decimal`, enter a value between 1 and 11.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`*. The default is `Bytes`.
Justification	Enumerated type	If you have set the *`Physical Type`* property to `External Decimal`, select `Left Justify` or `Right Justify` (the default value) from the list. If you have selected another value for *`Physical Type`*, this property is inactive.

Property	Type	Meaning
Padding Character	String	The padding character is used to fill out the remaining character positions when the string length is less than the specified string size. If you have set the *Physical Type* property to Extended Decimal, and the *Justification* property is either Left Justify or Right Justify, specify this character in one of the following ways: • Select NUL, '0', or SPACE from the displayed list. • Enter a character between quotation marks; for example, "c" or 'c', where c is any alphanumeric character. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form 0xYY, where YY is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, this is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Select (the default) or clear this property. This property is used with *Sign Orientation*.

Property	Type	Meaning
Sign EBCDIC Custom Overpunched	Check box	If the *Physical Type* is set to External Decimal and the *Signed EBCDIC Custom* property is set, this indicates that the Sign EBCDIC Custom Overpunched representation is to be used within an ASCII environment. If this check box is not selected (the default), the Sign ASCII representation is used. The setting of the *Sign EBCDIC Custom Overpunched* check box is appropriate only if the *Sign Orientation* property is set to Leading or Trailing (indicating that the element/attribute has an embedded sign representation). The check box is not available if the element/attribute is unsigned (for example, if the *Signed* check box is not set).
Sign Orientation	Enumerated type	If you have set *Physical Type* to External Decimal and you have selected *Signed*, choose from the following options that represent the COBOL options for displaying numeric data: • Leading Overpunched. This option sets a bit in the first byte if the number is negative. No setting is made if the number is positive. For example, the ASCII hexadecimal representation of the number 22 is x'3232'. Using this option, the number +22 would be x'3232' and the number -22 would be x'7232'. The default value. • Leading Separate. This option sets the first byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. • Trailing Overpunched. This option sets a bit in the last byte if the number is negative. No setting is made if the number is positive. Using this option, the number +22 would be x'3232' and the number -22 would be x'3272'. • Trailing Separate. This option sets the last byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. If you have set *Physical Type* to any other value, the value Not Applicable is set for you.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • 1 Bytes. The default value. • 2 Bytes • 4 Bytes • 8 Bytes • 16 Bytes
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.

Property	Type	Meaning
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. CWF properties for attribute reference and local attribute string types:

CWF properties for attribute reference and local attribute string types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- String schema types: anyURI, ENTITIES, ENTITY, ID, IDREF, IDREFS, language, Name, NCName, NMTOKEN, NMTOKENS, normalizedString, NOTATION, QName, string, token

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Fixed Length String`. The element's length is determined by other length properties as follows. • `Length Encoded String 1`. The first byte of the element contains the length of the string following the length byte in length units. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The element's first 2 bytes contain the length of the string following the two length bytes in length units. The maximum length of a `Length Encoded String 2` element is 65535 length units. The two length bytes are in the format of the WebSphere MQ queue manager Encoding. • `Null Terminated String`. The string ends with the hexadecimal NULL character, `X'00'`. The default is `Fixed Length String`.
Length	Button and Integer	If you have selected a *`Physical Type`* of `Fixed Length String` or `Binary`, and have selected the length to be defined by *`Length`*, enter the number of length units for the element. The minimum value that you can specify is `0` (zero), the maximum value that you can specify is `2147483647` The default value is `0` (zero).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *`Length Reference`*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see “Reordering objects” on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if *`Length Reference`* is set. If the check box is selected, the value of the sibling integer object that is identified by *`Length Reference`* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *`Length Reference`* is the length of the current object only. If the check box is selected, the *`Length Units`* property of the sibling integer object must be the same as that of the current object.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. The length is given in bytes. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`* or *`Length Reference`* property. The default is `Bytes`.
Justification	Enumerated type	If you have set the *`Physical Type`* property to `Fixed Length String`, select `Left Justify` (the default value) or `Right Justify` from the list. If you have selected another value for *`Physical Type`*, this property is inactive.

Property	Type	Meaning
Padding Character	String	If you have set the *Physical Type* property to `Fixed Length String`, and the *Justification* property is either `Left Justify` or `Right Justify`, this property is applicable. When writing an output message, use the padding character to fill out the remaining character positions when the string length is less than the length implied by the *Length* or *Length Reference* property. Whether the string is padded from the left or the right is governed by the *Justification* property. When parsing an input message, the padding character is trimmed from the end of the string. Whether the string is trimmed from the left or the right is governed by the *Justification* property. Specify this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the displayed list. • Enter a character between quotation marks; for example, `"c"` or `'c'`, where c is any alphanumeric character. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, it is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Attribute reference XML properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float

Type of object	Properties
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

XML properties for attribute reference, element reference, local attribute, local element binary types:

XML wire format properties for attribute reference, element reference, local attribute, and local element binary types.

The XML Wire Format properties described here apply to:

- Objects: Attribute Reference, Element Reference, Local Attribute, Local Element
- Binary schema types: base64Binary, hexBinary

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *`XML Name`*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *`XML Name`* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *`ID Attribute Name`* and a value as specified in *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *`Value Attribute Name`*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *`ID Attribute Name`*. The value is the value of *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Physical representation

Property	Type	Meaning
Encoding	String	Select one of the following values from the drop-down list: : • `CDatahex` (the default). Hexadecimal values in this field are specified with the CDATA qualifier, for example <e1><![CDATA[62]]></e1> • `hex`. Hexadecimal values in this field are specified as digits only, for example <e1>62</e1>. • `base64`. Values in this field are specified as digits only, coded in base 64.

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *XML Name*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *XML Name* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *ID Attribute Name* and a value as specified in *ID Attribute Value*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *XML Name*, *ID Attribute Name*, *ID Attribute Value* to the same values: – You must also set *Value Attribute Name* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *Value Attribute Name*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *ID Attribute Name*. The value is the value of *ID Attribute Value*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *XML Name*, *ID Attribute Name*, *ID Attribute Value* to the same values: – You must also set *Value Attribute Name* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

XML properties for attribute reference, element reference, local attribute, local element float types:

XML wire format properties for attribute reference, element reference, local attribute, and local element float types.

The XML Wire Format properties described here apply to:

- Objects: Attribute Reference, Element Reference, Local Attribute, Local Element
- Float schema types: double, float

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *`XML Name`*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *`XML Name`* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *`ID Attribute Name`* and a value as specified in *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *`Value Attribute Name`*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *`ID Attribute Name`*. The value is the value of *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *`XML Name`*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *`XML Name`* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *`ID Attribute Name`* and a value as specified in *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *`Value Attribute Name`*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *`ID Attribute Name`*. The value is the value of *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Attribute reference TDS properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float

Type of object	Properties
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

The following objects have properties that can be viewed or set.

TDS properties for attribute reference binary types:

The TDS wire format properties for attribute reference binary types.

The TDS Format properties described here apply to:

- Objects: Attribute Reference
- Binary schema types: base64Binary, hexBinary

Property	Type	Meaning
Length Reference	Enumerated type	This property is applicable only if `Physical Type` is `Text`, `Binary`, or `TLOG Specific`. If set, this property takes precedence over any value in the `Length Units` property. Specify the identifier of a sibling integer object, the value of which determines the length of the object in question. The sibling object must be defined before the current object within the message structure. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if `Length Reference` is set. If the check box is selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object only. If the check box is selected, the `Length Units` property of the sibling integer object must be the same as that of the current object.

TDS properties for attribute reference dateTime types:

The TDS wire format properties for attribute reference dateTime types.

The TDS Format properties described here apply to:

- Objects: Attribute Reference
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Property	Type	Meaning
Length Reference	Enumerated type	This property is applicable only if `Physical Type` is `Text`, `Binary`, or `TLOG Specific`. If set, this property takes precedence over any value in the `Length Units` property. Specify the identifier of a sibling integer object, the value of which determines the length of the object in question. The sibling object must be defined before the current object within the message structure. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if `Length Reference` is set. If the check box is selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object only. If the check box is selected, the `Length Units` property of the sibling integer object must be the same as that of the current object.

"Additional MRM domain information" on page 6251
More information about the MRM domain.

Complex type logical properties:

The logical properties of a complex type include properties that describe content and substitution settings.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.
Base Type	Enumerated type	You can use this property to select a type (simple or complex) that is used as the starting point to define a new complex type that is derived by restriction or extension.
Derived By	Enumerated type	If this property is active, select one of the following options: • restriction. If a complex type is derived by restriction, the content model of the complex type is a subset of the base type. • extension. If the complex type is derived by extension, the content model of the complex type is the content model of the base type plus the content model specified in the type derivation. Derivation by list or union is not supported.

Content

The following table shows the valid settings for `Composition` and `Content Validation`. These properties are located on the group which defines the content of this type. They can be edited only if the `Local group` button is selected. If the `Global group` button is selected, these properties are taken from the global group identified by the `Group name` field.

Valid children in a complex type that depend on both `Composition` and `Content Validation` are shown in "MRM content validation" on page 5422.

Property	Type	Meaning
Local Group	Button	Select this property if the content of your complex type is a local group.
Composition	Enumerated type	Define the order, and the number of occurrences, of the elements and groups in your messages. Composition does not affect the attributes in a complex type. Select one of the following options: • Empty • sequence. If you select this option, you can define members that are elements or groups. These members, if present, must appear in the specified order in the message. They can repeat, and the same element or group can appear more than once. • choice. If you select this option, you can define members that are elements or groups. Exactly one of the defined members must be present in the message, and can repeat. Use this option if you want to model C unions and COBOL REDEFINES in a Custom Wire Format, or an XML DTD element that uses choice in an XML Wire Format, or a SWIFT field that has more than one option. • all. If you select this option, you can define members that are elements; groups are not allowed. The elements in an all group can appear in any order. Each element can appear once, or not at all. An all group can be used only at the top level of a complex type; it cannot be a member of another group within a type. • unorderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements can appear in any order in the message. • orderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements must appear in the specified order in the message. • message. This option is supported only by the MRM domain.If you select this option, you can define only messages as members. Each member can repeat, but the same message cannot appear twice in the list of members. Like choice, only one of the defined members can be present in a message. Unlike choice, when writing a message, if the complex type or group has more than one member, the bit stream is not padded to the length of the longest member. Use this option to model multipart messages, which are used in some industry standards; for example, SWIFT. For more information, see the section on multipart messages in "Multipart messages" on page 1191.

Property	Type	Meaning
Content Validation	Enumerated type	`Content Validation` is used only by the MRM domain. If validation is enabled in your message flow, `Content Validation` specifies the strictness of the MRM validation for members of a complex type or group. See "MRM content validation" on page 5422 for further details. Select from the following options: • Closed. The complex type can only contain the child elements that you have added to it. • Open Defined. The complex type can contain any valid element defined within the message set. • Open. The complex type can contain any valid element, not just those that you have added to this complex type. See "Combinations of Composition and Content Validation" on page 5612 for further details of these options.
Group Reference	Button	Select this option if the content of your complex type is a reference to a group object
Group Name	Enumerated type	The `Group Name` is the name of the group that this complex type refers to. The groups available to be referenced can be selected from the drop down list.
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`.
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences.
Mixed	Check box	Select this option when the complex type has mixed content, and contains character data and sub-elements.

Substitution settings

Property	Type	Meaning
Final	Multiple selection enumerated type	The final attribute on a complex type controls whether other types can be derived from it. Valid values are extension/restriction/all. You can select from one or more of the following: • Empty • `restriction`. Prohibit type substitution by elements whose types are restrictions of the head element's type. • `extension`. Prohibit type substitution by elements whose types are extensions of the head element's type. • `#all`. Prohibit substitution by any method. To select more than one, you must type the selection into the property field.

Property	Type	Meaning
Block	Multiple selection enumerated type	The block attribute on a complex type restricts the types of substitutions which are allowed for elements based on that type. In the WebSphere Message Broker its effect is the same as if the block attribute were copied from the complex type onto every element based on the complex type. You can select from one or more of the following: • Empty • `restriction`. Prohibit type substitution by elements whose types are restrictions of the head element's type. • `extension`. Prohibit type substitution by elements whose types are extensions of the head element's type. • `#all`. Prohibit substitution by any method. To select more than one, you must type the selection into the property field.
Abstract	Check box	If selected, no elements based on this type can appear in the message.

Related concepts:

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

MRM content validation:

`Content Validation` is applied when the domain is MRM and validation is enabled. The `Content Validation` property specifies how strictly the MRM parser validates the members of a complex type or group.

The first of the following two tables shows the valid settings for `Content Validation` if `Composition` is set to `Message`. The second table shows the valid settings for `Content Validation` if `Composition` is not set to `Message`.

Content Validation options if Composition is set to Message

Option	Meaning
Open	When a message is parsed, this complex type or group can contain any message, not just those that you have defined in this message set. You can use this option for sparse messages (see "Self-defining elements and messages" on page 1198 for a definition of sparse messages).
Closed	When a message is parsed, this complex type or group can only contain the messages that are members of this complex type or group. This is always the case for messages represented in CWF format.
Open Defined	When a message is parsed, this complex type or group can contain any message defined within the message set.

Content Validation options if Composition is not set to Message

Option	Meaning
Open	When a message is parsed, this complex type or group can contain any elements and not just those that you have defined in this message set (see "Self-defining elements and messages" on page 1198 for a definition of sparse messages).
Closed	When a message is parsed, this complex type or group can only contain the elements that are members of this complex type or group.
Open Defined	When a message is parsed, this complex type or group can contain any element that you have defined within the message set.

When you are using `Content Validation` set to `open` or `open defined`, you cannot specify the precise position where the content that is not modeled is permitted to occur. If you want to do this, you should consider using a wildcard element as an alternative. Wildcard elements can appear only within a complex type or group with `Composition` of `sequence` and `Content Validation` of `closed`.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Combinations of Composition and Content Validation:

If your message is in the MRM domain, and validation is enabled, the members of each complex type or group are validated. The MRM validation logic is controlled by the `Composition` and `Content Validation` properties.

Content validation applies also to the IDOC domain because the IDoc parser uses the MRM parser internally. Content Validation does not affect validation in the XMLNSC domain.

Valid children in complex types dependent on Composition and Content Validation

Composition	Content Validation	Valid children
Empty	Closed	None
Empty	Open	None
Empty	Open Defined	None
Sequence	Open	Elements, group references, embedded simple types

Composition	Content Validation	Valid children
Sequence	Closed	Elements, group references, embedded simple types
Sequence	Open Defined	Elements, group references, embedded simple types
Choice	Closed	Elements, group references, embedded simple types
All	Closed	Elements
All	Open	Elements
All	Open Defined	Elements
Unordered Set	Open	Elements
Unordered Set	Closed	Elements
Unordered Set	Open Defined	Elements
Ordered Set	Open	Elements
Ordered Set	Closed	Elements
Ordered Set	Open Defined	Elements
Message	Open	Messages
Message	Closed	Messages
Message	Open Defined	Messages

The following objects have properties that can be viewed or set.

Valid combinations of repeat and duplicate elements in complex types:

Valid combinations of repeated and duplicate elements within a complex type depend on the `Composition` property value.

- A repeated element is an element that is included once within the complex type, and is defined with the property `Min Occurs` set to greater than 1. Repeated elements are therefore always contiguous and are always specified in the form A[n].
- A duplicate element is an element included more than once anywhere within the complex type. Duplicate elements do not have to be contiguous.

Repeated and duplicate elements in a complex type

Elements in type	Example	Unordered Set	Ordered Set	Sequence
No repeats, no duplicates	A, B, C	Yes	Yes	Yes
Repeated element (contiguous)	A[n], B, C	Yes	Yes	Yes
Duplicate element A (contiguous)	A, A, B, C	No	No	Yes
Duplicate element A (non-contiguous)	A, B, C, A	No	No	Yes

Complex type TDS properties:

The TDS properties of a complex type.

Field Identification

If the complex type is based on a global group, the TDS properties listed are located in the global group. If so, any changes to these properties are applied to the global group, and affect all references to the group (including any other complex types which are based on it).

Property	Type	Meaning
Data Element Separation	Enumerated type	Select one of the following values to specify the method that is used to separate the data elements within the type. • `Tagged Delimited`. This value indicates that all elements within the complex type are identified by a tag, and, if a value is specified in the optional `Delimiter` property, are separated by that value. You must set the `Tag` property for all child elements of simple type, and you can set the `Delimiter` property to a non-empty value. See "Global element TDS properties" on page 5513. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Fixed Length`. This value indicates that each element is identified by a tag, and the data has a fixed length. There are no delimiters. You must set the `Tag` property for each of the child elements of this complex type, and each child element must have a `Length` or `Length Reference` property assigned to it. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Encoded Length`. This value indicates that all elements within the complex type are separated by a tag, and a length field follows each tag. There are no delimiters. The tag can be fixed length, as set by the `Length of Tag` property, or variable length delimited by the `Tag Data Separator` property. You must also set the `Length Of Encoded Length` property so that the parser knows the size of the length field, and set the `Extra Chars in Encoded Length` property. This property tells the parser what to subtract from the value in the `Length Of Encoded Length` property to get the actual length of the data that follows the length field. This method provides a more flexible way of handling ACORD AL3 standard messages than using the `Fixed Length AL3` value, by allowing different parts of the messages to be at different versions of the ACORD AL3 standard. • `All Elements Delimited`. This value indicates that all elements within the complex type are separated by a delimiter. You must set a value in the `Delimiter` property. • `Variable Length Elements Delimited`. This value indicates that some of the elements within the complex type might be of variable length. Variable length elements must be delimited by the value specified in the `Delimiter` property. • `Use Data Pattern`. This value indicates that the parser determines the elements by matching the data with the regular expression that is set in the `Data Pattern` property of the element or type member. See "Message definition file properties" on page 5409. • `Fixed Length`. This value indicates that all elements within the complex type are fixed length. The next data element is accessed by adding the value of the `Length` property to the offset. See "Global element TDS properties" on page 5513. If you set the `Data Element Separation` property of a complex type to `Fixed Length`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length`. Each child element must have a `Length` or `Length Reference` property assigned to it. • `Fixed Length AL3`. This value has a similar meaning to the separation type `Fixed Length`, but also indicates to the parser that a number of predefined rules regarding missing optional elements, encoded lengths, and versioning, must be applied. If you set the `Data Element Separation` property of a complex type to `Fixed Length AL3`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length AL3`. • `Undefined`. This value is set automatically if you set the `Type Composition` property of a complex type to `Message`, and you cannot change it to any other value. Do not set the `Type Composition` property to `Empty`, `Choice`, `Unordered Set`, `Ordered Set`, `Sequence`, or `Simple Unordered Set`. If you do, you cannot check in the type.

Property	Type	Meaning
Group Indicator	String	Specify the value of a special character, or string, that precedes the data that belongs to a group, or a complex type, within the bit stream.
Group Terminator	String	Specify the value of a special character, or string, that terminates the data that belongs to a group, or a complex type, within the bit stream.
Delimiter	String	Specify the value of a special character, or string, that specifies the delimiter that is used between data elements. This property applies only to the delimited `Data Element Separation` methods (`Tagged Delimited`, `All Elements Delimited`, and `Variable Length Elements Delimited`).
Suppress Absent Element Delimiters	Enumerated type	Use this property to select whether you want delimiters to be suppressed for elements that are missing within a message. Select from: • `End Of Type`. Use this option to suppress the delimiter when an element is missing. For example, if the model has been defined to have up to three elements and only two are present, the last delimiter can be omitted from the message. • `Never`. Use this option to ensure that even if optional elements are not present, all delimiters are written out. Use this option when the same delimiter is used to delimit parent and child objects. For example, if an optional child element is missing, message processing applications cannot tell where the child elements in a message end and the next parent element starts, if the delimiters are all the same.
Observe Element Length	Check box	This property is applicable when `Data Element Separation` is `All Elements Delimited` or `Tagged Delimited`. Select this check box if the `Length` property of child simple elements is significant when parsing and writing. • During parsing, an exception is thrown if the length of the extracted data exceeds the specified length. Otherwise, the data is trimmed according to the `Justification` and `Padding Character` properties of the child element. • During writing, an exception is thrown if the data to write exceeds the specified length. Otherwise, the data is padded according to the `Justification` and `Padding Character` properties of the child element. Clear this check box to ignore the `Length` property when parsing and writing. The default value depends on the setting of the `Messaging Standard` property (at the message set level) and the `Data Element Separation` property. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is `TLOG`, the check box is selected. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is other than `TLOG`, the check box is cleared. • If `Data Element Separation` is `Tagged Delimited`, the check box is cleared. For all other data element separation methods, the check box is disabled and does not influence the behavior of the TDS parser.
Tag Data Separator	Button and String	Specify the value of a special character or string that separates the Tag from the data. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides `Length of Tag`. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).

Property	Type	Meaning
Length of Tag	Button and Integer	Specify the length of a tag value. When the message is parsed, this property allows tags to be extracted from the bit stream if the `Tag Data Separator` property is not set. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides this value. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).
Length of Encoded Length	Integer	Specifies the number of characters (not bytes) after a tag that are used for the length field. Enter a value from 0 to 2147483647. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`; it is not valid otherwise. The actual number of data characters that are parsed depends on the value of the `Extra Chars in Encoded Length` property.
Extra Chars in Encoded Length	Integer	(Only valid if the `Data Element Separation` method is set to `Tagged Encoded Length`.) Specifies the number of extra characters included in the value found in the length field. (For example, the value in the length might include the size of the length field itself as well as the size of the data field, or it might be the total size of the tag, length, and data fields.) Enter a value from 0 to 2147483647. The parser subtracts this number from the number found in the length field to get the number of data characters that follow the length field. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`, and the actual number of data characters is less than the value found in the length field.

Element reference logical properties:

The logical properties of an element reference include properties that specify the number of occurrences of the element reference.

Property	Type	Meaning
Reference Name	Enumerated type	The `Reference Name` is the name of the object that this object is referring to. The objects available to reference can be selected from the list.

Occurrences

Property	Type	Meaning
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`.

Property	Type	Meaning
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences.

The Min Occurs and Max Occurs properties are used in conjunction with an element's Value properties. The following table summarizes how an element reference can be constrained.

Min Occurs	Max Occurs	Fixed	Default	Notes
1	1			The element must appear once, and can have any value.
1	1	Delta		The element must appear once, and it must match the data that has been entered in the `Value` property. In this example, the element must contain the text Delta.
2	-1	Delta		The element must appear twice or more, and it must match the data that has been entered in the `Value` property. In this example, at least two elements must contain the text Delta.
0	1			The element is optional, can appear once, and can have any value.
0	1	Delta		The element is optional, and can appear once. If it does appear, its value must match the data that has been entered in the `Value` property. If it does not appear, its value is the data that has been entered in the `Value` property.
0	1		Delta	The element is optional, and can appear once. If it does not appear, its value is the data that has been entered in the `Value` property. If it does appear, it must be the value given in the element.
0	2		Delta	The element is optional and can appear once, twice, or not at all. If the element does not appear, it is not provided. If the element appears and it is empty, it set to the data held in the `Value` property, else it is the value given in the element.
0	0			The element is prohibited, and must not appear.

The following objects have properties that can be viewed or set.

Element reference CWF properties:

The properties, and permissible values, vary according to the type of object.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	Properties
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

CWF wire format properties for element reference and local element binary types.

The Custom Wire Format properties described here apply to:

- Objects: Element Reference, Local Element
- Binary schema types: base64Binary, hexBinary

Physical representation

Property	Type	Meaning
Length	Button and Integer	If you have selected the length to be defined by *Length*, enter the number of length units for the element. The minimum value that you can specify is 1. The maximum value that you can specify is 2147483647. The default value is empty (not set).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *Length Reference*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if *Length Reference* is set. If the check box is selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object only. If the check box is selected, the *Length Units* property of the sibling integer object must be the same as that of the current object.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. The length is given in bytes. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`* or *`Length Reference`* property. The default is `Bytes`.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.

Property	Type	Meaning
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *`Repeat Reference`* is specified, it overrides any setting for the *`Max Occurs`* logical property when parsing and writing the message, but not for validation of the message.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

CWF properties for element reference and local element dateTime types:

The CWF wire format properties for element reference and local element dateTime types.

The Custom Wire Format properties described here apply to:

- Objects: Element Reference, Local Element
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Fixed Length String`. The element's length is determined by other length properties as follows. • `Length Encoded String 1`. The first byte of the element contains the length of the string following the length byte in length units. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The element's first 2 bytes contain the length of the string following the two length bytes in length units. The maximum length of a `Length Encoded String 2` element is 65535 length units. The two length bytes are in the format of the WebSphere MQ queue manager Encoding. • `Null Terminated String`. The string ends with the hexadecimal NULL character, `X'00'`. • `Packed Decimal`. The dateTime is coded as a Packed Decimal number. It is valid only if the *`DateTime Format`* property represents numeric-only data. • `Binary`. The dateTime is encoded as a binary sequence of bytes. If you select this option, the range of symbols that you can specify for the Format String property is less than the range of symbols you can specify if you select a string option (see "DateTime formats" on page 6310 for details). • `Time Seconds`. This value supports C time_t and Java Date and Time objects. It is valid only if the *`DateTime Format`* property represents numeric-only data. • `Time Milliseconds`. This value supports C time_t and Java Date and Time objects. It is valid only if the *`DateTime Format`* property represents numeric-only data. The default value is `fixed length string`.
Length	Button and Integer	If you have selected a *`Physical Type`* of `Fixed Length String`, `Packed Decimal`, or `Binary`, and have selected the length to be defined by *`Length`*, enter the number of length units for the element. The minimum value that you can specify is `1` for all three physical types. The maximum value that you can specify is `256` for `Fixed Length String`, `10` for `Packed Decimal`, and `2147483647` for `Binary`. The default value is 0 (zero).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *`Length Reference`*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see "Reordering objects" on page 2900.

Property	Type	Meaning
Inclusive Length Reference	Check box	This property is applicable only if *Length Reference* is set. If the check box is selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object only. If the check box is selected, the *Length Units* property of the sibling integer object must be the same as that of the current object.
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. The length is given in bytes. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *Length Count* or *Length Reference* property. The default is `Bytes`.
Justification	Enumerated type	If you have set the *Physical Type* property to `Fixed Length String`, select `Left Justify` (the default value) or `Right Justify` from the list. If you have selected another value for *Physical Type*, this property is inactive.

Property	Type	Meaning
Padding Character	String	If you have set the *Physical Type* property to `Fixed Length String`, and the *Justification* property is either `Left Justify` or `Right Justify`, this property is applicable. When writing an output message, use the padding character to fill out the remaining character positions when the string length is less than the length implied by the *Length* or *Length Reference* property. Whether the string is padded from the left or the right is governed by the *Justification* property. When parsing an input message, the padding character is trimmed from the end of the string. Whether the string is trimmed from the left or the right is governed by the *Justification* property. Specify this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the displayed list. • Enter a character between quotation marks; for example, `"c"` or `'c'`, where c is any alphanumeric character. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, it is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.
DateTime Format	String	Specify a template for date and time. The default dateTime format is dependent on the logical type of the object. For information about the defaults for the dateTime format according to the logical type, see “DateTime defaults by logical type” on page 6320. See “DateTime formats” on page 6310 for details of date and time formats.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed. This property is applicable only if the *Physical type* property is Packed Decimal. By default, this check box is cleared, which indicates that the value is not signed.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the displayed list. The option that you select determines the value that you must set for the property *Encoding Null Value*: • NULLPadFill. This option is valid only if *Physical Type* is Fixed Length String. The field is filled with the value specified by the *Padding Character*. The default value. • NULLLogicalValue. The *Encoding Null Value* property is first converted to an actual value, and rendered in the way specified for the field. • NULLLiteralValue. This specifies that *Encoding Null Value* contains a value that is directly substituted as if it is a string. Use this option when the value you have set for *Encoding Null Value* to specify a null date is not a dateTime value, or does not conform to the standard dateTime format yyyy-MM-dd 'T'HH:mm:ss. • NULLLiteralFill. The field is filled with the value specified by the *Encoding Null Value*. *Encoding Null Value* must resolve to a single character.
Encoding Null Value	String	If you set the *Encoding Null* property to NULLPadFill, this property is disabled. If you set the *Encoding Null* property to NULLLogicalValue, you must set this property to an ISO8601 dateTime format. These formats are described in "DateTime as string data" on page 6311. For example, specify a value conforming to yyyy-MM-dd'T'HH:mm:ss such as 1970-12-01. If you set the *Encoding Null* property to NULLLiteralValue, you can enter any value that is the same length as the field. If you set the *Encoding Null* property to NULLLiteralFill, the value must resolve to a single character. Set the character in one of the following ways: • Select SPACE, NUL, 0x00 or 0xFF from the displayed list • Enter a character between quotation marks, for example 'c' or "c", where c is any alphanumeric character. • Enter a hexadecimal character code in the form 0xYY where YY is a hexadecimal value. • Enter a decimal character code in the form YY where YY is a decimal value. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal format.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *`Repeat Reference`* is specified, it overrides any setting for the *`Max Occurs`* logical property when parsing and writing the message, but not for validation of the message.

CWF properties for element reference and local element decimal types:

The CWF wire format properties for element reference and local element decimal types.

The Custom Wire Format properties described here apply to:

- Objects: Element Reference, Local Element
- Decimal schema types: decimal, integer, negativeInteger, nonNegativeInteger, nonPositiveInteger, positiveInteger, unsignedLong

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Integer`. This equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. Equates to the COMP-3 data type in COBOL. • `External Decimal`. Equates to the data type PIC 9 USAGE DISPLAY in COBOL. The representation of numeric elements can be affected by the Encoding and CodedCharSetId attributes that are set for the WebSphere MQ queue manager: • Elements that have *`Physical Type`* set to `Integer` and `Packed Decimal` are represented in the appropriate WebSphere MQ Encoding value. • Elements that have *`Physical Type`* set to `External Decimal` are represented in the WebSphere MQ CodedCharSetId value.

Property	Type	Meaning
Length	Integer	Enter the number of bytes to specify the element length: • If you set the *Physical Type* to Integer, select 1, 2, or 4 (the default) from the displayed list. • If you set the *Physical Type* to Packed Decimal, enter a value between 1 and 10. • If you set the *Physical Type* to Extended Decimal, enter a value between 1 and 256. (Numbers greater than the maximum COBOL PICTURE clause of 18 are assumed to be 18.)
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • Bytes. • Characters. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • Character Units. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to Characters. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the Length property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • End of Bitstream. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *Length Count*. The default is Bytes.
Justification	Enumerated type	If you have set the *Physical Type* property to External Decimal, select Left Justify or Right Justify (the default value) from the list. If you have selected another value for *Physical Type*, this property is inactive.

Property	Type	Meaning
Padding Character	String	The padding character is used to fill out the remaining character positions when the string length is less than the specified string size. If you have set the *Physical Type* property to `Extended Decimal`, and the *Justification* property is either `Left Justify` or `Right Justify`, specify this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the displayed list. • Enter a character between quotation marks; for example, `"c"` or `'c'`, where c is any alphanumeric character. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, this is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Select (the default) or clear this property. This property is used with *Sign Orientation*.

Property	Type	Meaning
Sign EBCDIC Custom Overpunched	Check box	If the *Physical Type* is set to External Decimal and the *Signed EBCDIC Custom* property is set, this indicates that the Sign EBCDIC Custom Overpunched representation is to be used within an ASCII environment. If this check box is not selected (the default), the Sign ASCII representation is used. The setting of the *Sign EBCDIC Custom Overpunched* check box is appropriate only if the *Sign Orientation* property is set to Leading or Trailing (indicating that the element/attribute has an embedded sign representation). The check box is not available if the element/attribute is unsigned (for example, if the *Signed* check box is not set).
Sign Orientation	Enumerated type	If you have set *Physical Type* to External Decimal and you have selected *Signed*, choose from the following options that represent the COBOL options for displaying numeric data: • Leading Overpunched. This option sets a bit in the first byte if the number is negative. No setting is made if the number is positive. For example, the ASCII hexadecimal representation of the number 22 is x'3232'. Using this option, the number +22 would be x'3232' and the number -22 would be x'7232'. The default value. • Leading Separate. This option sets the first byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. • Trailing Overpunched. This option sets a bit in the last byte if the number is negative. No setting is made if the number is positive. Using this option, the number +22 would be x'3232' and the number -22 would be x'3272'. • Trailing Separate. This option sets the last byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. If you have set *Physical Type* to any other value, the value Not Applicable is set for you.
Virtual Decimal Point	Integer	Specify the number of places to the left (for a positive value) or right (for a negative value) that a decimal point is to be moved from its assumed position. For example, a decimal element containing 1234 with a Virtual Decimal value of 3 is 1.234, equivalent to 'V' or 'P' in a COBOL picture clause. There is no C equivalent

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the displayed list: • NULLPadFill. This option is valid only if *Physical Type* is External Decimal. The field is filled with the value specified by the *Padding Character*. *Encoding Null Value* must be set to an empty string. • NULLLogicalValue. The *Encoding Null Value* is transformed to match the required format for the field. The default value. • NULLLiteralValue. The *Encoding Null Value* is directly substituted as if it is a string. You can specify a nonnumeric value for *Encoding Null Value*. • NULLLiteralFill. The field is filled with the value specified by the *Encoding Null Value*. *Encoding Null Value* must resolve to a single character.

Property	Type	Meaning
Encoding Null Value	String	The use of this property depends on the *Encoding Null* property, except for NULLLiteralFill. The default value is zero. If you set the *Encoding Null* property to NULLLiteralFill, the value must resolve to a single character. Set the character in one of the following ways: • Select SPACE, NUL, 0x00 or 0xFF from the displayed list • Enter a character between quotation marks, for example 'c' or "c", where c is any alphanumeric character. • Enter a hexadecimal character in the form 0xYY where YY is a hexadecimal value. • Enter a decimal character code in the form YY where YY is a decimal value. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal format.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • 1 Bytes. The default value. • 2 Bytes • 4 Bytes • 8 Bytes • 16 Bytes
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Integer`. This equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Float`. This equates to the data type FLOAT or DOUBLE in C or the COMP-1 or COMP-2 data type in COBOL and is the default value. • `Packed Decimal`. Equates to the COMP-3 data type in COBOL. • `External Decimal`. Equates to the data type PIC 9 USAGE DISPLAY in COBOL. The representation of numeric elements can be affected by the Encoding and CodedCharSetId attributes that are set for the WebSphere MQ queue manager: • Elements that have *`Physical Type`* set to `Integer`, `Packed Decimal`, and `Float` are represented in the appropriate WebSphere MQ Encoding value. • Elements that have *`Physical Type`* set to `External Decimal` are represented in the WebSphere MQ CodedCharSetId value.
Length	Integer	Enter the number of bytes to specify the element length: • If you set the *`Physical Type`* to `Float`, select a value from the displayed list. The default value is 8. • If you set the *`Physical Type`* to `Integer`, select `1`, `2`, or `4` (the default) from the displayed list. • If you set the *`Physical Type`* to `Packed Decimal`, enter a value between 1 and 10. • If you set the *`Physical Type`* to `Extended Decimal`, enter a value between 1 and 256. (Numbers greater than the maximum COBOL PICTURE clause of 18 are assumed to be 18.)

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`*. The default is `Bytes`.
Justification	Enumerated type	If you have set the *`Physical Type`* property to `External Decimal`, select `Left Justify` or `Right Justify` (the default value) from the list. If you have selected another value for *`Physical Type`*, this property is inactive.

Property	Type	Meaning
Padding Character	String	The padding character is used to fill out the remaining character positions when the string length is less than the specified string size. If you have set the *Physical Type* property to Extended Decimal, and the *Justification* property is either Left Justify or Right Justify, specify this character in one of the following ways: • Select NUL, '0', or SPACE from the displayed list. • Enter a character between quotation marks; for example, "c" or 'c', where c is any alphanumeric character. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form 0xYY, where YY is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, this is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Select or clear (unsigned, the default) this property. If you have set *Physical Type* to Float, this is selected. This property is used with *Sign Orientation*.

Property	Type	Meaning
Sign EBCDIC Custom Overpunched	Check box	If the *Physical Type* is set to External Decimal and the *Signed EBCDIC Custom* property is set, this indicates that the Sign EBCDIC Custom Overpunched representation is to be used within an ASCII environment. If this check box is not selected (the default), the Sign ASCII representation is used. The setting of the *Sign EBCDIC Custom Overpunched* check box is appropriate only if the *Sign Orientation* property is set to Leading or Trailing (indicating that the element/attribute has an embedded sign representation). The check box is not available if the element/attribute is unsigned (for example, if the *Signed* check box is not set).
Sign Orientation	Enumerated type	If you have set *Physical Type* to External Decimal and you have selected *Signed*, choose from the following options that represent the COBOL options for displaying numeric data: • Leading Overpunched. This option sets a bit in the first byte if the number is negative. No setting is made if the number is positive. For example, the ASCII hexadecimal representation of the number 22 is x'3232'. Using this option, the number +22 would be x'3232' and the number -22 would be x'7232'. The default value. • Leading Separate. This option sets the first byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. • Trailing Overpunched. This option sets a bit in the last byte if the number is negative. No setting is made if the number is positive. Using this option, the number +22 would be x'3232' and the number -22 would be x'3272'. • Trailing Separate. This option sets the last byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. If you have set *Physical Type* to any other value, the value Not Applicable is set for you.
Virtual Decimal Point	Integer	Specify the number of places to the left (for a positive value) or right (for a negative value) that a decimal point is to be moved from its assumed position. For example, a float element containing 1234 with a Virtual Decimal value of 3 is 1.234. This property is not applicable if you have set *Physical Type* to Float.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the displayed list: • NULLPadFill. This option is valid only if *Physical Type* is External Decimal. The field is filled with the value specified by the *Padding Character*. *Encoding Null Value* must be set to an empty string. • NULLLogicalValue. The *Encoding Null Value* is transformed to match the required format for the field. The default value. • NULLLiteralValue. The *Encoding Null Value* is directly substituted as if it is a string. You can specify a nonnumeric value for *Encoding Null Value*. • NULLLiteralFill. The field is filled with the value specified by the *Encoding Null Value*. *Encoding Null Value* must resolve to a single character.

Property	Type	Meaning
Encoding Null Value	String	The use of this property depends on the *Encoding Null* property, except for NULLLiteralFill. The default value is zero. If you set the *Encoding Null* property to NULLLiteralFill, the value must resolve to a single character. Set the character in one of the following ways: • Select SPACE, NUL, 0x00 or 0xFF from the displayed list • Enter a character between quotation marks, for example 'c' or "c", where c is any alphanumeric character. • Enter a hexadecimal character in the form 0xYY where YY is a hexadecimal value. • Enter a decimal character code in the form YY where YY is a decimal value. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal format.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • 1 Bytes. The default value. • 2 Bytes • 4 Bytes • 8 Bytes • 16 Bytes
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

CWF properties for element reference and local element integer types:

The CWF wire format properties for element reference and local element integer types.

The Custom Wire Format properties described here apply to:

- Objects: Element Reference, Local Element
- Integer schema types: byte, int, long, short, unsignedByte, unsignedInt, unsignedShort

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Integer`. This equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. Equates to the COMP-3 data type in COBOL. • `External Decimal`. Equates to the data type PIC 9 USAGE DISPLAY in COBOL. The representation of numeric elements can be affected by the Encoding and CodedCharSetId attributes that are set for the WebSphere MQ queue manager: • Elements that have *`Physical Type`* set to `Integer` and `Packed Decimal` are represented in the appropriate WebSphere MQ Encoding value. • Elements that have *`Physical Type`* set to `External Decimal` are represented in the WebSphere MQ CodedCharSetId value.
Length	Integer	Enter the number of bytes to specify the element length: • If you set the *`Physical Type`* to `Integer`, select `1`, `2`, or `4` (the default) from the displayed list. • If you have set *`Physical Type`* to `Packed Decimal`, enter a value between 1 and 6. • If you have set *`Physical Type`* to `Extended Decimal`, enter a value between 1 and 11.
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`*. The default is `Bytes`.

Property	Type	Meaning
Justification	Enumerated type	If you have set the *Physical Type* property to `External Decimal`, select `Left Justify` or `Right Justify` (the default value) from the list. If you have selected another value for *Physical Type*, this property is inactive.
Padding Character	String	The padding character is used to fill out the remaining character positions when the string length is less than the specified string size. If you have set the *Physical Type* property to `Extended Decimal`, and the *Justification* property is either `Left Justify` or `Right Justify`, specify this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the displayed list. • Enter a character between quotation marks; for example, `"c"` or `'c'`, where `c` is any alphanumeric character. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, this is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Numeric representation

Property	Type	Meaning
Signed	Check box	Select (the default) or clear this property. This property is used with *Sign Orientation*.

Property	Type	Meaning
Sign EBCDIC Custom Overpunched	Check box	If the *Physical Type* is set to External Decimal and the *Signed EBCDIC Custom* property is set, this indicates that the Sign EBCDIC Custom Overpunched representation is to be used within an ASCII environment. If this check box is not selected (the default), the Sign ASCII representation is used. The setting of the *Sign EBCDIC Custom Overpunched* check box is appropriate only if the *Sign Orientation* property is set to Leading or Trailing (indicating that the element/attribute has an embedded sign representation). The check box is not available if the element/attribute is unsigned (for example, if the *Signed* check box is not set).
Sign Orientation	Enumerated type	If you have set *Physical Type* to External Decimal and you have selected *Signed*, choose from the following options that represent the COBOL options for displaying numeric data: • Leading Overpunched. This option sets a bit in the first byte if the number is negative. No setting is made if the number is positive. For example, the ASCII hexadecimal representation of the number 22 is x'3232'. Using this option, the number +22 would be x'3232' and the number -22 would be x'7232'. The default value. • Leading Separate. This option sets the first byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. • Trailing Overpunched. This option sets a bit in the last byte if the number is negative. No setting is made if the number is positive. Using this option, the number +22 would be x'3232' and the number -22 would be x'3272'. • Trailing Separate. This option sets the last byte of the element to '+' if the number is positive and to '-' if the number is negative. For this option, the length must include the sign byte. If you have set *Physical Type* to any other value, the value Not Applicable is set for you.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the displayed list: • NULLPadFill. This option is valid only if *Physical Type* is External Decimal. The field is filled with the value specified by the *Padding Character*. *Encoding Null Value* must be set to an empty string. • NULLLogicalValue. The *Encoding Null Value* is transformed to match the required format for the field. The default value. • NULLLiteralValue. The *Encoding Null Value* is directly substituted as if it is a string. You can specify a nonnumeric value for *Encoding Null Value*. • NULLLiteralFill. The field is filled with the value specified by the *Encoding Null Value*. *Encoding Null Value* must resolve to a single character.

Property	Type	Meaning
Encoding Null Value	String	The use of this property depends on the *Encoding Null* property, except for NULLLiteralFill. The default value is zero. If you set the *Encoding Null* property to NULLLiteralFill, the value must resolve to a single character. Set the character in one of the following ways: • Select SPACE, NUL, 0x00 or 0xFF from the displayed list • Enter a character between quotation marks, for example 'c' or "c", where c is any alphanumeric character. • Enter a hexadecimal character in the form 0xYY where YY is a hexadecimal value. • Enter a decimal character code in the form YY where YY is a decimal value. • Enter a Unicode value in the form U+xxxx where xxxx is a Unicode value specified in hexadecimal format.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • 1 Bytes. The default value. • 2 Bytes • 4 Bytes • 8 Bytes • 16 Bytes
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is 0, the minimum value is 0, and the maximum value is 999999. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

CWF properties for element reference and local element string types:

The CWF wire format properties for element reference and local element string types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- String schema types: anyURI, ENTITIES, ENTITY, ID, IDREF, IDREFS, language, Name, NCName, NMTOKEN, NMTOKENS, normalizedString, NOTATION, QName, string, token

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select one from the displayed list: • `Fixed Length String`. The element's length is determined by other length properties as follows. • `Length Encoded String 1`. The first byte of the element contains the length of the string following the length byte in length units. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The element's first 2 bytes contain the length of the string following the two length bytes in length units. The maximum length of a `Length Encoded String 2` element is 65535 length units. The two length bytes are in the format of the WebSphere MQ queue manager Encoding. • `Null Terminated String`. The string ends with the hexadecimal NULL character, `X'00'`. The default is `Fixed Length String`.
Length	Button and Integer	If you have selected a *`Physical Type`* of `Fixed Length String` or `Binary`, and have selected the length to be defined by *`Length`*, enter the number of length units for the element. The minimum value that you can specify is `0` (zero), the maximum value that you can specify is `2147483647` The default value is `0` (zero).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *`Length Reference`*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see “Reordering objects” on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if *`Length Reference`* is set. If the check box is selected, the value of the sibling integer object that is identified by *`Length Reference`* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *`Length Reference`* is the length of the current object only. If the check box is selected, the *`Length Units`* property of the sibling integer object must be the same as that of the current object.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the element or attribute. Select one of the following options from the displayed list (some physical types do not offer all these options): • `Bytes`. The length is given in bytes. • `Characters`. The Length is given in characters. This means that the number of bytes that are processed in the bitstream depends on the code page of the characters that are being processed. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the bitstream content. The parser reads one character at a time and determines whether the character comprises one or more bytes. • `Character Units`. This option specifies that the size of each character (in bytes) is determined by the code page of the message. – For single-byte and double-byte code pages, this option is identical to `Characters`. – For a multibyte code page, this option provides improved parsing performance by assuming that every character is encoded in the smallest character unit that the code page supports. However, this means that a message must contain only these characters if it is to be processed correctly. For example, in code page "UTF-8" (CCSID 1208), the minimum character unit is 1 byte; therefore, the parser can make a single read (of the number of bytes specified by the `Length` property) to fetch the entire message. The message must contain only characters that are encoded in 1-byte units. • `End of Bitstream`. All data up to the end of the bitstream is processed. This option is valid only if the element is the last in the message. If you select this value, you do not need to enter a value for the *`Length Count`* or *`Length Reference`* property. The default is `Bytes`.
Justification	Enumerated type	If you have set the *`Physical Type`* property to `Fixed Length String`, select `Left Justify` (the default value) or `Right Justify` from the list. If you have selected another value for *`Physical Type`*, this property is inactive.

Property	Type	Meaning
Padding Character	String	If you have set the *Physical Type* property to `Fixed Length String`, and the *Justification* property is either `Left Justify` or `Right Justify`, this property is applicable. When writing an output message, use the padding character to fill out the remaining character positions when the string length is less than the length implied by the *Length* or *Length Reference* property. Whether the string is padded from the left or the right is governed by the *Justification* property. When parsing an input message, the padding character is trimmed from the end of the string. Whether the string is trimmed from the left or the right is governed by the *Justification* property. Specify this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the displayed list. • Enter a character between quotation marks; for example, `"c"` or `'c'`, where c is any alphanumeric character. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. • Enter a hexadecimal character in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a decimal byte value (from 0 to 255). The choice of which of these padding character forms is used for an MRM element depends on the padding character that is required and whether the padding character is to be subject to data conversion. In most cases, the specification of a padding character in quotation marks is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is being generated. For example, when converting from ASCII to the code page 500, if you have specified U+0008 as your padding character, it is converted from 0x08 to 0x15, the ASCII and EBCDIC representations of 'back space'. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is being generated. If you are converting a message from one code page to another, ensure that the converted value of the padding character is valid for this code page. If the padding character cannot be represented in the target code page, it is replaced by a substitution character. The substitution character is fixed and its value depends on the specified target code page. If a padding character is required that is not subject to data conversion, the hexadecimal or decimal format can be used and you then have the option of specifying an absolute value as a padding character that is inserted directly into the output message. If this format is used, ensure still that this value is valid for the code page of any output messages that are created using these MRM definitions.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the displayed list: • `NULLPadFill`. This is valid only if *`Physical Type`* is `Fixed Length String`. The field is filled with the value specified by the *`Padding Character`*. *`Encoding Null Value`* must be set to an empty string. • `NULLLogicalValue`. The *`Encoding Null Value`* is transformed to match the required format for the field. The default value. • `NULLLiteralValue`. The *`Encoding Null Value`* is directly substituted as if it is a string. • `NULLLiteralFill`. The field is filled with the value specified by the *`Encoding Null Value`*. *`Encoding Null Value`* must resolve to a single character.
Encoding Null Value	STRING	The use of this property depends on the *`Encoding Null`* property. If specified, its length must be equal to the length of the string element, except for `NULLLiteralFill`. The default value is empty (not set). If you set the *`Encoding Null`* property to `NULLLiteralFill`, the value must resolve to a single character. Set the character in one of the following ways: • Select `SPACE`, `NUL`, `0x00` or `0xFF` from the displayed list • Enter a character between quotation marks, for example `'c'` or `"c"`, where `c` is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY` where `YY` is a hexadecimal value. • Enter a decimal character code in the form `YY` where `YY` is a decimal value. • Enter a Unicode value in the form `U+xxxx` where `xxxx` is a Unicode value specified in hexadecimal format.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

Element reference XML properties:

The properties, and their permissible values, vary according to the type of object.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

Related concepts:

XML properties for attribute reference, element reference, local attribute, local element binary types:

XML wire format properties for attribute reference, element reference, local attribute, and local element binary types.

The XML Wire Format properties described here apply to:

- Objects: Attribute Reference, Element Reference, Local Attribute, Local Element
- Binary schema types: base64Binary, hexBinary

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *`XML Name`*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *`XML Name`* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *`ID Attribute Name`* and a value as specified in *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *`Value Attribute Name`*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *`ID Attribute Name`*. The value is the value of *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Physical representation

Property	Type	Meaning
Encoding	String	Select one of the following values from the drop-down list: : • `CDatahex` (the default). Hexadecimal values in this field are specified with the CDATA qualifier, for example <e1><![CDATA[62]]></e1> • `hex`. Hexadecimal values in this field are specified as digits only, for example <e1>62</e1>. • `base64`. Values in this field are specified as digits only, coded in base 64.

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *`XML Name`*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *`XML Name`* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *`ID Attribute Name`* and a value as specified in *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *`Value Attribute Name`*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *`ID Attribute Name`*. The value is the value of *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Physical representation

Property	Type	Meaning
DateTime Format	String	Specify a format string that specifies the rendering of the value for dateTime elements. The default dateTime format is dependent on the logical type of the object. For information about the defaults for the dateTime format according to the logical type see "DateTime defaults by logical type" on page 6320. See "DateTime formats" on page 6310 for details of dateTime formats.

XML properties for attribute reference, element reference, local attribute, local element decimal types:

XML wire format properties for attribute reference, element reference, local attribute, and local element decimal types.

The XML Wire Format properties described here apply to:

- Objects: Attribute Reference, Element Reference, Local Attribute, Local Element
- Decimal schema types: decimal, integer, negativeInteger, nonNegativeInteger, nonPositiveInteger, positiveInteger, unsignedLong

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *XML Name*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *XML Name* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *ID Attribute Name* and a value as specified in *ID Attribute Value*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *XML Name*, *ID Attribute Name*, *ID Attribute Value* to the same values: – You must also set *Value Attribute Name* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *Value Attribute Name*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *ID Attribute Name*. The value is the value of *ID Attribute Value*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *XML Name*, *ID Attribute Name*, *ID Attribute Value* to the same values: – You must also set *Value Attribute Name* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Field identification

A number of the following properties only become active depending on the value that *Render* property is set to.

Property	Type	Meaning
Render	Enumerated type	Specify how the instantiated object or type is rendered (output) in the resulting XML document. Select one of the following values from the drop-down list: • `XMLElement`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the content of the child element. If you select this value for more than one object, and set their *`XML Name`*property to the same value, both objects must refer to the same element. This is the default value for element objects. • `XMLAttribute`. If you select this value, the object (or type) is rendered as an attribute of the parent XML object. The identity of the child is determined by the attribute name. The value is the attribute value. This is only valid for simple elements. If you select this value for more than one object , you must set their *`XML Name`* property to different values. This is the default value for attribute objects. • `XMLElementAttrID`. If you select this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the value of a specified attribute of the child. The value is the content of the child element. You must add an attribute to the child element with an attribute name as specified in *`ID Attribute Name`* and a value as specified in *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrIDVal` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. • `XMLElementAttrVal`. If you specify this value, the object (or type) is rendered as a child XML element of the parent complex type. The identity of the child is determined by the tag name of the child. The value is the value of a specified attribute. The name of the attribute is specified in *`Value Attribute Name`*. • `XMLElementAttrIDVal`. This option combines the two options, `XMLElementAttrID` and `XMLElementAttrVal`. The object is rendered as a child of the parent complex type. The identity of the child is determined by the value of *`ID Attribute Name`*. The value is the value of *`ID Attribute Value`*. If you select this value for one object, and set this same value or the value `XMLElementAttrID` for a second object, and set *`XML Name`*, *`ID Attribute Name`*, *`ID Attribute Value`* to the same values: – You must also set *`Value Attribute Name`* to the same value for the two objects. – Both objects must refer to the same element. "XML rendering options" on page 6262 shows some examples of how these rendering options affect the XML output, and provides usage recommendations.

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).
ID Attribute Name	String	Specify the name of the attribute used to identify the child. This must be a valid XML Attribute Name. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is `id`.
Namespace	String	Enter the namespace associated with the *ID Attribute*.
ID Attribute Value	String	Specify the value of the attribute used to identify the child. This property is ignored and cannot be changed (the field is disabled) if *Render* is set to `XMLElement`, `XMLAttribute`, or `XMLElementAttrVal`. The default value is the identifier of the child.
Value Attribute Name	String	Specify the name of the attribute used for the value of the child. This must be a valid XML Attribute Name. This is only used if required by the setting of *Render*. The default value is `val`.
Namespace	String	Enter the namespace associated with the *Value Attribute*.

Element reference TDS properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
Complex types	
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong

Type of object	Properties
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

TDS properties for element reference binary types:

TDS wire format properties for element reference binary types.

The TDS Format properties described here apply to:

- Objects: Element Reference
- Binary schema types: base64Binary, hexBinary

Physical representation

Property	Type	Meaning
Length Reference	Enumerated type	This property is applicable only if `Physical Type` is `Text`, `Binary`, or `TLOG Specific`. If set, this property takes precedence over any value in the `Length Units` property. Specify the identifier of a sibling integer object, the value of which determines the length of the object in question. The sibling object must be defined before the current object within the message structure. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if `Length Reference` is set. If the check box is selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object only. If the check box is selected, the `Length Units` property of the sibling integer object must be the same as that of the current object.

Occurrences

Property	Type	Meaning
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, no integer objects exist before this one in the message structure. If a `Repeat Reference` is specified, it overrides any setting for the `Max Occurs` logical property when parsing and writing the message, but not for validating the message.
Repeating Element Delimiter	String	Specify the delimiter to use between repeating elements. This delimiter is used only when the element repeats and the `Data Element Separation` property of the parent group or complex type is set to `All Elements Delimited` or `Variable Length Elements Delimited`. A default value is provided if the previous conditions are true; if the messaging standard is HL7, the mnemonic <HL7_RS> is used; if the messaging standard is not HL7, and the maximum number of repeats is fixed, the delimiter of the parent group or complex type is used. If none of the previous conditions are true, a default is not applied.

TDS properties for element reference Boolean types:

TDS wire format properties for element reference Boolean types.

The TDS Format properties described here apply to:

- Objects: Element Reference
- Boolean schema types: Boolean

Occurrences

Property	Type	Meaning
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, no integer objects exist before this one in the message structure. If a `Repeat Reference` is specified, it overrides any setting for the `Max Occurs` logical property when parsing and writing the message, but not for validating the message.
Repeating Element Delimiter	String	Specify the delimiter to use between repeating elements. This delimiter is used only when the element repeats and the `Data Element Separation` property of the parent group or complex type is set to `All Elements Delimited` or `Variable Length Elements Delimited`. A default value is provided if the previous conditions are true; if the messaging standard is HL7, the mnemonic <HL7_RS> is used; if the messaging standard is not HL7, and the maximum number of repeats is fixed, the delimiter of the parent group or complex type is used. If none of the previous conditions are true, a default is not applied.

TDS properties for element reference dateTime types:

TDS wire format properties for attribute reference and element reference dateTime types.

The TDS Format properties described here apply to:

- Objects: Element Reference
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Physical representation

Property	Type	Meaning
Length Reference	Enumerated type	This property is applicable only if `Physical Type` is `Text`, `Binary`, or `TLOG Specific`. If set, this property takes precedence over any value in the `Length Units` property. Specify the identifier of a sibling integer object, the value of which determines the length of the object in question. The sibling object must be defined before the current object within the message structure. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if `Length Reference` is set. If the check box is selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object only. If the check box is selected, the `Length Units` property of the sibling integer object must be the same as that of the current object.

Occurrences

Property	Type	Meaning
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, no integer objects exist before this one in the message structure. TDS properties for element reference decimal types:

The TDS wire format properties for attribute reference and element reference decimal types.

The TDS Format properties described here apply to:

- Objects: Element Reference
- Decimal schema types: decimal, integer, negativeInteger, nonNegativeInteger, nonPositiveInteger, positiveInteger, unsignedLong

Physical representation

Property	Type	Meaning
Length Reference	Enumerated type	This property is applicable only if `Physical Type` is `Text`, `Binary`, or `TLOG Specific`. If set, this property takes precedence over any value in the `Length Units` property. Specify the identifier of a sibling integer object, the value of which determines the length of the object in question. The sibling object must be defined before the current object within the message structure. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if `Length Reference` is set. If the check box is selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by `Length Reference` is the length of the current object only. If the check box is selected, the `Length Units` property of the sibling integer object must be the same as that of the current object.

Occurrences

Property	Type	Meaning
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. Global attribute logical properties:

The logical properties of a global attribute.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Type	Enumerated type	The Type property constrains the type of data that can be present in the object. Select from the following options: • `int` • `string` • `Boolean` • `hexBinary` • `dateTime` • `date` • `time` • `decimal` • `float` • `(More...)` • `(New Simple Type)` • `(New Complex Type)` If you select (More...), the Type Selection wizard starts. In this wizard, you can select any of the available types. If you select (New Simple Type), the New Simple Type wizard starts. In this wizard, you can create an Anonymous simple type that is based on an existing type. This type can be created locally or globally. If you select (New Complex Type), the New Complex Type wizard starts. In this wizard, you can create an Anonymous complex type, which can be derived from an existing base type. This type can be created locally or globally. For further information about these types, and examples of their use, see the XML Schema Part 0: Primer. This document is available on the World Wide Web Consortium (W3C) Web site.
Namespace	Enumerated type	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. If <no target namespace> is displayed, a namespace has not been set for this object. If the property is inactive, the message set has not been configured to support namespaces. Where the property is active, namespaces that are available for selection are displayed in the drop-down list.

Value

The *Value* properties are used with the *Usage* property in an Attribute Reference or a Local Attribute.

Property	Type	Meaning
Default	Button and String	This property provides the default value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, default values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if they have default values. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the default value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for default values **Other domains** No support for default values.
Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.

Property	Type	Meaning
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

Use the documentation property of an object to add information that describes the function of the object.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Global attribute XML properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	Properties
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time

Type of object	Properties
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

XML properties for global attribute and global element binary types:

The XML wire format properties for global attribute and global element binary types.

The XML Wire Format properties described here apply to:

- Objects: Global Attribute, Global Element
- Binary schema types: base64Binary, hexBinary

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).

Physical representation

Property	Type	Meaning
Encoding	String	Select one of the following values from the drop-down list: : • `CDatahex` (the default). Hexadecimal values in this field are specified with the CDATA qualifier, for example <e1><![CDATA[62]]></e1> • `hex`. Hexadecimal values in this field are specified as digits only, for example <e1>62</e1>. • `base64`. Values in this field are specified as digits only, coded in base 64.

XML properties for global attribute and global element dateTime types:

The XML wire format properties for global attribute and global element dateTime types.

The XML Wire Format properties described here apply to:

- Objects: Global Attribute, Global Element
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).

Physical representation

Property	Type	Meaning
DateTime Format	String	Specify a format string that specifies the rendering of the value for dateTime elements. The default dateTime format is dependent on the logical type of the object. For information about the defaults for the dateTime format according to the logical type see "DateTime defaults by logical type" on page 6320. See "DateTime formats" on page 6310 for details of dateTime formats.

Global attribute TDS properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	Properties
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time

Type of object	Properties
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

TDS properties for global attribute binary types:

The TDS format properties for global attribute binary types.

The TDS Format properties described here apply to:

- Objects: Global Attribute
- Binary schema types: base64Binary, hexBinary

Field identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.

Property	Type	Meaning
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	This value of this property defaults to Binary. It cannot be changed.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. The default is dependent on the setting of the message set property `Derive default length from logical type`. If `Derive default length from logical type` is selected, the default value is derived from any length or maxLength value constraint (schema facet) on the object's simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.

Field identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Binary`. The data is in bit string format. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.

TDS properties for global attribute dateTime types:

The TDS format properties for global attribute dateTime types.

The TDS Format properties described here apply to:

- Objects: Global Attribute
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see “Regular expression syntax” on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Length Encoded String 1`. The first byte of the data contains the length (in length units) of the data string that follows the length byte. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The first two bytes of the data contain the length (in length units) of the data string that follows the two length bytes. The maximum length of a `Length Encoded String 2` element is 65535 length units. • `Null Terminated String`. The data string ends with the hexadecimal NULL character, `X'00'`. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `Binary`. The data is in bit string format. • `Time Seconds`. This value supports C time_t, and Java Date and Time objects. It is valid only if the `DateTime Format` property represents numeric-only data. • `Time Milliseconds`. This value supports C time_t, and Java Date and Time objects. It is valid only if the `DateTime Format` property represents numeric-only data. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.

Property	Type	Meaning
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.
DateTime Format	String	Specify a template for date and time. The default DateTime format is dependent on the logical type of the object. For information about the defaults for the dateTime format according to the logical type, see “DateTime defaults by logical type” on page 6320. See “DateTime formats” on page 6310 for details of date and time formats.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed. This property is applicable only if the `Physical type` property is `Packed Decimal`. By default, this check box is cleared, which indicates that the value is not signed.

TDS properties for global attribute decimal types:

The TDS format properties for global attribute decimal types.

The TDS Format properties described here apply to:

- Objects: Global Attribute
- Decimal schema types: decimal, integer, negativeInteger, nonNegativeInteger, nonPositiveInteger, positiveInteger, unsignedLong

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `TLOG Specific` - this option can be selected only if the `Message Standard` property of the message set is `TLOG`. This option indicates that the format of the data is specific to the TLOG messaging standard. • `Integer`. Equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `External Decimal`. The data is a decimal number that equates to the data type PIC 9 USAGE DISPLAY in COBOL. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.

Property	Type	Meaning
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Numeric representation

Property	Type	Meaning
Sign Orientation	Enumerated type	The values that you can choose for this property are: • Leading Separate • Trailing Separate • Leading Overpunched • Trailing Overpunched This property is enabled only if you have set Physical Type to Text or External Decimal, and you have selected Signed. If Physical Type is Text, the only valid values of Sign Orientation are Leading Separate and Trailing Separate. If Physical Type is External Decimal and Sign EBCDIC Customer Overpunched is selected, the only valid values of Sign Orientation are Leading Overpunched and Trailing Overpunched.
Positive Sign	String	Specify the value that represents the positive symbol. Do not specify a numeric value. If no value is set, "+" is assumed. The positive sign is not written when creating an output message; it is used only to recognize the positive sign when parsing a message bit stream. This property is applicable only if Physical Type is Text and Signed is selected.
Negative Sign	String	Specify the value that represents the negative symbol. Do not specify a numeric value. If no value is set, "-" is assumed. This property is applicable only if Physical Type is Text and Signed is selected.
Virtual Decimal Point	Button and Integer	Specify a non-zero integer that represents the position of an implied decimal point within a number, or specify 0, the default, to use the formatting of Float or Decimal numbers as specified by the Precision property. If you specify a positive integer, the position of the decimal point is moved left from the right side of the number. For example, if you specify 3, the decimal value 1234 represents 1.234 If you specify a negative integer, the position of the decimal point is moved right from the right side of the number. For example, if you specify -3, the decimal value 1234 represents 1,234,000.

Property	Type	Meaning
Precision	Button and Integer	This property is applicable only if `Physical Type` is `Text`. It is used if the value of the `Virtual Decimal Point` property is 0, which indicates that the decimal point is present in the data. It deals with truncation, and specifies how many digits are to follow the decimal point. Either specify a number of digits: • If you set `Precision` to 0, data is truncated so that the fractional part is lost. For example, the value `123.45` is truncated to `123`. • If you set `Precision` to a number less than the number of fractional digits, data is truncated. For example, the value `123.4567` is truncated to `123.45` if you set `Precision` to 2. • If you set `Precision` to a number greater than the number of fractional digits, the value is padded with extra zeros. For example, the value `12.345` is padded to `12.34500` if you set `Precision` to 5. Or select one option from the list: • `All Significant Digits - decimal separator only required if fractional digits` (the default): all significant digits are written to the output bit stream, and no decimal separator is written if no fractional digits are present. • `Explicit Decimal Separator - decimal separator always required`: all significant digits are written to the output bit stream and the decimal separator is always included, even when no fractional digits are present. The decimal separator must be present in the input bit stream, even when no fractional digits are present.

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Float`. Equates to the data type FLOAT or DOUBLE in C, or the COMP-1 or COMP-2 numeric data type in COBOL. • `Integer`. Equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `External Decimal`. The data is a decimal number that equates to the data type PIC 9 USAGE DISPLAY in COBOL. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Numeric representation

Property	Type	Meaning
Sign Orientation	Enumerated type	The values that you can choose for this property are: • `Leading Separate` • `Trailing Separate` • `Leading Overpunched` • `Trailing Overpunched` This property is enabled only if you have set `Physical Type` to `Text` or `External Decimal`, and you have selected `Signed`. If `Physical Type` is `Text`, the only valid values of `Sign Orientation` are `Leading Separate` and `Trailing Separate`. If `Physical Type` is `External Decimal` and `Sign EBCDIC Customer Overpunched` is selected, the only valid values of `Sign Orientation` are `Leading Overpunched` and `Trailing Overpunched`.
Positive Sign	String	Specify the value that represents the positive symbol. Do not specify a numeric value. If no value is set, "+" is assumed. The positive sign is not written when creating an output message; it is used only to recognize the positive sign when parsing a message bit stream. This property is applicable only if `Physical Type` is `Text` and `Signed` is selected.
Negative Sign	String	Specify the value that represents the negative symbol. Do not specify a numeric value. If no value is set, "-" is assumed. This property is applicable only if `Physical Type` is `Text` and `Signed` is selected.
Virtual Decimal Point	Button and Integer	Specify a non-zero integer that represents the position of an implied decimal point within a number, or specify 0, the default, to use the formatting of Float or Decimal numbers as specified by the `Precision` property. If you specify a positive integer, the position of the decimal point is moved left from the right side of the number. For example, if you specify 3, the decimal value 1234 represents 1.234 If you specify a negative integer, the position of the decimal point is moved right from the right side of the number. For example, if you specify -3, the decimal value 1234 represents 1,234,000.

Property	Type	Meaning
Precision	Button and Integer	This property is applicable only if `Physical Type` is `Text`. It is used if the value of the `Virtual Decimal Point` property is 0, which indicates that the decimal point is present in the data. It deals with truncation, and specifies how many digits are to follow the decimal point. Either specify a number of digits: • If you set `Precision` to 0, data is truncated so that the fractional part is lost. For example, the value `123.45` is truncated to `123`. • If you set `Precision` to a number less than the number of fractional digits, data is truncated. For example, the value `123.4567` is truncated to `123.45` if you set `Precision` to 2. • If you set `Precision` to a number greater than the number of fractional digits, the value is padded with extra zeros. For example, the value `12.345` is padded to `12.34500` if you set `Precision` to 5. Or select one option from the list: • `All Significant Digits - decimal separator only required if fractional digits` (the default): all significant digits are written to the output bit stream, and no decimal separator is written if no fractional digits are present. • `Explicit Decimal Separator - decimal separator always required`: all significant digits are written to the output bit stream and the decimal separator is always included, even when no fractional digits are present. The decimal separator must be present in the input bit stream, even when no fractional digits are present. • `Exponential Notation - Example "1.23456e002"`: data is written out to the bit stream as a signed value having the format `[sign1]a.bbbe[sign2]ccc` where: – `[sign1]` is the value of `Negative Sign` if the value is negative – `a` is a single decimal digit – `bbb` is one or more decimal digits – `[sign2]` is the value of `Negative Sign` if the exponent is negative – `ccc` is exactly three decimal digits (the exponent) `[sign1]` and `[sign2]` are absent if the value and exponent are positive. For example, the value -123.456 is represented as `-1.23456e002` and the value 0.00012 is represented as `1.2e-004` in the output bit stream, assuming that the value of `Negative Sign` is "-", and the value of `Sign Orientation` is `Leading`. The value -0.00012 is represented as `1.2*e*004` if `Negative Sign` is "*" and `Sign Orientation` is `Trailing`.

TDS properties for global attribute integer types:

The TDS format properties for global attribute integer types.

The TDS Format properties described here apply to:

- Objects: Global Attribute
- Integer schema types: byte, int, long, short, unsignedByte, unsignedInt, unsignedShort

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Integer`. Equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `External Decimal`. The data is a decimal number that equates to the data type PIC 9 USAGE DISPLAY in COBOL. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Numeric representation

Property	Type	Meaning
Sign Orientation	Enumerated type	The values that you can choose for this property are: • `Leading Separate` • `Trailing Separate` • `Leading Overpunched` • `Trailing Overpunched` This property is enabled only if you have set `Physical Type` to `Text` or `External Decimal`, and you have selected `Signed`. If `Physical Type` is `Text`, the only valid values of `Sign Orientation` are `Leading Separate` and `Trailing Separate`. If `Physical Type` is `External Decimal` and `Sign EBCDIC Customer Overpunched` is selected, the only valid values of `Sign Orientation` are `Leading Overpunched` and `Trailing Overpunched`.
Positive Sign	String	Specify the value that represents the positive symbol. Do not specify a numeric value. If no value is set, "+" is assumed. The positive sign is not written when creating an output message; it is used only to recognize the positive sign when parsing a message bit stream. This property is applicable only if `Physical Type` is `Text` and `Signed` is selected.
Negative Sign	String	Specify the value that represents the negative symbol. Do not specify a numeric value. If no value is set, "-" is assumed. This property is applicable only if `Physical Type` is `Text` and `Signed` is selected.

TDS properties for global attribute string types:

The TDS format properties for global attribute string types.

The TDS Format properties described here apply to:

- Objects: Global Attribute
- String schema types: anyURI, ENTITIES, ENTITY, ID, IDREF, IDREFS, language, Name, NCName, NMTOKEN, NMTOKENS, normalizedString, NOTATION, QName, string, token

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Property	Type	Meaning
Interpret Element Value	Enumerated type	Specify whether values stored within this object are interpreted as having significance for the parser and, if so, the type of interpretation that occurs. This interpretation is standard-specific and is therefore hard coded. The possible values for this property are: • `None` (the default value) • `EDIFACT Service String` • `X12 Service String` • `Message Key` • `EDIFACT Syntax Level ID` • `HL7 Service String` • `HL7 Field Separator` **Note:** The `Message Key` enumeration has been deprecated.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Length Encoded String 1`. The first byte of the data contains the length (in length units) of the data string that follows the length byte. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The first two bytes of the data contain the length (in length units) of the data string that follows the two length bytes. The maximum length of a `Length Encoded String 2` element is 65535 length units. • `Null Terminated String`. The data string ends with the hexadecimal NULL character, `X'00'`. • `TLOG Specific` - this option can be selected only if the `Message Standard` property of the message set is `TLOG`. This option indicates that the format of the data is specific to the TLOG messaging standard. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Global attribute group logical properties:

The logical properties of an attribute group.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

More information about the MRM domain.

Global element logical properties:

The logical properties of a global element.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Type	Enumerated type	The Type property constrains the type of data that can be present in the object. Select from the following options: • int • string • Boolean • hexBinary • dateTime • date • time • decimal • float • (More...) • (New Simple Type) • (New Complex Type) If you select (More...), the Type Selection wizard starts. In this wizard, you can select any of the available types. If you select (New Simple Type), the New Simple Type wizard starts. In this wizard, you can create an Anonymous simple type that is based on an existing type. This type can be created locally or globally. If you select (New Complex Type), the New Complex Type wizard starts. In this wizard, you can create an Anonymous complex type, which can be derived from an existing base type. This type can be created locally or globally. For further information about these types, and examples of their use, see the XML Schema Part 0: Primer. This document is available on the World Wide Web Consortium (W3C) Web site.
Namespace	Enumerated type	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. If <no target namespace> is displayed, a namespace has not been set for this object. If the property is inactive, the message set has not been configured to support namespaces. Where the property is active, namespaces that are available for selection are displayed in the drop-down list.

Value

Property	Type	Meaning
Default	Button and String	This property provides the default value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, default values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if they have default values. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the default value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for default values **Other domains** No support for default values.
Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.
Nillable	Check box	Select this option if you want the element to be able to be defined as null. A null value is distinct from being empty, when the element contains no data.

Property	Type	Meaning
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

Substitution settings

Substitution Groups provide a means by which one element may be substituted for another in a message. The element which can be substituted is called the 'head' element, and the substitution group is the list of elements that may be used in its place. An element can be in at most one substitution group.

Property	Type	Meaning
Final	Enumerated type	Limit the set of elements that can belong to its substitution group. • Empty • restriction. Prohibit element substitution by elements whose types are restrictions of the type of the head element. • extension. Prohibit element substitution by elements whose types are extensions of the type of the head element. • #all. Prohibit substitution by all methods.
Block	Enumerated type	Limit the set of elements that can be substituted for this element in a message. • Empty • restriction. Prohibit element substitution by elements whose types are restrictions of the type of the head element • extension. Prohibit element substitution by elements whose types are extensions of the type of the head element • substitution. Prohibit element substitution by members of the element's substitution group. • #all. Prohibit substitution by all methods.
Substitution Group	Enumerated type	Specify the name of a 'head' element. Setting this property indicates that this element is a member of the substitution group for the head element.
Abstract	Check box	Select this option if you do not want the element to appear in the message, but require one of the members of its substitution group to appear in its place.

"Message model object properties by object" on page 5536
The following objects have properties that can be viewed or set.

Global element XML properties:

The properties, and their permissible values, vary according to the type of object.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

XML properties for global attribute and global element binary types:

The XML wire format properties for global attribute and global element binary types.

The XML Wire Format properties described here apply to:

- Objects: Global Attribute, Global Element
- Binary schema types: base64Binary, hexBinary

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).

Physical representation

Property	Type	Meaning
Encoding	String	Select one of the following values from the drop-down list: : • `CDatahex` (the default). Hexadecimal values in this field are specified with the CDATA qualifier, for example <e1><![CDATA[62]]></e1> • `hex`. Hexadecimal values in this field are specified as digits only, for example <e1>62</e1>. • `base64`. Values in this field are specified as digits only, coded in base 64.

XML properties for global attribute and global element float types:

The XML wire format properties for global attribute and global element float types.

The XML Wire Format properties described here apply to:

- Objects: Global Attribute, Global Element
- Float schema types: double, float

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).

XML properties for global attribute and global element integer types:

The XML wire format properties for global attribute and global element integer types.

The XML Wire Format properties described here apply to:

- Objects: Global Attribute, Global Element
- Integer schema types: byte, int, long, short, unsignedByte, unsignedInt, unsignedShort

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).

XML properties for global attribute and global element string types:

The XML wire format properties for global attribute and global element string types.

The XML Wire Format properties described here apply to:

- Objects: Global Attribute, Global Element
- String schema types: anyURI, ENTITIES, ENTITY, ID, IDREF, IDREFS, language, Name, NCName, NMTOKEN, NMTOKENS, normalizedString, NOTATION, QName, string, token

Property	Type	Meaning
XML Name	String	Enter a value for the XML element name. This property specifies the name for the XML start tag or attribute for the element (or attribute) in an XML document (message). This can be used to provide name mapping when the MRM identifier needs to be different from the XML name, for example because of different namespace rules. It must be a valid XML name. You cannot specify a name that is already used for another element (or attribute) , or for a message. No two elements (or attribute) or messages can have the same XML name. If you do not set a value, it defaults to that of the element's identifier. If the element's identifier is a prefixed identifier, it defaults to the identifier with the caret character (^) replaced by an underscore (_).

Global element TDS properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	**Properties**
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
Complex types	
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float

Type of object	Properties
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

Related concepts:

TDS properties for global element binary types:

The TDS format properties for global element binary types.

The TDS Format properties described here apply to:

- Objects: Global Element
- Binary schema types: base64Binary, hexBinary

Field identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	For all `Messaging Standard` values, the `Physical Type` property is set to `Binary` and cannot be changed.

Property	Type	Meaning
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. The default is dependent on the setting of the message set property `Derive default length from logical type`. If `Derive default length from logical type` is selected, the default value is derived from any length or maxLength value constraint (schema facet) on the object's simple type.
Length Units	Enumerated type	Always set to `Bytes`.

TDS properties for global element Boolean types:

The TDS format properties for global element Boolean types.

The TDS Format properties described here apply to:

- Objects: Global Element
- Boolean schema types: Boolean

Field identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Binary`. The data is in bit string format. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.

TDS properties for global element dateTime types:

The TDS format properties for global element dateTime types.

The TDS Format properties described here apply to:

- Objects: Global Element
- DateTime schema types: date, dateTime, gDay, gMonth, gMonthDay, gYear, gYearMonth, time

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Length Encoded String 1`. The first byte of the data contains the length (in length units) of the data string that follows the length byte. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The first two bytes of the data contain the length (in length units) of the data string that follows the two length bytes. The maximum length of a `Length Encoded String 2` element is 65535 length units. • `Null Terminated String`. The data string ends with the hexadecimal NULL character, `X'00'`. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `Binary`. The data is in bit string format. • `Time Seconds`. This value supports C time_t, and Java Date and Time objects. It is valid only if the `DateTime Format` property represents numeric-only data. • `Time Milliseconds`. This value supports C time_t, and Java Date and Time objects. It is valid only if the `DateTime Format` property represents numeric-only data. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.

Property	Type	Meaning
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if one of the following statements is true: • `Physical Type` is `Packed Decimal`. • `Physical Type` is `Text`, no `Length Reference` is specified, and the `Data Element Separation` of the parent complex type or group is `Fixed Length`, `Tagged Fixed Length`, or `Fixed Length AL3`. The default is dependent on the physical type of the object. If `Physical Type` is `Length Encoded String 1`, `Length Encoded String 2`, or `Null Terminated String`, this property is not applicable. If `Physical Type` is `Time Seconds`, the value of this property is 4, and cannot be changed. If `Physical Type` is `Time Milliseconds`, the value of this property is 8, and cannot be changed.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.
DateTime Format	String	Specify a template for date and time. The default DateTime format is dependent on the logical type of the object. For information about the defaults for the dateTime format according to the logical type, see “DateTime defaults by logical type” on page 6320. See “DateTime formats” on page 6310 for details of date and time formats.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed. This property is applicable only if the `Physical type` property is `Packed Decimal`. By default, this check box is cleared, which indicates that the value is not signed.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the list: • `NULLPadFill`. This option is valid only for fixed-length objects and is the default value. • `NULLLogicalValue`. The `Encoding Null Value` property is first converted to an actual value, and rendered in the way specified for the field. • `NULLLiteralValue`. This option specifies that `Encoding Null Value` contains a value that is directly substituted as if it is a string. For dateTime elements, use this option if you want to use the `Encoding Null Value` property to test or compare the content of the field in the message. • `NULLLiteralFill`. This option specifies that the field is filled with the value specified by the `Encoding Null Value` property. `Encoding Null Value` must resolve to a single character. The option that you select determines the value that you must set for the property `Encoding Null Value`. For full information about using these options, see "TDS Null handling options" on page 6293.
Encoding Null Value	String	The use of this property depends on the `Encoding Null` property. The default value is zero. If you set the `Encoding Null` property for a dateTime object to `NULLLogicalValue`, the value that you set must be in an ISO8601 dateTime format. These formats are described in "DateTime as string data" on page 6311. For example, specify a value that conforms to the `yyyy-MM-dd'T'HH:mm:ss` format; for example, `1970-12-01`.

TDS properties for global element decimal types:

The TDS format properties for global element decimal types.

The TDS Format properties described here apply to:

- Objects: Global Element
- Decimal schema types: decimal, integer, negativeInteger, nonNegativeInteger, nonPositiveInteger, positiveInteger, unsignedLong

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `TLOG Specific` - this option can be selected only if the `Message Standard` property of the message set is `TLOG`. This option indicates that the format of the data is specific to the TLOG messaging standard. • `Integer`. Equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `External Decimal`. The data is a decimal number that equates to the data type PIC 9 USAGE DISPLAY in COBOL. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any totalDigits value constraint (schema facet) or, if none, any `minInclusive`, `maxInclusive`, `minExclusive`, or `maxExclusive` value constraints (schema facets), on the simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed.
Sign EBCDIC Custom Overpunched	Check box	Specify whether EBCDIC custom sign format is used. This property is applicable only if the `Signed` property is selected and the `Physical Type` property is set to `External Decimal`.

Property	Type	Meaning
Sign Orientation	Enumerated type	The values that you can choose for this property are: • Leading Separate • Trailing Separate • Leading Overpunched • Trailing Overpunched This property is enabled only if you have set Physical Type to Text or External Decimal, and you have selected Signed. If Physical Type is Text, the only valid values of Sign Orientation are Leading Separate and Trailing Separate. If Physical Type is External Decimal and Sign EBCDIC Customer Overpunched is selected, the only valid values of Sign Orientation are Leading Overpunched and Trailing Overpunched.
Positive Sign	String	Specify the value that represents the positive symbol. Do not specify a numeric value. If no value is set, "+" is assumed. The positive sign is not written when creating an output message; it is used only to recognize the positive sign when parsing a message bit stream. This property is applicable only if Physical Type is Text and Signed is selected.
Negative Sign	String	Specify the value that represents the negative symbol. Do not specify a numeric value. If no value is set, "-" is assumed. This property is applicable only if Physical Type is Text and Signed is selected.
Virtual Decimal Point	Button and Integer	Specify a non-zero integer that represents the position of an implied decimal point within a number, or specify 0, the default, to use the formatting of Float or Decimal numbers as specified by the Precision property. If you specify a positive integer, the position of the decimal point is moved left from the right side of the number. For example, if you specify 3, the decimal value 1234 represents 1.234 If you specify a negative integer, the position of the decimal point is moved right from the right side of the number. For example, if you specify -3, the decimal value 1234 represents 1,234,000.

Property	Type	Meaning
Precision	Button and Integer	This property is applicable only if `Physical Type` is `Text`. It is used if the value of the `Virtual Decimal Point` property is 0, which indicates that the decimal point is present in the data. It deals with truncation, and specifies how many digits are to follow the decimal point. Either specify a number of digits: • If you set `Precision` to 0, data is truncated so that the fractional part is lost. For example, the value `123.45` is truncated to `123`. • If you set `Precision` to a number less than the number of fractional digits, data is truncated. For example, the value `123.4567` is truncated to `123.45` if you set `Precision` to 2. • If you set `Precision` to a number greater than the number of fractional digits, the value is padded with extra zeros. For example, the value `12.345` is padded to `12.34500` if you set `Precision` to 5. Or select one option from the list: • `All Significant Digits - decimal separator only required if fractional digits` (the default): all significant digits are written to the output bit stream, and no decimal separator is written if no fractional digits are present. • `Explicit Decimal Separator - decimal separator always required`: all significant digits are written to the output bit stream and the decimal separator is always included, even when no fractional digits are present. The decimal separator must be present in the input bit stream, even when no fractional digits are present.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the list: • `NULLPadFill`. This option is valid only for fixed-length objects and is the default value. • `NULLLogicalValue`. The `Encoding Null Value` property is first converted to an actual value, and rendered in the way specified for the field. • `NULLLiteralValue`. This option specifies that `Encoding Null Value` contains a value that is directly substituted as if it is a string. For dateTime elements, use this option if you want to use the `Encoding Null Value` property to test or compare the content of the field in the message. • `NULLLiteralFill`. This option specifies that the field is filled with the value specified by the `Encoding Null Value` property. `Encoding Null Value` must resolve to a single character. The option that you select determines the value that you must set for the property `Encoding Null Value`. For full information about using these options, see “TDS Null handling options” on page 6293.
Encoding Null Value	String	The use of this property depends on the `Encoding Null` property. The default value is zero. If you set the `Encoding Null` property for a dateTime object to `NULLLogicalValue`, the value that you set must be in an ISO8601 dateTime format. These formats are described in “DateTime as string data” on page 6311. For example, specify a value that conforms to the `yyyy-MM-dd'T'HH:mm:ss` format; for example, `1970-12-01`.

TDS properties for global element float types:

The TDS format properties for global element float types.

The TDS Format properties described here apply to:

- Objects: Global Element
- Float schema types: double, float

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Float`. Equates to the data type FLOAT or DOUBLE in C, or the COMP-1 or COMP-2 numeric data type in COBOL. • `Integer`. Equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `External Decimal`. The data is a decimal number that equates to the data type PIC 9 USAGE DISPLAY in COBOL. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed.
Sign EBCDIC Custom Overpunched	Check box	Specify whether EBCDIC custom sign format is used. This property is applicable only if the `Signed` property is selected and the `Physical Type` property is set to `External Decimal`.

Property	Type	Meaning
Sign Orientation	Enumerated type	The values that you can choose for this property are: • Leading Separate • Trailing Separate • Leading Overpunched • Trailing Overpunched This property is enabled only if you have set Physical Type to Text or External Decimal, and you have selected Signed. If Physical Type is Text, the only valid values of Sign Orientation are Leading Separate and Trailing Separate. If Physical Type is External Decimal and Sign EBCDIC Customer Overpunched is selected, the only valid values of Sign Orientation are Leading Overpunched and Trailing Overpunched.
Positive Sign	String	Specify the value that represents the positive symbol. Do not specify a numeric value. If no value is set, "+" is assumed. The positive sign is not written when creating an output message; it is used only to recognize the positive sign when parsing a message bit stream. This property is applicable only if Physical Type is Text and Signed is selected.
Negative Sign	String	Specify the value that represents the negative symbol. Do not specify a numeric value. If no value is set, "-" is assumed. This property is applicable only if Physical Type is Text and Signed is selected.
Virtual Decimal Point	Button and Integer	Specify a non-zero integer that represents the position of an implied decimal point within a number, or specify 0, the default, to use the formatting of Float or Decimal numbers as specified by the Precision property. If you specify a positive integer, the position of the decimal point is moved left from the right side of the number. For example, if you specify 3, the decimal value 1234 represents 1.234 If you specify a negative integer, the position of the decimal point is moved right from the right side of the number. For example, if you specify -3, the decimal value 1234 represents 1,234,000.

Property	Type	Meaning
Precision	Button and Integer	This property is applicable only if `Physical Type` is `Text`. It is used if the value of the `Virtual Decimal Point` property is 0, which indicates that the decimal point is present in the data. It deals with truncation, and specifies how many digits are to follow the decimal point. Either specify a number of digits: • If you set `Precision` to 0, data is truncated so that the fractional part is lost. For example, the value `123.45` is truncated to `123`. • If you set `Precision` to a number less than the number of fractional digits, data is truncated. For example, the value `123.4567` is truncated to `123.45` if you set `Precision` to 2. • If you set `Precision` to a number greater than the number of fractional digits, the value is padded with extra zeros. For example, the value `12.345` is padded to `12.34500` if you set `Precision` to 5. Or select one option from the list: • `All Significant Digits - decimal separator only required if fractional digits` (the default): all significant digits are written to the output bit stream, and no decimal separator is written if no fractional digits are present. • `Explicit Decimal Separator - decimal separator always required`: all significant digits are written to the output bit stream and the decimal separator is always included, even when no fractional digits are present. The decimal separator must be present in the input bit stream, even when no fractional digits are present. • `Exponential Notation - Example "1.23456e002"`: data is written out to the bit stream as a signed value having the format `[sign1]a.bbbe[sign2]ccc` where: – `[sign1]` is the value of `Negative Sign` if the value is negative – `a` is a single decimal digit – `bbb` is one or more decimal digits – `[sign2]` is the value of `Negative Sign` if the exponent is negative – `ccc` is exactly three decimal digits (the exponent) `[sign1]` and `[sign2]` are absent if the value and exponent are positive. For example, the value -123.456 is represented as `-1.23456e002` and the value 0.00012 is represented as `1.2e-004` in the output bit stream, assuming that the value of `Negative Sign` is "-", and the value of `Sign Orientation` is `Leading`. The value -0.00012 is represented as `1.2*e*004` if `Negative Sign` is "*" and `Sign Orientation` is `Trailing`.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the list: • `NULLPadFill`. This option is valid only for fixed-length objects and is the default value. • `NULLLogicalValue`. The `Encoding Null Value` property is first converted to an actual value, and rendered in the way specified for the field. • `NULLLiteralValue`. This option specifies that `Encoding Null Value` contains a value that is directly substituted as if it is a string. For dateTime elements, use this option if you want to use the `Encoding Null Value` property to test or compare the content of the field in the message. • `NULLLiteralFill`. This option specifies that the field is filled with the value specified by the `Encoding Null Value` property. `Encoding Null Value` must resolve to a single character. The option that you select determines the value that you must set for the property `Encoding Null Value`. For full information about using these options, see "TDS Null handling options" on page 6293.
Encoding Null Value	String	The use of this property depends on the `Encoding Null` property. The default value is zero. If you set the `Encoding Null` property for a dateTime object to `NULLLogicalValue`, the value that you set must be in an ISO8601 dateTime format. These formats are described in "DateTime as string data" on page 6311. For example, specify a value that conforms to the `yyyy-MM-dd'T'HH:mm:ss` format; for example, `1970-12-01`.

TDS properties for global element integer types:

The TDS format properties for global element integer types.

The TDS Format properties described here apply to:

- Objects: Global Element
- Integer schema types: byte, int, long, short, unsignedByte, unsignedInt, unsignedShort

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Integer`. Equates to the data type SHORT or LONG in C, or the COMP, COMP-4, COMP-5, or BINARY numeric data type in COBOL. • `Packed Decimal`. The data is a packed decimal number that equates to the COMP-3 data type in COBOL. • `External Decimal`. The data is a decimal number that equates to the data type PIC 9 USAGE DISPLAY in COBOL. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any totalDigits value constraint (schema facet) or, if none, any `minInclusive`, `maxInclusive`, `minExclusive`, or `maxExclusive` value constraints (schema facets), on the simple type.
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Numeric representation

Property	Type	Meaning
Signed	Check box	Specify whether the value is signed.
Sign EBCDIC Custom Overpunched	Check box	Specify whether EBCDIC custom sign format is used. This property is applicable only if the `Signed` property is selected and the `Physical Type` property is set to `External Decimal`.

Property	Type	Meaning
Sign Orientation	Enumerated type	The values that you can choose for this property are: • Leading Separate • Trailing Separate • Leading Overpunched • Trailing Overpunched This property is enabled only if you have set Physical Type to Text or External Decimal, and you have selected Signed. If Physical Type is Text, the only valid values of Sign Orientation are Leading Separate and Trailing Separate. If Physical Type is External Decimal and Sign EBCDIC Customer Overpunched is selected, the only valid values of Sign Orientation are Leading Overpunched and Trailing Overpunched.
Positive Sign	String	Specify the value that represents the positive symbol. Do not specify a numeric value. If no value is set, "+" is assumed. The positive sign is not written when creating an output message; it is used only to recognize the positive sign when parsing a message bit stream. This property is applicable only if Physical Type is Text and Signed is selected.
Negative Sign	String	Specify the value that represents the negative symbol. Do not specify a numeric value. If no value is set, "-" is assumed. This property is applicable only if Physical Type is Text and Signed is selected.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the list: • NULLPadFill. This option is valid only for fixed-length objects and is the default value. • NULLLogicalValue. The Encoding Null Value property is first converted to an actual value, and rendered in the way specified for the field. • NULLLiteralValue. This option specifies that Encoding Null Value contains a value that is directly substituted as if it is a string. For dateTime elements, use this option if you want to use the Encoding Null Value property to test or compare the content of the field in the message. • NULLLiteralFill. This option specifies that the field is filled with the value specified by the Encoding Null Value property. Encoding Null Value must resolve to a single character. The option that you select determines the value that you must set for the property Encoding Null Value. For full information about using these options, see “TDS Null handling options” on page 6293.
Encoding Null Value	String	The use of this property depends on the Encoding Null property. The default value is zero. If you set the Encoding Null property for a dateTime object to NULLLogicalValue, the value that you set must be in an ISO8601 dateTime format. These formats are described in “DateTime as string data” on page 6311. For example, specify a value that conforms to the yyyy-MM-dd'T'HH:mm:ss format; for example, 1970-12-01.

TDS properties for global element interval types:

The TDS format properties for global element string types.

The TDS Format properties described here apply to:

- Objects: Global Element
- Interval schema types: duration

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see “Regular expression syntax” on page 6304.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Length Encoded String 1`. The first byte of the data contains the length (in length units) of the data string that follows the length byte. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The data's first 2 bytes contains the length (in length units) of the data string that follows the two length bytes. The maximum length of a `Length Encoded String 2` element is 65535 length units. • `Null Terminated String`. The data string ends with the hexadecimal NULL character, `X'00'`. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the list: • `NULLPadFill`. This option is valid only for fixed-length objects and is the default value. • `NULLLogicalValue`. The `Encoding Null Value` property is first converted to an actual value, and rendered in the way specified for the field. • `NULLLiteralValue`. This option specifies that `Encoding Null Value` contains a value that is directly substituted as if it is a string. For dateTime elements, use this option if you want to use the `Encoding Null Value` property to test or compare the content of the field in the message. • `NULLLiteralFill`. This option specifies that the field is filled with the value specified by the `Encoding Null Value` property. `Encoding Null Value` must resolve to a single character. The option that you select determines the value that you must set for the property `Encoding Null Value`. For full information about using these options, see "TDS Null handling options" on page 6293.
Encoding Null Value	String	The use of this property depends on the `Encoding Null` property. The default value is zero. If you set the `Encoding Null` property for a dateTime object to `NULLLogicalValue`, the value that you set must be in an ISO8601 dateTime format. These formats are described in "DateTime as string data" on page 6311. For example, specify a value that conforms to the `yyyy-MM-dd'T'HH:mm:ss` format; for example, `1970-12-01`.

TDS properties for global element string types:

The TDS format properties for global element string types.

The TDS Format properties described here apply to:

- Objects: Global Element
- String schema types: anyURI, ENTITIES, ENTITY, ID, IDREF, IDREFS, language, Name, NCName, NMTOKEN, NMTOKENS, normalizedString, NOTATION, QName, string, token

Field Identification

Property	Type	Meaning
Tag	String	Specify the value that is used to identify the object in a message bit stream. If the object is simple and the `Data Element Separation` property of the complex type or types in which the object is a child is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, this property must contain a non-empty value. If the object is a complex element, and the `Data Element Separation` property of its parent is `Tagged Delimited`, `Tagged Fixed Length`, or `Tagged Encoded Length`, the property can contain an empty value. The value for this property must be unique for every element in the message set; that is, no two elements in the message set can contain the same value for this property.
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Property	Type	Meaning
Interpret Element Value	Enumerated type	Specify whether values stored within this object are interpreted as having significance for the parser and, if so, the type of interpretation that occurs. This interpretation is standard-specific and is therefore hard coded. The possible values for this property are: • `None` (the default value) • `EDIFACT Service String` • `X12 Service String` • `Message Key` • `EDIFACT Syntax Level ID` • `HL7 Service String` • `HL7 Field Separator` **Note:** The `Message Key` enumeration has been deprecated.

Physical representation

Property	Type	Meaning
Physical Type	Enumerated type	Select the physical type of the object. If the `Messaging Standard` property of the message set is `User Defined Text`, `User Defined Mixed`, `CSV`, or `TLOG`, select one of the following values: • `Text`. The data is in character format. • `Length Encoded String 1`. The first byte of the data contains the length (in length units) of the data string that follows the length byte. The maximum length of a `Length Encoded String 1` element is 255 length units. • `Length Encoded String 2`. The first two bytes of the data contain the length (in length units) of the data string that follows the two length bytes. The maximum length of a `Length Encoded String 2` element is 65535 length units. • `Null Terminated String`. The data string ends with the hexadecimal NULL character, `X'00'`. • `TLOG Specific` - this option can be selected only if the `Message Standard` property of the message set is `TLOG`. This option indicates that the format of the data is specific to the TLOG messaging standard. The default is dependent on the `Messaging Standard` property. For all other `Messaging Standard` values, the `Physical Type` property is set to `Text`.
Length	Integer	Specify the expected length of the object in length units. A non-zero length must be specified if no `Length Reference` is specified. If this property is not set and the message set property `Derive default length from logical type` is selected, and the `Physical type` is 'Character', the default value is derived from any length or maxLength value constraint (schema facet) on the simple type.

Property	Type	Meaning
Length Units	Enumerated type	Select the unit of length for the object. Select one of the following options (some physical types do not offer both options): • `Bytes`. The length is given in bytes. • `Characters`. The length is given in characters. The number of bytes that are processed in the bit stream depends on the code page of the message. – For a single-byte code page (SBCS CCSID) such as "latin-1" (CCSID 850), the number of bytes is equal to the number of characters. – For a double-byte code page (DBCS CCSID) such as "UTF-16" (CCSID 1200), the number of bytes is exactly twice the number of characters. – For a multibyte code page (MBCS CCSID) such as "UTF-8" (CCSID 1208), the number of bytes depends on the contents of the bit stream. The parser reads one character at a time and determines whether the character comprises one or more bytes. The default is dependent on the physical type of the object.
Justification	Enumerated type	Specify the justification of the object if the data being written or parsed is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Select one of the following values from the list: • `Not Applicable` • `Left Justify` • `Right Justify`

Property	Type	Meaning
Padding Character	String	Specify the padding character to be inserted or interpreted on the writing or parsing of a fixed-length object, if the data is less than the fixed-length value. This property is used only when a value is written as a fixed-length string. Set this character in one of the following ways: • Select `NUL`, `'0'`, or `SPACE` from the drop-down list. • Enter a character between quotation marks, for example "c" or 'c', where c is any alphanumeric character. • Enter a hexadecimal character code in the form `0xYY`, where `YY` is a hexadecimal value. • Enter a Unicode value in the form `U+xxxx`, where `xxxx` is a Unicode value specified in hexadecimal. The maximum length of the string that you can enter is 10. The choice of which of these padding character forms is used for an MRM element depends on the padding character required and whether the padding character is subject to data conversion. In most cases, the specification of a padding character is sufficient, and when this padding character is used, it is converted to the target code page of the output MRM message that is generated. If a padding character is required that cannot easily be entered in the padding character field, the Unicode mnemonic format can be used to specify the required character. When used, this Unicode value is also converted to the target code page of the MRM message that is generated. If a padding character is required that is not subject to data conversion, the hexadecimal format can be used. This gives the option of specifying a padding character that is inserted directly into the output message. If this format is used, you must ensure that the hexadecimal value is valid for the code page of any output messages that are created using these MRM definitions. If you convert a message from one code page to another, you must ensure that the converted value of the padding character is valid for this code page. For example, when converting from ASCII to code page 500, if you have specified the numeric 8 as your padding character, it is converted from 0x08 to 0x15; the ASCII and EBCDIC representations of Backspace. There is a currently a restriction that the value of your padding character must not be greater than U+007F. If you enter a Unicode mnemonic or numeric value, it is considered to be the character that is represented by that number in UTF-8.

Representation of null values

Property	Type	Meaning
Encoding Null	Enumerated type	Select one of the following options from the list: • `NULLPadFill`. This option is valid only for fixed-length objects and is the default value. • `NULLLogicalValue`. The `Encoding Null Value` property is first converted to an actual value, and rendered in the way specified for the field. • `NULLLiteralValue`. This option specifies that `Encoding Null Value` contains a value that is directly substituted as if it is a string. For dateTime elements, use this option if you want to use the `Encoding Null Value` property to test or compare the content of the field in the message. • `NULLLiteralFill`. This option specifies that the field is filled with the value specified by the `Encoding Null Value` property. `Encoding Null Value` must resolve to a single character. The option that you select determines the value that you must set for the property `Encoding Null Value`. For full information about using these options, see "TDS Null handling options" on page 6293.
Encoding Null Value	String	The use of this property depends on the `Encoding Null` property. The default value is zero. If you set the `Encoding Null` property for a dateTime object to `NULLLogicalValue`, the value that you set must be in an ISO8601 dateTime format. These formats are described in "DateTime as string data" on page 6311. For example, specify a value that conforms to the `yyyy-MM-dd'T'HH:mm:ss` format; for example, `1970-12-01`.

Global group logical properties:

The logical properties of a global group.

Valid children in a global group that depend on both **`Composition`** and **`Content Validation`** are shown in "MRM content validation" on page 5422.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Composition	Enumerated type	Define the order, and the number of occurrences, of the elements and groups in your messages. Composition does not affect the attributes in a complex type. Select from the following options: • Empty • sequence. If you select this option, you can define members that are elements or groups. These members, if present, must appear in the specified order in the message. They can repeat, and the same element or group can appear more than once. • choice. If you select this option, you can define members that are elements or groups. Exactly one of the defined members must be present in the message, and can repeat. Use this option if you want to model C unions and COBOL REDEFINES in a Custom Wire Format, or an XML DTD element that uses choice in an XML Wire Format, or a SWIFT field that has more than one option. • all. If you select this option, you can define members that are elements; groups are not allowed. The elements in an all group can appear in any order. Each element can appear once, or not at all. An all group can be used only at the top level of a complex type; it cannot be a member of another group within a type. • unorderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements can appear in any order in the message. • orderedSet. This option is supported only by the MRM domain.If you select this option, you can define members that are elements. The elements can repeat, but the same element cannot appear twice in the list of members. The elements must appear in the specified order in the message. • message. This option is supported only by the MRM domain. If you select this option, you can define only messages as members. Each member can repeat, but the same message cannot appear twice in the list of members. Like choice, only one of the defined members can be present in a message. Unlike choice, when writing a message, if the complex type or group has more than one member, the bit stream is not padded to the length of the longest member. Use this option to model multipart messages, which are used in some industry standards; for example, SWIFT. For more information, see the section on multipart messages in “Multipart messages” on page 1191.

Property	Type	Meaning
Content Validation	Enumerated type	`Content Validation` is used only by the MRM domain. If validation is enabled in your message flow, `Content Validation` specifies the strictness of the MRM validation for members of a complex type or group. See "MRM content validation" on page 5422 for further details. Select from the following options: • Closed. The complex type can only contain the child elements that you have added to it. • Open Defined. The complex type can contain any valid element defined within the message set. • Open. The complex type can contain any valid element, not just those that you have added to this complex type. See "Combinations of Composition and Content Validation" on page 5612 for further details of these options.

Global group TDS properties:

The TDS properties of a global group.

Field Identification

Property	Type	Meaning
Data Element Separation	Enumerated type	Select one of the following values to specify the method that is used to separate the data elements within the type. • `Tagged Delimited`. This value indicates that all elements within the complex type are identified by a tag, and, if a value is specified in the optional `Delimiter` property, are separated by that value. You must set the `Tag` property for all child elements of simple type, and you can set the `Delimiter` property to a non-empty value. See "Global element TDS properties" on page 5513. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Fixed Length`. This value indicates that each element is identified by a tag, and the data has a fixed length. There are no delimiters. You must set the `Tag` property for each of the child elements of this complex type, and each child element must have a `Length` or `Length Reference` property assigned to it. You must also set the `Tag Data Separator` or the `Length of Tag` property. • `Tagged Encoded Length`. This value indicates that all elements within the complex type are separated by a tag, and a length field follows each tag. There are no delimiters. The tag can be fixed length, as set by the `Length of Tag` property, or variable length delimited by the `Tag Data Separator` property. You must also set the `Length Of Encoded Length` property so that the parser knows the size of the length field, and set the `Extra Chars in Encoded Length` property. This property tells the parser what to subtract from the value in the `Length Of Encoded Length` property to get the actual length of the data that follows the length field. This method provides a more flexible way of handling ACORD AL3 standard messages than using the `Fixed Length AL3` value, by allowing different parts of the messages to be at different versions of the ACORD AL3 standard. • `All Elements Delimited`. This value indicates that all elements within the complex type are separated by a delimiter. You must set a value in the `Delimiter` property. • `Variable Length Elements Delimited`. This value indicates that some of the elements within the complex type might be of variable length. Variable length elements must be delimited by the value specified in the `Delimiter` property. • `Use Data Pattern`. This value indicates that the parser determines the elements by matching the data with the regular expression that is set in the `Data Pattern` property of the element or type member. See "Message definition file properties" on page 5409. • `Fixed Length`. This value indicates that all elements within the complex type are fixed length. The next data element is accessed by adding the value of the `Length` property to the offset. See "Global element TDS properties" on page 5513. If you set the `Data Element Separation` property of a complex type to `Fixed Length`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length`. Each child element must have a `Length` or `Length Reference` property assigned to it. • `Fixed Length AL3`. This value has a similar meaning to the separation type `Fixed Length`, but also indicates to the parser that a number of predefined rules regarding missing optional elements, encoded lengths, and versioning, must be applied. If you set the `Data Element Separation` property of a complex type to `Fixed Length AL3`, you must also set the `Data Element Separation` property of all complex children of this type to `Fixed Length AL3`. • `Undefined`. This value is set automatically if you set the `Type Composition` property of a complex type to `Message`, and you cannot change it to any other value. Do not set the `Type Composition` property to `Empty`, `Choice`, `Unordered Set`, `Ordered Set`, `Sequence`, or `Simple Unordered Set`. If you do, you cannot check in the type.

Property	Type	Meaning
Group Indicator	String	Specify the value of a special character, or string, that precedes the data that belongs to a group, or a complex type, within the bit stream.
Group Terminator	String	Specify the value of a special character, or string, that terminates the data that belongs to a group, or a complex type, within the bit stream.
Delimiter	String	Specify the value of a special character, or string, that specifies the delimiter that is used between data elements. This property applies only to the delimited `Data Element Separation` methods (`Tagged Delimited`, `All Elements Delimited`, and `Variable Length Elements Delimited`).
Suppress Absent Element Delimiters	Enumerated type	Use this property to select whether you want delimiters to be suppressed for elements that are missing within a message. Select from: • `End Of Type`. Use this option to suppress the delimiter when an element is missing. For example, if the model has been defined to have up to three elements and only two are present, the last delimiter can be omitted from the message. • `Never`. Use this option to ensure that even if optional elements are not present, all delimiters are written out. Use this option when the same delimiter is used to delimit parent and child objects. For example, if an optional child element is missing, message processing applications cannot tell where the child elements in a message end and the next parent element starts, if the delimiters are all the same.
Observe Element Length	Check box	This property is applicable when `Data Element Separation` is `All Elements Delimited` or `Tagged Delimited`. Select this check box if the `Length` property of child simple elements is significant when parsing and writing. • During parsing, an exception is thrown if the length of the extracted data exceeds the specified length. Otherwise, the data is trimmed according to the `Justification` and `Padding Character` properties of the child element. • During writing, an exception is thrown if the data to write exceeds the specified length. Otherwise, the data is padded according to the `Justification` and `Padding Character` properties of the child element. Clear this check box to ignore the `Length` property when parsing and writing. The default value depends on the setting of the `Messaging Standard` property (at the message set level) and the `Data Element Separation` property. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is `TLOG`, the check box is selected. • If `Data Element Separation` is `All Elements Delimited` and the `Messaging Standard` is other than `TLOG`, the check box is cleared. • If `Data Element Separation` is `Tagged Delimited`, the check box is cleared. For all other data element separation methods, the check box is disabled and does not influence the behavior of the TDS parser.
Tag Data Separator	Button and String	Specify the value of a special character or string that separates the Tag from the data. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides `Length of Tag`. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).

Property	Type	Meaning
Length of Tag	Button and Integer	Specify the length of a tag value. When the message is parsed, this property allows tags to be extracted from the bit stream if the `Tag Data Separator` property is not set. The `Tag Data Separator` and `Length of Tag` properties are mutually exclusive. If you set the property `Tag Data Separator`, it overrides this value. This property applies only to the tagged `Data Element Separation` methods (`Tagged Delimited`, `Tagged Fixed Length`, and `Tagged Encoded Length`).
Length of Encoded Length	Integer	Specifies the number of characters (not bytes) after a tag that are used for the length field. Enter a value from 0 to 2147483647. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`; it is not valid otherwise. The actual number of data characters that are parsed depends on the value of the `Extra Chars in Encoded Length` property.
Extra Chars in Encoded Length	Integer	(Only valid if the `Data Element Separation` method is set to `Tagged Encoded Length`.) Specifies the number of extra characters included in the value found in the length field. (For example, the value in the length might include the size of the length field itself as well as the size of the data field, or it might be the total size of the tag, length, and data fields.) Enter a value from 0 to 2147483647. The parser subtracts this number from the number found in the length field to get the number of data characters that follow the length field. You must set this property if you have set the `Data Element Separation` property to `Tagged Encoded Length`, and the actual number of data characters is less than the value found in the length field.

Group reference logical properties:

The logical properties of a group reference include properties that specify the number of occurrences of the group reference.

Property	Type	Meaning
Reference Name	Enumerated type	The `Reference Name` is the name of the object that this object is referring to. The objects available to reference can be selected from the list.

Occurrence properties

Property	Type	Meaning
Min Occurs	Integer	Specify the minimum number of times that the object can repeat. The default value is 1. If the value is set to 0, the object is optional. With the exception of `Max Occurs` being set to -1, if a value is set for `Min Occurs`, it must be less than or equal to the value in `Max Occurs`.

Property	Type	Meaning
Max Occurs	Integer	Specify the maximum number of times that the object can repeat. The default value is 1. If this property is not set, the object cannot occur more than once. If this property is set to 0, it is interpreted as if the object does not exist in the message. It can also be set to -1, to indicate that the limit is unbounded and there is no maximum to the number of occurrences.

The following objects have properties that can be viewed or set.

Group reference CWF properties:

The CWF properties of a group reference.

Byte alignment

Property	Type	Meaning
Byte Alignment	Enumerated type	Specify how the object is aligned from the start of the message. Select one of: • `1 Bytes`. The default value. • `2 Bytes` • `4 Bytes` • `8 Bytes` • `16 Bytes`
Leading Skip Count	Integer	Specify the number of bytes to skip before reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a field defined by C or COBOL data which requires alignment on a 2, 4, 8 or 16 byte boundary. Specify the number of bytes to skip before reading or writing this object. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to the first instance only.
Trailing Skip Count	Integer	Specify the number of bytes to skip after reading or writing this object. The default is `0`, the minimum value is `0`, and the maximum value is `999999`. You can use this value to ignore unwanted fields in a structure, or to model a repeating structure containing fields which require alignment on a 2, 4, 8 or 16 byte boundary. When an output message is written, Skip Count bytes are assigned the value of the message set Byte Alignment Pad property. For repeating objects, this property is applied to all instances.

Occurrences

Property	Type	Meaning
Repeat Reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the displayed list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, there are no integer objects before this one in the message structure. If a *Repeat Reference* is specified, it overrides any setting for the *Max Occurs* logical property when parsing and writing the message, but not for validation of the message.

The following objects have properties that can be viewed or set.

Group reference TDS properties:

The following tables describe the TDS properties of a group reference.

Field identification

Property	Type	Meaning
Data Pattern	String	Specify the regular expression that the parser uses to identify the data in the message to assign to the object. This property is used when the `Data Element Separation` method is set to `Use Data Pattern` in the complex type. For more details, see "Regular expression syntax" on page 6304.

Occurrences

Property	Type	Meaning
Repeating Element Delimiter	String	Specify the delimiter to use between repeating elements. This delimiter is used only when the element repeats and the `Data Element Separation` property of the parent group or complex type is set to `All Elements Delimited` or `Variable Length Elements Delimited`. A default value is provided if the previous conditions are true; if the messaging standard is HL7, the mnemonic <HL7_RS> is used; if the messaging standard is not HL7, and the maximum number of repeats is fixed, the delimiter of the parent group or complex type is used. If none of the previous conditions are true, a default is not applied.
Repeat reference	Enumerated type	Use this property if the object occurs multiple times, and the number of occurrences is given dynamically by a field earlier in the message. Select an integer object from the list of integer objects that occur before this object in the structure of the message. The value of the selected integer specifies the number of occurrences of this object. If no objects are listed, no integer objects exist before this one in the message structure. If a `Repeat Reference` is specified, it overrides any setting for the `Max Occurs` logical property when parsing and writing the message, but not for validating the message.

Local attribute logical properties:

The logical properties of a local attribute.

Property	Type	Meaning
Name	String	Specify a name for the object when you create it. Names can consist of alphanumeric characters, including the letters *A* through *Z*, *a* through *z*, and the digits *0* through *9*. They might also include the following punctuation characters; • - the hyphen • _ the underscore • . the period Names can start only with a letter or the underscore character, and not with a number, hyphen, or period. Names that begin with `xml`, or any variant of these characters (for example `XmL`), are reserved by the XML standards specification. Further details of naming conventions and allowable characters can be found in the Extensible Markup Language (XML) specification that can be found on the World Wide Web Consortium (W3C) Web site.

Property	Type	Meaning
Type	Enumerated type	The Type property constrains the type of data that can be present in the object. Select from the following options: • `int` • `string` • `Boolean` • `hexBinary` • `dateTime` • `date` • `time` • `decimal` • `float` • `(More...)` • `(New Simple Type)` • `(New Complex Type)` If you select (More...), the Type Selection wizard starts. In this wizard, you can select any of the available types. If you select (New Simple Type), the New Simple Type wizard starts. In this wizard, you can create an Anonymous simple type that is based on an existing type. This type can be created locally or globally. If you select (New Complex Type), the New Complex Type wizard starts. In this wizard, you can create an Anonymous complex type, which can be derived from an existing base type. This type can be created locally or globally. For further information about these types, and examples of their use, see the XML Schema Part 0: Primer. This document is available on the World Wide Web Consortium (W3C) Web site.
Namespace	Enumerated type	Namespaces are a simple method for qualifying element and attribute names by associating them with namespaces identified by URI references. If <no target namespace> is displayed, a namespace has not been set for this object. If the property is inactive, the message set has not been configured to support namespaces. Where the property is active, namespaces that are available for selection are displayed in the drop-down list.

Value

The *Value* properties are used in conjunction with the *Usage* property in an Attribute Reference or a Local Attribute.

Property	Type	Meaning
Default	Button and String	This property provides the default value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, default values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if they have default values. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the default value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for default values **Other domains** No support for default values.
Fixed	Button and String	This property provides the fixed value for an element or attribute. **XMLNSC domain** When parsing with validation enabled, if an attribute or element is present, the value is validated against the fixed value. If the values are not equal, a validation error is signalled. Also, when parsing with validation enabled, fixed values are applied to missing attributes and empty elements as required by the XML Schema 1.0 specification. When writing, elements or attributes that are missing from the message tree are not automatically added to the output XML bit stream, even if a fixed value has been specified. If missing elements or attributes are required, the message tree can be serialized and then re-parsed with validation enabled. **MRM (CWF and TDS physical formats)** When writing a fixed-length portion of a message (CWF or fixed-length TDS), if an attribute or element is missing from the message tree, the fixed value is inserted into the bit stream so that the message structure is preserved. **MRM (XML physical format)** No support for fixed values **Other domains** No support for fixed values.

Property	Type	Meaning
Interpret Value As	Enumerated type	Specify if values stored within this object must be interpreted as having significance for the parser and, if so, the type of interpretation that must occur. Select one of the following options: • None This value is the default value, and indicates that the element or attribute does not have a key value associated with it. • MessageSetIdentity. Specifies that the value of the element or attribute corresponds to the identifier, name, or alias (in that priority order) that is associated with the message set where all subsequent embedded messages that are descendents of the enclosing message are defined. This value remains in force unless a new element or attribute MessageSetIdentity field is encountered which resets the MessageSetIdentity value. • MessageIdentity. Specifies that the value of the element or attribute corresponds to the name or alias (in that priority order) that is associated with a message, and acts as an identifier for subsequent embedded messages which are the immediate children of the enclosing message. This identity applies until a new element or attribute MessageIdentity field is encountered at the same level in the tree. The embedded message can be defined in either the current message set, or in a message set identified by using a MessageSetIdentity. **Note:** This property is applicable only when the type of the object is derived from xsd:string.

Usage properties

Property	Type	Meaning
Usage	Enumerated type	Use this property with the `Value` property found in an attribute object. The default value for the `Usage` property is optional. Select from the following options: • optional. – If the `Value` property is set to default, and no data has been entered in the `Value` property, the attribute can appear once and can have any value. – If the `Value` property is set to default, the attribute can appear once. If it does not appear, its value is the data that has been entered in the `Value` property. If it does appear, it is the value given. – Where the `Value` property is set to fixed, the attribute can appear once. If it does appear, its value must match the data that has been entered in the `Value` property. If it does not appear, its value is the data that has been entered in the `Value` property. • prohibited. The attribute must not appear. • required. – If the `Value` property is set to default, and no data has been entered in the `Value` property, the attribute must appear once and can have any value. – If the `Value` property is set to fixed, the attribute must appear once, and it must match the data that has been entered in the `Value` property.

The following objects have properties that can be viewed or set.

Local attribute CWF properties:

The properties, and their permissible values, vary according to the object type.

The properties that are displayed on the object page, and the values that those properties can take, can vary according to the type of the object. For example, the properties for type *string* are different from those of type *Boolean*. Select the link for the object type from the following table.

Type of object	Properties
Binary types	• base64Binary • hexBinary
Boolean types	• Boolean
DateTime types	• date • dateTime • gDay • gMonth • gMonthDay • gYear • gYearMonth • time
Decimal types	• decimal • integer • negativeInteger • nonNegativeInteger • nonPositiveInteger • positiveInteger • unsignedLong
Float types	• double • float
Integer types	• byte • int • long • short • unsignedByte • unsignedInt • unsignedShort
Interval types	• duration

Type of object	Properties
String types	• anyURI • ENTITIES • ENTITY • ID • IDREF • IDREFS • language • Name • NCName • NMTOKEN • NMTOKENS • normalizedString • NOTATION • QName • string • token

Note: The physical format properties for simple type *duration* are the same as the physical properties of the string logical types.

Related concepts:

"Physical formats in the MRM domain" on page 1211
Each message definition file within a message set describes both the *logical structure* of your messages, and the *physical formats* that describe the precise appearance of your message bit stream during transmission.

"MRM Custom Wire Format" on page 1214
Custom Wire Format (CWF) is the physical representation of a message that is composed of a number of fixed-format data structures or elements, which are not separated by delimiters.

"MRM Custom wire format: Relationship to the logical model" on page 1219
Some restrictions exist in relation to the logical model for messages that are defined by using the CWF.

Related tasks:

"Working with physical formats" on page 2847

CWF properties for attribute reference and local attribute binary types:

CWF properties for attribute reference and local attribute binary types.

The Custom Wire Format properties described here apply to:

- Objects: Attribute Reference, Local Attribute
- Binary schema types: base64Binary, hexBinary

Physical representation

Property	Type	Meaning
Length	Button and Integer	If you have selected the length to be defined by *Length*, enter the number of length units for the element. The minimum value that you can specify is 1. The maximum value that you can specify is 2147483647. The default value is empty (not set).
Length Reference	Button and Enumerated type	If you have selected the length to be defined by *Length Reference*, select the name of the integer object that specifies the length of this object. Make your selection from the displayed list of integer objects that are defined as siblings of the current object, and occur before it in the structure of the message. For information about reordering elements, see "Reordering objects" on page 2900.
Inclusive Length Reference	Check box	This property is applicable only if *Length Reference* is set. If the check box is selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object plus the length of the sibling integer object. If the check box is not selected, the value of the sibling integer object that is identified by *Length Reference* is the length of the current object only. If the check box is selected, the *Length Units* property of the sibling integer object must be the same as that of the current object.

Property	Type	Meaning
