ObjectMap interface
BackingMap interface
JavaMap interface

ObjectMap and JavaMap

A JavaMap instance is obtained from an ObjectMap object. The JavaMap interface has the same method signatures as ObjectMap, but with different exception handling. JavaMap extends the java.util.Map interface, so all exceptions are instances of the java.lang.RuntimeException class. Because JavaMap extends the java.util.Map interface, it is easy to quickly use WebSphere® eXtreme Scale with an existing application that uses a java.util.Map interface for object caching.

Obtain a JavaMap instance

An application gets a JavaMap instance from an ObjectMap object using the ObjectMap.getJavaMap method. The following code snippet demonstrates how to obtain a JavaMap instance.

```
ObjectGrid objectGrid = ...;
BackingMap backingMap = objectGrid.defineMap("mapA");
Session sess = objectGrid.getSession();
ObjectMap objectMap = sess.getMap("mapA");
java.util.Map map = objectMap.getJavaMap();
JavaMap javaMap = (JavaMap) javaMap;
```

A JavaMap is backed by the ObjectMap from which it was obtained. Calling the getJavaMap method multiple times using a particular ObjectMap always returns the same JavaMap instance.

Methods

The JavaMap interface only supports a subset of the methods on the java.util.Map interface. The java.util.Map interface supports the following methods:

containsKey(java.lang.Object) method
get(java.lang.Object) method
put(java.lang.Object, java.lang.Object) method
putAll(java.util.Map) method
remove(java.lang.Object) method
clear()

All other methods inherited from the java.util.Map interface result in a java.lang.UnsupportedOperationException exception.

Maps as FIFO queues

With WebSphere® eXtreme Scale, you can provide a first-in first-out (FIFO) queue-like capability for all maps. WebSphere eXtreme Scale tracks the insertion order for all maps. A client can ask a map for the next unlocked entry in a map in the order of insertion and lock the entry. This process allows multiple clients to consume entries from the map efficiently.

FIFO example

The following code snippet shows a client entering a loop to process entries from the map until the map is exhausted. The loop starts a transaction, then calls the ObjectMap.getNextKey(5000) method. This method returns the key of the next available unlocked entry and locks it. If the transaction is blocked for more than 5000 milliseconds, then the method returns null.

```
Session session = ...;
ObjectMap map = session.getMap("xxx");
// this needs to be set somewhere to stop this loop
boolean timeToStop = false;

while(!timeToStop)
{
  session.begin();
  Object msgKey = map.getNextKey(5000);
  if(msgKey == null)
  {
    // current partition is exhausted, call it again in
    // a new transaction to move to next partition
    session.rollback();
    continue;
  }
  Message m = (Message)map.get(msgKey);
  // now consume the message
  ...
  // need to remove it
  map.remove(msgKey);
  session.commit();
}
```

Local mode versus client mode

If the application is using a local core, that is, it is not a client, then the mechanism works as described previously.
For client mode, if the Java™ virtual machine (JVM) is a client, then the client initially connects to a random partition primary. If no work exists in that partition, then the client moves to the next partition to look for work. The client either finds a partition with entries or loops around to the initial random partition. If the client loops around to the initial partition, then it returns a null value to the application. If the client finds a partition with a map that has entries, then it consumes

entries from there until no entries are available for the timeout period. After the timeout passes, then null is returned. This action means that when null is returned and a partitioned map is used, then it you should start a new transaction and resume listening. The previous code sample fragment has this behavior.

Example

When you are running as a client and a key is returned, that transaction is now bound to the partition with the entry for that key. If you do not want to update any other maps during that transaction, then a problem does not exist. If you do want to update, then you can only update maps from the same partition as the map from which you got the key. The entry that is returned from the getNextKey method needs to give the application a way to discover relevant data in that partition. As an example, if you have two maps; one for events and another for jobs that the events impact. You define the two maps with the following entities:

```
Job.java
package tutorial.fifo;

import com.ibm.websphere.projector.annotations.Entity;
import com.ibm.websphere.projector.annotations.Id;

@Entity
public class Job
{
        @Id String jobId;

        int jobState;
}

JobEvent.java
package tutorial.fifo;

import com.ibm.websphere.projector.annotations.Entity;
import com.ibm.websphere.projector.annotations.Id;
import com.ibm.websphere.projector.annotations.OneToOne;

@Entity
public class JobEvent
{
        @Id String eventId;
        @OneToOne Job job;
}
```

The job has as ID and state, which is an integer. Suppose you want to increment the state whenever an event arrived. The events are stored in the JobEvent Map. Each entry has a reference to the job the event concerns. The code for the listener to do this looks like the following example:

```
JobEventListener.java
package tutorial.fifo;

import com.ibm.websphere.objectgrid.ObjectGridException;
import com.ibm.websphere.objectgrid.ObjectMap;
import com.ibm.websphere.objectgrid.Session;
import com.ibm.websphere.objectgrid.em.EntityManager;

public class JobEventListener
{
        boolean stopListening;

        public synchronized void stopListening()
        {
                stopListening = true;
        }

        synchronized boolean isStopped()
        {
                return stopListening;
        }

        public void processJobEvents(Session session)
                throws ObjectGridException
        {
                EntityManager em = session.getEntityManager();
                ObjectMap jobEvents = session.getMap("JobEvent");
                while(!isStopped())
                {
                        em.getTransaction().begin();

                        Object jobEventKey = jobEvents.getNextKey(5000);
                        if(jobEventKey == null)
                        {
                                em.getTransaction().rollback();
                                continue;
                        }
                        JobEvent event = (JobEvent)em.find(JobEvent.class, jobEventKey);
                        // process the event, here we just increment the
                        // job state
                        event.job.jobState++;
                        em.getTransaction().commit();
                }
        }
}
```

The listener is started on a thread by the application. The listener runs until the stopListening method is called. The processJobEvents method is run on the thread until the stopListening method is called. The loop blocks waiting for an eventKey from the JobEvent Map and then uses the EntityManager to access the event object, dereference to the job and increment the state.

The EntityManager API does not have a getNextKey method, but the ObjectMap does. So, the code uses the ObjectMap for JobEvent to get the key. If a map is used with entities then it does not store objects anymore. Instead, it stores Tuples; a Tuple object for the key and a Tuple object for the value. The EntityManager.find method accepts a Tuple for the key.

The code to create an event looks like the following example:

```
em.getTransaction().begin();
Job job = em.find(Job.class, "Job Key");
JobEvent event = new JobEvent();
event.id = Random.toString();
event.job = job;
em.persist(event); // insert it
em.getTransaction().commit();
```

You find the job for the event, construct an event, point it to the job, insert it in the JobEvent Map and commit the transaction.

Loaders and FIFO maps

If you want to back a map that is used as a FIFO queue with a Loader, then you might need to do some additional work. If the order of the entries in the map is not a concern, you have no extra work. If the order is important, then you need to add a sequence number to all of the inserted records when you are persisting the records to the backend. The preload mechanism should be written to insert the records on startup using this order.

Caching objects and their relationships (EntityManager API)

Most cache products use map-based APIs to store data as key-value pairs. The ObjectMap API and the dynamic cache in WebSphere® Application Server, among others, use this approach. However, map-based APIs have limitations. The EntityManager API simplifies the interaction with the data grid by providing an easy way to declare and interact with a complex graph of related objects.

Map-based API limitations

If you are using a map-based API, such as the dynamic cache in WebSphere Application Server or the ObjectMap API, take the following limitations into consideration:

- Indexes and queries must use reflection to query fields and properties in cache objects.
- Custom data serialization is required to achieve performance for complex objects.
- It is difficult to work with graphs of objects. You must develop the application to store artificial references between objects and manually join the objects.

Benefits of the EntityManager API

The EntityManager API uses the existing map-based infrastructure, but it converts entity objects to and from tuples before storing or reading them from the map. An entity object is transformed into a key tuple and a value tuple, which are then stored as key-value pairs. A tuple is an array of primitive attributes.

This set of APIs follows the Plain Old Java™ Object (POJO) style of programming that is adopted by most frameworks.

- Relationship management
  Object-oriented languages such as Java, and relational databases support relationships or associations. Relationships decrease the amount of storage through the use of object references or foreign keys.
- Defining an entity schema
  An ObjectGrid can have any number of logical entity schemas. Entities are defined using annotated Java classes, XML, or a combination of both XML and Java classes. Defined entities are then registered with an eXtreme Scale server and bound to BackingMaps, indexes and other plug-ins.
- Entity manager in a distributed environment
  You can use EntityManager API with a local ObjectGrid or in a distributed eXtreme Scale environment. The main difference is how you connect to this remote environment. After you establish a connection, there is no difference between using a Session object or using the EntityManager API.
- Interacting with EntityManager
  Applications typically first obtain an ObjectGrid reference, and then a Session from that reference for each thread. Sessions cannot be shared between threads. An extra method on Session, the getEntityManager method, is available. This method returns a reference to an entity manager to use for this thread. The EntityManager interface can replace the Session and ObjectMap interfaces for all applications. You can use these EntityManager APIs if the client has access to the defined entity classes.
- EntityManager fetch plan support
  A FetchPlan is the strategy that the entity manager uses for retrieving associated objects if the application needs to access relationships.
- Entity query queues
  Query queues allow applications to create a queue qualified by a query in the server-side or local eXtreme Scale over an entity. Entities from the query result are stored in this queue. Currently, query queue is only supported in a map that is using the pessimistic lock strategy.

- EntityTransaction interface
  You can use the EntityTransaction interface to demarcate transactions.

Relationship management

Object-oriented languages such as Java™, and relational databases support relationships or associations. Relationships decrease the amount of storage through the use of object references or foreign keys.

When you are using relationships in a data grid, the data must be organized in a constrained tree. One root type must exist in the tree and all children must be associated to only one root. For example: Department can have many Employees and an Employee can have many Projects. But a Project cannot have many Employees that belong to different departments. Once a root is defined, all access to that root object and its descendants are managed through the root. WebSphere® eXtreme Scale uses the hash code of the root object's key to choose a partition. For example:

```
partition = (hashCode MOD numPartitions).
```

When all of the data for a relationship is tied to a single object instance, the entire tree can be collocated in a single partition and can be accessed very efficiently using one transaction. If the data spans multiple relationships, then multiple partitions must be involved which involves additional remote calls, which can lead to performance bottlenecks.

Reference data

Some relationships include look-up or reference data such as: `CountryName`. For look-up or reference data, the data must exist in every partition. The data can be accessed by any root key and the same result is returned. Reference data such as this should only be used in cases where the data is fairly static. Updating this data can be expensive because the data needs to be updated in every partition. The DataGrid API is a common technique to keeping reference data up-to-date.

Costs and benefits of normalization

Normalizing the data using relationships can help reduce the amount of memory used by the data grid since duplication of data is decreased. However, in general, the more relational data that is added, the less it will scale out. When data is grouped together, it becomes more expensive to maintain the relationships and to keep the sizes manageable. Since the grid partitions data based on the key of the root of the tree, the size of the tree isn't taken into account. Therefore, if you have a lot of relationships for one tree instance, the data grid may become unbalanced, causing one partition to hold more data than the others.

When the data is denormalized or flattened, the data that would normally be shared between two objects is instead duplicated and each table can be partitioned independently, providing a much more balanced data grid. Although this increases the amount of memory used, it allows the application to scale since a single row of data can be accessed that has all of the necessary data. This is ideal for read-mostly grids since maintaining the data becomes more expensive.

For more information, see Classifying XTP systems and scaling.

Managing relationships using the data access APIs

The ObjectMap API is the fastest, most flexible and granular of the data access APIs, providing a transactional, session-based approach at accessing data in the grid of maps. The ObjectMap API allows clients to use common CRUD (create, read, update and delete) operations to manage key-value pairs of objects in the distributed data grid.

When using the ObjectMap API, object relationships must be expressed by embedding the foreign key for all relationships in the parent object.

An example follows.

```
public class Department {
        Collection<String> employeeIds;
}
```

The EntityManager API simplifies relationship management by extracting the persistent data from the objects including the foreign keys. When the object is later retrieved from the data grid, the relationship graph is rebuilt, as in the following example.

```
@Entity
public class Department {
        Collection<String> employees;
}
```

The EntityManager API is very similar to other Java object persistence technologies such as JPA and Hibernate in that it synchronizes a graph of managed Java object instances with the persistent store. In this case, the persistent store is an eXtreme Scale data grid, where each entity is represented as a map and the map contains the entity data rather than the object instances.

Defining an entity schema

An ObjectGrid can have any number of logical entity schemas. Entities are defined using annotated Java™ classes, XML, or a combination of both XML and Java classes. Defined entities are then registered with an eXtreme Scale server and bound to BackingMaps, indexes and other plug-ins.

When designing an entity schema, you must complete the following tasks:

1. Define the entities and their relationships.
2. Configure eXtreme Scale.
3. Register the entities.
4. Create entity-based applications that interact with the eXtreme Scale EntityManager APIs.

Entity schema configuration

An entity schema is a set of entities and the relationships between the entities. In an eXtreme Scale application with multiple partitions, the following restrictions and options apply to entity schemas:

- Each entity schema must have a single root defined. This is known as the schema root.
- All the entities for a given schema must be in the same map set, which means that all the entities that are reachable from a schema root with key or non-key relationships must be defined in the same map set as the schema root.
- Each entity can belong to only one entity schema.
- Each eXtreme Scale application can have multiple schemas.

Entities are registered with an ObjectGrid instance before it is initialized. Each defined entity must be uniquely named and is automatically bound to an ObjectGrid BackingMap of the same name. The initialization method varies depending on the configuration you are using:
Local eXtreme Scale configuration

If you are using a local ObjectGrid, you can programmatically configure the entity schema. In this mode, you can use the ObjectGrid.registerEntities methods to register annotated entity classes or an entity metadata descriptor file.
Distributed eXtreme Scale configuration

If you are using a distributed eXtreme Scale configuration, you must provide an entity metadata descriptor file with the entity schema.
For more details, see Entity manager in a distributed environment.

Entity requirements

Entity metadata is configured using Java class files, an entity descriptor XML file or both. At minimum, the entity descriptor XML is required to identify which eXtreme Scale BackingMaps are to be associated with entities. The persistent attributes of the entity and its relationships to other entities are described in either an annotated Java class (entity metadata class) or the entity descriptor XML file. The entity metadata class, when specified, is also used by the EntityManager API to interact with the data in the grid.

An eXtreme Scale grid can be defined without providing any entity classes. This can be beneficial when the server and client are interacting directly with the tuple data stored in the underlying maps. Such entities are defined completely in the entity descriptor XML file and are referred to as classless entities.

Classless entities

Classless entities are useful when it is not possible to include application classes in the server or client classpath. Such entities are defined in the entity metadata descriptor XML file, where the class name of the entity is specified using a classless entity identifier in the form: @<entity identifier>. The @ symbol identifies the entity as classless and is used for mapping associations between entities. See the "Classless entity metadata" figure an example of an entity metadata descriptor XML file with two classless entities defined.

If an eXtreme Scale server or client does not have access to the classes, they can still use the EntityManager API using classless entities. Common use cases include the following:

- The eXtreme Scale container is hosted in a server that does not allow application classes in the classpath. In this case, the clients can still access the grid using the EntityManager API from a client, where the classes are allowed.

- The eXtreme Scale client does not require access to the entity classes because the client is either using a non-Java client, such as the eXtreme Scale REST data service or the client is accessing the tuple data in the grid using the ObjectMap API.

If the entity metadata is compatible between the client and server, entity metadata can be created using entity metadata classes, an XML file, or both.

For example, the "Programmatic entity class" in the following figure is compatible with the classless metadata code in the next section.

```
Programmatic entity class
@Entity
public class Employee {
    @Id long serialNumber;
    @Basic byte[] picture;
    @Version int ver;
    @ManyToOne(fetch=FetchType.EAGER, cascade=CascadeType.PERSIST)
    Department department;
}

@Entity
public static class Department {
    @Id int number;
    @Basic String name;
    @OneToMany(fetch=FetchType.LAZY, cascade=CascadeType.ALL, mappedBy="department")
    Collection<Employee> employees;
}
```

Classless fields, keys, and versions

As previously mentioned, classless entities are configured completely in the entity XML descriptor file. Class-based entities define their attributes using Java fields, properties and annotations. So classless entities need to define key and attribute structure in the entity XML descriptor with the `<basic>` and `<id>` tags.

```
Classless entity metadata
<?xml version="1.0" encoding="UTF-8"?>
<entity-mappings xmlns="http://ibm.com/ws/projector/config/emd"
    xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/projector/config/emd ./emd.xsd">

<entity class-name="@Employee" name="Employee">
    <attributes>
        <id name="serialNumber" type="long"/>
        <basic name="firstName" type="java.lang.String"/>
        <basic name="picture" type="[B"/>
        <version name="ver" type="int"/>
        <many-to-one
            name="department"
            target-entity="@Department"
            fetch="EAGER"">
                <cascade><cascade-persist/></cascade>
        </many-to-one>
    </attributes>
</entity>

<entity class-name="@Department" name="Department" >
    <attributes>
        <id name="number" type="int"/>
        <basic name="name" type="java.lang.String"/>
        <version name="ver" type="int"/>
        <one-to-many
            name="employees"
            target-entity="@Employee"
            fetch="LAZY"
            mapped-by="department">
            <cascade><cascade-all/></cascade>
        </one-to-many>
    </attributes>
</entity>
```

Note that each entity above has an <id> element. A classless entity must have either one or more of an <id> element defined, or a single-valued association that represents the key for the entity. The fields of the entity are represented by <basic> elements. The <id>, <version>, and <basic> elements require a name and type in classless entities. See the following supported attribute types section for details on supported types.

Entity class requirements

Class-based entities are identified by associating various metadata with a Java class. The metadata can be specified usingJava Platform, Standard Edition Version 5 annotations, an entity metadata descriptor file, or a combination of annotations and the descriptor file. Entity classes must meet the following criteria:

- The `@Entity` annotation is specified in the entity XML descriptor file.
- The class has a public or protected no-argument constructor.
- It must be a top-level class. Interfaces and enumerated types are not valid entity classes.
- Cannot use the final keyword.
- Cannot use inheritance.
- Must have a unique name and type for each ObjectGrid instance.

Entities all have a unique name and type. The name, if using annotations, is the simple (short) name of the class by default, but can be overridden using the name attribute of the `@Entity` annotation.

Persistent attributes

The persistent state of an entity is accessed by clients and the entity manager by using either fields (instance variables) or Enterprise JavaBeans-style property accessors. Each entity must define either field- or property-based access. Annotated entities are field-access if the class fields are annotated and are property-access if the getter method of the property is annotated. A mixture of field- and property-access is not allowed. If the type cannot be automatically determined, the accessType attribute on the `@Entity` annotation or equivalent XML can be used to identify the access type.

Persistent fields
: Field-access entity instance variables are accessed directly from the entity manager and clients. Fields that are marked with the transient modifier or transient annotation are ignored. Persistent fields must not have final or static modifiers.

Persistent properties
: Property-access entities must adhere to the JavaBeans signature conventions for read and write properties. Methods that do not follow JavaBeans conventions or have the Transient annotation on the getter method are ignored. For a property of type `T`, there must be a getter method getProperty which returns a value of type T and a void setter method setProperty(T). For boolean types, the getter method can be expressed as isProperty, returning true or false. Persistent properties cannot have the static modifier.

Supported attribute types
: The following persistent field and property types are supported:

  - Java primitive types including wrappers
  - java.lang.String
  - java.math.BigInteger
  - java.math.BigDecimal
  - java.util.Date
  - java.util.Calendar
  - java.sql.Date
  - java.sql.Time
  - java.sql.Timestamp
  - byte[]
  - java.lang.Byte[]
  - char[]
  - java.lang.Character[]
  - enum

  User serializable attribute types are supported but have performance, query and change-detection limitations. Persistent data that cannot be proxied, such as arrays and user serializable objects, must be reassigned to the entity if altered.

Serializable attributes are represented in the entity descriptor XML file using the class name of the object. If the object is an array, the data type is represented using the Java internal form. For example, if an attribute data type is java.lang.Byte[][], the string representation is [[Ljava.lang.Byte;

User serializable types should adhere to the following best practices:

- Implement high performance serialization methods. Implement the java.lang.Cloneable interface and public clone method.
- Implement the java.io.Externalizable interface.
- Implement equals and hashCode

Entity associations

Bi-directional and uni-directional entity associations, or relationships between entities can be defined as one-to-one, many-to-one, one-to-many and many-to-many. The entity manager automatically resolves the entity relationships to the appropriate key references when storing the entities.
The eXtreme Scale grid is a data cache and does not enforce referential integrity like a database. Although relationships allow cascading persist and remove operations for child entities, it does not detect or enforce broken links to objects. When removing a child object, the reference to that object must be removed from the parent.

If you define a bi-directional association between two entities, you must identify the owner of the relationship. In a to-many association, the many side of the relationship is always the owning side. If ownership cannot be determined automatically, then the mappedBy attribute of the annotation, or XML equivalent, must be specified. The mappedBy attribute identifies the field in the target entity that is the owner of the relationship. This attribute also helps identify the related fields when there are multiple attributes of the same type and cardinality.

Single-valued associations

One-to-one and many-to-one associations are denoted using the @OneToOne and @ManyToOne annotations or equivalent XML attributes. The target entity type is determined by the attribute type. The following example defines a uni-directional association between Person and Address. The Customer entity has a reference to one Address entity. In this case, the association could also be many-to-one since there is no inverse relationship.

```
@Entity
public class Customer {
  @Id id;
  @OneToOne Address homeAddress;
}

@Entity
public class Address{
  @Id id
  @Basic String city;
}
```

To specify a bi-directional relationship between the Customer and Address classes, add a reference to the Customer class from the Address class and add the appropriate annotation to mark the inverse side of the relationship. Because this association is one-to-one, you have to specify an owner of the relationship using the mappedBy attribute on the @OneToOne annotation.

```
@Entity
public class Address{
  @Id id
  @Basic String city;
  @OneToOne(mappedBy="homeAddress") Customer customer;
}
```

Collection-valued associations

One-to-many and many-to-many associations are denoted using the `@OneToMany` and `@ManyToMany` annotations or equivalent XML attributes. All many relationships are represented using the types: java.util.Collection, java.util.List or java.util.Set. The target entity type is determined by the generic type of the Collection, List or Set or explicitly using the targetEntity attribute on the `@OneToMany` or `@ManyToMany` annotation (or XML equivalent).
In the previous example, it is not practical to have one address object per customer because many customers might share an address or might have multiple addresses. This situation is better solved using a many association:

```
@Entity
public class Customer {
  @Id id;
  @ManyToOne Address homeAddress;
  @ManyToOne Address workAddress;
}

@Entity
public class Address{
  @Id id
  @Basic String city;
  @OneToMany(mappedBy="homeAddress") Collection<Customer> homeCustomers;

  @OneToMany(mappedBy="workAddress", targetEntity=Customer.class)
               Collection workCustomers;
}
```

In this example, two different relationships exist between the same entities: a Home and Work address relationship. A non-generic Collection is used for the workCustomers attribute to demonstrate how to use the targetEntity attribute when generics are not available.
Classless associations

Classless entity associations are defined in the entity metadata descriptor XML file similar to how class-based associations are defined. The only difference is that instead of the target entity pointing to an actual class, it points to the classless entity identifier used for the class name of the entity.

An example follows:

```
<many-to-one name="department" target-entity="@Department" fetch="EAGER">
      <cascade><cascade-all/></cascade>
</many-to-one>
<one-to-many name="employees" target-entity="@Employee" fetch="LAZY">
      <cascade><cascade-all/></cascade>
</one-to-many>
```

Primary keys

All entities must have a primary key, which can be a simple (single attribute) or composite (multiple attribute) key. The key attributes are denoted using the Id annotation or defined in the entity XML descriptor file. Key attributes have the following requirements:

- The value of a primary key cannot change.
- A primary key attribute should be one of the following types: Java primitive type and wrappers, java.lang.String, java.util.Date or java.sql.Date.
- A primary key can contain any number of single-valued associations. The target entity of the primary key association must not have an inverse association directly or indirectly to the source entity.

Composite primary keys can optionally define a primary key class. An entity is associated with a primary key class using the `@IdClass` annotation or the entity XML descriptor file. An `@IdClass` annotation is useful in conjunction with the EntityManager.find method.
Primary key classes have the following requirements:

- It should be public with a no-argument constructor.
- The access type of the primary key class is determined by the entity that declares the primary key class.
- If property-access, the properties of the primary key class must be public or protected.
- The primary key fields or properties must match the key attribute names and types defined in the referencing entity.
- Primary key classes must implement the equals and hashCode methods.

An example follows:

```
@Entity
@IdClass(CustomerKey.class)
public class Customer {
    @Id @ManyToOne Zone zone;
    @Id int custId;
    String name;
    ...
}

@Entity
public class Zone{
    @Id String zoneCode;
    String name;
}
```

```
public class CustomerKey {
    Zone zone;
    int custId;

    public int hashCode() {...}
    public boolean equals(Object o) {...}
}
```

Classless primary keys

Classless entities are required to either have at least one <id> element or an association in the XML file with the attribute `id=true`. An example of both would look like the following:

```
<id name="serialNumber" type="int"/>
<many-to-one name="department" target-entity="@Department"
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsentmgrschema_true">
<cascade><cascade-all/></cascade>
</many-to-one>
```

Remember:
The <id-class> XML tag is not supported for classless entities.

Entity proxies and field interception

Entity classes and mutable supported attribute types are extended by proxy classes for property-access entities and bytecode-enhanced for field-access entities. All access to the entity, even by internal business methods and the equals methods, must use the appropriate field or property access methods. Proxies and field interceptors are used to allow the entity manager to track the state of the entity, determine if the entity has changed, and improve performance.

Attention: When using property-access entities, the equals method should use the instanceof operator for comparing the current instance to the input object. All introspection of the target object should be through the properties of the object, not the fields themselves, because the object instance will be the proxy.

Entity manager in a distributed environment

You can use EntityManager API with a local ObjectGrid or in a distributed eXtreme Scale environment. The main difference is how you connect to this remote environment. After you establish a connection, there is no difference between using a Session object or using the EntityManager API.

Required configuration files

The following XML configuration files are required:

- ObjectGrid descriptor XML file
- Entity descriptor XML file
- Deployment or data grid descriptor XML file

These files specify the entities and BackingMaps that a server hosts.

The entity metadata descriptor file contains a description of the entities that are used. At minimum, you must specify the entity class and name. If you are running in a Java™ Platform, Standard Edition 5 environment, eXtreme Scale automatically reads the entity class and its annotations. You can define additional XML attributes if the entity class has no annotations or if you are required to override the class attributes. If you are registering the entities classless , provide all of entity information in the XML file only.

You can use the following XML configuration snippet to define a data grid with entities. In this snippet, the server creates an ObjectGrid with the name `bookstore` and an associated backing map with the name `order`.The objectgrid.xml file snippet refers to the entity.xml file. In this case, the entity.xml file contains one entity, the Order entity.

```
objectgrid.xml
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">

 <objectGrids>
    <objectGrid name="bookstore" entityMetadataXMLFile="entity.xml">
     <backingMap name="Order"/>
    </objectGrid>
</objectGrids>

</objectGridConfig>
```

This objectgrid.xml file specifies the entity.xml file by including the entityMetadataXMLFile attribute. The value can be a relative directory or an absolute path.

- **For a relative directory:** Specify the location relative to the location of the objectgrid.xml file.
- **For an absolute path:** Specify the location with a URL format, such as file:// or http://.

An example of the entity.xml file follows:

```
entity.xml
<entity-mappings xmlns="http://ibm.com/ws/projector/config/emd"
        xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/projector/config/emd ./emd.xsd">
        <entity class-name="com.ibm.websphere.tutorials.objectgrid.em.
                            distributed.step1.Order" name="Order"/>
</entity-mappings>
```

This example assumes that the Order class would have the orderNumber and desc fields annotated similarly.
An equivalent classless entity.xml file would be as follows:

```
classless entity.xml
<entity-mappings xmlns="http://ibm.com/ws/projector/config/emd"
        xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/projector/config/emd ./emd.xsd">
        <entity class-name="@Order " name="Order">
            <description>"Entity named: Order"</description>
        <attributes>
            <id name="orderNumber" type="int"/>
            <basic name="desc" type="java.lang.String"/>
        </attributes>
        </entity>
</entity-mappings>
```

For information about starting servers, see Starting and stopping stand-alone servers. You use both the deployment.xml and objectgrid.xml files to start the catalog server.

Connecting to a distributed eXtreme Scale server

The following code enables the connect mechanism for a client and server on the same computer:

```
String catalogEndpoints="localhost:2809";
URL clientOverrideURL= new URL("file:etc/emtutorial/distributed/step1/objectgrid.xml");
ClientClusterContext clusterCtx = ogMgr.connect(catalogEndpoints, null, clientOverrideURL);
ObjectGrid objectGrid=ogMgr.getObjectGrid(clusterCtx, "bookstore");
```

In the preceding code snippet, note the reference to the remote eXtreme Scale server. After you establish a connection , you can invoke EntityManager API methods such as persist, update, remove and find.
Attention: When you are using entities, pass the client override ObjectGrid descriptor XML file to the connect method. If a null value is passed to the clientOverrideURL property and the client has a different directory structure than the server, then the client might fail to locate the ObjectGrid or entity descriptor XML files. At minimum, the ObjectGrid and entity XML files for the server can be copied to the client.
Previously, using entities on an ObjectGrid client required you to make the ObjectGrid XML and entity XML available to the client in one of the following two ways:

1. Pass an overriding ObjectGrid XML configuration to the ObjectGridManager.connect(String catalogServerEndpoints, ClientSecurityConfiguration securityProps, URL overRideObjectGridXml) method.

   ```
   String catalogEndpoints="myHost:2809";
   URL clientOverrideURL= new URL("file:etc/emtutorial/distributed/step1/objectgrid.xml");
   ClientClusterContext clusterCtx = ogMgr.connect(catalogEndpoints, null, clientOverrideURL);
   ObjectGrid objectGrid=ogMgr.getObjectGrid(clusterCtx, "bookstore");
   ```

2. Pass null for the override file and ensure that the ObjectGrid XML and referenced entity XML are available to the client on the same path as on the server.

   ```
   String catalogEndpoints="myHost:2809";
   ClientClusterContext clusterCtx = ogMgr.connect(catalogEndpoints, null, null);
   ObjectGrid objectGrid=ogMgr.getObjectGrid(clusterCtx, "bookstore");
   ```

The XML files were required regardless of whether or not you wanted to use subset entities on the client side. These files are no longer required to use the entities as defined by the server. Instead, pass null as the overRideObjectGridXml parameter as in option 2 of the previous section. If the XML file is not found on the same path set on the server, the client uses the entity configuration on the server.

However, if you use subset entities on the client, you must provide an overriding ObjectGrid XML as in option 1.

Client and server-side schema

The server-side schema defines the type of data stored in the maps on a server. The client-side schema is a mapping to application objects from the schema on the server. For example, you might have the following server-side schema:

```
@Entity
class ServerPerson
{
  @Id String ssn;
  String firstName;
  String surname;
  int age;
  int salary;
}
```

A client can have an object annotated as in the following example:

```
@Entity(name="ServerPerson")
class ClientPerson
{
  @Id @Basic(alias="ssn") String socialSecurityNumber;
  String surname;
}
```

This client then takes a server-side entity and projects the subset of the entity into the client object. This projection leads to bandwidth and memory savings on a client because the client has only the information it needs instead of all of the information that is in the server-side entity. Different applications can use their own objects instead of forcing all applications to share a set of classes for data access.
The client-side entity descriptor XML file is required in the following cases: if the server is running with class-based entities while the client side is running classless; or if the server is classless and the client uses class-based entities. A classless client mode allows the client to still run entity queries without having access to the physical classes. Assuming the server has registered the ServerPerson entity above, the client would override the data grid with an entity.xml file such as follows:

```
<entity-mappings xmlns="http://ibm.com/ws/projector/config/emd"
        xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/projector/config/emd ./emd.xsd">
        <entity class-name="@ServerPerson" name="Order">
            <description>"Entity named: Order"</description>
        <attributes>
            <id name="socialSecurityNumber" type="java.lang.String"/>
            <basic name="surname" type="java.lang.String"/>
        </attributes>
        </entity>
</entity-mappings>
```

This file achieves an equivalent subset entity on the client, without requiring the client to provide the actual annotated class. If the server is classless, and the client is not classless, then the client provides an overriding entity descriptor XML file. This entity descriptor XML file contains an override to the class file reference.

Referencing the schema

If your application is running in Java SE 5, then the application can be added to the objects by using annotations. The EntityManager can read the schema from the annotations on those objects. The application provides the eXtreme Scale run time with references to these objects using the entity.xml file, which is referenced from the objectgrid.xml file. The entity.xml file lists all the entities, each of which is associated with either a class or a schema. If a proper class name is specified, then the application attempts to read the Java SE 5 annotations from those classes to determine the schema. If you do not annotate the class file or specify a classless identifier as the class name, then the schema is taken from the XML file. The XML file is used to specify all the attributes, keys, and relationships for each entity.
A local data grid does not need XML files. The program can obtain an ObjectGrid reference and invoke the ObjectGrid.registerEntities method to specify a list of Java SE 5 annotated classes or an XML file.

The run time uses the XML file or a list of annotated classes to find entity names, attribute names and types, key fields and types, and relationships between entities. If eXtreme Scale is running on a server or in stand-alone mode, then it automatically makes a map named after each entity. These maps can be customized further using the objectgrid.xml file or APIs set either by the application or injection frameworks such as Spring.

Entity metadata descriptor file

See emd.xsd file for more information about the metadata descriptor file.

Interacting with EntityManager

Applications typically first obtain an ObjectGrid reference, and then a Session from that reference for each thread. Sessions cannot be shared between threads. An extra method on Session, the getEntityManager method, is available. This method returns a reference to an entity manager to use for this thread. The EntityManager interface can replace the Session and ObjectMap interfaces for all applications. You can use these EntityManager APIs if the client has access to the defined entity classes.

Obtaining an EntityManager instance from a session

The getEntityManager method is available on a Session object. The following code example illustrates how to create a local ObjectGrid instance and access the EntityManager. See the EntityManager interface in the API documentation for details about all the supported methods.

```
ObjectGrid og =
ObjectGridManagerFactory.getObjectGridManager().createObjectGrid("intro-grid");
Session s = og.getSession();
EntityManager em = s.getEntityManager();
```

A one-to-one relationship exists between the Session object and EntityManager object. You can use the EntityManager object more than once.

Persisting an entity

Persisting an entity means saving the state of a new entity in an ObjectGrid cache. After the persist method is called, the entity is in the managed state. Persist is a transactional operation, and the new entity is stored in the ObjectGrid cache after the transaction commits.

Every entity has a corresponding BackingMap in which the tuples are stored. The BackingMap has the same name as the entity, and is created when the class is registered. The following code example demonstrates how to create an Order object by using the persist operation.

```
Order order = new Order(123);
em.persist(order);
order.setX();
...
```

The Order object is created with the key 123, and the object is passed to the persist method. You can continue to modify the state of the object before you commit the transaction.
Important: The preceding example does not include any required transactional boundaries, such as begin and commit. See the Tutorial: Storing order information in entities for more information.

Finding an entity

You can locate the entity in the ObjectGrid cache with the find method by providing a key after the entity is stored in the cache. This method does not require any transactional boundary, which is useful for read-only semantics. The following example illustrates that only one line of code is needed to locate the entity.

```
Order foundOrder = (Order)em.find(Order.class, new Integer(123));
```

Removing an entity

The remove method, like the persist method, is a transactional operation. The following example shows the transactional boundary by calling the begin and commit methods.

```
em.getTransaction().begin();
Order foundOrder = (Order)em.find(Order.class, new Integer(123));
em.remove(foundOrder );
em.getTransaction().commit();
```

The entity must first be managed before it can be removed, which you can accomplish by calling the find method within the transactional boundary. Then call the remove method on the EntityManager interface.

Invalidating an entity

The invalidate method behaves much like the remove method, but does not invoke any Loader plug-ins. Use this method to remove entities from the ObjectGrid, but to preserve them in the backend data store.

```
em.getTransaction().begin();
Order foundOrder = (Order)em.find(Order.class, new Integer(123));
em.invalidate(foundOrder );
em.getTransaction().commit();
```

The entity must first be managed before it can be invalidated, which you can accomplish by calling the find method within the transactional boundary. After you call the find method, you can call the invalidate method on the EntityManager interface.

Updating an entity

The update method is also a transactional operation. The entity must be managed before any updates can be applied.

```
em.getTransaction().begin();
Order foundOrder = (Order)em.find(Order.class, new Integer(123));
foundOrder.date = new Date(); // update the date of the order
em.getTransaction().commit();
```

In the preceding example, the persist method is not called after the entity is updated. The entity is updated in the ObjectGrid cache when the transaction is committed.

Queries and query queues

With the flexible query engine, you can retrieve entities by using EntityManager API. Create SELECT type queries over an entity or Object-based schema by using the ObjectGrid query language. Query interface explains in detail how you can run the queries by using the EntityManager API. See the Query API for more information about using queries.

An entity QueryQueue is a queue-like data structure associated with an entity query. It selects all the entities that match the WHERE condition on the query filter and puts the result entities in a queue. Clients can then iteratively retrieve entities from this queue. See Entity query queues for more information.

- Entity listeners and callback methods
  Applications can be notified when the state of an entity transitions from state to state. Two callback mechanisms exist for state change events: lifecycle callback methods that are defined on an entity class and are invoked whenever the entity state changes, and entity listeners, which are more general because the entity listener can be registered on several entities.
- Entity listener examples
  You can write EntityListeners based on your requirements. Several example scripts follow.

Entity listeners and callback methods

Applications can be notified when the state of an entity transitions from state to state. Two callback mechanisms exist for state change events: lifecycle callback methods that are defined on an entity class and are invoked whenever the entity state changes, and entity listeners, which are more general because the entity listener can be registered on several entities.

Lifecycle of an entity instance

An entity instance has the following states:

- **New**: A newly created entity instance that does not exist in the eXtreme Scale cache.
- **Managed**: The entity instance exists in the eXtreme Scale cache and is retrieved or persisted using the entity manager. An entity must be associated with an active transaction to be in the managed state.
- **Detached**: The entity instance exists in the eXtreme Scale cache, but is no longer associated with an active transaction.
- **Removed**: The entity instance is removed, or is scheduled to be removed, from the eXtreme Scale cache when the transaction is flushed or committed.
- **Invalidated**: The entity instance is invalidated, or is scheduled to be invalidated, from the eXtreme Scale cache when the transaction is flushed or committed.

When entities change from state to state, you can invoke life-cycle, call-back methods.

The following sections further describe the meanings of New, Managed, Detached, Removed and Invalidated states as the states apply to an entity.

Entity lifecycle callback methods

Entity lifecycle callback methods can be defined on the entity class and are invoked when the entity state changes. These methods are useful for validating entity fields and updating transient state that is not usually persisted with the entity. Entity lifecycle callback methods can also be defined on classes that are not using entities. Such classes are entity listener classes, which can be associated with multiple entity types. Lifecycle callback methods can be defined using both metadata annotations and a entity metadata XML descriptor file:

- **Annotations**: lifecycle callback methods can be denoted using the PrePersist, PostPersist, PreRemove, PostRemove, PreUpdate, PostUpdate, and PostLoad annotations in an entity class.
- **Entity XML descriptor** : lifecycle callback methods can be described using XML when annotations are not available.

Entity listeners

An entity listener class is a class that does not use entities that defines one or more entity lifecycle callback methods. Entity listeners are useful for general purpose auditing or logging applications. Entity listeners can be defined using both metadata annotations and a entity metadata XML descriptor file:

- **Annotation**: The EntityListeners annotation can be used to denote one or more entity listener classes on an entity class. If multiple entity listeners are defined, the order in which they are invoked is determined by the order in which they are specified in the EntityListeners annotation.
- **Entity XML descriptor**: The XML descriptor can be used as an alternative to specify the invocation order of entity listeners or to override the order that is specified in metadata annotations.

Callback method requirements

Any subset or combination of annotations can be specified on an entity class or a listener class. A single class cannot have more than one lifecycle callback method for the same lifecycle event. However, the same method can be used for multiple callback events. The entity listener class must have a public no-arg constructor. Entity listeners are stateless. The lifecycle of an entity listener is unspecified. eXtreme Scale does not support entity inheritance, so callback methods can only be defined in the entity class, but not in the superclass.

Callback method signature

Entity lifecycle callback methods can be defined on an entity listener class, directly on an entity class, or both. Entity lifecycle callback methods can be defined using both metadata annotations and the entity XML descriptor. The annotations used for callback methods on the entity class and on the entity listener class are the same. The signatures of the callback methods are different when defined on an entity class versus an entity listener class. Callback methods defined on an entity class or mapped superclass have the following signature:

```
void <METHOD>()
```

Callback methods that are defined on an entity listener class have the following signature:

```
void <METHOD>(Object)
```

The Object argument is the entity instance for which the callback method is invoked. The Object argument can be declared as a java.lang.Object object or the actual entity type.
Callback methods can have public, private, protected, or package level access, but must not be static or final.

The following annotations are defined to designate lifecycle event callback methods of the corresponding types:

- com.ibm.websphere.projector.annotations.PrePersist
- com.ibm.websphere.projector.annotations.PostPersist
- com.ibm.websphere.projector.annotations.PreRemove
- com.ibm.websphere.projector.annotations.PostRemove
- com.ibm.websphere.projector.annotations.PreUpdate
- com.ibm.websphere.projector.annotations.PostUpdate
- com.ibm.websphere.projector.annotations.PostLoad

See the API Documentation for more details. Each annotation has an equivalent XML attribute defined in the entity metadata XML descriptor file.

Lifecycle callback method semantics

Each of the different lifecycle callback methods has a different purpose and is called in different phases of the entity lifecycle:

PrePersist
: Invoked for an entity before the entity has been persisted to the store, which includes entities that have been persisted due to a cascading operation. This method is invoked on the thread of the EntityManager.persist operation.

PostPersist
: Invoked for an entity after the entity has been persisted to the store, which includes entities that have been persisted due to a cascading operation. This method is invoked on the thread of the EntityManager.persist operation. It is called after the EntityManager.flush or EntityManager.commit is called.

PreRemove
: Invoked for an entity before the entity has been removed, which includes entities that have been removed due to a cascading operation. This method is invoked on the thread of the EntityManager.remove operation.

PostRemove

Invoked for an entity after the entity has been removed, which includes entities that have been removed due to a cascading operation. This method is invoked on the thread of the EntityManager.remove operation. It is called after the EntityManager.flush or EntityManager.commit is called.

PreUpdate
: Invoked for an entity before the entity has been updated to the store. This method is invoked on the thread of the transaction flush or commit operation.

PostUpdate
: Invoked for an entity after the entity has been updated to the store. This method is invoked on the thread of the transaction flush or commit operation.

PostLoad
: Invoked for an entity after the entity has been loaded from the store which includes any entities that are loaded through an association. This method is invoked on the thread of the loading operation, such as EntityManager.find or a query.

Duplicate lifecycle callback methods

If multiple callback methods are defined for an entity lifecycle event, the ordering of the invocation of these methods is as follows:

1. **Lifecycle callback methods defined in the entity listeners**: The lifecycle callback methods that are defined on the entity listener classes for an entity class are invoked in the same order as the specification of the entity listener classes in the EntityListeners annotation or the XML descriptor.
2. **Listener super class**: Callback methods defined in the super class of the entity listener are invoked before the children.
3. **Entity lifecycle methods**: WebSphere® eXtreme Scale does not support entity inheritance, so the entity lifecycle methods can only be defined in the entity class.

Exceptions

Lifecycle callback methods might result in run time exceptions. If a lifecycle callback method results in a run time exception within a transaction, the transaction is rolled back. No further lifecycle callback methods are invoked after a runtime exception results.

Entity listener examples

You can write EntityListeners based on your requirements. Several example scripts follow.

EntityListeners example using annotations

The following example shows the life-cycle callback method invocations and order of the invocations. Assume an entity class Employee and two entity listeners exist: EmployeeListener and EmployeeListener2.

```
@Entity
@EntityListeners({EmployeeListener.class, EmployeeListener2.class})
public class Employee {
    @PrePersist
    public void checkEmployeeID() {
        ....
    }
}

public class EmployeeListener {
    @PrePersist
    public void onEmployeePrePersist(Employee e) {
        ....
    }
}

public class PersonListener {
    @PrePersist
    public void onPersonPrePersist(Object person) {
        ....
    }
}

public class EmployeeListener2 extends PersonListener {
    @PrePersist
    public void onEmployeePrePersist2(Object employee) {
        ....
    }
}
```

If a PrePersist event occurs on an Employee instance, the following methods are called in order:

1. onEmployeePrePersist method
2. onPersonPrePersist method
3. onEmployeePrePersist2 method
4. checkEmployeeID method

Entity listeners example using XML

The following example shows how to set an entity listener on an entity using the entity descriptor XML file:

```
<entity
    class-name="com.ibm.websphere.objectgrid.sample.Employee"
    name="Employee" access="FIELD">
    <attributes>
        <id name="id" />
        <basic name="value" />
    </attributes>
    <entity-listeners>
        <entity-listener
            class-name="com.ibm.websphere.objectgrid.sample.EmployeeListener">
            <pre-persist method-name="onListenerPrePersist" />
            <post-persist method-name="onListenerPostPersist" />
        </entity-listener>
    </entity-listeners>
    <pre-persist method-name="checkEmployeeID" />
</entity>
```

The entity Employee is configured with a com.ibm.websphere.objectgrid.sample.EmployeeListener entity listener class , which has two life-cycle callback methods defined. The onListenerPrePersist method is for the PrePersist event, and the onListenerPostPersist method is for the PostPersist event. Also, the checkEmployeeID method in the Employee class is configured to listen for the PrePersist event.

EntityManager fetch plan support

A FetchPlan is the strategy that the entity manager uses for retrieving associated objects if the application needs to access relationships.

Example

Assume for example that your application has two entities: Department and Employee. The relationship between the Department entity and the Employee entity is a bi-directional one-to-many relationship: One department has many employees, and one employee belongs to only one department. Since most of the time, when Department entity is fetched, its employees are likely to be fetched, the fetch type of this one-to-many relationship is set to be EAGER.

Here is a snippet of the Department class.

```
        @Entity
public class Department {

    @Id
    private String deptId;

    @Basic
    String deptName;

                @OneToMany(fetch = FetchType.EAGER, mappedBy="department", cascade = {CascadeType.PERSIST})
                public Collection<Employee> employees;

}
```

In a distributed environment, when an application calls `em.find(Department.class, "dept1")` to find a Department entity with key "dept1", this find operation will get the Department entity and all its eager-fetched relations. In the case of the preceding snippet, these are all the employees of department "dept1".

Prior to WebSphere® eXtreme Scale 6.1.0.5, the retrieval of one Department entity and N Employee entities incurred N+1 client-server trips because the client retrieved one entity for one client-server trip. You can improve performance if you retrieve these N+1 entities in one trip.

Fetch plan

A fetch plan can be used to customize how to fetch eager relationships by customizing the maximum depth of the relationships. The fetch depth overrides eager relations greater than the specified depth to lazy relations. By default, the fetch depth is the maximum fetch depth. This means that eager relationships of all levels that are eager-navigable from the root entity will be fetched. An EAGER relationship is eager-navigable from a root entity if and only if all the relations starting from the root entity to it are configured as eager-fetched.

In the previous example, the Employee entity is eager-navigable from the Department entity because the Department-Employee relationship is configured as eager-fetched.

If the Employee entity has another eager relationship to an Address entity for instance, then the Address entity is also eager-navigable from the Department entity. However, if the Department-Employee relationships were configured as lazy-fetch, then the Address entity is not eager-navigable from the Department entity because the Department-Employee relationship breaks the eager fetch chain.

A FetchPlan object can be retrieved from the EntityManager instance. The application can use the setMaxFetchDepth method to change the maximum fetch depth.

A fetch plan is associated with an EntityManager instance. The fetch plan applies to any fetch operation, more specifically as follows.

- EntityManager `find(Class class, Object key)` and `findForUpdate(Class class, Object key)` operations
- Query operations
- QueryQueue operations

The FetchPlan object is mutable. Once changed, the changed value will be applied to the fetch operations executed afterward.

A fetch plan is important for a distributed deployment because it decides whether the eager-fetched relationship entities are retrieved with the root entity in one client-server trip or more than one.

Continuing with the previous example, consider further that the fetch plan has maximum depth set to infinity. In that case, when an application calls `em.find(Department.class, "dept1")` to find a Department, this find operation will get one Department entity and N employee entities in one client-server trip. However, for a fetch plan with maximum fetch depth set to zero, only the Department object will be retrieved from the server, while the Employee entities are retrieved from the server only when the employees collection of the Department object is accessed.

Different fetch plans

You have several different fetch plans based on your requirements, explained in the following sections.

Impact on a distributed grid

- *Infinite-depth fetch plan:* An infinite-depth fetch plan has its maximum fetch depth set to `FetchPlan.DEPTH_INFINITE`.
  In a client-server environment, if an infinite-depth fetch plan is used, then all the relations that are eager-navigable from the root entity will be retrieved in one client-server trip.

  Example: If the application is interested in all the Address entities of all employees of a particular Department, then it uses an infinite-depth fetch plan to retrieve all the associated Address entities. The following code only incurs one client-server trip.

  ```
  em.getFetchPlan().setMaxFetchDepth(FetchPlan.DEPTH_INFINITE);

  tran.begin();
  Department dept = (Department) em.find(Department.class, "dept1");
  // do something with Address object.
  for (Employee e: dept.employees) {
      for (Address addr: e.addresses) {
      // do something with addresses.
      }
  }
  tran.commit();
  ```

- *Zero-depth fetch plan:* A zero-depth fetch plan has its maximum fetch depth set to 0.
  In a client-server environment, if a zero fetch plan is used, then only the root entity will be retrieved in the first client-server trip. All the eager relationships are treated as if they were lazy.

  Example: In this example, the application is only interested in the Department entity attribute. It does not need to access its employees, so the application sets the fetch plan depth to 0.

  ```
  Session session = objectGrid.getSession();
  EntityManager em = session.getEntityManager();
  EntityTransaction tran = em.getTransaction();
  em.getFetchPlan().setMaxFetchDepth(0);

  tran.begin();
  Department dept = (Department) em.find(Department.class, "dept1");
  // do something with dept object.
  tran.commit();
  ```

- *Fetch plan with depth k* :
  A *k*-depth fetch plan has its maximum fetch depth set to *k*.

  In a client-server eXtreme Scale environment, if a *k*-depth fetch plan is used, then all the relationships eager-navigable from the root entity within *k* steps will be retrieved in the first client-server trip.

  The infinite-depth fetch plan (*k* = infinity) and zero-depth fetch plan (*k* = 0) are just two examples of the *k*-depth fetch plan.

To continue expanding on the previous example, assume there is another eager relationship from the entity Employee to the entity Address. If the fetch plan has maximum fetch depth set to 1, then the `em.find(Department.class, "dept1")` operation will retrieve the Department entity and all its Employee entities in one client-server trip. However, the Address entities will not be retrieved because they are not eager-navigable to the Department entity within 1 step, but 2 steps.

If you use a fetch plan with depth set to 2, then the `em.find(Department.class, "dept1")` operation will retrieve the Department entity, all its Employee entities, and all Address entities associated with the Employee entities in one client-server trip.

Tip: The default fetch plan has maximum fetch depth set to infinity, so the default behavior of a fetch operation can change. All the eager-navigable relationships from the root entity are retrieved. Instead of multiple trips, now the fetch operation only incurs one client-server trip with the default fetch plan. To keep the settings for the product from the prior version, set the fetch depth to 0.

- *Fetch plan used on query:*
  If you execute an entity query you can also use a fetch plan to customize relationship retrieval.

  For example, the query `SELECT d FROM Department d WHERE "d.deptName='Department'"` result has a relationship to the Department entity. Notice the fetch plan depth starts with the query result association: In this case, the Department entity, not the query result itself. That is, the Department entity is on fetch-depth level 0. Therefore a fetch plan with maximum fetch depth 1 will retrieve the Department entity and its Employee entities in one client-server trip.

  Example: In this example, the fetch plan depth is set to 1, so the Department entity and its Employee entities are retrieved in one client-server trip, but the Address entities will not be retrieved in the same trip.

Important: If a relationship is ordered, using either OrderBy annotation or configuration, then it is considered an eager relationship even if it is configured as lazy-fetch.

Performance considerations in a distributed environment

By default, all relationships that are eager-navigable from the root entity will be retrieved in one client-server trip. This can improve performance if all the relationships are going to be used. However, in certain usage scenarios, not all relationships eager-navigable from the root entity are used, so they incur both run-time overhead and bandwidth overhead by retrieving those unused entities.

For such cases, the application can set the maximum fetch depth to a small number to decrease the depth of entities to be retrieved by making all the eager relations after that certain depth lazy. This setting can improve performance.

Proceeding still further with the previous Department-Employee-Address example, by default, all the Address entities associated with employees of the Department "dept1" will be retrieved when `em.find(Department.class, "dept1")` is called. If the application does not use Address entities, it can set the maximum fetch depth to 1, so the Address entities will not be retrieved with the Department entity.

Entity query queues

Query queues allow applications to create a queue qualified by a query in the server-side or local eXtreme Scale over an entity. Entities from the query result are stored in this queue. Currently, query queue is only supported in a map that is using the pessimistic lock strategy.

A query queue is shared by multiple transactions and clients. After the query queue becomes empty, the entity query associated with this queue is rerun and new results are added to the queue. A query queue is uniquely identified by the entity query string and parameters. There is only one instance for each unique query queue in one ObjectGrid instance. See the EntityManager API documentation for additional information.

Query queue example

The following example shows how query queue can be used.

```
/**
 * Get a unassigned question type task
 */
private void getUnassignedQuestionTask() throws Exception {
    EntityManager em = og.getSession().getEntityManager();
    EntityTransaction tran = em.getTransaction();

    QueryQueue queue = em.createQueryQueue("SELECT t FROM Task t
                                WHERE t.type=?1 AND t.status=?2", Task.class);
    queue.setParameter(1, new Integer(Task.TYPE_QUESTION));
    queue.setParameter(2, new Integer(Task.STATUS_UNASSIGNED));

    tran.begin();
    Task nextTask = (Task) queue.getNextEntity(10000);
    System.out.println("next task is " + nextTask);
    if (nextTask != null) {
        assignTask(em, nextTask);
    }
    tran.commit();
}
```

The previous example first creates a QueryQueue with a entity query string, "SELECT t FROM Task t WHERE t.type=?1 AND t.status=?2". Then it sets the parameters for the QueryQueue object. This query queue represents all "unassigned" tasks of the type "question". The QueryQueue object is very similar to an entity Query object.

After the QueryQueue is created, an entity transaction is started and the getNextEntity method is invoked, which retrieves the next available entity with a timeout value set to 10 seconds. After the entity is retrieved, it is processed in the assignTask method. The assignTask modifies the Task entity instance and changes the status to "assigned" which effectively removes it from the queue since it no longer matches the QueryQueue's filter. Once assigned, the transaction is committed.

From this simple example, you can see a query queue is similar to an entity query. However, they differ in the following ways:

1. Entities in the query queue can be retrieved in an iterative manner. The user application decides the number of entities to be retrieved. For example, if QueryQueue.getNextEntity(timeout) is used, only one entity is retrieved, and if QueryQueue.getNextEntities(5, timeout) is used, 5 entities are retrieved. In a distributed environment, the number of entities directly decides the number of bytes to be transferred from the server to client.
2. When an entity is retrieved from the query queue, a U lock is placed on the entity so no other transactions can access it.

Retrieve entities in a loop

You can retrieve entities in a loop. An example that illustrates how to get all the unassigned, question type tasks completed follows.

```
/**
 * Get all unassigned question type tasks
 */
private void getAllUnassignedQuestionTask() throws Exception {
    EntityManager em = og.getSession().getEntityManager();
    EntityTransaction tran = em.getTransaction();

    QueryQueue queue = em.createQueryQueue("SELECT t FROM Task t WHERE
                        t.type=?1 AND t.status=?2", Task.class);
    queue.setParameter(1, new Integer(Task.TYPE_QUESTION));
    queue.setParameter(2, new Integer(Task.STATUS_UNASSIGNED));

    Task nextTask = null;

    do {
        tran.begin();
        nextTask = (Task) queue.getNextEntity(10000);
        if (nextTask != null) {
            System.out.println("next task is " + nextTask);
        }
        tran.commit();
    } while (nextTask != null);
}
```

If there are 10 unassigned question-type tasks in the entity map, you might expect that you will have 10 entities printed to the console. However, if this example is run, you will see the program never exits, which might be contrary to what you assumed.

When a query queue is created and the getNextEntity is called, the entity query associated with the queue is executed and the 10 results are populated into the queue. When getNextEntity is called, an entity is taken off the queue. After 10 getNextEntity calls are executed, the queue is empty. The entity query will automatically re-run. Since these 10 entities still exist and match the query queue's filter criteria, they are populated into the queue again.

If the following line is added after the println() statement, you will see only 10 entities printed.

```
em.remove(nextTask);
```

For information on using SessionHandle with QueryQueue in a per-container placement deployment, read about SessionHandle integration.

Query queues deployed to all partitions

In a distributed eXtreme Scale, a query queue can be created for one partition or all partitions. If a query queue is created for all partitions, there will be one query queue instance in each partition.

When a client tries to get the next entity using the QueryQueue.getNextEntity or QueryQueue.getNextEntities method, the client sends a request to one of the partitions. A client sends peek and pin requests to the server:

- With a peek request, the client sends a request to one partition and the server returns immediately. If there is an entity in the queue, the server sends a response with the entity; if there is not, the server sends a response with no entity. In either case, the server will return immediately.
- With a pin request, the client sends a request to one partition and the server waits until an entity is available. If there is an entity in the queue, the server sends a response with the entity immediately; if there is not, the server waits on the queue until either an entity is available or the request times out.

An example of how an entity is retrieved for a query queue which is deployed to all partitions (n) follows:

1. When a QueryQueue.getNextEntity or QueryQueue.getNextEntities method is called, the client picks a random partition number from 0 to n-1.
2. The client sends peek request to the random partition.
    - If an entity is available, the QueryQueue.getNextEntity or QueryQueue.getNextEntities method exits by returning the entity.
    - If an entity is not available and is not the last unvisited partition, the client sends a peek request to the next partition.
    - If an entity is not available and it is the last unvisited partition, the client instead sends a pin request.
    - If the pin request to the last partition times-out and there is still no data available, the client will make a last effort by sending peek request to all partitions serially one more round. Therefore, if any entity is available in the previous partitions, the client will be able to get it.

Subset entity and no-entity support

The method to create a QueryQueue object in the entity manager follows:

```
public QueryQueue createQueryQueue(String qlString, Class entityClass);
```

The result in the query queue should be projected to the object defined by the second parameter to the method, Class entityClass.

If this parameter is specified, the class must have the same entity name as specified in the query string. This is useful if you want to project an entity into a subset entity. If a null value is used as the entity class, then the result will not be projected. The value stored in the map will be in a entity tuple format.

Client-side key collision

In distributed eXtreme Scale environment, query queue is only supported for eXtreme Scale maps with pessimistic locking mode. Therefore, there is no near cache on the client side. However, a client could have data (key and value) in the transactional map. This potentially could lead to a key collision when an entity retrieved from the server share the same key as an entry already in the transactional map.

When a key collision happens, the eXtreme Scale client run time uses the following rule to either throw an exception or silently override the data.

1. If the collided key is the key of the entity specified in the entity query associated with the query queue, then an exception is thrown. In this case, the transaction is rolled back, and the U lock on this entity key will be released on the server side.
2. Otherwise, if the collided key is the key of the entity association, the data in the transactional map will be overridden without warning.

The key collision only happens when there is a data in the transactional map. In other words, it only happens when a getNextEntity or getNextEntities call is called in a transaction which has already been dirtied (a new data has been inserted or a data has been updated). If an application does not want a key collision happen, it should always call getNextEntity or getNextEntities in a transaction which has not been dirtied.

Client failures

After a client sends a getNextEntity or getNextEntities request to the server, the client could fail as follows:

1. The client sends a request to the server and then goes down.
2. The client gets one or more entities from the server and then goes down.

In the first case, the server discovers that the client is going down when it tries to send back the response to the client. In the second case, when the client gets one or more entities from the server, an X lock is placed on these entities. If the client goes down, the transaction will eventually time out, and the X lock will be released.

Query with ORDER BY clause
Generally, query queues do not honor the ORDER BY clause. If you call getNextEntity or getNextEntities from the query queue, there is no guarantee the entities are returned according to the order. The reason is that the entities cannot be ordered across partitions. In the case that the query queue is deployed to all partitions, when a getNextEntity or getNextEntities call is executed, a random partition is picked to process the request. Therefore, the order is not guaranteed.

ORDER BY is honored if a query queue is deployed to a single partition.

For more information see EntityManager Query API.

One call per transaction

Each QueryQueue.getNextEntity or QueryQueue.getNextEntities call retrieves matched entities from one random partition. Applications should call exactly one QueryQueue.getNextEntity or QueryQueue.getNextEntities on one transaction. Otherwise eXtreme Scale could end up touching entities from multiple partitions, causing an exception to be thrown at the commit time.

EntityTransaction interface

You can use the EntityTransaction interface to demarcate transactions.

Purpose

To demarcate a transaction, you can use the EntityTransaction interface, which is associated with an entity manager instance. Use the EntityManager.getTransaction method to retrieve the EntityTransaction instance for the entity manager. Each EntityManager and EntityTransaction instance are associated with the Session. You can demarcate transactions with either the EntityTransaction or Session. Methods on the EntityTransaction interface do not have any checked exceptions. Only runtime exceptions of type PersistenceException or its subclasses result.

For more information about the EntityTransaction interface, see the API documentation.

Retrieving entities and objects (Query API)

WebSphere® eXtreme Scale provides a flexible query engine for retrieving entities using the EntityManager API and Java™ objects using the ObjectQuery API.

WebSphere eXtreme Scale query capabilities

With the eXtreme Scale query engine, you can perform SELECT type queries over an entity or object-based schema using the eXtreme Scale query language.

This query language provides the following capabilities:

- Single and multi-valued results
- Aggregate functions
- Sorting and grouping
- Joins
- Conditional expressions with subqueries
- Named and positional parameters
- eXtreme Scale index use

- Path expression syntax for object navigation
- Pagination

Query interface

Use the query interface to control entity query execution.

Use the EntityManager.createQuery(String) method to create a Query. You can use each query instance multiple times with the EntityManager instance in which it was retrieved.

Each query result produces an entity, where the entity key is the row ID (of type long) and the entity value contains the field results of the SELECT clause. You can use each query result in subsequent queries.

The following methods are available on the com.ibm.websphere.objectgrid.em.Query interface.

public ObjectMap getResultMap()
The getResultMap method runs a SELECT query and returns the results in an ObjectMap object with the results in query-specified order. The resulting ObjectMap is valid only for the current transaction.

The map key is the result number, of type long, starting at 1. The map value is of type com.ibm.websphere.projector.Tuple where each attribute and association is named based on its ordinal position within the select clause of the query. Use the method to retrieve the EntityMetadata for the Tuple object that is stored within the map.

The getResultMap method is the fastest method for retrieving query result data where multiple results can exist. You can retrieve the name of the resulting entity using the ObjectMap.getEntityMetadata() and EntityMetadata.getName() methods.

Example: The following query returns two rows.

```
String ql = SELECT e.name, e.id, d from Employee e join e.dept d WHERE d.number=5
 Query q = em.createQuery(ql);
 ObjectMap resultMap = q.getResultMap();
 long rowID = 1; // starts with index 1
 Tuple tResult = (Tuple) resultMap.get(new Long(rowID));
 while(tResult != null) {
     // The first attribute is name and has an attribute name of 1
     // But has an ordinal position of 0.
     String name = (String)tResult.getAttribute(0);
     Integer id = (String)tResult.getAttribute(1);

     // Dept is an association with a name of 3, but
     // an ordinal position of 0 since it's the first association.
     // The association is always a OneToOne relationship,
     // so there is only one key.
     Tuple deptKey = tResult.getAssociation(0,0);
     ...
     ++rowID;
     tResult = (Tuple) resultMap.get(new Long(rowID));

 }
```

public Iterator getResultIterator

The getResultIterator method runs a SELECT query and returns the query results using an Iterator where each result is either an Object for a single-valued query, or an Object array for a multiple-valued query. The values in the Object[] result are stored in query order. The result Iterator is valid for the current transaction only.

This method is preferred for retrieving query results within the EntityManager context. You can use the optional setResultEntityName(String) method to name the resulting entity so that it can be used in further queries.

Example: The following query returns two rows.

```
String ql = SELECT e.name, e.id, e.dept from Employee e WHERE e.dept.number=5
 Query q = em.createQuery(ql);
 Iterator results = q.getResultIterator();
 while(results.hasNext()) {
     Object[] curEmp = (Object[]) results.next();
     String name = (String) curEmp[0];
     Integer id = (Integer) curEmp[1];
     Dept d = (Dept) curEmp[2];
     ...
 }
```

public Iterator getResultIterator(Class resultType)

The getResultIterator(Class resultType) method runs a SELECT query and returns the query results using an entity Iterator. The entity type is determined by the resultType parameter. The result Iterator is valid only for the current transaction.

Use this method when you want to use the EntityManager APIs to access the resulting entities.

Example: The following query returns all of the employees and the department to which they belong for one division, ordering by salary. To print out the five employees with the highest salaries and then select work with employees from only one department in the same working set, use the following code.

```
String string_ql = "SELECT e.name, e.id, e.dept from Employee e WHERE
                e.dept.division='Manufacturing' ORDER BY e.salary DESC";
Query query1 = em.createQuery(string_ql);
```

```
query1.setResultEntityName("AllEmployees");
Iterator results1 = query1.getResultIterator(EmployeeResult.class);
int curEmployee = 0;
System.out.println("Highest paid employees");
while (results1.hasNext() && curEmployee++ < 5) {
        EmployeeResult curEmp = (EmployeeResult) results1.next();
        System.out.println(curEmp);
        // Remove the employee from the resultset.
        em.remove(curEmp);
}

// Flush the changes to the result map.
em.flush();

// Run a query against the local working set without the employees we
// removed
String string_q2 = "SELECT e.name, e.id, e.dept from AllEmployees e
                WHERE e.dept.name='Hardware'";
Query query2 = em.createQuery(string_q2);
Iterator results2 = query2.getResultIterator(EmployeeResult.class);
System.out.println("Subset list of Employees");
while (results2.hasNext()) {
        EmployeeResult curEmp = (EmployeeResult) results2.next();
        System.out.println(curEmp);
}
```

public Object getSingleResult

The getSingleResult method runs a SELECT query that returns a single result.

If the SELECT clause has more than one field defined, then the result is an object array, where each element in the array is based on its ordinal position within the SELECT clause of the query.

```
String ql = SELECT e from Employee e WHERE e.id=100"
 Employee e = em.createQuery(ql).getSingleResult();

 String ql = SELECT e.name, e.dept from Employee e WHERE e.id=100"
 Object[] empData = em.createQuery(ql).getSingleResult();
 String empName= (String) empData[0];
 Department empDept = (Department) empData[1];
```

public Query setResultEntityName(String entityName)

The setResultEntityName(String entityName) method specifies the name of the query result entity.

Each time the getResultIterator or getResultMap methods are invoked, an entity with an ObjectMap is dynamically created to hold the results of the query. If the entity is not specified, or null, the entity and ObjectMap name are automatically generated.

Because all query results are available for the duration of a transaction, a query name cannot be reused in a single transaction.

public Query setPartition(int partitionId)

Set the partition to where the query routes.

This method is required if the maps in the query are partitioned and if the entity manager does not have affinity to a single schema root entity partition.

Use the PartitionManager Interface to determine the number of partitions for the backing map of a given entity.

The following table provides descriptions of the other methods that are available through the query interface.

Table 1. Other methods.

Method	Result
public Query setMaxResults(int maxResult)	Set the maximum number of results to retrieve.
public Query setFirstResult(int startPosition)	Set the position of the first result to retrieve.
public Query setParameter(String name, Object value)	Bind an argument to a named parameter.
public Query setParameter(int position, Object value)	Bind an argument to a positional parameter.
public Query setFlushMode(FlushModeType flushMode)	Set the flush mode type to be used when the query runs, overriding the flush mode type set on the EntityManager.

eXtreme Scale query elements

With the eXtreme Scale query engine, you can use a single query language for searching the eXtreme Scale cache. This query language can query Java objects that are stored in ObjectMap objects and Entity objects. Use the following syntax for creating a query string.

An eXtreme Scale query is a string that contains the following elements:

- A SELECT clause that specifies the objects or values to return.
- A FROM clause that names the object collections.
- An optional WHERE clause that contains search predicates over the collections.

- An optional GROUP BY and HAVING clause (see eXtreme Scale query aggregation functions).
- An optional ORDER BY clause that specifies the ordering of the result collection.

Collections of Java objects are identified in queries through the use of their name in the query FROM clause.

The elements of query language are discussed in more detail in the following related topics:

- ObjectGrid query Backus-Naur Form syntax
- Reference for eXtreme Scale queries

The following topics describe the means to use the Query API:

- EntityManager Query API
- Using the ObjectQuery API

- Querying data in multiple time zones
  In a distributed scenario, queries actually run on servers. When querying data with predicates of type calendar, java.util.Date and timestamp, the specified date time value in a query is based on the local time zone of the server.
- Data for different time zones
  When inserting data with calendar, java.util.Date, and timestamp attributes into an ObjectGrid, you must ensure these date time attributes are created based on same time zone, especially when deployed into multiple servers in various time zones. Using the same time zone based date time objects can ensure the application is time-zone safe and data can be queried by calendar, java.util.Date and timestamp predicates.
- Using the ObjectQuery API
  The ObjectQuery API provides methods for querying data in the ObjectGrid that is stored using the ObjectMap API. When a schema is defined in the ObjectGrid instance, the ObjectQuery API can be used to create and run queries over the heterogeneous objects stored in the object maps.
- EntityManager Query API
  The EntityManager API provides methods for querying data in the ObjectGrid that is stored using the EntityManager API. The EntityManager Query API is used to create and run queries over one or more entities defined in eXtreme Scale.
- Reference for eXtreme Scale queries
  WebSphere eXtreme Scale has its own language by which the user can query data.

Querying data in multiple time zones

In a distributed scenario, queries actually run on servers. When querying data with predicates of type calendar, java.util.Date and timestamp, the specified date time value in a query is based on the local time zone of the server.

In a single time-zone system where all clients and servers run on same time zone, you do not need to consider issues related to predicate types with calendar, java.util.Date and timestamp. However, when clients and servers are in different time zones, the specified date time value in queries is based on the server time zone and may return unwanted data back to client. Without knowing the server time zone, the specified date time value is meaningless. So the specified date time value should consider the time zone offset difference between the target time zone and the server time zone.

Time zone offset

For example, assume that a client is in [GMT-0] time zone and the server is in [GMT-6] time zone. The server time zone is 6 hours behind the client. The client would like to run the following query:

```
SELECT e FROM Employee e WHERE e.birthDate='1999-12-31 06:00:00'
```

Assuming the entity Employee has a birthDate attribute that is of type java.util.Date, the client is in [GMT-0] time zone and wants to retrieve Employees with birthDate value as '1999-12-31 06:00:00 [GMT-0]' based on its time zone.

The query will run on the server and the birthDate value used by the query engine will be '1999-12-31 06:00:00 [GMT-6]' that equals to '1999-12-31 12:00:00 [GMT-0]'. Employees with birthDate value equal to '1999-12-31 12:00:00 [GMT-0]' will be returned to the client. Thus, the client will not get wanted Employees with birthDate value '1999-12-31 06:00:00 [GMT-0]'.

The problem described occurs because of the time zone difference between client and server. To solve this problem, one approach is to calculate the time zone offset between client and server and apply the time zone offset on the target date time value in the query. In the previous query example, the time zone offset is -6 hours, and the adjusted birthDate predicate should be “birthDate='1999-12-31 00:00:00'” if the client intends to retrieve Employees with birthDate value '12-31 06:00:00 [GMT-0]'. With the adjusted birthDate value, the server will use '1999-12-31 00:00:00 [GMT-6]' that equals to target value '12-31 06:00:00 [GMT-0]', and the required Employees will be returned to the client.

Distributed deployment in multiple time zones

If the distributed eXtreme Scale grid is deployed into multiple ObjectGrid servers in various time zones, the adjusting time zone offset approach will not work because the client will not know which server will run the query and thus cannot determine the time zone offset to use. The only solution is to use suffix ‘Z' (not case sensitive) on JDBC date and time escape format to indicate using GMT time zone based date time value. The suffix ‘Z' (not case sensitive) indicates to use GMT time zone based date time value. Without the suffix ‘Z', the local time zone based date time value will be used in the process that runs the query.

The following query is equivalent to the previous example, but uses the suffix ‘Z' instead:

```
SELECT e FROM Employee e WHERE e.birthDate='1999-12-31 06:00:00Z'
```

The query should find Employees with birthDate value ‘1999-12-31 06:00:00'. The suffix ‘Z' indicates the specified birthDate value is GMT time zone based, so the GMT time zone based birthDate value ‘1999-12-31 06:00:00 [GMT-0]' will be used by the query engine for matching criteria value. Employees with birthDate attribute value equal to this GMT based birthDate value ‘1999-12-31 06:00:00 [GMT-0]' will be included in query result. Using the suffix ‘Z' on JDBC date time

escape format in any query is crucial to make applications time zone safe. Without this approach, the date time value is server time zone based and is meaningless from the client perspective when clients and servers are in different time zones.

For more information, see Data for different time zones.

Data for different time zones

Data for different time zones

When inserting data with calendar, java.util.Date, and timestamp attributes into an ObjectGrid, you must ensure these date time attributes are created based on same time zone, especially when deployed into multiple servers in various time zones. Using the same time zone based date time objects can ensure the application is time-zone safe and data can be queried by calendar, java.util.Date and timestamp predicates.

Without explicitly specifying a time zone when creating date time objects, Java™ uses the local time zone and may cause inconsistent date time values in clients and servers.

Consider an example in a distributed deployment in which client1 is in time zone [GMT-0] and client2 is in [GMT-6] and both want to create a java.util.Date object with value '1999-12-31 06:00:00'. Then client1 will create java.util.Date object with value '1999-12-31 06:00:00 [GMT-0]' and client2 will create java.util.Date object with value '1999-12-31 06:00:00 [GMT-6]'. Both java.util.Date objects are not equal because the time zone is different. A similar problem occurs when preloading data into partitions residing in servers in different time zones if local time zone is used to create date time objects.

To avoid the described problem, the application can choose a time zone such as [GMT-0] as the base time zone for creating calendar, java.util.Date, and timestamp objects.

Querying data in multiple time zones

Using the ObjectQuery API

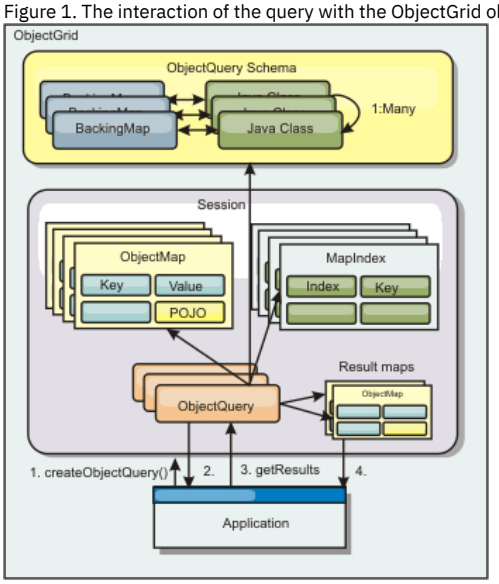
The ObjectQuery API provides methods for querying data in the ObjectGrid that is stored using the ObjectMap API. When a schema is defined in the ObjectGrid instance, the ObjectQuery API can be used to create and run queries over the heterogeneous objects stored in the object maps.

Query and object maps

You can use an enhanced query capability for objects that are stored using the ObjectMap API. These queries allow retrieval of objects using non-key attributes and performs simple aggregations such as sum, avg, min, and max against all the data that matches a query. Applications can construct a query using the Session.createObjectQuery method. This method returns an ObjectQuery object which can then be interrogated to obtain the query results. The query object also allows the query to be customized before running the query. The query is run automatically when any method returning the result is called.

Figure 1. The interaction of the query with the ObjectGrid object maps and how a schema is defined for classes and associated with an ObjectGrid map



Defining an ObjectMap schema

Object maps are used to store objects in various forms and are largely unaware of the format. A schema must be defined in the ObjectGrid that defines the format of the data. A schema is composed of the following pieces:

- The type of object stored in the ObjectMap
- Relationships between ObjectMaps
- The method for which each query should access the data attributes in the objects (fields or property methods)
- The primary key attribute name in the object.

See Configuring an ObjectQuery schema for details.

For an example on creating a schema programmatically or using the ObjectGrid descriptor XML file, see ObjectQuery tutorial - step 3.

Querying objects with the ObjectQuery API

The ObjectQuery interface allows the querying of non-entity objects, which are heterogeneous objects that are stored directly in the ObjectGrid ObjectMaps. The ObjectQuery API provides an easy way to find ObjectMap objects without using the index mechanism directly.

There are two methods for retrieving results from an ObjectQuery: getResultIterator and getResultMap.

Retrieving query results using getResultIterator

Query results are basically a list of attributes. Suppose the query was select a,b,c from X where y=z. This query returns a list of rows containing a, b and c. This list is actually stored in a transaction scoped Map, which means that you must associate an artificial key with each row and use an integer that increases with each row. This map is obtained using the ObjectQuery.getResultMap() method. You can access the elements of each row using code similar to the following:

```
ObjectQuery q = session.createQuery(
    "select c.id, c.firstName, c.surname from Customer c where c.surname=?1");

  q.setParameter(1, "Claus");

  Iterator iter = q.getResultIterator();
  while(iter.hasNext())
  {
    Object[] row = (Object[])iter.next();
    System.out.println("Found a Claus with id "
      + row[objectgrid: 0 ] + ", firstName: "
      + row[objectgrid: 1 ] + ", surname: "
      + row[objectgrid: 2 ]);
  }
```

Retrieving query results using getResultMap

Query results can also be retrieved using the result map directly. The following example shows a query retrieving specific parts of the matching Customers and demonstrates how to access the resulting rows. Notice that if you use the ObjectQuery object to access the data, then the generated long row identifier is hidden. The long row is only visible when using the ObjectMap to access the result.

When the transaction is completed this map disappears. The map is also only visible to the session used, that is, normally to just the thread that created it. The map uses a key of type Long which represents the row ID. The values stored in the map either are of type Object or Object[], where each element matches the type of the element in the select clause of query.

```
ObjectQuery q = em.createQuery(
      "select c.id, c.firstName, c.surname from Customer c where c.surname=?1");
  q.setParameter(1, "Claus");
  ObjectMap qmap = q.getResultMap();
  for(long rowId = 0; true; ++rowId)
  {
    Object[] row = (Object[]) qmap.get(new Long(rowId));
    if(row == null) break;
    System.out.println(" I Found a Claus with id " + row[0]
      + ", firstName: " + row[1]
      + ", surname: " + row[2]);
  }
```

For examples on using the ObjectQuery, see Tutorial: Querying a local in-memory data grid.

- Configuring an ObjectQuery schema
  ObjectQuery relies on schema or shape information to perform semantic checking and to evaluate path expressions. This section describes how to define the schema in XML or programmatically.

Data for different time zones
EntityManager Query API
Reference for eXtreme Scale queries

Configuring an ObjectQuery schema

ObjectQuery relies on schema or shape information to perform semantic checking and to evaluate path expressions. This section describes how to define the schema in XML or programmatically.

Defining the schema

The ObjectMap schema is defined in the ObjectGrid deployment descriptor XML or programmatically using the normal eXtreme Scale configuration techniques. For an example on how to create a schema, see ObjectQuery tutorial - step 4.

Schema information describes plain old Java™ objects (POJOs): which attributes they consist of and what types of attributes there might be, whether the attributes are primary key fields, single-valued or multi-valued relationships, or bidirectional relationships. Schema information directs ObjectQuery to use field access or property access.

Queryable attributes

When the schema is defined in the ObjectGrid, the objects in the schema are introspected using reflection to determine which attributes are available for querying. You can query the following attribute types:

- Java primitive types including wrappers
- java.lang.String
- java.math.BigInteger
- java.math.BigDecimal
- java.util.Date
- java.sql.Date
- java.sql.Time
- java.sql.Timestamp
- java.util.Calendar
- byte[]
- java.lang.Byte[]
- char[]
- java.lang.Character[]
- J2SE enum

Embedded serializable types other than those stated previously can also be included in a query result, but cannot be included in the WHERE or FROM clause of the query. Serializable attributes are not navigable.

Attribute types can be excluded from the schema if the type is not serializable, the field or property is static, or the field is transient. Since all map objects must be serializable, the ObjectGrid only includes attributes that can be persisted from the object. Other objects are ignored.

Field attributes

When the schema is configured to access the object using fields, all serializable, non-transient fields are automatically incorporated into the schema. To select a field attribute in a query, use the field identifier name as it exists in the class definition.

All public, private, protected and package protected fields are included in the schema.

Property attributes

When the schema is configured to access the object using properties, all serializable methods that follow the JavaBeans property naming conventions will automatically be incorporated into the schema. To select a property attribute for the query, use the JavaBeans style property name conventions.

All public, private, protected and package protected properties are included in the schema.

In the following class, the following attributes are added to the schema: name, birthday, valid.

```
public class Person {
  public String getName(){}
  private java.util.Date getBirthday(){}
  boolean isValid(){}
  public NonSerializableObject getData(){}
}
```

When using a CopyMode of COPY_ON_WRITE, the query schema must always use property-based access. COPY_ON_WRITE creates proxy objects whenever objects are retrieved from the map and can only access those objects using property methods. Failure to do so will result in each query result being set to null.

Relationships

Each relationship must be explicitly defined in the schema configuration. The cardinality of the relationship is automatically determined by the type of the attribute. If the attribute implements the java.util.Collection interface, then the relationship is either a one-to-many or many-to-many relationship.

Unlike entity queries, attributes that refer to other cached objects must not store direct references to the object. References to other objects are serialized as part of the containing object's data. Instead, store the key to the related object.

For example, if there is a many-to-one relationship between a Customer and Order:

```
Incorrect. Storing an object reference.

public class Customer {
  String customerId;
  Collection<Order> orders;
}
```

```
public class Order {
  String orderId;
  Customer customer;
}

Correct. The key to the related object.

public class Customer {
  String customerId;
  Collection<String> orders;
}

public class Order {
  String orderId;
  String customer;
}
```

When you run a query that joins two object maps together, the key is automatically inflated. For example, the following query would return Customer objects:

```
SELECT c FROM Order o JOIN Customer c WHERE orderId=5
```

Using indexes

ObjectGrid uses index plugins to add indexes to maps. The query engine automatically incorporates any indexes that are defined on a schema map element of the type: com.ibm.websphere.objectgrid.plugins.index.HashIndex and the rangeIndex property is set to true. If the index type is not HashIndex and the rangeIndex property is not set to true, then the index is ignored by the query. See ObjectQuery tutorial - step 2 for an example on how to add an index to the schema.

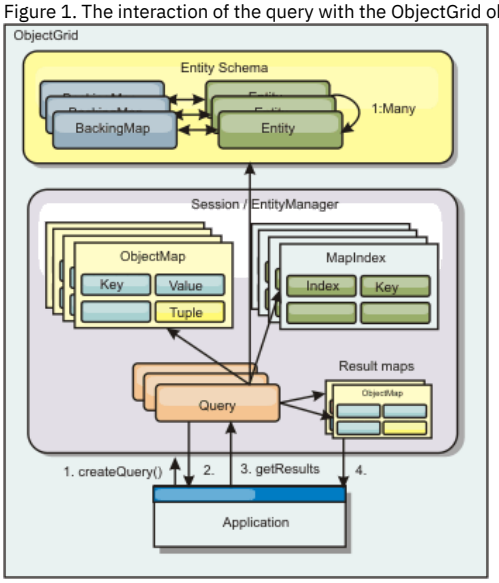
EntityManager Query API

The EntityManager API provides methods for querying data in the ObjectGrid that is stored using the EntityManager API. The EntityManager Query API is used to create and run queries over one or more entities defined in eXtreme Scale.

Query and ObjectMaps for entities

WebSphere® Extended Deployment v6.1 introduced an enhanced query capability for entities stored in eXtreme Scale. These queries allow objects to be retrieved using non-key attributes and to perform simple aggregations such as the sum, average, minimum, and maximum against all the data that matches a query. Applications construct a query using the EntityManager.createQuery API. This returns a Query object and can then be interrogated to obtain the query results. The query object also allows the query to be customized before running the query. The query is run automatically when any method returning the result is called.

Figure 1. The interaction of the query with the ObjectGrid object maps and how the entity schema is defined and associated with an ObjectGrid map.



Retrieving query results using the getResultIterator method

Query results are a list of attributes. If the query was select a,b,c from X where y=z, then a list of rows containing a, b and c is returned. This list is stored in a transaction scoped Map, which means that you must associated an artificial key with each row and use an integer that increases with each row. This map is obtained using the Query.getResultMap method. The map has EntityMetaData, which describes each row in the Map associated with it. You can access the elements of each row using code similar to the following:

```
Query q = em.createQuery("select c.id, c.firstName, c.surname from Customer c where c.surname=?1");

  q.setParameter(1, "Claus");
```

```
  Iterator iter = q.getResultIterator();
  while(iter.hasNext())
  {
    Object[] row = (Object[])iter.next();
    System.out.println("Found a Claus with id "  + row[objectgrid: 0 ]
      + ", firstName: " + row[objectgrid: 1 ]
      + ", surname: " + row[objectgrid: 2 ]);
  }
```

Retrieving query results using getResultMap

The following code shows the retrieval of specific parts of the matching Customers and shows how to access the resulting rows. If you use the Query object to access the data, then the generated long row identifier is hidden. The long is only visible when using the ObjectMap to access the result. When the transaction is completed, then this Map disappears. The Map is only visible to the Session used, that is, normally to just the thread that created it. The Map uses a Tuple for the key with a single attribute, a long with the row ID. The value is another tuple with an attribute for each column in the result set.

The following sample code demonstrates this:

```
Query q = em.createQuery("select c.id, c.firstName, c.surname from
Customer c where c.surname=?1");
q.setParameter(1, "Claus");
ObjectMap qmap = q.getResultMap();
Tuple keyTuple = qmap.getEntityMetadata().getKeyMetadata().createTuple();
for(long i = 0; true; ++i)
{
  keyTuple.setAttribute(0, new Long(i));
  Tuple row = (Tuple)qmap.get(keyTuple);
  if(row == null) break;
  System.out.println(" I Found a Claus with id "  + row.getAttribute(0)
    + ", firstName: " + row.getAttribute(1)
    + ", surname: " + row.getAttribute(2));
}
```

Retrieving query results using an entity result iterator

The following code shows the query and the loop that retrieves each result row using the normal Map APIs. The key for the Map is a Tuple. So, construct one of the correct types using the createTuple method result in keyTuple. Try to retrieve all rows with rowIds from 0 onwards. When you get returns null (indicating key not found), then the loop finishes. Set the first attribute of keyTuple to be the long that you want to find. The value returned by get is also a Tuple with an attribute for each column in the query result. Then, pull each attribute from the value Tuple using getAttribute.

Following is the next code fragment:

```
Query q2 = em.createQuery("select c.id, c.firstName, c.surname from Customer c where c.surname=?1");
q2.setResultEntityName("CustomerQueryResult");
q2.setParameter(1, "Claus");

Iterator iter2 = q2.getResultIterator(CustomerQueryResult.class);
while(iter2.hasNext())
{
  CustomerQueryResult row = (CustomerQueryResult)iter2.next();
  // firstName is the id not the firstName.
  System.out.println("Found a Claus with id " + row.id
    + ", firstName: " + row.firstName
    + ", surname: " + row.surname);
}

em.getTransaction().commit();
```

Specified is a ResultEntityName value on the query. This value tells the query engine that you want to project each row to a specific object, CustomerQueryResult in this case. The class follows:

```
@Entity
public class CustomerQueryResult {
        @Id long rowId;
        String id;
        String firstName;
        String surname;
};
```

In the first snippet, notice that the each query row is returned as a CustomerQueryResult object rather than an Object[]. The result columns of the query are projected to the CustomerQueryResult object. Projecting the result is slightly slower at run time but more readable. Query result Entities should not be registered with eXtreme Scale at startup. If the entities are registered, then a global Map with the same name is created, and the query fails with an error indicating duplicate Map name.

- Simple queries with EntityManager
  WebSphere eXtreme Scale comes with EntityManager query API.

Related concepts:
Querying data in multiple time zones
Data for different time zones
Using the ObjectQuery API
Reference for eXtreme Scale queries

Simple queries with EntityManager

WebSphere® eXtreme Scale comes with EntityManager query API.

The EntityManager query API is very similar to SQL other query engines that query over objects. A query is defined, then the result is retrieved from the query using various getResult methods.

The following examples refer to the entities used in the EntityManager tutorial in the Product Overview.

Running a simple query

In this example, customers with the surname of Claus are queried:

```
em.getTransaction().begin();

  Query q = em.createQuery("select c from Customer c where c.surname='Claus'");

  Iterator iter = q.getResultIterator();
  while(iter.hasNext())
  {
    Customer c = (Customer)iter.next();
    System.out.println("Found a claus with id " + c.id);
  }

  em.getTransaction().commit();
```

Using parameters

Since you want to find all customers with a surname of Claus, a parameter to specify the surname is used since you might may want to use this query more than once.

Positional Parameter Example

```
Query q = em.createQuery("select c from Customer c where c.surname=?1");
  q.setParameter(1, "Claus");
```

Using parameters is very important when the query is used more than once. The EntityManager needs to parse the query string and build a plan for the query, which is expensive. By using a parameter, the EntityManager caches the plan for the query, thereby reducing the time it takes to run a query.

Both positional and named parameters are used:

Named Parameter Example

```
Query q = em.createQuery("select c from Customer c where c.surname=:name");
  q.setParameter("name", "Claus");
```

Using an index to improve performance

If there are millions of customers, then the previous query needs to scan over all rows in the Customer Map. This is not very efficient. But eXtreme Scale provides a mechanism for defining indexes over individual attributes in an entity. The query automatically uses this index when appropriate, which can speed up queries dramatically.

You can specify which attributes to index very simply by using the @Index annotation on the entity attribute:

```
@Entity
public class Customer
{
  @Id String id;
  String firstName;
  @Index String surname;
  String address;
  String phoneNumber;
}
```

The EntityManager creates an appropriate ObjectGrid index for the surname attribute in the Customer entity and the query engine automatically uses the index, which greatly decreases the query time.

Using pagination to improve performance

If there are a million customers named Claus, then it is not likely that you would want to display a page displaying a million customers. It is more likely that you would want to display 10 or 25 customers at a time.

The Query setFirstResult and setMaxResults methods helps by only returning a subset of the results.

Pagination Example

```
Query q = em.createQuery("select c from Customer c where c.surname=:name");
  q.setParameter("name", "Claus");
  // Display the first page
  q.setFirstResult=1;
```

```
q.setMaxResults=25;
displayPage(q.getResultIterator());

// Display the second page
q.setFirstResult=26;
displayPage(q.getResultIterator());
```

Reference for eXtreme Scale queries

WebSphere® eXtreme Scale has its own language by which the user can query data.

ObjectGrid query FROM clause

The FROM clause specifies the collections of objects to which to apply the query. Each collection is identified either by an abstract schema name and an identification variable, called a range variable, or by a collection member declaration that identifies either a single or multi-valued relationship and an identification variable.

Conceptually, the semantics of the query is to first form a temporary collection of tuples, referred to as R. Tuples are composed of elements from the collections that are identified in the FROM clause. Each tuple contains one element from each of the collections in the FROM clause. All possible combinations are formed subject to the constraints that are imposed by the collection member declarations. If any schema name identifies a collection for which there are no records in the persistent store, then the temporary collection R is empty.

Examples using FROM
The DeptBean object contains records 10, 20 and 30. The EmpBean object contains records 1, 2 and 3 that are related to department 10 and records 4 and 5 that are related to department 20. Department 30 has no related employees.

```
FROM DeptBean d, EmpBean e
```

This clause forms a temporary collection R that contains 15 tuples.

```
FROM DeptBean d, DeptBean d1
```

This clause forms a temporary collection R that contains 9 tuples.

```
FROM DeptBean d, IN (d.emps) AS e
```

This clause forms a temporary collection R that contains 5 tuples. Department 30 is not in the R temporary collection because it contains no employees. Department 10 is contained in the R temporary collection three times and department 20 is contained in R twice.

Instead of using IN(d.emps) as e, you can use a JOIN predicate:

```
FROM DeptBean d JOIN d.emps as e
```

After forming the temporary collection, the search conditions of the WHERE clause are applied to the R temporary collection, yielding a new temporary collection R1. The ORDER BY and SELECT clauses are applied to R1 to yield the final result set.

An identification variable is a variable that is declared in the FROM clause using the IN operator or the optional AS operator.

```
FROM DeptBean AS d, IN (d.emps) AS e
```

is equivalent to:

```
FROM DeptBean d, IN (d.emps) e
```

An identification variable that is declared to be an abstract schema name is called a range variable. In the previous query, "d" is a range variable. An identification variable that is declared to be a multi-valued path expression is called a collection member declaration. The "d" and "e" values in the previous example are collection member declarations.

An example of using a single-valued path expression in the FROM clause follows:

```
FROM EmpBean e, IN(e.dept.mgr) as m
```

ObjectGrid query SELECT clause

The syntax of the SELECT clause is illustrated in the following example:

```
SELECT { ALL | DISTINCT } [ selection , ]* selection

selection  ::= {single_valued_path_expression |
                identification_variable |
                OBJECT ( identification_variable) |
               aggregate_functions } [[ AS ] id ]
```

The SELECT clause consists of one or more of the following elements: a single identification variable that is defined in the FROM clause, a single-valued path expression that evaluates to object references or values, and an aggregate function. You can use the DISTINCT keyword to eliminate duplicate references.

A scalar-subselect is a subselect that returns a single value.

Examples using SELECT
Find all employees that earn more than the John employee:

```
SELECT OBJECT(e) FROM EmpBean ej, EmpBean eWHERE ej.name = 'John' and e.salary > ej.salary
```

Find all departments that have one or more employees who earn less than 20000:

```
SELECT DISTINCT e.dept FROM EmpBean e where e.salary < 20000
```

A query can have a path expression that evaluates to an arbitrary value:

```
SELECT e.dept.name FROM EmpBean e where e.salary < 20000
```

The previous query returns a collection of name values for the departments that have employees who earn less than 20000.

A query can return an aggregate value:

```
SELECT avg(e.salary) FROM EmpBean e
```

A query that retrieves the names and object references for underpaid employees follows:

```
SELECT e.name as name , object(e) as emp from EmpBean e where e.salary < 50000
```

ObjectGrid query WHERE clause

The WHERE clause contains search conditions that are composed of the elements presented below. When a search condition evaluates to TRUE, the tuple is added to the result set.

ObjectGrid query literals

A string literal is enclosed in single quotes. A single quotation mark that occurs within a string literal is represented by two single quotes, for example: 'Tom''s'.

A numeric literal can be any of the following values:

- An exact value such as 57, -957, or +66
- Any value supported by Java™ long type
- A decimal literal such as 57.5 or -47.02
- An approximate numeric value such as 7E3 or -57.4E-2
- Float types must include the "F" qualifier, for example 1.0F
- Long types must include the "L" qualifier, for example 123L

Boolean literals are TRUE and FALSE.

Temporal literals follow JDBC escape syntax based on the type of attribute:

- java.util.Date: yyyy-mm-ss
- java.sql.Date: yyyy-mm-ss
- java.sql.Time: hh-mm-ss
- java.sql.Timestamp: yyyy-mm-dd hh:mm:ss.f...
- java.util.Calendar: yyyy-mm-dd hh:mm:ss.f...

Enum literals are expressed using Java enum literal syntax using the fully qualified enum class name.

ObjectGrid query input parameters

You can specify input parameters by either using an ordinal position or by using a variable name. Writing queries that use input parameters is strongly encouraged, because using input parameters increases performance by allowing the ObjectGrid to catch the query plan between running actions.

An input parameter can be any of the following types: Byte, Short, Integer, Long, Float, Double, BigDecimal, BigInteger, String, Boolean, Char, java.util.Date, java.sql.Date, java.sql.Time, java.sql.Timestamp, java.util.Calendar, a Java SE 5 enum, an Entity or POJO Object, or a binary data string in the form of Java byte[].

An input parameter must not have a NULL value. To search for the occurrence of a NULL value, use the NULL predicate.

Positional Parameters

Positional input parameters are defined by using question mark followed by a positive number:

```
?[positive integer].
```

Positional input parameters are numbered starting at 1 and correspond to the arguments of the query; therefore, a query must not contain an input parameter that exceeds the number of input arguments.

Example: `SELECT e FROM Employee e WHERE e.city = ?1 and e.salary >= ?2`

Named Parameters

Named input parameters are defined using a variable name in the format: :[parameter name].

Example: `SELECT e FROM Employee e WHERE e.city = :city and e.salary >= :salary`

ObjectGrid query BETWEEN predicate

The BETWEEN predicate determines whether a given value lies between two other given values.

```
expression [NOT] BETWEEN expression-2 AND expression-3
```

Example 1

```
e.salary BETWEEN 50000 AND 60000
```

is equivalent to:

```
e.salary >= 50000 AND e.salary <= 60000
```

Example 2

```
e.name NOT BETWEEN 'A' AND 'B'
```

is equivalent to:

```
e.name < 'A' OR e.name > 'B'
```

ObjectGrid query IN predicate

The IN predicate compares a value to a set of values. You can use the IN predicate in one of two forms:

```
expression [NOT] IN ( subselect )expression [NOT] IN ( value1, value2, .... )
```

The ValueN value can either be a literal value or an input parameter. The expression cannot evaluate to a reference type.

Example 1

```
e.salary IN ( 10000, 15000 )
```

is equivalent to

```
( e.salary = 10000 OR e.salary = 15000 )
```

Example 2

```
e.salary IN ( select e1.salary from EmpBean e1 where e1.dept.deptno = 10)
```

is equivalent to

```
e.salary = ANY ( select e1.salary from EmpBean e1 where e1.dept.deptno = 10)
```

Example 3

```
e.salary NOT IN ( select e1.salary from EmpBean e1 where e1.dept.deptno = 10)
```

is equivalent to

```
e.salary <> ALL ( select e1.salary from EmpBean e1 where e1.dept.deptno = 10)
```

ObjectGrid query LIKE predicate

The LIKE predicate searches a string value for a certain pattern.

```
string-expression [NOT] LIKE pattern [ ESCAPE escape-character ]
```

The pattern value is a string literal or parameter marker of type string in which the underscore (_) stands for any single character and percent (%) stands for any sequence of characters, including an empty sequence. Any other character stands for itself. The escape character can be used to search for character _ and %. The escape character can be specified as a string literal or as an input parameter.

If the string-expression is null, then the result is unknown.

If both string-expression and pattern are empty, then the result is true.

Example

```
'' LIKE '' is true
'' LIKE '%' is true
e.name LIKE '12%3' is true for '123' '12993' and false for '1234'
e.name LIKE 's_me' is true for 'some' and 'same', false for 'soome'
e.name LIKE '/_foo' escape '/' is true for '_foo', false for 'afoo'
e.name LIKE '//_foo' escape '/' is true for '/afoo' and for '/bfoo'
e.name LIKE '///_foo' escape '/' is true for '/_foo' but false for '/afoo'
```

ObjectGrid query NULL predicate

The NULL predicate tests for null values.

```
{single-valued-path-expression | input_parameter} IS [NOT] NULL
```

Example

```
e.name IS NULL
e.dept.name IS NOT NULL
e.dept IS NOT NULL
```

ObjectGrid query EMPTY collection predicate

Use the EMPTY collection predicate to test for an empty collection.

To test if a multi-valued relationship is empty, use the following syntax:

```
collection-valued-path-expression IS [NOT] EMPTY
```

Example

Empty collection predicate To find all the departments that have no employees:

```
SELECT OBJECT(d) FROM DeptBean d WHERE d.emps IS EMPTY
```

ObjectGrid query MEMBER OF predicate

The following expression tests whether the object reference that is specified by the single valued path expression or input parameter is a member of the designated collection. If the collection valued path expression designates an empty collection, then the value of the MEMBER OF expression is FALSE.

```
{ single-valued-path-expression | input_parameter } [ NOT ] MEMBER [ OF ] collection-valued-path-expression
```

Example

Find employees that are not members of a given department number:

```
SELECT OBJECT(e) FROM EmpBean e , DeptBean d
WHERE e NOT MEMBER OF d.emps AND d.deptno = ?1
```

Find employees whose manager is a member of a given department number:

```
SELECT OBJECT(e) FROM EmpBean e, DeptBean d
WHERE e.dept.mgr MEMBER  OF d.emps  and d.deptno=?1
```

ObjectGrid query EXISTS predicate

The EXISTS predicate tests for the presence or absence of a condition that specified by a subselect.

```
EXISTS ( subselect )
```

The result of EXISTS is true if the subselect returns at least one value, otherwise the result is false.

To negate an EXISTS predicate, precede the predicate with the NOT logical operator.

Example

Return departments that have at least one employee that earns more than 1000000:

```
SELECT  OBJECT(d) FROM  DeptBean d
WHERE EXISTS ( SELECT  e  FROM IN (d.emps) e WHERE  e.salary > 1000000 )
```

Return departments that have no employees:

```
SELECT OBJECT(d) FROM DeptBean d
WHERE NOT EXISTS  ( SELECT e FROM IN (d.emps) e)
```

You can also rewrite the previous query like in the following example:

```
SELECT OBJECT(d) FROM DeptBean d WHERE SIZE(d.emps)=0
```

ObjectGrid query ORDER BY clause

The ORDER BY clause specifies an ordering of the objects in the result collection. An example follows:

ORDER BY [order_element ,]* order_element order_element ::={ path-expression }[ASC | DESC]

The path expression must specify a single-valued field that is a primitive type of byte, short, int, long, float, double, char, or a wrapper type of Byte, Short, Integer, Long, Float, Double, BigDecimal, String, Character, java.util.Date, java.sql.Date, java.sql.Time, java.sql.Timestamp and java.util.Calendar. The ASC order element specifies that the results are displayed in ascending order, which is the default. A DESC order element specifies that the results are displayed in descending order.

Example

Return department objects. Display the department numbers in decreasing order:

```
SELECT OBJECT(d) FROM DeptBean d ORDER BY d.deptno DESC
```

Return employee objects, sorted by department number and name:

```
SELECT OBJECT(e) FROM EmpBean e ORDER BY e.dept.deptno ASC, e.name DESC
```

ObjectGrid query aggregation functions

Aggregation functions operate on a set of values to return a single scalar value. You can use these functions in the select and subselect methods. The following example illustrates an aggregation:

```
SELECT SUM (e.salary) FROM EmpBean e WHERE e.dept.deptno =20
```

This aggregation computes the total salary for department 20.

The aggregation functions are: AVG, COUNT, MAX, MIN, and SUM. The syntax of an aggregation function is illustrated in the following example:

```
aggregation-function ( [ ALL | DISTINCT ] expression )
```

or:

```
COUNT( [ ALL | DISTINCT ] identification-variable )
```

The DISTINCT option eliminates duplicate values before applying the function. The ALL option is the default option, and does not eliminate duplicate values. Null values are ignored in computing the aggregate function except when you use the COUNT(identification-variable) function, which returns a count of all the elements in the set.

Defining return type

The MAX and MIN functions can apply to any numeric, string or date-time data type and return the corresponding data type. The SUM and AVG functions take a numeric type as input. The AVG function returns a double type. The SUM function returns a long type if the input type is an integer type, except when the input is a Java BigInteger type, then the function returns a Java BigInteger type. The SUM function returns a double type if the input type is not an integer type, except when the input is a Java BigDecimal type, then the function returns a Java BigDecimal type. The COUNT function can take any data type except collections, and returns a long type.

When applied to an empty set, the SUM, AVG, MAX, and MIN functions can return a null value. The COUNT function returns zero (0) when it is applied to an empty set.

Using GROUP BY and HAVING clauses

The set of values that is used for the aggregate function is determined by the collection that results from the FROM and WHERE clause of the query. You can divide the set into groups and apply the aggregation function to each group. To perform this action, use a GROUP BY clause in the query. The GROUP BY clause defines grouping members, which comprise a list of path expressions. Each path expression specifies a field that is a primitive type of byte, short, int, long, float, double, boolean, char, or a wrapper type of Byte, Short, Integer, Long, Float, Double, BigDecimal, String, Boolean, Character, java.util.Date, java.sql.Date, java.sql.Time, java.sql.Timestamp, java.util.Calendar or a Java SE 5 enum.

The following example illustrates the use of the GROUP BY clause in a query that computes the average salary for each department:

```
SELECT e.dept.deptno, AVG ( e.salary) FROM EmpBean e GROUP BY e.dept.deptno
```

In division of a set into groups, a NULL value is considered equal to another NULL value.

Groups can be filtered using a HAVING clause that tests group properties before involving aggregate functions or grouping members. This filtering is similar to how the WHERE clause filters tuples (that is, records of the return collection values) from the FROM clause. An example of the HAVING clause follows:

```
SELECT e.dept.deptno, AVG ( e.salary) FROM EmpBean e
GROUP BY e.dept.deptno
HAVING COUNT(e) > 3 AND e.dept.deptno > 5
```

This query returns the average salary for departments that have more than three employees and the department number is greater than five.
You can use a HAVING clause without a GROUP BY clause. In this case, the entire set is treated as a single group, to which the HAVING clause is applied.

Programming for transactions in Java applications

When you write a Java™ application that requires transactions, you must consider issues such as lock handling, collision handling, and transaction isolation.

- Interacting with data in a transaction for Java applications
  Use sessions to interact with data, including insert and update operations.
- Using locking
  Locks have life cycles and different types of locks are compatible with others in various ways. Locks must be handled in the correct order to avoid deadlock scenarios.

Transaction processing overview

WebSphere® eXtreme Scale uses transactions as its mechanism for interaction with data.

Transaction processing in Java applications

To interact with data, the thread in your application needs its own session. When the application wants to use the ObjectGrid on a thread, call one of the ObjectGrid.getSession methods to obtain a session. With the session, the application can work with data that is stored in the ObjectGrid maps.

When an application uses a Session object, the session must be in the context of a transaction. A transaction begins and commits or begins and rolls back with the begin, commit, and rollback methods on the Session object. Applications can also work in auto-commit mode, in which the Session automatically begins and commits a transaction whenever an operation runs on the map. Auto-commit mode cannot group multiple operations into a single transaction. Auto-commit mode is the slower option if you are creating a batch of multiple operations into a single transaction. However, for transactions that contain only one operation, auto-commit is the faster option.

When your application is finished with the Session, use the optional Session.close() method to close the session. Closing the Session releases it from the heap and allows subsequent calls to the getSession() method to be reused, improving performance.

- Transactions
  Transactions have many advantages for data storage and manipulation. You can use transactions to protect the data grid from concurrent changes, to apply multiple changes as a concurrent unit, to replicate data, and to implement a lifecycle for locks on changes.
- CopyMode attribute
  You can tune the number of copies by defining the CopyMode attribute of the BackingMap or ObjectMap objects in the ObjectGrid descriptor XML file.
- Locking strategies
  Locking strategies include pessimistic, optimistic, and none. To choose a locking strategy, you must consider issues such as the percentage of each type of operations you have, whether you use a loader, and so on.
- Lock types
  When you are using pessimistic and optimistic locking, shared (S), upgradeable (U) and exclusive (X) locks are used to maintain consistency. Understanding locking and its behavior is important when you have pessimistic locking enabled. With optimistic locking, the locks are not held. Different types of locks are compatible with others in various ways. Locks must be handled in the correct order to avoid deadlock scenarios.
- Deadlocks
  Deadlocks can occur when two transactions try to update the same cache entry.
- Data access and transactions
  WebSphere eXtreme Scale uses transactions. After an application has a connection to a data grid, you can access and interact with data in the data grid.
- Transaction isolation
  You can use one of three transaction isolation levels to tune the locking semantics that maintain consistency in each cache map: repeatable read, read committed and read uncommitted.
- Single-partition and cross-data-grid transactions
  The major distinction between WebSphere eXtreme Scale and traditional data storage solutions like relational databases or in-memory databases is the use of partitioning, which allows the cache to scale linearly. The important types of transactions to consider are single-partition and every-partition (cross-data-grid) transactions.
- JMS for distributed transaction changes
  Use Java™ Message Service (JMS) for distributed transaction changes between different tiers or in environments on mixed platforms.

Resolving lock timeout exceptions

Data access and transactions

WebSphere® eXtreme Scale uses transactions. After an application has a connection to a data grid, you can access and interact with data in the data grid.

Transactions in Java applications

With Java applications, you can establish a client connection to a distributed instance or create a local instance.
When an application interacts with a Session, it must be in the context of a transaction. A transaction is begun and committed or rolled back using the Session.begin, Session.commit, and Session.rollback methods on the Session object. Applications can also work in auto-commit mode, where the Session automatically begins and commits a transaction whenever the application interacts with Maps. However, the auto-commit mode is slower.

A thread in a Java application needs its own Session. When you want your application to use the ObjectGrid on a thread, call one of the getSession methods to obtain a Session. After the application is finished with the Session, call the Session.close() method. This method closes the session, returning it to the pool and releasing its resources. Closing a session is optional, but improves the performance of subsequent calls to the getSession() method. If the application is using a dependency injection framework such as Spring, you can inject a Session into an application bean when necessary.

After you obtain a Session, the application can access data stored in maps in the ObjectGrid. If the ObjectGrid uses entities, you can use the EntityManager API, which you can obtain with the Session.getEntityManager method. Because it is closer to Java specifications, the EntityManager interface is simpler than the map-based API. However, the EntityManager API carries a performance overhead because it tracks changes in objects. The map-based API is obtained by using the Session.getMap method.

The logic of using transactions

Transactions may seem to be slow. You must use transactions for the following reasons:

1. To allow rollback of changes if an exception occurs or business logic needs to undo state changes.
2. To hold locks on data and release locks within the lifetime of a transaction, allowing a set of changes to be made atomically, that is, all changes or no changes to data.
3. To produce an atomic unit of replication.
4. To update multiple partitions.

You can customize how much transaction support is needed. Your application can turn off rollback support and locking but at a cost to the application. The application must handle the lack of these features. Examples of how the application can manage transaction support follow:

- An application can turn off locking by configuring the BackingMap locking strategy to be NONE. This strategy is fast, but concurrent transactions can now modify the same data with no protection from each other. The application is responsible for all locking and data consistency when NONE is used.

- An application can change the way objects are copied when accessed by the transaction. The application can specify how objects are copied with the ObjectMap.setCopyMode method. With this method, you can turn off CopyMode. Turning off CopyMode is normally used for read-only transactions if different values can be returned for the same object within a transaction. Different values can be returned for the same object within a transaction.

For example, if the transaction called the ObjectMap.get method for the object at T1, it got the value at that point in time. If it calls the get method again within that transaction at a later time T2, another thread might have changed the value. Because the value was changed by another thread, the application sees a different value.

If the application modifies an object retrieved using a NONE CopyMode value, it is changing the committed copy of that object directly. Rolling back the transaction has no meaning in this mode. You are changing the only copy in the ObjectGrid. Although using the NONE CopyMode is fast, be aware of its consequences. An application that uses a NONE CopyMode must never roll back the transaction. If the application rolls back the transaction, the indexes are not updated with the changes *and* the changes are not replicated if replication is turned on.

The default values are easy to use and less prone to errors. If you start trading performance in exchange for less reliable data, the application needs to be aware of what it is doing to avoid unintended problems.

CAUTION:
Be careful when you are changing either the locking or the CopyMode values. If you change the values, unpredictable application behavior occurs.

Queries and partitions

If a transaction has already searched for an Entity, the transaction is associated with the partition for that Entity. Any queries that run on a transaction that is associated with an Entity are routed to the associated partition.

If a query is run on a transaction before it is associated with a partition, you must set the partition ID to use for the query. The partition ID is an integer value. The query is then routed to that partition. This only applies if the transaction is configured to use a one-phase commitment protocol.

Queries only search within a single partition. However, if the session is set using a two-phase commitment protocol, then set the partition ID for the query to -1. This fetches results from all partitions. You can use the DataGrid APIs to run the same query in parallel on all partitions or a subset of partitions. Use the DataGrid APIs to find an entry that might be in any partition.

Related tasks:
Interacting with data in a transaction for Java applications

Transactions

Transactions have many advantages for data storage and manipulation. You can use transactions to protect the data grid from concurrent changes, to apply multiple changes as a concurrent unit, to replicate data, and to implement a lifecycle for locks on changes.

When a transaction starts, WebSphere® eXtreme Scale allocates a special difference map to hold the current changes or copies of key and value pairs that the transaction uses. Typically, when a key and value pair is accessed, the value is copied before the application receives the value. In Java™ applications, the difference map tracks all changes for operations such as insert, update, get, and remove. Keys are not copied because they are assumed to be immutable. If a transaction is rolled back, then the difference map information is discarded, and locks on entries are released. When a transaction commits, the changes are applied to the maps and locks are released.

If an ObjectTransformer object is specified in a Java application, then this object is used for copying the value. If the transaction is using optimistic locking, then before images of the values are also tracked for comparison when the transaction commits.

If optimistic locking is being used in a Java application, then eXtreme Scale compares the before image versions of the values with the values that are in the map. These values must match for the transaction to commit. This comparison enables a multiple version locking scheme, but at a cost of two copies being made when the transaction accesses the entry. All values are copied again and the new copy is stored in the map. WebSphere eXtreme Scale performs this copy to protect itself against the application changing the application reference to the value after a commit.

You can avoid using several copies of the information. The application can save a copy by using pessimistic locking instead of optimistic locking as the cost of limiting concurrency. The copy of the value at commit time can also be avoided if the application agrees not to change a value after a commit.

Advantages of transactions

Use transactions for the following reasons:
By using transactions, you can:

- Roll back changes if an exception occurs or business logic needs to undo state changes.
- To apply multiple changes as an atomic unit at commit time.
- Hold and release locks on data to apply multiple changes as an atomic unit at commit time.
- Protect a thread from concurrent changes.
- Implement a lifecycle for locks on changes.
- Produce an atomic unit of replication.

Transaction size

Larger transactions are more efficient, especially for replication. However, larger transactions can adversely affect concurrency because the locks on entries are held for a longer time. If you use larger transactions, you can increase replication performance. This performance increase is important when you are pre-loading a Map. Experiment with different batch sizes to determine what works best for your scenario.

Larger transactions also help with loaders. If a loader is being used that can run SQL batching, then significant performance gains are possible depending on the transaction and significant load reductions on the database side. This performance gain depends on the Loader implementation.

Automatic commit mode

If no transaction is actively started, then when an application interacts with an ObjectMap object, an automatic begin and commit operation is done on behalf of the application. This automatic begin and commit operation works, but prevents rollback and locking from working effectively. Synchronous replication speed is impacted because of the very small transaction size. If you are using an entity manager application, then do not use automatic commit mode because objects that are looked up with the EntityManager.find method immediately become unmanaged on the method return and become unusable.

External transaction coordinators

Typically, transactions begin with the session.begin method and end with the session.commit method. However, when eXtreme Scale is embedded, the transactions might be started and ended by an external transaction coordinator. If you are using an external transaction coordinator, you do not need to call the session.begin method and end with the session.commit method. If you are using WebSphere Application Server, you can use the WebSphereTranscationCallback plug-in.
8.5+

Java EE transaction integration

eXtreme Scale includes a Java Connector Architecture (JCA) 1.5 compliant resource adapter that supports both client connections to a remote data grid and local transaction management. Java Platform, Enterprise Edition (Java EE) applications such as servlets, JavaServer Pages (JSP) files and Enterprise JavaBeans (EJB) components can demarcate eXtreme Scale transactions using the standard javax.resource.cci.LocalTransaction interface or the eXtreme Scale session interface.
When the running in WebSphere Application Server with last participant support enabled in the application, you can enlist the eXtreme Scale transaction in a global transaction with other two-phase commit transactional resources.

- Transaction processing in Java EE applications
  WebSphere eXtreme Scale provides its own resource adapter that you can use to connect applications to the data grid and process local transactions.

CopyMode attribute

You can tune the number of copies by defining the CopyMode attribute of the BackingMap or ObjectMap objects in the ObjectGrid descriptor XML file.

For Java™ applications, you can tune the number of copies by defining the CopyMode attribute of the BackingMap or ObjectMap objects.

The copy mode has the following values:

- COPY_ON_READ_AND_COMMIT
- COPY_ON_READ
- NO_COPY
- COPY_ON_WRITE
- COPY_TO_BYTES
- COPY_TO_BYTES_RAW

The COPY_ON_READ_AND_COMMIT value is the default. The COPY_ON_READ value copies the initial data when it is retrieved, but does not copy at commit time. This mode is safe if the application does not modify a value after committing a transaction. The NO_COPY value does not copy data, which is only safe for read-only data. If the data never changes, then you do not need to copy it for isolation reasons.
Be careful when you use the NO_COPY attribute value with maps that can be updated. WebSphere® eXtreme Scale uses the copy on first touch to allow the transaction rollback. The application only changed the copy, and as a result, eXtreme Scale discards the copy. If the NO_COPY attribute value is used, and the application modifies the committed value, completing a rollback is not possible. Modifying the committed value leads to problems with indexes, replication, and so on because the indexes and replicas update when the transaction commits. If you modify committed data and then roll back the transaction, which does not actually roll back at all, then the indexes are not updated and replication does not take place. Other threads can see the uncommitted changes immediately, even if they have locks. Use the NO_COPY attribute value for read-only maps or for applications that complete the appropriate copy before modifying the value. If you use the NO_COPY attribute value and call IBM® support with a data integrity problem, you are asked to reproduce the problem with the copy mode set to COPY_ON_READ_AND_COMMIT.

The COPY_TO_BYTES value stores values in the map in a serialized form. At read time, eXtreme Scale inflates the value from a serialized form and at commit time it stores the value to a serialized form. With this method, a copy occurs at both read and commit time.

The default copy mode for a map can be configured on the BackingMap object. You can also change the copy mode on maps before you start a transaction by using the ObjectMap.setCopyMode method.

An example of a backing map snippet from an objectgrid.xml file that shows how to set the copy mode for a backing map follows. This example assumes that you are using cc as the objectgrid/config namespace.

```
<cc:backingMap name="RuntimeLifespan" copyMode="NO_COPY"/>
```

Locking strategies

Locking strategies include pessimistic, optimistic, and none. To choose a locking strategy, you must consider issues such as the percentage of each type of operations you have, whether you use a loader, and so on.

Locks are bound by transactions. You can specify the following locking settings:

No locking
: Running without the locking setting is the fastest. If you are using read-only data, then you might not need locking.

Pessimistic locking
: Acquires locks on entries, then and holds the locks until commit time. This locking strategy provides good consistency at the expense of throughput.

Optimistic locking
: Takes a before image of every record that the transaction touches and compares the image to the current entry values when the transaction commits. If the entry values change, then the transaction rolls back. No locks are held until commit time. This locking strategy provides better concurrency than the pessimistic strategy, at the risk of the transaction rolling back and the memory cost of making the extra copy of the entry.

Optimistic no versioning locking
: This locking strategy allows you to disable version control. This is important because near cache is only enabled if you are doing Optimistic locking. With the current implementation, you need a plug-in or callback handler to handle version control. However, using the OPTIMISTIC_NO_VERSIONING locking strategy to disable version control on the client and only enable it on the server, is an additional performance savings.

Lock manager

When either a PESSIMISTIC or an OPTIMISTIC locking strategy is used, a lock manager is created for the BackingMap. The lock manager uses a hash map to track entries that are locked by one or more transactions. If many map entries exist in the hash map, more lock buckets can result in better performance. The risk of Java™ synchronization collisions is lower as the number of buckets grows. More lock buckets also lead to more concurrency. The previous examples show how an application can set the number of lock buckets to use for a given BackingMap instance.

8.5 To avoid a java.lang.IllegalStateException exception, you must call the setNumberOfLockBuckets method before the initialize or getSession methods on the ObjectGrid instance. The setNumberOfLockBuckets method parameter is a Java primitive integer that specifies the number of lock buckets to use. Using a prime number can allow for a uniform distribution of map entries over the lock buckets. A good starting point for best performance is to set the number of lock buckets to about 10 percent of the expected number of BackingMap entries.

Pessimistic locking

The PESSIMISTIC lock strategy acquires locks for cache entries and should be used when data is changed frequently. Any time a cache entry is read, a lock is acquired and conditionally held until the transaction completes. The duration of some locks can be tuned using transaction isolation levels for the session.

Use the pessimistic locking strategy for read and write maps when other locking strategies are not possible. When an ObjectGrid map is configured to use the pessimistic locking strategy, a pessimistic transaction lock for a map entry is obtained when a transaction first gets the entry from the BackingMap. The pessimistic lock is held until the application completes the transaction. Typically, the pessimistic locking strategy is used in the following situations:

- When the BackingMap is configured with or without a loader and versioning information is not available.
- When the BackingMap is used directly by an application that needs help from the eXtreme Scale for concurrency control.
- When versioning information is available, but update transactions frequently collide on the backing entries, resulting in optimistic update failures.

The pessimistic locking strategy has the greatest impact on performance and scalability. Therefore, use this strategy only for read and write maps when other locking strategies are not viable. For example, these situations might include when optimistic update failures occur frequently, or when recovery from optimistic failure is difficult for an application to handle.

When you use pessimistic locking, you can use lock methods to lock data, or keys, without returning any data values. For a list of the methods and what kind of locks they acquire, see Lock types.

Optimistic locking

The default lock strategy is OPTIMISTIC. Use optimistic locking when data is changed infrequently. Locks are only held for a short duration while data is being read from the cache and copied to the transaction. When the transaction cache is synchronized with the main cache, any cache objects that have been updated are checked against the original version. If the check fails, then the transaction is rolled back and an OptimisticCollisionException exception results.

The optimistic locking strategy assumes that no two transactions might attempt to update the same map entry while the transactions are running concurrently. The lock is not held for the lifecycle of the transaction because it is unlikely that more than one transaction might update the map entry concurrently. The optimistic locking strategy is typically used in the following situations:

- When a BackingMap is configured and versioning information is available. The BackingMap can be configured with or without a loader.
- When a BackingMap has mostly transactions that are read operations. Insert, update, or remove operations on map entries do not occur often on the BackingMap.
- When a BackingMap is inserted, updated, or removed more frequently than it is read, but transactions rarely collide on the same map entry.

Like the pessimistic locking strategy, the methods on the ObjectMap interface determine how eXtreme Scale automatically attempts to acquire a lock mode for the map entry that is being accessed. However, the following differences between the pessimistic and optimistic strategies exist:

- Like the pessimistic locking strategy, an S lock mode is acquired by the get and getAll methods when the method is called. However, with optimistic locking, the S lock mode is not held until the transaction is completed. Instead, the S lock mode is released before the method returns to the application. The purpose of acquiring the lock mode is so that eXtreme Scale can ensure that only committed data from other transactions is visible to the current transaction. After eXtreme Scale has verified that the data is committed, the S lock mode is released. At commit time, an optimistic versioning check is

performed to ensure that no other transaction has changed the map entry after the current transaction released its S lock mode. If an entry is not fetched from the map before it is updated, invalidated, or deleted, the eXtreme Scale run time implicitly fetches the entry from the map. This implicit get operation is performed to get the current value at the time the entry was requested to be modified.
- Unlike pessimistic locking strategy, the getForUpdate and getAllForUpdate methods are handled exactly like the get and getAll methods when the optimistic locking strategy is used. That is, an S lock mode is acquired at the start of the method and the S lock mode is released before returning to the application.

All other ObjectMap methods are handled the same as the pessimistic locking strategy. When the commit method is called, an X lock mode is obtained for any map entry that is inserted, updated, removed, touched, or invalidated. The X lock mode is held until the transaction completes commit processing.

The optimistic locking strategy assumes that no concurrently running transactions attempt to update the same map entry. Because of this assumption, the lock mode does not need to be held for the life of the transaction because it is unlikely that more than one transaction might update the map entry concurrently. However, because a lock mode was not held, another concurrent transaction might potentially update the map entry after the current transaction has released its S lock mode.
To handle this possibility, eXtreme Scale gets an X lock at commit time and performs an optimistic versioning check to verify that no other transaction has changed the map entry after the current transaction read the map entry from the BackingMap. If another transaction changes the map entry, the version check fails and an OptimisticCollisionException exception occurs. This exception forces the current transaction to be rolled back and the application must try the entire transaction again. The optimistic locking strategy is useful when a map is mostly read and it is unlikely that updates for the same map entry might occur.

Optimistic no versioning

You can enable OPTIMISTIC_NO_VERSIONING locking either through the client override XML file or programmatically. See the following examples of both approaches:
Client override XML file example

```
<objectGrid name="lockStrategyGrid">
            <backingMap name="opt_with_noversion" lockStrategy="OPTIMISTIC_NO_VERSIONING"/>
            <backingMap name="opt_with_none" lockStrategy="NONE"/>
            <backingMap name="optnoversion_with_opt" lockStrategy="OPTIMISTIC"/>
            <backingMap name="optnoversion_with_none" lockStrategy="NONE"/>
        </objectGrid>
```

Programmatic example

```
ObjectGridConfiguration lsConfig = ObjectGridConfigFactory.createObjectGridConfiguration("lockStrategyGrid");
                BackingMapConfiguration oMapWithOVConfig =
ObjectGridConfigFactory.createBackingMapConfiguration("opt_with_noversion");
                oMapWithOVConfig.setLockStrategy(LockStrategy.OPTIMISTIC_NO_VERSIONING);
                lsConfig.addBackingMapConfiguration(oMapWithOVConfig);
```

No locking

If locking is not required because the data is never updated or is only updated during quiet periods, you can disable locking by using the NONE lock strategy. This strategy is very fast because a lock manager is not required. The NONE lock strategy is ideal for look-up tables or read-only maps.

When a BackingMap is configured to use no locking strategy, no transaction locks for a map entry are obtained.
Using no locking strategy is useful when an application is a persistence manager such as an Enterprise JavaBeans (EJB) container or when an application uses Hibernate to obtain persistent data. In this scenario, the BackingMap is configured without a loader and the persistence manager uses the BackingMap as a data cache. In this scenario, the persistence manager provides concurrency control between transactions that are accessing the same Map entries.

WebSphere® eXtreme Scale does not need to obtain any transaction locks for concurrency control. This situation assumes that the persistence manager does not release its transaction locks before updating the ObjectGrid map with committed changes. If the persistence manager releases its locks, then a pessimistic or optimistic lock strategy must be used. For example, suppose that the persistence manager of an EJB container is updating an ObjectGrid map with data that was committed in the EJB container-managed transaction. If the update of the ObjectGrid map occurs before the persistence manager transaction locks are released, then you can use the no lock strategy. If the ObjectGrid map update occurs after the persistence manager transaction locks are released, then you must use either the optimistic or pessimistic lock strategy.

Another scenario where no locking strategy can be used is when the application uses a BackingMap directly and a Loader is configured for the map. In this scenario, the loader uses the concurrency control support that is provided by a relational database management system (RDBMS) by using either Java database connectivity (JDBC) or Hibernate to access data in a relational database. The loader implementation can use either an optimistic or pessimistic approach. A loader that uses an optimistic locking or versioning approach helps to achieve the greatest amount of concurrency and performance. For more information about implementing an optimistic locking approach, see the OptimisticCallback section in Configuring database loaders. If you are using a loader that uses pessimistic locking support of an underlying backend, you might want to use the forUpdate parameter that is passed on the get method of the Loader interface. Set this parameter to true if the getForUpdate method of the ObjectMap interface was used by the application to get the data. The loader can use this parameter to determine whether to request an upgradeable lock on the row that is being read. For example, DB2® obtains an upgradeable lock when an SQL select statement contains a `FOR UPDATE` clause. This approach offers the same deadlock prevention that is described in Pessimistic locking.

JMS for distributed transaction changes

Use Java™ Message Service (JMS) for distributed transaction changes between different tiers or in environments on mixed platforms.

JMS is an ideal protocol for distributed changes between different tiers or in environments on mixed platforms. For example, some applications that use eXtreme Scale might be deployed on IBM® WebSphere® Application Server Community Edition, Apache Geronimo, or Apache Tomcat, whereas other applications might run on WebSphere Application Server Version 6.x. JMS is ideal for distributed changes between eXtreme Scale peers in these different environments. The high availability manager message transport is very fast, but can only distribute changes to Java virtual machines that are in a single core group. JMS is slower, but allows larger and more diverse sets of application clients to share an ObjectGrid. JMS is ideal when sharing data in an ObjectGrid between a fat Swing client and an application deployed on WebSphere Extended Deployment.

The built-in Client Invalidation Mechanism and Peer-to-Peer Replication are examples of JMS-based transactional changes distribution. See Configuring Java Message Service (JMS)-based client synchronization and Configuring peer-to-peer replication with JMS for more information.

Implementing JMS

JMS is implemented for distributing transaction changes by using a Java object that behaves as an ObjectGridEventListener. This object can propagate the state in the following four ways:

1. Invalidate: Any entry that is evicted, updated or deleted is removed on all peer Java virtual machines when they receive the message.
2. Invalidate conditional: The entry is evicted only if the local version is the same or older than the version on the publisher.
3. Push: Any entry that was evicted, updated, deleted or inserted is added or overwritten on all peer Java virtual machines when they receive the JMS message.
4. Push conditional: The entry is only updated or added on the receive side if the local entry is less recent than the version that is being published.

Listen for changes for publishing

The plug-in implements the ObjectGridEventListener interface to intercept the transactionEnd event. When eXtreme Scale invokes this method, the plug-in attempts to convert the LogSequence list for each map that is touched by the transaction to a JMS message and then publish it. The plug-in can be configured to publish changes for all maps or a subset of maps. LogSequence objects are processed for the maps that have publishing enabled. The LogSequenceTransformer ObjectGrid class serializes a filtered LogSequence for each map to a stream. After all LogSequences are serialized to the stream, then a JMS ObjectMessage is created and published to a well-known topic.

Listen for JMS messages and apply them to the local ObjectGrid

The same plug-in also starts a thread that spins in a loop, receiving all messages that are published to the well known topic. When a message arrives, it passes the message contents to the LogSequenceTransformer class where it is converted to a set of LogSequence objects. Then, a no-write-through transaction is started. Each LogSequence object is provided to the Session.processLogSequence method, which updates the local Maps with the changes. The processLogSequence method understands the distribution mode. The transaction is committed and the local cache now reflects the changes. For more information about using JMS to distribute transaction changes, see Distributing changes between peer JVMs.

Single-partition and cross-data-grid transactions

The major distinction between WebSphere® eXtreme Scale and traditional data storage solutions like relational databases or in-memory databases is the use of partitioning, which allows the cache to scale linearly. The important types of transactions to consider are single-partition and every-partition (cross-data-grid) transactions.

In general, interactions with the cache can be categorized as single-partition transactions or cross-data-grid transactions.

Single-partition transactions

Single-partition transactions are the preferable method for interacting with caches that are hosted by WebSphere eXtreme Scale. When a transaction is limited to a single partition, then by default it is limited to a single Java™ virtual machine, and therefore a single server computer. A server can complete *M* number of these transactions per second, and if you have *N* computers, you can complete `M*N` transactions per second. If your business increases and you need to perform twice as many of these transactions per second, you can double *N* by buying more computers. Then you can meet capacity demands without changing the application, upgrading hardware, or even taking the application offline.

In addition to letting the cache scale so significantly, single-partition transactions also maximize the availability of the cache. Each transaction only depends on one computer. Any of the other `(N-1)` computers can fail without affecting the success or response time of the transaction. So if you are running 100 computers and one of them fails, only 1 percent of the transactions in flight at the moment that server failed are rolled back. After the server fails, WebSphere eXtreme Scale relocates the partitions that are hosted by the failed server to the other 99 computers. During this brief period, before the operation completes, the other 99 computers can still complete transactions. Only the transactions that would involve the partitions that are being relocated are blocked. After the failover process is complete, the cache can continue running, fully operational, at 99 percent of its original throughput capacity. After the failed server is replaced and returned to the data grid, the cache returns to 100 percent throughput capacity.

Cross-data-grid transactions

In terms of performance, availability and scalability, cross-data-grid transactions are the opposite of single-partition transactions. Cross-data-grid transactions access every partition and therefore every computer in the configuration. Each computer in the data grid is asked to look up some data and then return the result. The transaction cannot complete until every computer has responded, and therefore the throughput of the entire data grid is limited by the slowest computer. Adding computers does not make the slowest computer faster and therefore does not improve the throughput of the cache.

Cross-data-grid transactions have a similar effect on availability. Extending the previous example, if you are running 100 servers and one server fails, then 100 percent of the transactions that are in progress at the moment that server failed are rolled back. After the server fails, WebSphere eXtreme Scale starts to relocate the partitions that are hosted by that server to the other 99 computers. During this time, before the failover process completes, the data grid cannot

process any of these transactions. After the failover process is complete, the cache can continue running, but at reduced capacity. If each computer in the data grid serviced 10 partitions, then 10 of the remaining 99 computers receive at least one extra partition as part of the failover process. Adding an extra partition increases the workload of that computer by at least 10 percent. Because the throughput of the data grid is limited to the throughput of the slowest computer in a cross-data-grid transaction, on average, the throughput is reduced by 10 percent.

Single-partition transactions are preferable to cross-data-grid transactions for scaling out with a distributed, highly available, object cache like WebSphere eXtreme Scale. Maximizing the performance of these kinds of systems requires the use of techniques that are different from traditional relational methodologies, but you can turn cross-data-grid transactions into scalable single-partition transactions.

Best practices for building scalable data models

The best practices for building scalable applications with products like WebSphere eXtreme Scale include two categories: foundational principles and implementation tips. Foundational principles are core ideas that need to be captured in the design of the data itself. An application that does not observe these principles is unlikely to scale well, even for its mainline transactions. Implementation tips are applied for problematic transactions in an otherwise well-designed application that observes the general principles for scalable data models.

Foundational principles

Some of the important means of optimizing scalability are basic concepts or principles to keep in mind.

Duplicate instead of normalizing

The key thing to remember about products like WebSphere eXtreme Scale is that they are designed to spread data across a large number of computers. If the goal is to make most or all transactions complete on a single partition, then the data model design needs to ensure that all the data the transaction might need is in the partition. Most of the time, the only way to achieve this is by duplicating data.

For example, consider an application like a message board. Two important transactions for a message board are showing all the posts from a user and all the posts on a topic. First, consider how these transactions would work with a normalized data model that contains a user record, a topic record, and a post record that contains the actual text. If posts are partitioned with user records, then displaying the topic becomes a cross-grid transaction, and vice versa. Topics and users cannot be partitioned together because they have a many-to-many relationship.

The best way to make this message board scale is to duplicate the posts, storing one copy with the topic record and one copy with the user record. Then, displaying the posts from a user is a single-partition transaction, displaying the posts on a topic is a single-partition transaction, and updating or deleting a post is a two-partition transaction. All three of these transactions scale linearly as the number of computers in the data grid increases.

Scalability rather than resources

The biggest obstacle to overcome when you are considering denormalized data models is the impact that these models have on resources. Keeping two, three, or more copies of some data can seem to use too many resources to be practical. When you are confronted with this scenario, remember the following facts: Hardware resources get cheaper every year. Second, and more importantly, WebSphere eXtreme Scale eliminates most hidden costs that are associated with deploying more resources.

Measure resources in terms of cost rather than computer terms such as megabytes and processors. Data stores that work with normalized relational data generally must be on the same computer. This required collocation means that a single larger enterprise computer must be purchased rather than several smaller computers. With enterprise hardware, it is not uncommon for one computer that is capable of completing one million transactions per second to cost much more than the combined cost of 10 computers capable of doing 100,000 transactions per second each.

A business cost in adding resources also exists. A growing business eventually runs out of capacity. When you run out of capacity, you either need to shut down while moving to a bigger, faster computer, or create a second production environment to which you can switch. Either way, additional costs will come in the form of lost business or maintaining almost twice the capacity needed during the transition period.

With WebSphere eXtreme Scale, the application does not need to be shut down to add capacity. If your business projects that you need 10 percent more capacity for the coming year, then increase the number of computers in the data grid by 10 percent. You can increase this percentage without application downtime and without purchasing excess capacity.

Avoid data transformations

When you are using WebSphere eXtreme Scale, data should be stored in a format that is directly consumable by the business logic. Breaking the data down into a more primitive form is costly. The transformation needs to be done when the data is written and when the data is read. With relational databases, this transformation is done out of necessity because the data is ultimately persisted to disk frequently. With WebSphere eXtreme Scale, these transformations are not necessary. Usually, data is stored in memory and can therefore be stored in the exact form that the application needs.

Observing this simple rule helps denormalize your data in accordance with the first principle. The most common type of transformation for business data is the JOIN operations that are necessary to turn normalized data into a result set that fits the needs of the application. Storing the data in the correct format implicitly avoids performing these JOIN operations and produces a denormalized data model.

Eliminate unbounded queries

No matter how well you structure your data, unbounded queries do not scale well. For example, do not have a transaction that asks for a list of all items that are sorted by value. This transaction might work at first when the total number of items is 1000, but when the total number of items reaches 10 million, the transaction returns all 10 million items. If you run this transaction, the two most likely outcomes are the transaction timing out, or the client encounters an out-of-memory error.

The best option is to alter the business logic so that only the top 10 or 20 items can be returned. This logic alteration keeps the size of the transaction manageable no matter how many items are in the cache.

Define schema

The main advantage of normalizing data is that the database system can take care of data consistency behind the scenes. When data is denormalized for scalability, this automatic data consistency management no longer exists. You must implement a data model that can work in the application layer or as a plug-in to the distributed data grid to guarantee data consistency.

Consider the message board example. If a transaction removes a post from a topic, then the duplicate post on the user record must be removed. Without a data model, it is possible a developer might write the application code to remove the post from the topic and forget to remove the post from the user record. However, if the developer is using a data model instead of interacting with the cache directly, the removePost method on the data model pulls the user ID from the post, looks up the user record, and removes the duplicate post behind the scenes.

Alternately, you can implement a listener that runs on the actual partition that detects the change to the topic and automatically adjusts the user record. A listener might be beneficial because the adjustment to the user record might happen locally if the partition happens to have the user record. If the user record is on a different partition, the transaction takes place between servers instead of between the client and server. The network connection between servers is likely to be faster than the network connection between the client and the server.

Avoid contention

Avoid scenarios such as having a global counter. The data grid does not scale if a single record is being used a disproportionate number of times compared to the rest of the records. The performance of the data grid is limited by the performance of the computer that holds the record.

In these situations, try to break up the record so it is managed per partition. For example, consider a transaction that returns the total number of entries in the distributed cache. Instead of having every insert and remove operation access a single record that increments, have a listener on each partition track the insert and remove operations. With this listener tracking, insert and remove can become single-partition operations.

Reading the counter becomes a cross-data-grid operation. Usually, it was already as inefficient as a cross-data-grid operation because its performance was tied to the performance of the computer that is hosting the record.

Implementation tips

You can also consider the following tips to achieve the best scalability.

Use reverse-lookup indexes

Consider a properly denormalized data model where customer records are partitioned based on the customer ID number. This partitioning method is the logical choice because nearly every business operation that is performed with the customer record uses the customer ID number. However, an important transaction that does not use the customer ID number is the login transaction. It is more common to have user names or email addresses for login instead of customer ID numbers.

The simple approach to the login scenario is to use a cross-data-grid transaction to find the customer record. As explained previously, this approach does not scale.

The next option might be to partition on user name or email. This option is not practical because all the customer ID-based operations become cross-data-grid transactions. Also, the customers on your site might want to change their user name or email address. Products like WebSphere eXtreme Scale need the value that is used to partition the data to remain constant.

The correct solution is to use a reverse lookup index. With WebSphere eXtreme Scale, a cache can be created in the same distributed grid as the cache that holds all the user records. This cache is highly available, partitioned, and scalable. This cache can be used to map a user name or email address to a customer ID. This cache turns login into a two partition operation instead of a cross-grid operation. This scenario is not as good as a single-partition transaction, but the throughput still scales linearly as the number of computers increases.

Compute at write time

Commonly calculated values like averages or totals can be expensive to produce because these operations usually require reading a large number of entries. Because reads are more common than writes in most applications, it is efficient to compute these values at write time and then store the result in the cache. This practice makes read operations both faster and more scalable.

Optional fields

Consider a user record that holds a business, home, and telephone number. A user might have all, none or any combination of these numbers defined. If the data were normalized, then a user table and a telephone number table would exist. The telephone numbers for a user can be found with a JOIN operation between the two tables.

De-normalizing this record does not require data duplication, because most users do not share telephone numbers. Instead, empty slots in the user record must be allowed. Instead of having a telephone number table, add three attributes to each user record, one for each telephone number type. This addition of attributes eliminates the JOIN operation and makes a telephone number lookup for a user a single-partition operation.

Placement of many-to-many relationships

Consider an application that tracks products and the stores in which the products are sold. A single product is sold in many stores, and a single store sells many products. Assume that this application tracks 50 large retailers. Each product is sold in a maximum of 50 stores. Each store sells thousands of products.

Keep a list of stores inside the product entity (arrangement A), instead of keeping a list of products inside each store entity (arrangement B). Looking at some of the transactions this application must run illustrates why arrangement A is more scalable.

First look at updates. With arrangement A, removing a product from the inventory of a store locks the product entity. If the data grid holds 10000 products, only 1/10000 of the grid must be locked to complete the update. With arrangement B, the data grid only contains only 50 stores, so 1/50 of the data grid must be locked to complete the update. So even though both of these updates might be considered single-partition operations, arrangement A scales out more efficiently.

Now, considering reads with arrangement A, looking up the stores at which a product is sold is a single-partition transaction that scales and is fast because the transaction only transmits a small amount of data. With arrangement B, this transaction becomes a cross-data-grid transaction because each store entity must be accessed to see if the product is sold at that store, which reveals an enormous performance advantage for arrangement A.

Scaling with normalized data

One legitimate use of cross-data-grid transactions is to scale data processing. If a data grid has 5 computers and a cross-data-grid transaction is dispatched that sorts through about 100,000 records on each computer, then that transaction sorts through 500,000 records. If the slowest computer in the data grid can perform 10 of these transactions per second, then the data grid is capable of sorting through 5,000,000 records per second. If the data in the grid doubles, then each computer must sort through 200,000 records, and each transaction sorts through 1,000,000 records. This data increase

decreases the throughput of the slowest computer to 5 transactions per second, reducing the throughput of the data grid to 5 transactions per second. Still, the data grid sorts through 5,000,000 records per second.

In this scenario, doubling the number of computers allows each computer to return to its previous load of sorting through 100,000 records, allowing the slowest computer to process 10 of these transactions per second. The throughput of the data grid stays the same at 10 requests per second, but now each transaction processes 1,000,000 records. As a result, the data grid doubled its capacity in terms of processing records to 10,000,000 per second.

Applications such as a search engine that needs to scale both in terms of data processing to accommodate the increasing size of the Internet and throughput to accommodate growth in the number of users, you must create multiple data grids, with a round robin of the requests between the data grids. If you must scale up the throughput, add computers and add another data grid to service requests. If data processing must be scaled up, add more computers and keep the number of data grids constant.

Developing eXtreme Scale client components to use transactions

8.5+ The WebSphere® eXtreme Scale resource adapter provides client connection management and local transaction support. With this support, Java™ Platform, Enterprise Edition (Java EE) applications can look up eXtreme Scale client connections and demarcate local transactions with Java EE local transactions or the eXtreme Scale APIs.

Before you begin

Create an eXtreme Scale connection factory resource reference.

About this task

There are several options for working with eXtreme Scale data access APIs. In all cases, the eXtreme Scale connection factory must be injected into the application component, or looked up in Java Naming Directory Interface (JNDI). After the connection factory is looked up, you can demarcate transactions and create connections to access the eXtreme Scale APIs.
You can optionally cast the javax.resource.cci.ConnectionFactory instance to a com.ibm.websphere.xs.ra.XSConnectionFactory that provides additional options for retrieving connection handles. The resulting connection handles must be cast to the com.ibm.websphere.xs.ra.XSConnection interface, which provides the getSession method. The getSession method returns a com.ibm.websphere.objectgrid.Session object handle that allows applications to use any of the eXtreme Scale data access APIs, such as the ObjectMap API and EntityManager API.

The Session handle and any derived objects are valid for the life of the XSConnection handle.

The following procedures can be used to demarcate eXtreme Scale transactions. You cannot mix each of the procedures. For example, you cannot mix global transaction demarcation and local transaction demarcation in the same application component context.

Procedure

- Use autocommit, local transactions. Use the following steps to automatically commit data access operations or operations that do not support an active transaction:
  1. Retrieve a com.ibm.websphere.xs.ra.XSConnection connection outside of the context of a global transaction.
  2. Retrieve and use the com.ibm.websphere.objectgrid.Session session to interact with the data grid.
  3. Invoke any data access operation that supports autocommit transactions.
  4. Close the connection.
- Use an ObjectGrid session to demarcate a local transaction. Use the following steps to demarcate an ObjectGrid transaction using the Session object:
  1. Retrieve a com.ibm.websphere.xs.ra.XSConnection connection.
  2. Retrieve the com.ibm.websphere.objectgrid.Session session.
  3. Use the Session.begin() method to start the transaction.
  4. Use the session to interact with the data grid.
  5. Use the Session.commit() or rollback() methods to end the transaction.
  6. Close the connection.
- Use a javax.resource.cci.LocalTransction transaction to demarcate a local transaction. Use the following steps to demarcate an ObjectGrid transaction using the javax.resource.cci.LocalTransaction interface:
  1. Retrieve a com.ibm.websphere.xs.ra.XSConnection connection.
  2. Retrieve the javax.resource.cci.LocalTransaction transaction using the XSConnection.getLocalTransaction() method.
  3. Use the LocalTransaction.begin() method to start the transaction.
  4. Retrieve and use the com.ibm.websphere.objectgrid.Session session to interact with the data grid.
  5. Use the LocalTransaction.commit() or rollback() methods to end the transaction.
  6. Close the connection.
- Enlist the connection in a global transaction. This procedure also applies to container-managed transactions:
  1. Begin the global transaction through the javax.transaction.UserTransaction interface or with a container-managed transaction.
  2. Retrieve a com.ibm.websphere.xs.ra.XSConnection connection.
  3. Retrieve and use the com.ibm.websphere.objectgrid.Session session.
  4. Close the connection.
  5. Commit or roll back the global transaction.

Example

See the following code example, which demonstrates the previous steps for demarcating eXtreme Scale transactions.

Using locking

Locks have life cycles and different types of locks are compatible with others in various ways. Locks must be handled in the correct order to avoid deadlock scenarios.

- Configuring and implementing locking in Java applications
  You can define an optimistic, a pessimistic, or no locking strategy on each BackingMap in the WebSphere® eXtreme Scale configuration.
- Example: flush method lock ordering
  Invoking the flush method on the ObjectMap interface before a commit can introduce additional lock ordering considerations. The flush method is typically used to force changes that are made to the map out to the backend through the Loader plug-in.
- Implementing exception handling in locking scenarios for Java applications
  To prevent locks from being held for excessive amounts of time when a LockTimeoutException exception or a LockDeadlockException exception occurs, your application must catch unexpected exceptions and call the rollback method when an unexpected event occurs.
- Map entry locks with query and indexes
  The eXtreme Scale Query APIs and the MapRangeIndex indexing plug-in interact with locks. You can increase concurrency and decrease deadlocks when you are using the pessimistic locking strategy for maps.
- Java examples for transaction isolation
  Transaction isolation defines how the changes that are made by one operation become visible to other concurrent operations. You can use the following examples to define the transaction isolation level in your Java application.
- Optimistic collision exception
  You can receive an OptimisticCollisionException directly, or receive it with an ObjectGridException.
- Running parallel business logic on the data grid (DataGrid API)
  The DataGrid API provides a simple programming interface to run business logic over all or a subset of the data grid in parallel with where the data is located.

Lock types

When you are using pessimistic and optimistic locking, shared (S), upgradeable (U) and exclusive (X) locks are used to maintain consistency. Understanding locking and its behavior is important when you have pessimistic locking enabled. With optimistic locking, the locks are not held. Different types of locks are compatible with others in various ways. Locks must be handled in the correct order to avoid deadlock scenarios.

Shared, upgradeable, and exclusive locks

When an application calls any method of the map programming interface, WebSphere® eXtreme Scale automatically attempts to acquire a lock for the map entry that is being accessed.
In Java applications, locks are also acquired when the applications uses the find methods on an index, or does a query.

WebSphere eXtreme Scale uses the following lock modes that are based on the method the application calls in the map programming interface.

S lock
: A shared lock mode for the key of a map entry. The duration that the S lock is held depends on the transaction isolation level used. An S lock mode allows concurrency between transactions that attempt to acquire an S or an upgradeable lock (U lock) mode for the same key, but blocks other transactions that attempt to get an exclusive lock (X lock) mode for the same key.

U lock
: An upgradeable lock mode for the key of a map entry. The U lock is held until the transaction completes. A U lock mode allows concurrency between transactions that acquire an S lock mode for the same key, but blocks other transactions that attempt to acquire a U lock or X lock mode for the same key.

X lock
: Exclusive lock mode for the key of a map entry. The X lock is held until the transaction completes. An X lock mode ensures that only one transaction is inserting, updating, or removing a map entry of a given key value. An X lock blocks all other transactions that attempt to acquire an S, U, or X lock mode for the same key.

An S lock mode is weaker than a U lock mode because it allows more transactions to run concurrently when they are accessing the same map entry. The U lock mode is slightly stronger than the S lock mode because it blocks other transactions that are requesting either a U or X lock mode. The S lock mode only blocks other transactions that are requesting an X lock mode. This small difference is important in preventing some deadlocks from occurring. The X lock mode is the strongest lock mode because it blocks all other transactions that are attempting to get an S, U, or X lock mode for the same map entry. The X lock mode ensures that only one transaction can insert, update, or remove a map entry and to prevent updates from being lost when more than one transaction is attempting to update the same map entry.
See the following table to understand the relationship between these lock modes and the behavior of equivalent methods:

Table 1. Lock modes and ObjectMap method equivalents

Lock mode	Method equivalent
S (shared)	get() and getAll()
U (upgradeable)	getForUpdate(), getAllForUpdate()
X (exclusive)	getNextKey() and commit()

The following table is a lock mode compatibility matrix that summarizes the described lock modes, which you can use to determine which lock modes are compatible with each other. To read this matrix, the row in the matrix indicates a lock mode that is already granted. The column indicates the lock mode that is requested by another transaction. If `Yes` is displayed in the column, then the lock mode that is requested by the other transaction is granted because it is

compatible with the lock mode that is already granted. `No` indicates that the lock mode is not compatible and the other transaction must wait for the first transaction to release the lock that it owns.

Table 2. Lock mode compatibility matrix

Lock	Lock type S (shared)	Lock type U (upgradeable)	Lock type X (exclusive)	Strength
S (shared)	Yes	Yes	No	weakest
U (upgradeable)	Yes	No	No	normal
X (exclusive)	No	No	No	strongest

Troubleshooting deadlocks

Implementing exception handling in locking scenarios for Java™ applications

To prevent locks from being held for excessive amounts of time when a LockTimeoutException exception or a LockDeadlockException exception occurs, your application must catch unexpected exceptions and call the rollback method when an unexpected event occurs.

Procedure

1. Catch the exception, and display resulting message.

   ```
   try {
   ...
   } catch (ObjectGridException oe) {
   System.out.println(oe);
   }
   ```

   The following exception displays as a result:

   ```
   com.ibm.websphere.objectgrid.plugins.LockDeadlockException: Message
   ```

   This message represents the string that is passed as a parameter when the exception is created and thrown.
2. Roll back the transaction after an exception:

   ```
   Session sess = ...;
   ObjectMap person = sess.getMap("PERSON");
   boolean activeTran = false;
   try
   {
       sess.begin();
       activeTran = true;
       Person p = (IPerson)person.get("Lynn");
       // Lynn had a birthday, so we make her 1 year older.
       p.setAge( p.getAge() + 1 );
       person.put( "Lynn", p );
       sess.commit();
       activeTran = false;
   }
   finally
   {
       if ( activeTran ) sess.rollback();
   }
   ```

   The `finally` block in the snippet of code ensures that a transaction is rolled back when an unexpected exception occurs. It not only handles a LockDeadlockException exception, but any other unexpected exception that might occur. The `finally` block handles the case where an exception occurs during a commit method invocation. This example is not the only way to deal with unexpected exceptions, and there might be cases where an application wants to catch some of the unexpected exceptions that can occur and display one of its application exceptions. You can add catch blocks as appropriate, but the application must ensure that the snippet of code does not exit without completing the transaction.

Configuring a locking strategy in the ObjectGrid descriptor XML file

You can define an optimistic, a pessimistic, or no locking strategy on each BackingMap in the WebSphere® eXtreme Scale configuration.

Before you begin

Decide which locking strategy you want to use. For more information, see Locking strategies.

About this task

You can configure each BackingMap instance to use one of the following locking strategies:

- Optimistic locking mode (default)
- Pessimistic locking mode

- None

Procedure

- **Configure a pessimistic locking strategy**
  - With the lockStrategy attribute in the ObjectGrid descriptor XML file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">

    <objectGrids>
        <objectGrid name="test">
            <backingMap name="pessimisticMap"
                lockStrategy="PESSIMISTIC"/>
        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

- **Configure an optimistic locking strategy**
  - With the lockStrategy attribute in the ObjectGrid descriptor XML file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="test">
            <backingMap name="optimisticMap"
                lockStrategy="OPTIMISTIC"/>
        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

- **Configure a no locking strategy**
  - With the lockStrategy attribute in the ObjectGrid descriptor XML file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">

    <objectGrids>
        <objectGrid name="test">
            <backingMap name="noLockingMap"
                lockStrategy="NONE"/>
        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

Configuring the lock timeout value in the ObjectGrid descriptor XML file

The lock timeout value on a BackingMap instance is used to ensure that an application does not wait endlessly for a lock mode to be granted because of a deadlock condition that occurs due to an application error.

Before you begin

To configure the lock timeout value, the locking strategy must be set to either OPTIMISTIC or PESSIMISTIC. See Configuring a locking strategy in the ObjectGrid descriptor XML file for more information.

About this task

When a LockTimeoutException exception occurs, the application must determine if the timeout is occurring because the application is running slower than expected, or if the timeout occurred because of a deadlock condition. If an actual deadlock condition occurred, then increasing the lock wait timeout value does not eliminate the exception. Increasing the timeout results in the exception taking longer to occur. However, if increasing the lock wait timeout value does eliminate the exception, then the problem occurred because the application was running slower than expected. The application in this case must determine why performance is slow.

To prevent deadlocks from occurring, the lock manager has a default timeout value of 15 seconds. If the timeout limit is exceeded, a LockTimeoutException exception occurs. If your system is heavily loaded, the default timeout value might cause the LockTimeoutException exceptions to occur when no deadlock exists. In this situation, you can increase the lock timeout value programmatically or in the ObjectGrid descriptor XML file.

Procedure

Configure the lock timeout value with the lockTimeout attribute in the ObjectGrid descriptor XML file.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="test">
            <backingMap name="optimisticMap"
                lockStrategy="OPTIMISTIC"
                lockTimeout="60"/>
        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

Map entry locks with query and indexes

The eXtreme Scale Query APIs and the MapRangeIndex indexing plug-in interact with locks. You can increase concurrency and decrease deadlocks when you are using the pessimistic locking strategy for maps.

Overview

The ObjectGrid Query API allows SELECT queries over ObjectMap cache objects and entities. When a query is run, the query engine uses a MapRangeIndex when possible to find matching keys that match values in the query's WHERE clause or to bridge relationships. When an index isn't available, the query engine will scan each entry in one or more maps to find the appropriate entries. Both the query engine and index plug-ins acquire locks to verify consistent data, depending on the locking strategy, transaction isolation level, and transaction state.

Locking with the HashIndex plug-in

The eXtreme Scale HashIndex plug-in allows finding keys that are based on a single attribute that is stored in the cache entry value. The index stores the indexed value in a separate data structure from the cache map. The index validates the keys against map entries before returning to the user to try to achieve an accurate result set. When you are using the pessimistic lock strategy and the index against a local ObjectMap instance (versus a client/server ObjectMap), the index acquires locks for each matching entry. When you are using optimistic locking or a remote ObjectMap, the locks are always immediately released.

The type of lock that is acquired depends upon the forUpdate argument that is passed to the ObjectMap.getIndex method. The forUpdate argument specifies the type of lock that the index should acquire. If false, a shareable (S) lock is acquired and if true, an upgradeable (U) lock is acquired.

If the lock type is shareable, the transaction isolation setting for the session is applied and affects the duration of the lock. See the transaction isolation topic for details on how transaction isolation is used to add concurrency to applications.

Shared locks with query

The eXtreme Scale query engine acquires S locks when needed to introspect the cache entries to discover if they satisfy the query's filter criteria. When you are using repeatable read transaction isolation with pessimistic locking, the S locks are only retained for the elements that are included in the query result. The locks are released for any entries that are not included in the result. If you are using a lower transaction isolation level or optimistic locking, the S locks are not retained.

Shared locks with client to server query

When you are using the eXtreme Scale query from a client, the query typically runs on the server unless all of the maps or entities referenced in the query are local to the client, for example, a client-replicated map or a query result entity. All queries that run in a read/write transaction retain S locks. If the transaction is not a read/write transaction, then a session is not retained on the server and the S locks are released.

A read/write transaction is only routed to a primary partition and a session is maintained on the server for the client session. A transaction can be promoted to read/write under the following conditions:

1. Any map that is configured to use pessimistic locking is accessed with the ObjectMap get and getAll API methods or the EntityManager.find methods.
2. The transaction is flushed, causing updates to be sent to the server.
3. Any map that is configured to use optimistic locking is accessed with the ObjectMap.getForUpdate or EntityManager.findForUpdate method.

Upgradeable locks with query

Shareable locks are useful when concurrency and consistency are important. It guarantees that an entry's value does not change for the life of the transaction. No other transaction can change the value while any other S locks are held, and only one other transaction can establish an intent to update the entry.

Upgradeable locks are used to identify the intent to update a cache entry when using the pessimistic lock strategy. It allows synchronization between transactions that want to modify a cache entry. Transactions can still view the entry using an S lock, but other transactions are prevented from acquiring a U lock or an X lock. In many scenarios, acquiring a U lock without first acquiring an S lock is necessary to avoid deadlocks. See the Pessimistic Locking Mode topic for common deadlock examples.

The ObjectQuery and EntityManager Query interfaces provide the setForUpdate method to identify the intended use for the query result. Specifically, the query engine acquires U locks instead of S locks for each map entry that is involved in the query result:

```
ObjectMap orderMap = session.getMap("Order");
ObjectQuery q = session.createQuery("SELECT o FROM Order o WHERE o.orderDate=?1");
q.setParameter(1, "20080101");
q.setForUpdate(true);
session.begin();
// Run the query.  Each order has  U lock
Iterator result = q.getResultIterator();
// For each order, update the status.
while(result.hasNext()) {
    Order o = (Order) result.next();
    o.status = "shipped";
    orderMap.update(o.getId(), o);
}
// When committed, the
session.commit();
```

```
Query q = em.createQuery("SELECT o FROM Order o WHERE o.orderDate=?1");
q.setParameter(1, "20080101");
q.setForUpdate(true);
emTran.begin();
// Run the query.  Each order has  U lock
Iterator result = q.getResultIterator();
// For each order, update the status.
while(result.hasNext()) {
    Order o = (Order) result.next();
    o.status = "shipped";
}
tmTran.commit();
```

When the setForUpdate attribute is enabled, the transaction is automatically converted to a read/write transaction and the locks are held on the server as expected. If the query cannot use any indexes, then the map must be scanned which results in temporary U locks for map entries that do not satisfy the query result. U locks are held for entries that are included in the result.

Transaction isolation

You can use one of three transaction isolation levels to tune the locking semantics that maintain consistency in each cache map: repeatable read, read committed and read uncommitted.

Transaction isolation overview

Transaction isolation defines how the changes that are made by one operation become visible to other concurrent operations.

You can define the following transaction isolation levels to tune the locking semantics that eXtreme Scale uses to maintain consistency in each cache map: repeatable read, read committed and read uncommitted.

You can set the transaction isolation level in one of the following ways:

- With the txIsolation attribute in the ObjectGrid descriptor XML file. For more information, see ObjectGrid descriptor XML file.
- On the Session interface with the setTransactionIsolation method. The transaction isolation can be changed any time during the life of the session, if a transaction is not currently in progress.

The product enforces the various transaction isolation semantics by adjusting the way in which shared (S) locks are requested and held. Transaction isolation has no effect on maps that are configured to use the optimistic locking or no locking or when upgradeable (U) locks are acquired.

Repeatable read with pessimistic locking

The repeatable read transaction isolation level is the default. This isolation level prevents dirty reads and non-repeatable reads, but does not prevent phantom reads. A dirty read is a read operation that occurs on data that has been modified by a transaction but has not been committed. A non-repeatable read might occur when read locks are not acquired when performing a read operation. A phantom read can occur when two identical read operations are performed, but two different sets of results are returned because an update has occurred on the data between the read operations. In Java applications, phantom reads are possible when you are using queries or indexes because locks are not acquired for ranges of data, only for the cache entries that match the index or query criteria. The product achieves a repeatable read by holding onto any S locks until the transaction that owns the lock completes. Because an X lock is not granted until all S locks are released, all transactions holding the S lock are guaranteed to see the same value when re-read.

Read committed with pessimistic locking

The read committed transaction isolation level can be used with eXtreme Scale, which prevents dirty reads, but does not prevent non-repeatable reads or phantom reads, so eXtreme Scale continues to use S locks to read data from the cache map, but immediately releases the locks.

Read uncommitted with pessimistic locking

The read uncommitted transaction isolation level can be used with eXtreme Scale, which is a level that allows dirty reads, non-repeatable reads and phantom reads.

Java examples for transaction isolation

Optimistic collision exception

You can receive an OptimisticCollisionException directly, or receive it with an ObjectGridException.

The following code is an example of how to catch the exception and then display its message:

```
try {
...
} catch (ObjectGridException oe) {
    System.out.println(oe);
}
```

Exception cause

OptimisticCollisionException is created in a situation in which two different clients try to update the same map entry at relatively the same time. For example, if one client attempts to commit a session and update the map entry after another client reads the data before the commit, that data is then incorrect. The exception is created when the other client attempts to commit the incorrect data.

Retrieving the key that triggered the exception

It might be useful, when troubleshooting such an exception, to retrieve the key corresponding to the entry that triggered the exception. The benefit of the OptimisticCollisionException is it contains the getKey method, which returns the object representing that key. The following example demonstrates how to retrieve and print the key when catching OptimisticCollisionException:

```
try {
...
} catch (OptimisticCollisionException oce) {
    System.out.println(oce.getKey());
}
```

ObjectGridException causes an OptimisticCollisionException

OptimisticCollisionException might be the cause of ObjectGridException displaying. If this is the case, you can use the following code to determine the exception type and print out the key. The following code uses the findRootCause utility method as described in the section below.

```
try {
...
}
catch (ObjectGridException oe) {
    Throwable Root = findRootCause( oe );
    if (Root instanceof OptimisticCollisionException) {
        OptimisticCollisionException oce = (OptimisticCollisionException)Root;
        System.out.println(oce.getKey());
    }
}
```

General exception handling technique

Knowing the root cause of a Throwable object is helpful in isolating the source of an error. The following example demonstrates how an exception handler uses a utility method to find the root cause of the Throwable object.

Example:

```
static public Throwable findRootCause( Throwable t )
{
     // Start with Throwable that occurred as the root.
     Throwable root = t;

     // Follow cause chain until last Throwable in chain is found.
     Throwable cause = root.getCause();
     while ( cause != null )
     {
        root = cause;
```

```
            cause = root.getCause();
        }

        // Return last Throwable in the chain as the root cause.
        return root;
    }
```

Running parallel business logic on the data grid (DataGrid API)

The DataGrid API provides a simple programming interface to run business logic over all or a subset of the data grid in parallel with where the data is located.

- DataGrid APIs and partitioning
  With the DataGrid APIs, a client can send requests to one partition, a subset of partitions, or all the partitions in a data grid. The client can specify a list of keys, and WebSphere® eXtreme Scale determines the set of partitions that are hosting the keys. The request is then sent to all the partitions in the set in parallel and the client waits for the results. The client can also send requests without specifying keys, therefore, requests are sent to all partitions.
- DataGrid agents and entity-based Maps
  A map contains key objects and value objects. The key object is a generated tuple as is the value.
- DataGrid API example
  The DataGrid APIs support two common grid programming patterns: parallel map and parallel reduce.

DataGrid API

DataGrid APIs and partitioning

With the DataGrid APIs, a client can send requests to one partition, a subset of partitions, or all the partitions in a data grid. The client can specify a list of keys, and WebSphere® eXtreme Scale determines the set of partitions that are hosting the keys. The request is then sent to all the partitions in the set in parallel and the client waits for the results. The client can also send requests without specifying keys, therefore, requests are sent to all partitions.

Agents that are deployed to the data grid do not work in client mode. These agents work directly against the primary shard. Working directly against the primary shard results in maximum performance, allowing tens of thousands or more transactions per second because the agent works with the data at full memory speeds. Working directly with the primary shard also means that an agent can only see data that is within that shard. This provides some interesting opportunities that cannot be done on a client.

A typical eXtreme Scale client must be able determine the partition from the transaction, because the client needs to route the request. If an agent is directly attached to a shard, then no routing is needed. All requests go against that shard. Because the agent is directly attached to a shard, data in other maps in the shard can be accessed without worrying about common partitioning keys, and so on, because no routing occurs.

Related information:
DataGrid API

DataGrid agents and entity-based Maps

A map contains key objects and value objects. The key object is a generated tuple as is the value.

The key object is a generated tuple as is the value. An agent is normally provided with the application specified key objects. This will be the key objects used by the application or Tuples if it is an entity Map. An application using Entities will not want to deal with Tuples directly and would prefer to work with the Java™ objects mapped to the Entity.

Therefore, an Agent class can implement the EntityAgentMixin interface. This forces the class to implement one more method, getClassForEntity(). This returns the entity class to use with the agent on the server side. The keys are converted to this Entity before invoking the process and reduce methods.

This is a different semantic to a non EntityAgentMixin agent where those methods are provided with just the keys. An agent implementing EntityAgentMixin receives the Entity object which includes keys and values in one object.
Note: If the entity does not exist on the server, the keys are the raw Tuple format of the key instead of the managed entity.
Related information:
DataGrid API

DataGrid API example

The DataGrid APIs support two common grid programming patterns: parallel map and parallel reduce.

Parallel Map

The parallel map allows the entries for a set of keys to be processed and returns a result for each entry processed. The application makes a list of keys and receives a Map of key/result pairs after invoking a Map operation. The result is the result of applying a function to the entry of each key. The function is supplied by the application.

MapGridAgent call flow

When the AgentManager.callMapAgent method is invoked with a collection of keys, the MapGridAgent instance is serialized and sent to each primary partition that the keys resolve to. This means that any instance data stored in the agent can be sent to the server. Each primary partition therefore has one instance of the agent. The process method is invoked for each instance one time for each key that resolves to the partition. The result of each process method is then serialized back to the client and returned to the caller in a Map instance, where the result is represented as the value in the map.

When the AgentManager.callMapAgent method is invoked without a collection of keys, the MapGridAgent instance is serialized and sent to every primary partition. This means that any instance data stored in the agent can be sent to the server. Each primary partition therefore has one instance (partition) of the agent. The processAllEntries method is invoked for each partition. The result of each processAllEntries method is then serialized back to the client and returned to the caller in a Map instance. The following example assumes that a Person entity exists with the following shape:

```
import com.ibm.websphere.projector.annotations.Entity;
import com.ibm.websphere.projector.annotations.Id;
@Entity
public class Person
{
  @Id String ssn;
  String firstName;
  String surname;
  int age;
}
```

The application supplied function is written as a class that implements the MapAgentGrid interface. An example agent that shows a function to return the age of a Person multiplied by two.

```
public class DoublePersonAgeAgent implements MapGridAgent, EntityAgentMixin
{
  private static final long serialVersionUID = -2006093916067992974L;

  int lowAge;
  int highAge;

  public Object process(Session s, ObjectMap map, Object key)
  {
    Person p = (Person)key;
    return new Integer(p.age * 2);
  }

  public Map processAllEntries(Session s, ObjectMap map)
  {
    EntityManager em = s.getEntityManager();
    Query q = em.createQuery("select p from Person p where p.age > ?1 and p.age < ?2");
    q.setParameter(1, lowAge);
    q.setParameter(2, highAge);
    Iterator iter = q.getResultIterator();
    Map<Person, Interger> rc = new HashMap<Person, Integer>();
         while(iter.hasNext())
    {
                        Person p = (Person)iter.next();
                        rc.put(p, (Integer)process(s, map, p));
                }
                return rc;
        }
        public Class getClassForEntity()
        {
                return Person.class;
        }
}
```

The previous example shows the Map agent for doubling a Person. The first process method is supplied with the Person to work with and returns double the age of that entry. The second process method is called for each partition and finds all Person objects with an age between lowAge and highAge and returns their ages doubled.

```
Session s = grid.getSession();
ObjectMap map = s.getMap("Person");
AgentManager amgr = map.getAgentManager();

DoublePersonAgeAgent agent = new DoublePersonAgeAgent();

// make a list of keys
ArrayList<Person> keyList = new ArrayList<Person>();
Person p = new Person();
p.ssn = "1";
keyList.add(p);
p = new Person ();
p.ssn = "2";
keyList.add(p);

// get the results for those entries
Map<Tuple, Object> = amgr.callMapAgent(agent, keyList);
// Close the session (optional in Version 7.1.1 and later) for improved performance
s.close();
```

The previous example shows a client obtaining a Session and a reference to the Person Map. The agent operation is performed against a specific Map. The AgentManager interface is retrieved from that Map. An instance of the agent to invoke is created and any necessary state is added to the object by setting attributes, there are none in this case. A list of keys are then constructed. A Map with the values for person 1 doubled, and the same values for person 2 are returned.

The agent is then invoked for that set of keys. The agents process method is invoked on each partition with some of the specified keys in the grid in parallel. A Map is returned providing the merged results for the specified key. In this case, a Map with the values holding the age for person 1 doubled and the same for person 2 is returned.

If the key does not exist, the agent is still invoked. This invocation gives the agent the opportunity to create the map entry. If you are using an EntityAgentMixin, the key to process is not the entity, but the actual Tuple key value for the entity. If the keys are unknown, then you can ask all partitions to find Person objects of a certain shape and return their ages doubled. An example follows:

```
Session s = grid.getSession();
  ObjectMap map = s.getMap("Person");
  AgentManager amgr = map.getAgentManager();

  DoublePersonAgeAgent agent = new DoublePersonAgeAgent();
  agent.lowAge = 20;
  agent.highAge = 9999;

  Map m = amgr.callMapAgent(agent);
```

The previous example shows the AgentManager being obtained for the Person Map, and the agent constructed and initialized with the low and high ages for Persons of interest. The agent is then invoked using the callMapAgent method. Notice, no keys are supplied. As a result, the ObjectGrid invokes the agent on every partition in the grid in parallel and returns the merged results to the client. This set of returns contains all Person objects in the grid with an age between low and high and calculates the age of those Person objects doubled. This example shows how the grid APIs can be used to run a query to find entities that match a certain query. The agent is serialized and transported by the ObjectGrid to the partitions with the needed entries. The results are similarly serialized for transport back to the client. Care needs to be taken with the Map APIs. If the ObjectGrid was hosting terabytes of objects and running on many servers, then potentially this processing would overwhelm client machines. Use Map APIs to process a small subset. If a large subset needs processing, use a reduce agent to do the processing out in the data grid rather than on a client.

Parallel Reduction or aggregation agents

This style of programming processes a subset of the entries and calculates a single result for the group of entries. Examples of such a result would be:

- Minimum value
- Maximum value
- Some other business-specific function

A reduce agent is coded and invoked in a similar manner to the Map agents.

ReduceGridAgent call flow

When the AgentManager.callReduceAgent method is invoked with a collection of keys, the ReduceGridAgent instance is serialized and sent to each primary partition that the keys resolve to. This means that any instance data stored in the agent can be sent to the server. Each primary partition therefore has one instance of the agent. The reduce(Session s, ObjectMap map, Collection keys) method is invoked once per instance (partition) with the subset of keys that resolves to the partition. The result of each reduce method is then serialized back to the client. The reduceResults method is invoked on the client ReduceGridAgent instance with the collection of each result from each remote reduce invocation. The result from the reduceResults method is returned to the caller of the callReduceAgent method.

When the AgentManager.callReduceAgent method is invoked without a collection of keys, the ReduceGridAgentinstance is serialized and sent to each primary partition. This means that any instance data stored in the agent can be sent to the server. Each primary partition therefore has one instance of the agent. The reduce(Session s, ObjectMap map) method is invoked once per instance (partition). The result of each reduce method is then serialized back to the client. The reduceResults method is invoked on the client ReduceGridAgent instance with the collection of each result from each remote reduce invocation. The result from the reduceResults method is returned to the caller of the callReduceAgent method. Here is an example of a reduce agent that simply adds the ages of the matching entries.

```
package com.ibm.ws.objectgrid.test.agent.jdk5;

import java.util.Collection;
import java.util.Iterator;

import com.ibm.websphere.objectgrid.ObjectMap;
import com.ibm.websphere.objectgrid.Session;
import com.ibm.websphere.objectgrid.datagrid.EntryErrorValue;
import com.ibm.websphere.objectgrid.datagrid.ReduceGridAgent;
import com.ibm.websphere.objectgrid.query.ObjectQuery;
import com.ibm.websphere.samples.objectgrid.entityxmlgen.PersonFeature1Entity.PersonKey;

public class SumAgeReduceAgent implements ReduceGridAgent {
        private static final long serialVersionUID = 2521080771723284899L;

        /**
         * Invoked on the server if a collection of keys is passed to
         * AgentManager.callReduceAgent(). This is invoked on each primary shard
         * where the key applies.
         */
        public Object reduce(Session s, ObjectMap map, Collection keyList) {
                try {
                        int sum = 0;
                        Iterator<PersonKey> iter = keyList.iterator();
                        while (iter.hasNext()) {
                                Object nextKey = iter.next();
                                PersonKey pk = (PersonKey) nextKey;
                                Person p = (Person) map.get(pk);
                                sum += p.age;
                        }

                        return sum;
                } catch (Exception e) {
                        throw new RuntimeException(e.getMessage(), e);
```

```
                }
        }

        /**
         * Invoked on the server if a collection of keys is NOT passed to
         * AgentManager.callReduceAgent(). This is invoked on every primary shard.
         */
        public Object reduce(Session s, ObjectMap map) {
                ObjectQuery q = s
                                .createObjectQuery("select p from Person p where p.age > -1");
                Iterator<Person> iter = q.getResultIterator();
                int sum = 0;
                while (iter.hasNext()) {
                        Object nextKey = iter.next();
                        Person p = (Person) nextKey;
                        sum += p.age;
                }
                return sum;
        }

        /**
         * Invoked on the client to reduce the results from all partitions.
         */
        public Object reduceResults(Collection results) {
                // If we encounter an EntryErrorValue, then throw a RuntimeException
                // to indicate that there was at least one failure and include each
                // EntryErrorValue
                // as part of the thrown exception.
                Iterator<Integer> iter = results.iterator();
                int sum = 0;
                while (iter.hasNext()) {
                        Object nextResult = iter.next();
                        if (nextResult instanceof EntryErrorValue) {
                                EntryErrorValue eev = (EntryErrorValue) nextResult;
                                throw new RuntimeException(
                                                "Error encountered on one of the partitions: "
                                                                + nextResult, eev.getException());
                        }

                        sum += ((Integer) nextResult).intValue();
                }
                return new Integer(sum);
        }
}
```

The previous example shows the agent. The agent has three important parts. The first allows a specific set of entries to be processed without a query. It iterates over the set of entries, adding the ages. The sum is returned from the method. The second uses a query to select the entries to be aggregated. It then sums all the matching Person ages. The third method is used to aggregate the results from each partition to a single result. The ObjectGrid performs the entry aggregation in parallel across the grid. Each partition produces an intermediate result that must be aggregated with other partition intermediate results. This third method performs that task. In the following example the agent is invoked, and the ages of all Persons with ages 10 - 20 exclusively are aggregated:

```
Session s = grid.getSession();
ObjectMap map = s.getMap("Person");
AgentManager amgr = map.getAgentManager();

SumAgeReduceAgent agent = new SumAgeReduceAgent();

Person p = new Person();
p.ssn = "1";
ArrayList<Person> list = new ArrayList<Person>();
list.add(p);
p = new Person ();
p.ssn = "2";
list.add(p);
Integer v = (Integer)amgr.callReduceAgent(agent, list);
// Close the session (optional in Version 7.1.1 and later) for improved performance
s.close();
```

Agent functions

The agent is free to do ObjectMap or EntityManager operations within the local shard where it is running. The agent receives a Session and can add, update, query, read, or remove data from the partition the Session represents. Some applications query only data from the grid, but you can also write an agent to increment all the Person ages by 1 that match a certain query. There is a transaction on the Session when the agent is called, and is committed when the agent returns unless an exception is thrown

Error handling

If a map agent is invoked with an unknown key then the value that is returned is an error object that implements the EntryErrorValue interface.

Transactions

A map agent runs in a separate transaction from the client. Agent invocations may be grouped into a single transaction. If an agent fails and throws an exception, the transaction is rolled back. Any agents that ran successfully in a transaction rolls back with the failed agent. The AgentManager reruns the rolled-back agents that ran successfully in a new transaction.

Java client overrides

You can configure a WebSphere® eXtreme Scale client based on your requirements by overriding the server settings. You can override several plug-ins and attributes.

To override settings on a client, you can use either XML or programmatic configuration. For more information about overriding client settings, see Configuring Java clients with an XML configuration and Configuring Java clients programmatically.
You can override the following plug-ins on a client:

- **BackingMap plug-ins**
  - Evictor plug-in
  - MapEventListener plug-in
  - BackingMapLifecycleListener plug-in
  - MapSerializerPlugin plug-in
- **BackingMap attributes**
  - numberOfBuckets attribute
  - timeToLive attribute
  - ttlEvictorType attribute
  - evictionTriggers attribute
  - readOnly
  - nearCacheCopyMode
  - lockStrategy
- **ObjectGrid plug-ins**
  - TransactionCallback plug-in
  - ObjectGridEventListener plug-in
  - ObjectGridLifecycleListener plug-in
- **ObjectGrid attributes**
  - entityMetadataXMLFile attribute
  - txTimeout attribute
  - txIsolation attribute

Enabling client-side map replication

You can also enable replication of maps on the client side to make data available faster.

With eXtreme Scale, you can replicate a server map to one or more clients by using asynchronous replication. A client can request a local read-only copy of a server side map by using the ClientReplicableMap.enableClientReplication method.

```
void enableClientReplication(Mode mode, int[] partitions,
        ReplicationMapListener listener) throws ObjectGridException;
```

The first parameter is the replication mode. This mode can be a continuous replication or a snapshot replication. The second parameter is an array of partition IDs that represent the partitions from which to replicate the data. If the value is null or an empty array, the data is replicated from all the partitions. The last parameter is a listener to receive client replication events. See ClientReplicableMap and ReplicationMapListener in the API documentation for details.

After the replication is enabled, then the server starts to replicate the map to the client. The client is eventually only a few transactions behind the server at any point in time.

Accessing data with the REST data service

Develop applications that perform operations using REST data service protocols.

Operations with the REST data service

After you start the eXtreme Scale REST data service, you can use any HTTP client to interact with it. A Web browser, PHP client, Java™ client or WCF Data Services client can be used to issue any of the supported request operations.

The REST service implements a subset of the Microsoft Atom Publishing Protocol: Data Services URI and Payload Extensions specification, Version 1.0 which is part of OData protocol. This topic describes which of the features of the specification are supported and how they are mapped to eXtreme Scale.

Service root URI

Microsoft WCF Data Services typically defines a service per data source or entity model. The eXtreme Scale REST data service defines a service per defined ObjectGrid. Each ObjectGrid that is defined in the eXtreme Scale ObjectGrid client override XML file is automatically exposed as a separate REST service root.

The URI for the service root is:

`http://`*`host`*`:`*`port`*`/`*`contextroot`*`/restservice/`*`gridname`*

Where:

- *contextroot* is defined when you deploy the REST data service application, and depends on the application server
- *gridname* is the name of the ObjectGrid

Request types

The following list describes the Microsoft WCF Data Services request types which the eXtreme Scale REST data service supports. For details about each request type that WCF Data Services supports, see: MSDN: Request Types.

Insert request types
: Clients can insert resources using the POST HTTP verb with the following limitations:

  - InsertEntity Request: Supported.
  - InsertLink request: Supported.
  - InsertMediaResource request: Not supported due to media resource support restriction.

  For additional information, see: MSDN: Insert Request Types.

Update request types
: Clients can update resources using the PUT and MERGE HTTP verbs with the following limitations:

  Note: The upsert and upsertAll methods replace the ObjectMap put and putAll methods. Use the upsert method to tell the BackingMap and loader that an entry in the data grid needs to place the key and value into the grid. The BackingMap and loader does either an insert or an update to place the value into the grid and loader. If you run the upsert API within your applications, then the loader gets an UPSERT LogElement type, which allows loaders to do database merge or upsert calls instead of using insert or update.

  - UpdateEntity Request: Supported.
  - UpdateComplexType Request: Not Supported due to complex type restriction.
  - UpdatePrimitiveProperty Request: Supported.
  - UpdateValue Request: Supported.
  - UpdateLink Request: Supported.
  - UpdateMediaResource Request: Not supported due to media resource support restriction.

  For additional information, see: MSDN: Insert Request types.

Delete request types
: Clients can delete resources using the DELETE HTTP verb with the following limitations:

  - DeleteEntity Request: Supported.
  - DeleteLink Request: Supported.
  - DeleteValue request: Supported.

  For additional information, see: MSDN: Delete Request Types.

Retrieve request types
: Clients can retrieve resources using the GET HTTP verb with the following limitations:

  - RetrieveEntitySet Request: Supported.
  - RetrieveEntity Request: Supported.
  - RetrieveComplexType Request: Not supported due to complex type restriction.
  - RetrievePrimitiveProperty Request: Supported.
  - RetrieveValue Request: Supported.
  - RetrieveServiceMetadata Request: Supported.
  - RetrieveServiceDocument Request: Supported.
  - RetrieveLink Request: Supported.
  - Retrieve Request Containing a Customizable Feed Mapping: Not supported
  - RetrieveMediaResource: Not supported due to media resource restriction.

  For additional information, see: MSDN: Retrieve Request Types.

System query options
: Queries are supported which allow clients to identify a collection of entities or a single entity. System query options are specified in a data service URI and are supported with the following limitations:

- $expand: Supported
- $filter: Supported.
- $orderby: Supported.
- $format: Not supported. The acceptable format is identified in the HTTP Accept request header.
- $skip: Supported
- $top: Supported

For additional information, see: MSDN: System Query Options.

Partition routing

Partition routing is based on the root entity. A request URI infers a root entity if its resource path starts with a root entity or with an entity that has a direct or indirect association to the entity. In a partitioned environment, any request that cannot infer a root entity will be rejected. Any request that infers a root entity will be routed to the correct partition.

For additional information on defining a schema with associations and root entities, see Scalable data model in eXtreme Scale and Partitioning.

Invoke request

Invoke requests are not supported. For additional information, see MSDN: Invoke Request.

Batch request

Clients can batch multiple Change Sets or Query Operations within a single request. This can reduce the number of round trips to the server and allows multiple requests to participate in a single transaction. For additional information, see MSDN: Batch Request.

Tunneled requests

Tunneled requests are not supported. For additional information, see MSDN: Tunneled Requests.

Optimistic concurrency in the REST data service

The eXtreme Scale REST data service uses an optimistic locking model by using native HTTP headers: If-Match, If-None-Match, and ETag. These headers are sent in request and response messages to relay an entity's version information from the server to client and client to server.

For more details on optimistic concurrency, refer to MSDN Library: Optimistic Concurrency (ADO.NET).

The eXtreme Scale REST data service enables optimistic concurrency for an entity if a version attribute is defined in the entity schema for that entity. A version property can be defined in the entity schema by a @Version annotation for Java™ classes or a <version/> attribute for entities defined using an entity descriptor XML file. The eXtreme Scale REST data service automatically propagates the value of the version property to the client in the ETag header for single entity responses using an m:etag attribute in the payload for multiple entity XML responses, and an etag attribute in the payload for multiple entity JSON responses.

For more details on defining an eXtreme Scale entity schema, see Defining an entity schema.

Request protocols for the REST data service

In general, the protocols for interacting with the REST service are the same as those described in the WCF Data Services AtomPub protocol. However, eXtreme Scale does provide additional details, from eXtreme Scale Entity Model perspective. Users are expected to be familiar with the WCF Data Services protocols before reading this section. Alternatively, users can read this section with the WCF Data Services protocol section.

Examples are provided to illustrate the request and response. These examples apply to both the eXtreme Scale REST data service and WCF Data Services. Because Web browsers can only retrieve data, the CUD (create, update and delete) operations must be performed by another client such as Java™, JavaScript, RUBY or PHP.

Retrieve requests with the REST data service

A RetrieveEntity Request is used by a client to retrieve an eXtreme Scale entity. The response payload contains the entity data in AtomPub or JSON format. Also, the system operator $expand can be used to expand the relations. The relations are represented in line within the data service response as an Atom Feed Document, which is a to-many relation, or an Atom Entry Document which is a to-one relation.

Tip: For more details on the RetrieveEntity protocol defined in WCF Data Services, refer to MSDN: RetrieveEntity Request.

Retrieving an entity

The following RetrieveEntity example retrieves a Customer entity with key.

AtomPub

- Method
  GET
- Request URI:
  http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('ACME')
- Request Header:
  Accept: application/atom+xml
- Request Payload:
  None
- Response Header:
  Content-Type: application/atom+xml
- Response Payload:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<entry xml:base = "http://localhost:8080/wxsrestservice/
restservice" xmlns:d= "http://schemas.microsoft.com/ado/2007/
08/dataservices" xmlns:m = "http://schemas.microsoft.com/ado/2007/
08/dataservices/metadata" xmlns = "http://www.w3.org/2005/Atom">

- Request Header:
  Accept: application/json
- Request Payload:
  None
- Response Header:
  Content-Type: application/json
- Response Payload:

```
{"d":{"__metadata":{"uri":"http://localhost:8080/wxsrestservice/
                        restservice/NorthwindGrid/Customer('ACME')",
                        "type":"NorthwindGridModel.Customer"},
                        "customerId":"ACME",
                        "city":null,
                        "companyName":"RoaderRunner",
                        "contactName":"ACME",
                        "country":null,
                        "version":3,
                        "orders":{"__deferred":{"uri":"http://localhost:8080/
                                                wxsrestservice/restservice/
                        NorthwindGrid/Customer('ACME')/orders"}}}}
```

- Response Code:
  200 OK

Queries

A query can also be used with a RetrieveEntitySet or RetrieveEntity request. A query is specified by the system $filter operator.

For details on the $filter operator, refer to: MSDN: Filter System Query Option ($filter)

The OData protocol supports several common expressions. The eXtreme Scale REST data service supports a subset of the expressions defined in the specification:

- Boolean expressions:
  - eq, ne, lt, le, gt, ge
  - negate
  - not
  - parenthesis
  - and, or
- Arithmetic expressions:
  - add
  - sub
  - mul
  - div
- Primitive literals
  - String
  - date-time
  - decimal
  - single
  - double
  - int16
  - int32
  - int64
  - binary
  - null
  - byte

The following expressions are *not* available:

- Boolean expressions:
  - isof
  - cast
- Method call expressions
- Arithmetic expressions:
  - mod
- Primitive literals:
  - Guid
- Member expressions

For a complete list and description of the expressions that are available in Microsoft WCF Data Services, see section 2.2.3.6.1.1 : Common Expression Syntax.

The following example demonstrates a RetrieveEntity request with a query. In this example, all customers whose contact name is “RoadRunner” are retrieved. The only customer which matches this filter is Customer('ACME') as shown in the response payload.

Restriction: This query will only work for non-partitioned entities. If Customer is partitioned, then the key belonging to the customer is required.
AtomPub

                                        Customer('ACME')/orders"}}}]}
```

- Response Code: 200 OK

System operator $expand

The system operator $expand can be used to expand associations. The associations are represented in line in the data service response. Multi-valued (to-many) associations are represented as an Atom Feed Document or JSON array. Single-valued (to-one) associations, are represented as n Atom Entry Document or

JSON object.

For more details on the $expand system operator, refer to Expand System Query Option ($expand).

Here is an example of using the $expand system operator. In this example, we retrieve the entity Customer('IBM')which has an Orders 5000, 5001 and others associated with it. The $expand clause is set to “orders”, so the order collection is expand as inline in the response payload. Only orders 5000 and 5001 are displayed here.

Retrieving non-entities with REST data services

The REST data service allows you to retrieve more than only entities, such as entity collections and properties.

Retrieve an entity collection

A RetrieveEntitySet Request can be used by a client to retrieve a set of eXtreme Scale entities. The entities are represented as an Atom Feed Document or JSON array in the response payload. For more details on the RetrieveEntitySet protocol defined in WCF Data Services, refer to MSDN: RetrieveEntitySet Request.

The following RetrieveEntitySet request example retrieves all the Order entities associated with the Customer('IBM') entity. Only orders 5000 and 5001 are displayed here.

AtomPub

- Method: GET

Retrieve a property

A RetrievePrimitiveProperty request can be used to get the value of a property of an eXtreme Scale entity instance. The property value is represented as XML format for AtomPub requests and a JSON object for JSON requests in the response payload. For more details on RetrievePrimitiveProperty request, refer to MSDN: RetrievePrimitiveProperty Request.

The following RetrievePrimitiveProperty request example retrieves the contactName property of the Customer('IBM') entity.

AtomPub

- Method: GET
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/contactName
- Request Header: Accept: application/xml
- Request Payload: None
- Response Header: Content-Type: application/atom+xml
- Response Payload:

```
<contactName xmlns:d="http://schemas.microsoft.com/ado/2007/08/dataservices">
    John Doe
</contactName>
```

- Response Code: 200 OK

JSON

- Method: GET
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/contactName
- Request Header: Accept: application/json
- Request Payload: None
- Response Header: Content-Type: application/json
- Response Payload: `{"d":{"contactName":"John Doe"}}`
- Response Code: 200 OK

Retrieve a property value

A RetrieveValue request can be used to get the raw value of a property on an eXtreme Scale entity instance. The property value is represented as a raw value in the response payload. If the entity type is one of the following, then the media type of the response is “text/plain." Otherwise the response' media type is “application/octet-stream." These types are:

- Java™ primitive types and their respective wrappers
- java.lang.String
- byte[]
- Byte[]
- char[]
- Character[]
- enums
- java.math.BigInteger
- java.math.BigDecimal
- java.util.Date
- java.util.Calendar
- java.sql.Date
- java.sql.Time
- java.sql.Timestamp

For more details on the RetrieveValue request, refer to MSDN: RetrieveValue Request.

The following RetrieveValue request example retrieves the raw value of the contactName property of the Customer('IBM') entity.

- Request Method: GET
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/contactName/$value
- Request Header: Accept: text/plain
- Request Payload: None
- Response Header: Content-Type: text/plain
- Response Payload: John Doe
- Response Code: 200 OK

Retrieve a link

A RetrieveLink Request can be used to get the link(s) representing a to-one association or to-many association. For the to-one association, the link is from one eXtreme Scale Entity instance to another, and the link is represented in the response payload. For the to-many association, the links are from one eXtreme Scale Entity instance to all others in a specified eXtreme Scale entity collection, and the response is represented as a set of links in the response payload. For more details on RetrieveLink request, refer to MSDN: RetrieveLink Request.

Here is a RetrieveLink request example. In this example, we retrieve the association between entity Order(orderId=5000,customer_customerId='IBM') and its customer. The response shows the Customer entity URI.

AtomPub

- Method: GET
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Order(orderId=5000,customer_customerId='IBM')/$links/customer
- Request Header: Accept: application/xml
- Request Payload: None
- Response Header: Content-Type: application/xml
- Response Payload:

```
<?xml version="1.0" encoding="utf-8"?>
<uri>http://localhost:8080/wxsrestservice/restservice/
                        NorthwindGrid/Customer('IBM')</uri>
```

- Response Code: 200 OK

JSON

- Method: GET
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Order(orderId=5000,customer_customerId='IBM')/$links/customer
- Request Header: Accept: application/json
- Request Payload: None
- Response Header: Content-Type: application/json
- Response Payload: {"d":{"uri":"http:\/\/localhost:8080\/wxsrestservice\/restservice\/NorthwindGrid\/Customer('IBM')"}}

Retrieve service metadata

A RetrieveServiceMetadata Request can be used to get the conceptual schema definition language (CSDL) document, which describes the data model associated with the eXtreme Scale REST data service. For more details on RetrieveServiceMetadata request, refer to MSDN: RetrieveServiceMetadata Request.

Retrieve service document

A RetrieveServiceDocument Request can be used to retrieve the Service Document describing the collection of resources exposed by the eXtreme Scale REST data service. For more details on RetrieveServiceDocument request, refer to MSDN: RetrieveServiceDocument Request.

Insert requests with REST data services

An InsertEntity Request can be used to insert a new eXtreme Scale entity instance, potentially with new related entities, into the eXtreme Scale REST data service.

Insert entity request

An InsertEntity Request can be used to insert a new eXtreme Scale entity instance, potentially with new related entities, into the eXtreme Scale REST data service. When inserting an entity, the client may specify if the resource or entity should be automatically linked to other existing entities in the data service.

The client must include the required binding information in the representation of the associated relation in the request payload.

In addition to supporting the insertion of a new EntityType instance (E1), the InsertEntity request also allows inserting new entities related to E1 (described by an entity relation) in a single Request. For example, when inserting a Customer('IBM'), we can insert all the orders with Customer('IBM'). This form of an InsertEntity Request is also known as a *deep insert*. With a deep insert, the related entities must be represented using the inline representation of the relation associated with E1 that identifies the link to the to-be-inserted related entities.

The properties of the entity to be inserted are specified in the request payload. The properties are parsed by the REST data service and then set to the correspondent property on the entity instance. For the AtomPub format, the property is specified as a <d:PROPERTY_NAME> XML element. For JSON, the property is specified as a property of a JSON object.

If a property is missing in the request payload, then the REST data service sets the entity property value to the java default value. However, the database backend might reject such a default value, for example, if the column is not nullable in the database. Then a 500 response code will be returned to indicate an Internal Server error.

If there are duplicate properties specified in the payload, the last property will be used. All the previous values for the same property name are ignored by the REST data service.

If the payload contains a non-existent property, then the REST data service returns a 400 (Bad Request) response code to indicate the request sent by the client was syntactically incorrect.

If the key properties are missing, then the REST data service returns a response code of 400 (Bad Request) to indicate a missing key property.

If the payload contains a link to a related entity with a non-existent key, then the REST data service returns a 404 (Not Found) response code to indicate the linked entity cannot be found.

If the payload contains a link to a related entity with an incorrect association name, then the REST data service returns a 400 (Bad Request) response code to indicate the link cannot be found.

If the payload contains more than one link to a one-to-one relation, the last link will be used. All the previous links for the same association are ignored.

For more details on the InsertEntity request, see MSDN Library: InsertEntity Request.

An InsertEntity request inserts a Customer entity with key 'IBM'.

```

- Response Code: 201 Created

Insert link request

An InsertLink Request can be used to create a new Link between two eXtreme Scale entity instances. The URI of the request must resolve to an eXtreme Scale one-to-many association. The payload of the request contains a single link which points to the one-to-many association target entity.

If the URI of the InsertLink request represents a to-one association, the REST data service returns a 400 (Bad request) response.

If the URI of the InsertLink request points to an association which does not exist, the REST data service returns a 404 (Not Found) response to indicate the link cannot be found.

If the payload contains a link with a key which does not exist, the REST data service returns a 404 (Not Found) response to indicate the linked entity cannot be found.

If the payload contains more than one link, the eXtreme Scale Rest Data Service will parse the first link. The remaining links are ignored.

For more details on InsertLink request, refer to: MSDN Library: InsertLink Request.

The following InsertLink request example creates a link from Customer('IBM') to Order(orderId=5000,customer_customerId='IBM').

AtomPub

- Method: POST
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/$link/orders
- Request Header: Content-Type: application/xml
- Request Payload:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<uri>http://host:1000/wxsrestservice/restservice/NorthwindGrid/Order(orderId=
                          5000,customer_customerId='IBM')</uri>
```

- Response Payload: None
- Response Code: 204 No Content

JSON

- Method: POST
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/$links/orders
- Request Header: Content-Type: application/json
- Request Payload:

```
{"uri": "http://host:1000/wxsrestservice/restservice/NorthwindGrid/Order(orderId
                                =5000,customer_customerId='IBM')"}
```

- Response Payload: None
- Response Code: 204 No Content

Update requests with REST data services

The WebSphere® eXtreme Scale REST data service supports update requests for entities, entity primitive properties, and so on.

Update an entity

An UpdateEntity Request can be used to update an existing eXtreme Scale entity. The client can use an HTTP PUT method to replace an existing eXtreme Scale entity, or use an HTTP MERGE method to merge the changes into an existing eXtreme Scale entity.
Note: The upsert and upsertAll methods replace the ObjectMap put and putAll methods. Use the upsert method to tell the BackingMap and loader that an entry in the data grid needs to place the key and value into the grid. The BackingMap and loader does either an insert or an update to place the value into the grid and loader. If you run the upsert API within your applications, then the loader gets an UPSERT LogElement type, which allows loaders to do database merge or upsert calls instead of using insert or update.
When updating the entity, the client can specify if the entity, in addition to being updated, must be automatically linked to other existing entities in the data service that are related through single valued to-one associations.

The property of the entity to be updated is in the request payload. The property is parsed by the REST data service and then set to the correspondent property on the entity. For the AtomPub format, the property is specified as a `<d:PROPERTY_NAME>` XML element. For JSON, the property is specified as a property of a JSON object.

If a property is missing in the request payload, the REST data service sets the entity property value to the Java default value for HTTP PUT method. However, the database backend might reject such a default value if, for example, the column is not nullable in the database. Then a 500 (Internal Server Error) response code is returned to indicate an Internal Server Error. If a property is missing in the HTTP MERGE request payload, the REST data service does not change the existing property value.

If there are duplicate properties specified in the payload, the last property is used. All the previous values with the same property name are ignored by the REST data service.

If the payload contains a non-existent property, the REST data service returns a 400 (Bad Request) response code to indicate the request sent by the client was syntactically incorrect.

As part of the serialization of a resource, if the payload of an Update request contains any of the key properties for the entity, the REST data service ignores those key values since entity keys are immutable.

For details on UpdateEntity request, refer to: MSDN Library: UpdateEntity Request.

An UpdateEntity request updates the city name of Customer('IBM') to 'Raleigh'.

AtomPub

- Method: PUT
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')
- Request Header: Content-Type: application/atom+xml
- Request Payload:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<entry xmlns:d="http://schemas.microsoft.com/ado/2007/08/dataservices"
 xmlns:m="http://schemas.microsoft.com/ado/2007/08/dataservices/metadata"
 xmlns="http://www.w3.org/2005/Atom">
 <category term="NorthwindGridModel.Customer"
  scheme="http://schemas.microsoft.com/ado/2007/08/dataservices/scheme" />

   <d:companyName>IBM Corporation</d:companyName>
   <d:contactName>Big Blue</d:contactName>
   <d:country>USA</d:country>
  </m:properties>
 </content>
</entry>
```

- Response Payload: None
- Response Code: 204 No Content

JSON

- Method: PUT

- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')
- Request Header: Content-Type: application/json
- Request Payload:

```
{"customerId":"IBM",
"city":"Raleigh",
"companyName":"IBM Corporation",
"contactName":"Big Blue",
"country":"USA",}
```

- Response Payload: None
- Response Code: 204 No Content

Update an entity primitive property

The UpdatePrimitiveProperty Request can update a property value of an eXtreme Scale entity. The property and value to be updated are in the request payload. The property cannot be a key property since eXtreme Scale does not allow clients to change entity keys.

For more details on the UpdatePrimitiveProperty request, refer to: MSDN Library: UpdatePrimitiveProperty Request.

Here is an UpdatePrimitiveProperty request example. In this example, we update the city name of Customer('IBM') to 'Raleigh'.

AtomPub

- Method: PUT
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/city
- Request Header: Content-Type: application/xml
- Request Payload:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<city xmlns:d="http://schemas.microsoft.com/ado/2007/08/dataservices">
        Raleigh
</city>
```

- Response Payload: None
- Response Code: 204 No Content

JSON

- Method: PUT
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/city
- Request Header: Content-Type: application/json
- Request Payload: {"city":"Raleigh"}
- Response Payload: None
- Response Code: 204 No Content

Update an entity primitive property value

The UpdateValue Request can update a raw property value of an eXtreme Scale entity. The value to be updated is represented as a raw value in the request payload. The property cannot be a key property since eXtreme Scale does not allow clients to change entity keys.

The content type of the request can be “text/plain” or “application/octet-stream” depending on the property type. For more information, see Retrieving non-entities with REST data services.

For more details on the UpdateValue request, refer to: MSDN Library: UpdateValue Request

Here is an UpdateValue request example. In this example, update the city name of Customer('IBM') to 'Raleigh'.

- Method: PUT
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/city/$value
- Request Header: Content-Type: text/plain
- Request Payload: Raleigh
- Response Payload: None
- Response Code: 204 No Content

Update a link

The UpdateLink request can be used to establish an association between two eXtreme Scale entity instances. The association can be a single valued (to-one) relation or a multi-valued (to-many) relation.

Updating a link between two eXtreme Scale entity instances can establish associations or remove associations. For example, if the client establishes a to-one association between an `Order(orderId=5000,customer_customerId='IBM')` entity and `Customer('ALFKI')` instance, it has to dissociate the `Order(orderId=5000,customer_customerId='IBM')` entity and entity from its currently associated Customer instance.

If either of the entity instances specified in the UpdateLink request cannot be found, the REST data service returns a 404 (Not Found) response.

If the URI of the UpdateLink request specifies a non-existent association, the REST data service returns a 404 (Not Found) response to indicate the link cannot be found.

If the URI specified in the UpdateLink request payload does not resolve to the same entity or the same key as specified in the URI, if exists, then the eXtreme Scale Rest Data Service returns a 400 (Bad Request) response.

If the UpdateLink request payload contains multiple links, then the REST data service parses the first link only. The rest of the links are ignored.

For more details on the UpdateLink request, refer to: MSDN Library: UpdateLink Request.

Here is an UpdateLink request example. In this example, we update the customer relation of `Order(orderId=5000,customer_customerId='IBM')` entity and from Customer('IBM') to Customer('IBM').

Remember: The previous example is for illustration only. Because all associations are typically key-associations for a partitioned grid, the link cannot be changed.
AtomPub

- Method: PUT
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Order(101)/$links/customer
- Request Header: Content-Type: application/xml
- Request Payload:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<uri>
        http://host:1000/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')
</uri>
```

- Response Payload: None
- Response Code: 204 No Content

JSON

- Method: PUT
- Request URI: `http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Order(orderId=5000,customer_customerId='IBM')/$links/customer`
- Request Header: Content-Type: application/xml
- Request Payload: `{"uri": "http://host:1000/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')"}`
- Response Payload: None
- Response Code: 204 No Content

Delete requests with REST data services

The WebSphere® eXtreme Scale REST data service can delete entities, property values and links.

Delete an entity

The DeleteEntity Request can delete an eXtreme Scale entity from the REST data service.

If any relation to the to-be-deleted entity has cascade-delete set, then the eXtreme Scale Rest data service will delete the related entity or entities. For more details on the DeleteEntity request, refer to MSDN Library: DeleteEntity Request.

The following DeleteEntity request deletes the customer with key 'IBM'.

- Method: DELETE
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')
- Request Payload: None
- Response Payload: None
- Response Code: 204 No Content

Delete a property value

The DeleteValue Request sets an eXtreme Scale entity property to null.

Any property of an eXtreme Scale entity can be set to null with a DeleteValue request. To set a property to null, ensure all of the following:

- For any primitive number type and its wrapper, BigInteger, or BigDecimal, the property value is set to 0.
- For Boolean or boolean type, the property value is set to false.
- For char or Character type, the property value is set to character #X1 (NIL).
- For enum type, the property value is set to the enum value with ordinal 0.
- For all other types, the property value is set to null.

However, such a delete request could be rejected by the database backend if, for example, the property is not nullable in the database. In this case, the REST data service returns a 500 (Internal Server Error) response. For more details on the DeleteValue request, refer to: MSDN Library: DeleteValue Request.

Here is a DeleteValue request example. In this example, we set the contact name of Customer('IBM') to null.

- Method: DELETE
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Customer('IBM')/contactName
- Request Payload: None
- Response Payload: None
- Response Code: 204 No Content

Delete a link

The DeleteLink request can removes an association between two eXtreme Scale entity instances. The association can be a to-one relation or a to-many relation. However, such a delete request could be rejected by the database backend if, for example, the foreign key constraint is set. In this case, the REST data service returns a 500 (Internal Server Error) response. For more details on the DeleteLink request, refer to: MSDN Library: DeleteLink Request.

The following DeleteLink request removes the association between Order(101) and its associated Customer.

- Method: DELETE
- Request URI: http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/Order(101)/$links/customer
- Request Payload: None
- Response Payload: None
- Response Code: 204 No Content

System APIs and plug-ins

A plug-in is a component that provides a function to the pluggable components, which include ObjectGrid and BackingMap. To most effectively use eXtreme Scale as an in-memory data grid or database processing space, you should carefully determine how best you can maximize performance with available plug-ins.

- Managing plug-in life cycles
  You can manage plug-in life cycles with specialized methods from each plug-in, which are available to be invoked at designated functional points. Both initialize and destroy methods define the life cycle of plug-ins, which are controlled by their *owner* objects. An owner object is the object that actually uses the given plug-in. An owner can be a grid client, server, or a backing map.
- Plug-ins for multimaster replication
  Consider transforming cached objects to increase the performance of your cache. You can use the ObjectTransformer plug-in when your processor usage is high. Up to 60-70 percent of the total processor time is spent serializing and copying entries. By implementing the ObjectTransformer plug-in, you can serialize and deserialize objects with your own implementation. You can use a CollisionArbiter plug-in to define how change collisions are handled in your domains.
- Plug-ins for versioning and comparing cache objects
  Use the OptimisticCallback plug-in to customize versioning and comparison operations of cache objects when you are using the optimistic locking strategy.
- Plug-ins for serializing cached objects
  WebSphere® eXtreme Scale uses multiple Java processes to serialize the data, by converting the Java object instances to bytes and back to objects again, as needed, to move the data between client and server processes.
- Plug-ins for providing event listeners
  You can use the ObjectGridEventListener, MapEventListener, ObjectGridLifecycleListener and BackingMapLifecycleListener plug-ins to configure notifications for various events in the eXtreme Scale cache. Listener plug-ins are registered with an ObjectGrid or BackingMap instance like other eXtreme Scale plug-ins and add integration and customization points for applications and cache providers.
- Plug-ins for evicting cache objects
  WebSphere eXtreme Scale provides a default mechanism for evicting cache entries and a plug-in for creating custom evictors. An evictor controls the membership of entries in each BackingMap. The default evictor uses a time to live (TTL) eviction policy for each BackingMap. If you provide a pluggable evictor mechanism, it typically uses an eviction policy that is based on the number of entries instead of on time.
- Plug-ins for indexing data
  Depending on the type of indexes you want to build, WebSphere eXtreme Scale provides built-in plug-ins that you can add to the BackingMap to build an index.
- Plug-ins for communicating with databases
  With a Loader plug-in, an ObjectGrid map can behave as a memory cache for data that is typically kept in a persistent store on either the same system or some other system. Typically, a database or file system is used as the persistent store. A remote Java™ virtual machine (JVM) can also be used as the source of data, allowing hub-based caches to be built using ObjectGrid. A loader has the logic for reading and writing data to and from a persistent store.
- Plug-ins for managing transaction life cycle events
  Use the TransactionCallback plug-in to customize versioning and comparison operations of cache objects when you are using the optimistic locking strategy.

Managing plug-in life cycles

You can manage plug-in life cycles with specialized methods from each plug-in, which are available to be invoked at designated functional points. Both initialize and destroy methods define the life cycle of plug-ins, which are controlled by their *owner* objects. An owner object is the object that actually uses the given plug-in. An owner can be a grid client, server, or a backing map.

About this task

Similarly all plug-ins can implement the optional mix-in interfaces appropriate for their owner object. Any ObjectGrid plug-in can implement the optional mix-in interface ObjectGridPlugin. Any BackingMap plug-in can implement the optional mix-in interface BackingMapPlugin. The optional mix-in interfaces require implementation of several additional methods beyond the initialize() and destroy() methods for the basic plug-ins. For more information about these interfaces, see the API documentation.

When owner objects are initializing, those objects set attributes on the plug-in, then invoke the initialize method of their owned plug-ins. During the destroy cycle of owner objects, the destroy method of plug-ins are consequently invoked also. For details on the specifics of initialize and destroy methods, along with other methods capable with each plug-in, refer to the topics relevant to each plug-in.

As an example, consider a distributed environment. Both the client-side ObjectGrids and the server-side ObjectGrids can have their own plug-ins. The life cycle of a client-side ObjectGrid, and therefore, its plug-in instances are independent from all server-side ObjectGrid and plug-in instances.

In such a distributed topology, assume that you have an ObjectGrid named `myGrid` defined in the objectGrid.xml file and configured with a customized ObjectGridEventListener named myObjectGridEventListener. The objectGridDeployment.xml file defines the deployment policy for the `myGrid` ObjectGrid. Both the objectGrid.xml and `objectGridDeployment.xml` files are used to start container servers. During the startup of the container server, the server-side `myGrid` ObjectGrid instance is initialized. Meanwhile, the initialize method of the myObjectGridEventListener instance that is owned by the myObjectGrid instance is invoked. After the container server is started, your application can connect to the server-side `myGrid` ObjectGrid instance and obtain a client-side instance.

When obtaining the client-side myGrid ObjectGrid instance, the client-side `myGrid` instance goes through its own initialization cycle and invokes the initialize method of its own client-side myObjectGridEventListener instance. This client-side myObjectGridEventListener instance is independent from the server-side myObjectGridEventListener instance. Its life cycle is controlled by its owner, which is the client-side `myGrid` ObjectGrid instance.

If your application disconnects or destroys the client-side `myGrid` ObjectGrid instance, then the destroy method that belongs to the client-side myObjectGridEventListener instance is invoked automatically. However, this process has no impact on server-side myObjectGridEventListener instance. The destroy method of the server-side myObjectGridEventListener instance can only be invoked during the destroy life cycle of the server-side `myGrid` ObjectGrid instance, when stopping a container server. Specifically, when stopping a container server, the contained ObjectGrid instances are destroyed and the destroy method of all their owned plug-ins is invoked.

Although the previous example applies specifically to the case of a client and a server instance of an ObjectGrid, the owner of a plug-in can also be a BackingMap interface. In addition, carefully to determine your configurations for plug-ins that you might write, based on these life cycle considerations. Use the following topics to write plug-ins that provide extended life cycle management events that you can use to set up or remove resources in your environment:

- Writing an ObjectGridPlugin plug-in
  An ObjectGridPlugin is an optional mix-in interface that you can use to provide extended life cycle management events to all other ObjectGrid plug-ins.
- Writing a BackingMapPlugin plug-in
  A BackingMap plug-in implements the BackingMapPlugin mix-in interface, which you can use to receive extended capabilities for managing its life cycle.

Related concepts:
OSGi framework overview

API documentation

Writing an ObjectGridPlugin plug-in

An ObjectGridPlugin is an optional mix-in interface that you can use to provide extended life cycle management events to all other ObjectGrid plug-ins.

About this task

Any ObjectGrid plug-in that implements the ObjectGridPlugin receives the extended set of life cycle events, and can provide more control, which you can use to set up or remove resources. In a container for a partitioned data grid, there will be one ObjectGrid instance (the plugin owner) for each partition managed by the container.When individual partitions are removed, the resources that are used by that ObjectGrid instance must also be removed. Therefore, you might need to close or end a resource, such as an open configuration file or a running thread that is managed by a plug-in, when the owning partition for that resource is removed.

The ObjectGridPlugin interface provides methods to set or modify the state of the plug-in, as well as methods to introspect the current state of the plug-in. All methods must be implemented correctly, and the WebSphere® eXtreme Scale runtime environment verifies the method behavior under certain circumstances.

For example, after calling the initialize() method, the eXtreme Scale runtime environment calls the isInitialized() method to ensure that the method successfully completed the appropriate initialization.

Procedure

1. Implement the ObjectGridPlugin interface so that the ObjectGridPlugin plug-in receives notifications about significant eXtreme Scale events. Three main categories of methods exist:

Properties methods	Purpose
setObjectGrid()	Called to set the ObjectGrid instance the plug-in is used for.
getObjectGrid()	Called to get or confirm the ObjectGrid instance the plug-in is used for.

Initialization methods	Purpose
initialize()	Called to initialize the ObjectGridPlugin.
isInitialized()	Called to get or confirm the initialization status of the plug-in.

Destruction methods	Purpose
destroy()	Called to destroy the ObjectGridPlugin.
isDestroyed()	Called to get or confirm the destroyed status of the plug-in.

   See the API documentation for more information about these interfaces.

2. Configure an ObjectGridPlugin plug-in with XML. Use the com.company.org.MyObjectGridPluginTxCallback class, which implements the TransactionCallback interface and the ObjectGridPlugin interface.
   In the following code example, the custom transaction callback, which will ultimately receive extended life cycle events, is generated and added to an ObjectGrid.
   Important: The TransactionCallback interface already has an initialize method, a new initialize method is added as well as the destroy method and other ObjectGridPlugin methods. Each method is used, and the initialize methods only perform initialization one time. The following XML creates a configuration that uses the enhanced TransactionCallback interface.
   The following text must be in the myGrid.xml file:

```
?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txsobjgridplug_TransactionCallba
ck"
                  className="com.company.org.MyObjectGridPluginTxCallback" />
            <backingMap name="Book"/>
        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

   Notice the bean declarations come before the `backingMap` declarations.

3. Provide the myGrid.xml file to the ObjectGridManager plug-in to facilitate the creation of this configuration.

../com.ibm.websphere.extremescale.javadoc.doc/topics/com/ibm/websphere/objectgrid/management/package-summary.html

Writing a BackingMapPlugin plug-in

A BackingMap plug-in implements the BackingMapPlugin mix-in interface, which you can use to receive extended capabilities for managing its life cycle.

About this task

Any existing BackingMap plug-in that also implements the BackingMapPlugin interface will automatically receive the extended set of lifecycle events during its construction and use.

The BackingMapPlugin interface provides methods to set or modify the state of the plug-in, as well as methods to introspect the current state of the plug-in.

All methods must be implemented correctly, and the WebSphere® eXtreme Scale runtime environment verifies the method behavior under certain circumstances. For example, after calling the initialize() method, the eXtreme Scale runtime environment calls the isInitialized() method to ensure that the method successfully completed the appropriate initialization.

Procedure

1. Implement the BackingMapPlugin interface so that the BackingMapPlugin plug-in receives notifications about significant eXtreme Scale events. Three main categories of methods exist:

Properties methods	Purpose
setBackingMap()	Called to set the BackingMap instance the plug-in is used for.
getBackingMap()	Called to get or confirm the BackingMap instance the plug-in is used for.

Initialization methods	Purpose
initialize()	Called to initialize the BackingMapPlugin plug-in.
isInitialized()	Called to get or confirm the initialization status of the plug-in.

Destruction methods	Purpose
destroy()	Called to destroy the BackingMapPlugin plug-in.
isDestroyed()	Called to get or confirm the destroyed status of the plug-in.

See the API documentation for more information about these interfaces.

2. Configure a BackingMapPlugin plug-in with XML. Assume that the class name of an eXtreme Scale Loader plug-in is the com.company.org.MyBackingMapPluginLoader class, which implements the Loader interface and the BackingMapPlugin interface.
In the following code example, the custom transaction callback, which will ultimately receive extended life cycle events, is generated and added to a BackingMap.

   You can also configure a BackingMapPlugin plug-in using XML. The following text must be in the myGrid.xml file:

```
<?xml version="1.0" encoding="UTF-8" ?>
<objectGridconfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xsi:schemaLocation="http://ibm.com/ws/objectgrid/config../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <backingMap name="Book" pluginCollectionRef="myPlugins" />
        </objectGrid>
    </objectGrids>
    <backingMapPluginCollections>
        <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txsbackmapplug_myPlugins">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txsbackmapplug_Loader"
                  className="com.company.org.MyBackingMapPluginLoader" />
        </backingMapPluginCollection>
    </backingMapPluginCollections>
</objectGridConfig>
```

3. Provide the myGrid.xml file to the ObjectGridManager plug-in to facilitate the creation of this configuration.

Results

The BackingMap instance that is created has a Loader that receives BackingMapPlugin life cycle events.

Plug-ins for multimaster replication

Consider transforming cached objects to increase the performance of your cache. You can use the ObjectTransformer plug-in when your processor usage is high. Up to 60-70 percent of the total processor time is spent serializing and copying entries. By implementing the ObjectTransformer plug-in, you can serialize and deserialize objects with your own implementation. You can use a CollisionArbiter plug-in to define how change collisions are handled in your domains.

- Developing custom arbiters for multi-master replication
  Change collisions might occur if the same records can be changed simultaneously in two places. In a multi-master replication topology, catalog service domains detect collisions automatically. When a catalog service domain detects a collision, it invokes an arbiter. Typically, collisions are resolved with the default collision arbiter. However, an application can provide a custom collision arbiter.

Developing custom arbiters for multi-master replication

Change collisions might occur if the same records can be changed simultaneously in two places. In a multi-master replication topology, catalog service domains detect collisions automatically. When a catalog service domain detects a collision, it invokes an arbiter. Typically, collisions are resolved with the default collision arbiter. However, an application can provide a custom collision arbiter.

Before you begin

- See Planning multiple data center topologies for more information about planning and designing the multi-master replication topology.
- See Configuring multiple data center topologies for more information about setting up links between catalog service domains.

About this task

If a catalog service domain receives a replicated entry that collides with a collision record, the default arbiter uses the changes from the lexically lowest named catalog service domain. For example, if domain A and B generate a conflict for a record, then the change from domain B is ignored. Domain A keeps its version and the record in domain B is changed to match the record from domain A. Domain names are converted to uppercase for comparison.

An alternative option is for the multi-master replication topology to call on a custom collision plug-in to decide the outcome. These instructions outline how to develop a custom collision arbiter and configure a multi-master replication topology to use it.

Procedure

1. Develop a custom collision arbiter and integrate it into your application.
   The class must implement the interface:

   ```
   com.ibm.websphere.objectgrid.revision.CollisionArbiter
   ```

   A collision plug-in has three choices for deciding the outcome of a collision. It can choose the local copy or the remote copy or it can provide a revised version of the entry. A catalog service domain provides the following information to a custom collision arbiter:
   - The existing version of the record
   - The collision version of the record
   - A Session object that must be used to create the revised version of the collided entry

   The plug-in method returns an object that indicates its decision. The method invoked by the domain to call the plug-in must return true or false, where false means to ignore the collision. When the collision is ignored, the local version remains unchanged and the arbiter forgets that it ever saw the existing version. The method returns a true value if the method used the provided session to create a new, merged version of the record, reconciling the change.
2. In the objectgrid.xml file, specify the custom arbiter plug-in.
   The ID must be `CollisionArbiter`.

   ```
   <dgc:objectGrid name="revisionGrid" txTimeout="10">
          <dgc:bean className="com.you.your_application.
                                                 CustomArbiter"
   id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txsmultimasterprog_CollisionArbi
   ter">
                  <dgc:property name="property" type="java.lang.String"
                                                 value="propertyValue"/>
          </dgc:bean>
   </dgc:objectGrid>
   ```

Plug-ins for versioning and comparing cache objects

Use the OptimisticCallback plug-in to customize versioning and comparison operations of cache objects when you are using the optimistic locking strategy.

You can provide a pluggable optimistic callback object that implements the com.ibm.websphere.objectgrid.plugins.OptimisticCallback interface. For entity maps, a high performance OptimisticCallback plug-in is automatically configured.

Purpose

Use the OptimisticCallback interface to provide optimistic comparison operations for the values of a map. An OptimisticCallback plug-in is required when you use the optimistic locking strategy. The product provides a default OptimisticCallback implementation. However, typically your application must plug in its own implementation of the OptimisticCallback interface.

Default implementation

The eXtreme Scale framework provides a default implementation of the OptimisticCallback interface that is used if the application does not plug in an application-provided OptimisticCallback object. The default implementation always returns the special value of NULL_OPTIMISTIC_VERSION as the version object for the value and never updates the version object. This action makes optimistic comparison a "no operation" function. In most cases, you do not want the "no operation" function to occur when you are using the optimistic locking strategy. Your applications must implement the OptimisticCallback interface and plug in their own OptimisticCallback implementations so that the default implementation is not used. However, at least one scenario exists where the default provided OptimisticCallback implementation is useful. Consider the following situation:

- A loader is plugged in for the backing map.
- The loader knows how to perform the optimistic comparison without assistance from an OptimisticCallback plug-in.

How can the loader perform optimistic versioning without assistance from an OptimisticCallback object? The loader has knowledge of the value class object and knows which field of the value object is used as an optimistic versioning value. For example, suppose the following interface is used for the value object for the employees map:

```
public interface Employee
{
    // Sequential sequence number used for optimistic versioning.
    public long getSequenceNumber();
    public void setSequenceNumber(long newSequenceNumber);
    // Other get/set methods for other fields of Employee object.
}
```

In this example, the loader knows that it can use the getSequenceNumber method to get the current version information for an Employee value object. The loader increments the returned value to generate a new version number before it updates the persistent storage with the new Employee value. For a Java™ database connectivity (JDBC) loader, the current sequence number in the WHERE clause of an overqualified SQL UPDATE statement is used, and it uses the new generated sequence number to set the sequence number column to the new sequence number value. Another possibility is that the loader makes use of some backend-provided function that automatically updates a hidden column that can be used for optimistic versioning.

In some situations, a stored procedure or trigger can possibly be used to help maintain a column that holds versioning information. If the loader is using one of these techniques for maintaining optimistic versioning information, then the application does not need to provide an OptimisticCallback implementation. The default OptimisticCallback implementation is usable in this scenario because the loader can handle optimistic versioning without any assistance from an OptimisticCallback object.

Default implementation for entities

Entities are stored in the ObjectGrid using tuple objects. The default OptimisticCallback implementation behavior is similar to the behavior for non-entity maps. However, the version field in the entity is identified using the @Version annotation or the version attribute in the entity descriptor XML file.

The version attribute can be of the following types: int, Integer, short, Short, long, Long or java.sql.Timestamp. An entity must only have one version attribute defined. Only set the version attribute during construction. After the entity is persisted, the value of the version attribute should not be modified.

If a version attribute is not configured and the optimistic locking strategy is used, then the entire tuple is implicitly versioned using the entire state of the tuple, which is much more expensive

In the following example, the Employee entity has a long version attribute named SequenceNumber:

```
@Entity
public class Employee
{
private long sequence;
    // Sequential sequence number used for optimistic versioning.
    @Version
    public long getSequenceNumber() {
        return sequence;
    }
    public void setSequenceNumber(long newSequenceNumber) {
        this.sequence = newSequenceNumber;
    }
    // Other get/set methods for other fields of Employee object.
}
```

Writing an OptimisticCallback plug-in

An OptimisticCallback plug-in must to implement the OptimisticCallback interface and follow the common ObjectGrid plug-in conventions. See OptimisticCallback interface for more information.

The following list provides a description or consideration for each of the methods in the OptimisticCallback interface:

NULL_OPTIMISTIC_VERSION

This special value is returned by the getVersionedObjectForValue method if the OptimisticCallback implementation does not require version checking. The built-in plugin implementation of the com.ibm.websphere.objectgrid.plugins.builtins.NoVersioningOptimisticCallback class uses this value because versioning is disabled when you are specifying this plug-in implementation.

getVersionedObjectForValue method

The getVersionedObjectForValue method might return a copy of the value or an attribute of the value that can be used for versioning purposes. This method is called whenever an object is associated with a transaction. When no Loader is plugged into a backing map, the backing map uses this value at commit time to perform an optimistic version comparison. The optimistic version comparison is used by the backing map to ensure that the version has not changed after this transaction first accessed the map entry that was modified by this transaction. If another transaction had already modified the version for this map entry, the version comparison fails and the backing map displays an OptimisticCollisionException exception to force the transaction to roll back. If a Loader is plugged in, the backing map does not use the optimistic versioning information. Instead, the Loader is responsible for performing the optimistic versioning comparison and updating the versioning information when necessary. The Loader typically gets the initial versioning object from the LogElement passed to the batchUpdate method on the loader, which is called when a flush operation occurs or a transaction is committed.

The following code shows the implementation used by the EmployeeOptimisticCallbackImpl object:

```
public Object getVersionedObjectForValue(Object value)
{
    if (value == null)
    {
        return null;
    }
    else
```

```
    {
        Employee emp = (Employee) value;
        return new Long( emp.getSequenceNumber() );
    }
}
```

As demonstrated in the previous example, the sequenceNumber attribute is returned in a java.lang.Long object as expected by the Loader, which implies that the same person that wrote the Loader either wrote the EmployeeOptimisticCallbackImpl implementation or worked closely with the person that implemented the EmployeeOptimisticCallbackImpl - for example, agreed on the value returned by the getVersionedObjectForValue method. The default OptimisticCallback plug-in returns the special value NULL_OPTIMISTIC_VERSION as the version object.

updateVersionedObjectForValue method

This method is called whenever a transaction has updated a value and a new versioned object is needed. If the getVersionedObjectForValue method returns an attribute of the value, this method typically updates the attribute value with a new version object. If getVersionedObjectForValue method returns a copy of the value, this method typically does not complete any actions. The default OptimisticCallback plug-in does not complete any actions with this method because the default implementation of getVersionedObjectForValue always returns the special value NULL_OPTIMISTIC_VERSION as the version object. The following example shows the implementation used by the EmployeeOptimisticCallbackImpl object that is used in the OptimisticCallback section:

```
public void updateVersionedObjectForValue(Object value)
{
    if ( value != null )
    {
        Employee emp = (Employee) value;
        long next = emp.getSequenceNumber() + 1;
        emp.updateSequenceNumber( next );
    }
}
```

As demonstrated in the previous example, the sequenceNumber attribute increments by one so that the next time the getVersionedObjectForValue method is called, the java.lang.Long value that is returned has a long value that is the original sequence number value plus one, for example, is the next version value for this employee instance. This example implies that the same person that wrote the Loader either wrote EmployeeOptimisticCallbackImpl or worked closely with the person that implemented the EmployeeOptimisticCallbackImpl.

serializeVersionedValue method

This method writes the versioned value to the specified stream. Depending on the implementation, the versioned value can be used to identify optimistic update collisions. In some implementations, the versioned value is a copy of the original value. Other implementations might have a sequence number or some other object to indicate the version of the value. Because the actual implementation is unknown, this method is provided to perform the appropriate serialization. The default implementation calls the writeObject method.

inflateVersionedValue method

This method takes the serialized version of the versioned value and returns the actual versioned value object. Depending on the implementation, the versioned value can be used to identify optimistic update collisions. In some implementations, the versioned value is a copy of the original value. Other implementations might have a sequence number or some other object to indicate the version of the value. Because the actual implementation is unknown, this method is provided to perform the appropriate deserialization. The default implementation calls the readObject method.

Using application-provided OptimisticCallback object

You have two approaches to add an application-provided OptimisticCallback object into the BackingMap configuration: XML configuration and programmatic configuration.

Programmatically plug in an OptimisticCallback object

The following example demonstrates how an application can programmatically plug in an OptimisticCallback object for the employee backing map in the local grid1 ObjectGrid instance:

```
import com.ibm.websphere.objectgrid.ObjectGridManagerFactory;
import com.ibm.websphere.objectgrid.ObjectGridManager;
import com.ibm.websphere.objectgrid.ObjectGrid;
import com.ibm.websphere.objectgrid.BackingMap;
ObjectGridManager ogManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid og = ogManager.createObjectGrid( "grid1" );
BackingMap bm = dg.defineMap("employees");
EmployeeOptimisticCallbackImpl cb = new EmployeeOptimisticCallbackImpl();
bm.setOptimisticCallback( cb );
```

XML configuration approach to plug in an OptimisticCallback object

The application can use an XML file to plug in its OptimisticCallback object as shown in the following example:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
<objectGrids>
    <objectGrid name="grid1">
```

```
        <backingMap name="employees" pluginCollectionRef="employees" lockStrategy="OPTIMISTIC" />
    </objectGrid>
</objectGrids>

<backingMapPluginCollections>
    <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugcall_employees">
        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugcall_OptimisticCallback"
className="com.xyz.EmployeeOptimisticCallbackImpl" />
    </backingMapPluginCollection>
</backingMapPluginCollections>
</objectGridConfig>
```

Plug-ins for serializing cached objects

WebSphere® eXtreme Scale uses multiple Java processes to serialize the data, by converting the Java object instances to bytes and back to objects again, as needed, to move the data between client and server processes.

To serialize data in eXtreme Scale, you can use Java serialization, the ObjectTransformer plug-in, or the DataSerializer plug-ins.

The ObjectTransformer interface has been replaced by the DataSerializer plug-ins, which you can use to efficiently store arbitrary data in WebSphere eXtreme Scale so that existing product APIs can efficiently interact with your data.

- Serializer programming overview
  You can use the DataSerializer plug-ins to write optimized serializers for storing Java objects and other data in binary form in the grid. The plug-in also provides methods that you can use to query attributes within the binary data without requiring the entire data object to be inflated.
- Avoiding object inflation when updating and retrieving cache data
  You can use the DataSerializer plug-ins to bypass automatic object inflation and manually retrieve attributes from data that has already been serialized. You can also use the DataSerializer to insert and update data in its serialized form. This usage can be useful when only part of the data needs to be accessed or when the data needs to be passed between systems.
- ObjectTransformer plug-in
  With the ObjectTransformer plug-in, you can serialize, deserialize, and copy objects in the cache for increased performance.

Serializer programming overview

You can use the DataSerializer plug-ins to write optimized serializers for storing Java™ objects and other data in binary form in the grid. The plug-in also provides methods that you can use to query attributes within the binary data without requiring the entire data object to be inflated.

The DataSerializer plug-ins include three main plug-ins and several optional mix-in interfaces. The MapSerializerPlugin plug-in includes metadata about the relationship between a map and other maps. It also includes a reference to a KeySerializerPlugin and ValueSerializerPlugin. The key and value serializer plug-ins include metadata and serialization code responsible for interacting with the respective key and value data for a map. A MapSerializerPlugin plug-in must include one or both key and value serializers.

The KeySerializerPlugin plug-in provides methods and metadata for serializing, inflating and introspecting keys. The ValueSerializer plug-in provides methods and metadata for serializing, inflating and introspecting values. Both interfaces have different requirements. For details on what methods are available on the DataSerializer plug-ins, see the API documentation for the com.ibm.websphere.objectgrid.plugins.io package.

MapSerializerPlugin plug-in
: The MapSerializerPlugin is the main plug-in point to the BackingMap interface, and it includes two nested plug-ins: the KeySerializerPlugin and ValueSerializerPlugin plug-ins. Since eXtreme Scale does not support nested or wired plug-ins, the BasicMapSerializerPlugin plug-in accesses these nested plug-ins artificially. When you use these plug-ins with the OSGi framework, the only proxy is the MapSerializerPlugin plug-in. All nested plug-ins must not be cached within other dependent plug-ins, such as loaders, unless those plug-ins also listen for BackingMap life cycle events. This is important when running in an OSGi framework, because references to those plug-ins can continue to be refreshed.

KeySerializerPlugin plug-in
: The KeySerializerPlugin plug-in extends the DataSerializer interface and includes other mix-in interfaces and metadata that describes the key. Use this plug-in to serialize and inflate key data objects and attributes.

ValueSerializerPlugin plug-in
: The ValueSerializerPlugin plug-in extends the DataSerializer interface, but exposes no additional methods. Use this plug-in to serialize and inflate value data objects and attributes.

Optional and mix-in interfaces

Optional and mix-in interfaces provide additional capabilities, such as:

Optimistic versioning
: The Versionable interface allows the ValueSerializerPlugin plug-in to handle version checking and version updates when using optimistic locking. If the Versioning is not implemented and optimistic locking is enabled, then the version is the entire serialized form of the data object value.

Non-hashCode-based routing
: The Partitionable interface allows KeySerializerPlugin implementations to route requests to explicit partitions. This is equivalent to the PartitionableKey interface, when used with the ObjectMap API without a KeySerializerPlugin. Without this feature, the key is routed to the partition based on the resulting hashCode.

UserReadable (toString) interface
: The UserReadable (toString) interface allows all DataSerializer implementations to provide an alternative method to display data in log files and debuggers. With this capability, you can hide sensitive data such as passwords. If DataSerializer implementations do not implement this interface, then the runtime environment might call toString() directly on the object or include alternative representations, if appropriate.

Evolution support
: The Mergeable interface can be implemented on ValueSerializerPlugin plug-in implementations to allow interoperability between multiple versions of objects when there are different DataSerializer versions updating data in the grid through it's lifetime. The Mergeable methods allow the DataSerializer plug-in to retain any data that it might not otherwise understand.

Avoiding object inflation when updating and retrieving cache data

You can use the DataSerializer plug-ins to bypass automatic object inflation and manually retrieve attributes from data that has already been serialized. You can also use the DataSerializer to insert and update data in its serialized form. This usage can be useful when only part of the data needs to be accessed or when the data needs to be passed between systems.

About this task

This task uses the COPY_TO_BYTES_RAW copy mode with the MapSerializerPlugin and ValueSerializerPlugin plug-ins. The MapSerializer is the main plug-in point to the BackingMap interface. It includes two nested plug-ins, the KeyDataSerializer and ValueDataSerializer. Since the product does not support nested plug-ins, the BaseMapSerializer supports nested or wired plug-ins artificially. Therefore, when you use these APIs in the OSGi container, the MapSerializer is the only proxy. All nested plug-ins must not be cached within other dependent plug-ins, such as a loader, unless it also listens for BackingMap life cycle events, so that it can refresh its supporting references.

When COPY_TO_BYTES_RAW is set, all ObjectMap methods return SerializedValue objects, allowing the user to retrieve the serialized form or the Java object form of the value.

When using a KeySerializerPlugin plug-in, all methods that return keys, such as the MapIndexPlugin or Loader plug-ins return SerializedKey objects.

When the data is already in serialized form, the data is inserted using the same SerializedKey and SerializedValue objects. When the data is in byte[] format, the DataObjectKeyFactory and DataObjectValueFactory factories are used to create the appropriate key or value wrapper. The factories are available on the DataObjectContext, which can be accessed from the SerializerAccessor for the BackingMap, or from within the DataSerializer implementation.

The example in this topic demonstrates how to complete the following actions:

Procedure

1. Use the DataSerializer plug-ins to serialize and inflate data objects.
2. Retrieve serialized values.
3. Retrieve individual attributes from a serialized value.
4. Insert pre-serialized keys and values.

Example

Use this example to update and retrieve cache data:

```
import java.io.IOException;
import com.ibm.websphere.objectgrid.CopyMode;
import com.ibm.websphere.objectgrid.ObjectGrid;
import com.ibm.websphere.objectgrid.ObjectGridException;
import com.ibm.websphere.objectgrid.ObjectMap;
import com.ibm.websphere.objectgrid.Session;
import com.ibm.websphere.objectgrid.io.XsDataOutputStream;
import com.ibm.websphere.objectgrid.plugins.io.SerializerAccessor;
import com.ibm.websphere.objectgrid.plugins.io.ValueSerializerPlugin;
import com.ibm.websphere.objectgrid.plugins.io.dataobject.DataObjectContext;
import com.ibm.websphere.objectgrid.plugins.io.dataobject.SerializedKey;
import com.ibm.websphere.objectgrid.plugins.io.dataobject.SerializedValue;

    /**
     * Use the DataSerializer to serialize an Order key.
     */
    public byte[] serializeOrderKey(ObjectGrid grid, String key)
            throws IOException {
        SerializerAccessor sa = grid.getMap("Order").getSerializerAccessor();
        DataObjectContext dftObjCtx = sa.getDefaultContext();
        XsDataOutputStream out = dftObjCtx.getDataStreamManager()
                .createOutputStream();
        sa.getMapSerializerPlugin().getKeySerializerPlugin()
                .serializeDataObject(sa.getDefaultContext(), key, out);
        return out.toByteArray();
    }

    /**
     * Use the DataSerializer to serialize an Order value.
     */
    public byte[] serializeOrderValue(ObjectGrid grid, Order value)
            throws IOException {
        SerializerAccessor sa = grid.getMap("Order").getSerializerAccessor();
        DataObjectContext dftObjCtx = sa.getDefaultContext();
        XsDataOutputStream out = dftObjCtx.getDataStreamManager()
                .createOutputStream();
        sa.getMapSerializerPlugin().getValueSerializerPlugin()
                .serializeDataObject(sa.getDefaultContext(), value, out);
        return out.toByteArray();
    }

    /**
     * Retrieve a single Order in serialized form.
     */
    public byte[] fetchOrderRAWBytes(Session session, String key)
            throws ObjectGridException {
        ObjectMap map = session.getMap("Order");

        // Override the CopyMode to retrieve the serialized form of the value.
        // This process affects all API methods from this point on for the life
        // of the Session.
        map.setCopyMode(CopyMode.COPY_TO_BYTES_RAW, null);
        SerializedValue serValue = (SerializedValue) map.get(key);

        if (serValue == null)
            return null;

        // Retrieve the byte array and return it to the caller.
        return serValue.getInputStream().toByteArray();
    }

    /**
     * Retrieve one or more attributes from the Order without inflating the
     * Order object.
     */
    public Object[] fetchOrderAttribute(Session session, String key,
            String... attributes) throws ObjectGridException, IOException {
        ObjectMap map = session.getMap("Order");

        // Override the CopyMode to retrieve the serialized form of the value.
        // This process affects all API methods from this point on for the life
        // of the Session.
        map.setCopyMode(CopyMode.COPY_TO_BYTES_RAW, null);
        SerializedValue serValue = (SerializedValue) map.get(key);

        if (serValue == null)
            return null;

        // Retrieve a single attribute from the byte buffer.
```

```
        ValueSerializerPlugin valSer = session.getObjectGrid()
                .getMap(map.getName()).getSerializerAccessor()
                .getMapSerializerPlugin().getValueSerializerPlugin();
        Object attrCtx = valSer.getAttributeContexts(attributes);
        return valSer.inflateDataObjectAttributes(serValue.getContext(),
                serValue.getInputStream(), attrCtx);
    }

    /**
     * Inserts a pre-serialized key and value into the Order map.
     */
    public void insertRAWOrder(Session session, byte[] key, byte[] value)
            throws ObjectGridException {
        ObjectMap map = session.getMap("Order");

        // Get a referece to the default DataObjectContext for the map.
        DataObjectContext dftDtaObjCtx = session.getObjectGrid()
                .getMap(map.getName()).getSerializerAccessor()
                .getDefaultContext();

        // Wrap the key and value in a SerializedKey and SerializedValue
        // wrapper.
        SerializedKey serKey = dftDtaObjCtx.getKeyFactory().createKey(key);
        SerializedValue serValue = dftDtaObjCtx.getValueFactory().createValue(
                value);

        // Insert the serialized form of the key and value.
        map.insert(serKey, serValue);
    }
}
```

ObjectTransformer plug-in

With the ObjectTransformer plug-in, you can serialize, deserialize, and copy objects in the cache for increased performance.

The ObjectTransformer interface has been replaced by the DataSerializer plug-ins, which you can use to efficiently store arbitrary data in WebSphere® eXtreme Scale so that existing product APIs can efficiently interact with your data.

If you see performance issues with processor usage, add an ObjectTransformer plug-in to each map. If you do not provide an ObjectTransformer plug-in, up to 60-70 percent of the total processor time is spent serializing and copying entries.

Purpose

With the ObjectTransformer plug-in, your applications can provide custom methods for the following operations:

- Serialize or deserialize the key for an entry
- Serialize or deserialize the value for an entry
- Copy a key or value for an entry

If no ObjectTransformer plug-in is provided, you must be able to serialize the keys and values because the ObjectGrid uses a serialize and deserialize sequence to copy the objects. This method is expensive, so use an ObjectTransformer plug-in when performance is critical. The copying occurs when an application looks up an object in a transaction for the first time. You can avoid this copying by setting the copy mode of the Map to NO_COPY or reduce the copying by setting the copy mode to COPY_ON_READ. Optimize the copy operation when needed by the application by providing a custom copy method on this plug-in. Such a plug-in can reduce the copy overhead from 65–70 percent to 2/3 percent of total processor time.

The default copyKey and copyValue method implementations first attempt to use the clone method, if the method is provided. If no clone method implementation is provided, the implementation defaults to serialization.

Object serialization is also used directly when the eXtreme Scale is running in distributed mode. The LogSequence uses the ObjectTransformer plug-in to help serialize keys and values before transmitting the changes to peers in the ObjectGrid. You must take care when providing a custom serialization method instead of

using the built-in Java™ developer kit serialization. Object versioning is a complex issue and you might encounter problems with version compatibility if you do not ensure that your custom methods are designed for versioning.

The following list describes how the eXtreme Scale tries to serialize both keys and values:

- If a custom ObjectTransformer plug-in is written and plugged in, eXtreme Scale calls methods in the ObjectTransformer interface to serialize keys and values and get copies of object keys and values.
- If a custom ObjectTransformer plug-in is not used, eXtreme Scale serializes and deserializes values according to the default. If the default plug-in is used, each object is implemented as externalizable or is implemented as serializable.
  - If the object supports the Externalizable interface, the writeExternal method is called. Objects that are implemented as externalizable lead to better performance.
  - If the object does not support the Externalizable interface and does implement the Serializable interface, the object is saved using the ObjectOutputStream method.

Using the ObjectTransformer interface

An ObjectTransformer object must implement the ObjectTransformer interface and follow the common ObjectGrid plug-in conventions.

Two approaches, programmatic configuration and XML configuration, are used to add an ObjectTransformer object into the BackingMap configuration as follows.

Programmatically plug in an ObjectTransformer object

The following code snippet creates the custom ObjectTransformer object and adds it to a BackingMap:

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid myGrid = objectGridManager.createObjectGrid("myGrid", false);
BackingMap backingMap = myGrid.getMap("myMap");
MyObjectTransformer myObjectTransformer = new MyObjectTransformer();
backingMap.setObjectTransformer(myObjectTransformer);
```

XML configuration approach to plug in an ObjectTransformer

Assume that the class name of the ObjectTransformer implementation is the com.company.org.MyObjectTransformer class. This class implements the ObjectTransformer interface. An ObjectTransformer implementation can be configured using the following XML:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <backingMap name="myMap" pluginCollectionRef="myMap" />
        </objectGrid>
    </objectGrids>

    <backingMapPluginCollections>
        <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugobjtrans_2_myMap">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugobjtrans_2_ObjectTransformer"
className="com.company.org.MyObjectTransformer" />
        </backingMapPluginCollection>
    </backingMapPluginCollections>
</objectGridConfig>
```

ObjectTransformer usage scenarios

You can use the ObjectTransformer plug-in in the following situations:

- Non-serializable object
- Serializable object but improve serialization performance
- Key or value copy

In the following example, ObjectGrid is used to store the Stock class:

```
/**
* Stock object for ObjectGrid demo
*
*
*/
public class Stock implements Cloneable {
    String ticket;
    double price;
    String company;
    String description;
    int serialNumber;
    long lastTransactionTime;
    /**
    * @return Returns the description.
    */
    public String getDescription() {
        return description;
```

```
    }
    /**
    * @param description The description to set.
    */
    public void setDescription(String description) {
        this.description = description;
    }
    /**
    * @return Returns the lastTransactionTime.
    */
    public long getLastTransactionTime() {
        return lastTransactionTime;
    }
    /**
    * @param lastTransactionTime The lastTransactionTime to set.
    */
    public void setLastTransactionTime(long lastTransactionTime) {
        this.lastTransactionTime = lastTransactionTime;
    }
    /**
    * @return Returns the price.
    */
    public double getPrice() {
        return price;
    }
    /**
    * @param price The price to set.
    */
    public void setPrice(double price) {
        this.price = price;
    }
    /**
    * @return Returns the serialNumber.
    */
    public int getSerialNumber() {
        return serialNumber;
    }
    /**
    * @param serialNumber The serialNumber to set.
    */
    public void setSerialNumber(int serialNumber) {
        this.serialNumber = serialNumber;
    }
    /**
    * @return Returns the ticket.
    */
    public String getTicket() {
        return ticket;
    }
    /**
    * @param ticket The ticket to set.
    */
    public void setTicket(String ticket) {
        this.ticket = ticket;
    }
    /**
    * @return Returns the company.
    */
    public String getCompany() {
        return company;
    }
    /**
    * @param company The company to set.
    */
    public void setCompany(String company) {
        this.company = company;
    }
    //clone
    public Object clone() throws CloneNotSupportedException
    {
        return super.clone();
    }
}
```

You can write a custom object transformer class for the Stock class:

```
/**
* Custom implementation of ObjectGrid ObjectTransformer for stock object
*
*/
public class MyStockObjectTransformer implements ObjectTransformer {
/* (non-Javadoc)
* @see
* com.ibm.websphere.objectgrid.plugins.ObjectTransformer#serializeKey
* (java.lang.Object,
* java.io.ObjectOutputStream)
*/
public void serializeKey(Object key, ObjectOutputStream stream) throws IOException {
    String ticket= (String) key;
    stream.writeUTF(ticket);
}
```

```
/* (non-Javadoc)
* @see com.ibm.websphere.objectgrid.plugins.
ObjectTransformer#serializeValue(java.lang.Object,
java.io.ObjectOutputStream)
*/
public void serializeValue(Object value, ObjectOutputStream stream) throws IOException {
    Stock stock= (Stock) value;
    stream.writeUTF(stock.getTicket());
    stream.writeUTF(stock.getCompany());
    stream.writeUTF(stock.getDescription());
    stream.writeDouble(stock.getPrice());
    stream.writeLong(stock.getLastTransactionTime());
    stream.writeInt(stock.getSerialNumber());
}

/* (non-Javadoc)
* @see com.ibm.websphere.objectgrid.plugins.
ObjectTransformer#inflateKey(java.io.ObjectInputStream)
*/
public Object inflateKey(ObjectInputStream stream) throws IOException, ClassNotFoundException {
    String ticket=stream.readUTF();
    return ticket;
}

/* (non-Javadoc)
* @see com.ibm.websphere.objectgrid.plugins.
ObjectTransformer#inflateValue(java.io.ObjectInputStream)
*/

public Object inflateValue(ObjectInputStream stream) throws IOException,        ClassNotFoundException {
    Stock stock=new Stock();
    stock.setTicket(stream.readUTF());
    stock.setCompany(stream.readUTF());
    stock.setDescription(stream.readUTF());
    stock.setPrice(stream.readDouble());
    stock.setLastTransactionTime(stream.readLong());
    stock.setSerialNumber(stream.readInt());
    return stock;
}

/* (non-Javadoc)
* @see com.ibm.websphere.objectgrid.plugins.
ObjectTransformer#copyValue(java.lang.Object)
*/
public Object copyValue(Object value) {
    Stock stock = (Stock) value;
    try {
        return stock.clone();
    }
    catch (CloneNotSupportedException e)
    {
        // display exception message    }
}

/* (non-Javadoc)
* @see com.ibm.websphere.objectgrid.plugins.
ObjectTransformer#copyKey(java.lang.Object)
*/
public Object copyKey(Object key) {
    String ticket=(String) key;
    String ticketCopy= new String (ticket);
    return ticketCopy;
}
}
```

Then, plug in this custom MyStockObjectTransformer class into the BackingMap:

```
ObjectGridManager ogf=ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid og = ogf.getObjectGrid("NYSE");
BackingMap bm = og.defineMap("NYSEStocks");
MyStockObjectTransformer ot = new MyStockObjectTransformer();
bm.setObjectTransformer(ot);
```

Plug-ins for providing event listeners

You can use the ObjectGridEventListener, MapEventListener, ObjectGridLifecycleListener and BackingMapLifecycleListener plug-ins to configure notifications for various events in the eXtreme Scale cache. Listener plug-ins are registered with an ObjectGrid or BackingMap instance like other eXtreme Scale plug-ins and add integration and customization points for applications and cache providers.

ObjectGridEventListener plug-in

An ObjectGridEventListener plug-in provides eXtreme Scale life cycle events for the ObjectGrid instance, shards, and transactions. Use the ObjectGridEventListener plug-in to receive notifications when significant events occur on an ObjectGrid. These events include ObjectGrid initialization, the beginning of a transaction, the ending a transaction, and destroying an ObjectGrid. To listen for these events, create a class that implements the ObjectGridEventListener interface and add it to the eXtreme Scale.
For more information about writing an ObjectGridEventListener plug-in, see ObjectGridEventListener plug-in. You can also refer to the API documentation for more information.

Adding and removing ObjectGridEventListener instances

An ObjectGrid can have multiple ObjectGridEventListener listeners. Add and remove the listeners using the addEventListener, and removeEventListener methods on the ObjectGrid interface. You can also declaratively registerObjectGridEventListener plug-ins with the ObjectGrid descriptor file. For examples, see ObjectGridEventListener plug-in.

MapEventListener plug-in

A MapEventListener plug-in provides callback notifications and significant cache state changes that occur for a BackingMap instance. For details on writing a MapEventListener plug-in, see MapEventListener plug-in. You can also refer to the API documentation for more information.
Adding and removing MapEventListener instances

An eXtreme Scale can have multiple MapEventListener listeners. Add and remove listeners with the addMapEventListener, and removeMapEventListener methods on the BackingMap interface. You can also declaratively register MapEventListener listeners with the ObjectGrid descriptor file. For examples, see MapEventListener plug-in.

BackingMapLifecycleListener plug-in

A BackingMapLifecycleListener plug-in provides callback notifications for life cycle state changes that occur for a BackingMap instance. The BackingMap instance proceeds through a predefined set of states during its life time.
Adding and removing BackingMapLifecycleListener instances

An eXtreme Scale server can have multiple BackingMapLifecycleListener listeners. Add and remove listeners with the addMapEventListener and removeMapEventListener methods on the BackingMap interface. Any BackingMap plug-ins that implement the BackingMapLifecycleListener interface are also automatically added as a BackingMapLifecycleListener for the ObjectGrid instance they are registered with. You can also declaratively register BackingMapLifecycleListener listeners with the ObjectGrid descriptor file. For examples, see BackingMapLifecycleListener plug-in.

ObjectGridLifecycleListener plug-in

An ObjectGridLifecycleListener plug-in provides callback notifications for life cycle state changes that occur for an ObjectGrid instance. The ObjectGrid instance proceeds through a predefined set of states during its life time.
Adding and removing ObjectGridLifecycleListener instances

An eXtreme Scale can have multiple ObjectGridLifecycleListener listeners. Add and remove listeners with the addEventListener and removeEventListener methods on the ObjectGrid interface. Any ObjectGrid plug-ins that implement the ObjectGridLifecycleListener interface are automatically added as an ObjectGridLifecycleListener for the ObjectGrid instance that they are registered with. You can also declaratively register ObjectGridLifecycleListener listeners with the ObjectGrid deployment descriptor file. For examples, see ObjectGridLifecycleListener plug-in.

- MapEventListener plug-in
  A MapEventListener plug-in provides callback notifications and significant cache state changes that occur for a BackingMap object: when a map has finished pre-loading or when an entry is evicted from the map. A particular MapEventListener plug-in is a custom class you write implementing the MapEventListener interface.
- ObjectGridEventListener plug-in
  An ObjectGridEventListener plug-in provides WebSphere eXtreme Scale life cycle events for the ObjectGrid, shards and transactions. An ObjectGridEventListener plug-in provides notifications when an ObjectGrid is initialized or destroyed, and when a transaction is started or ended. ObjectGridEventListener plug-ins are custom classes you write implementing the ObjectGridEventListener interface. Optionally, the implementation includes ObjectGridEventGroup sub-interfaces and follow the common eXtreme Scale plug-in conventions.
- BackingMapLifecycleListener plug-in
  A BackingMapLifecycleListener plug-in receives notification of WebSphere eXtreme Scale life cycle state change events for the backing map.
- ObjectGridLifecycleListener plug-in
  An ObjectGridLifecycleListener plug-in receives notification of WebSphere eXtreme Scale life cycle, state change events for the data grid.

MapEventListener plug-in

A MapEventListener plug-in provides callback notifications and significant cache state changes that occur for a BackingMap object: when a map has finished pre-loading or when an entry is evicted from the map. A particular MapEventListener plug-in is a custom class you write implementing the MapEventListener interface.

MapEventListener plug-in conventions

When you develop a MapEventListener plug-in, you must follow common plug-in conventions. For more information about plug-in conventions, see Java plug-ins overview. For other types of listener plug-ins, see Plug-ins for providing event listeners.
After you write a MapEventListener implementation, you can plug it in to the BackingMap configuration programmatically or with an XML configuration.

Write a MapEventListener implementation

Your application can include an implementation of the MapEventListener plug-in. The plug-in must implement the MapEventListener interface to receive significant events about a map. Events are sent to the MapEventListener plug-in when an entry is evicted from the map and when the preload of a map completes.

Programmatically plug in a MapEventListener implementation

The class name for the custom MapEventListener is the com.company.org.MyMapEventListener class. This class implements the MapEventListener interface. The following code snippet creates the custom MapEventListener object and adds it to a BackingMap object:

```
ObjectGridManager objectGridManager =
        ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid myGrid = objectGridManager.createObjectGrid("myGrid", false);
BackingMap myMap = myGrid.defineMap("myMap");
MyMapEventListener myListener = new MyMapEventListener();
myMap.addMapEventListener(myListener);
```

Plug in a MapEventListener implementation using XML

A MapEventListner implementation can be configured using XML. The following XML must be in the myGrid.xml file:

```
<?xml version="1.0" encoding="UTF-8" ?>
<objectGridconfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xsi:schemaLocation="http://ibm.com/ws/objectgrid/config../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <backingMap name="myMap" pluginCollectionRef="myPlugins" />
        </objectGrid>
    </objectGrids>
    <backingMapPluginCollections>
        <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsmapeventlistplugin_myPlugins">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsmapeventlistplugin_MapEventListene
r" className=
                                                    "com.company.org.MyMapEventListener" />
        </backingMapPluginCollection>
    </backingMapPluginCollections>
</objectGridConfig>
```

Providing this file to the ObjectGridManager instance facilitates the creation of this configuration. The following code snippet shows how to create an ObjectGrid instance using this XML file. The newly created ObjectGrid instance has a MapEventListener set on the myMap BackingMap.

```
ObjectGridManager objectGridManager =
        ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid myGrid =
        objectGridManager.createObjectGrid("myGrid", new URL("file:etc/test/myGrid.xml"),
                true, false);
```

ObjectGridEventListener plug-in

An ObjectGridEventListener plug-in provides WebSphere® eXtreme Scale life cycle events for the ObjectGrid, shards and transactions. An ObjectGridEventListener plug-in provides notifications when an ObjectGrid is initialized or destroyed, and when a transaction is started or ended. ObjectGridEventListener plug-ins are custom classes you write implementing the ObjectGridEventListener interface. Optionally, the implementation includes ObjectGridEventGroup sub-interfaces and follow the common eXtreme Scale plug-in conventions.

Overview

An ObjectGridEventListener plug-in is useful when a Loader plug-in is available, and you must initialize Java™ Database Connectivity (JDBC) connections or connections to a back end when transactions start and end. Typically, an ObjectGridEventListener plug-in and a Loader plug-in are written together.

Writing an ObjectGridEventListener plug-in

An ObjectGridEventListener plug-in must implement the ObjectGridEventListener interface to receive notifications about significant eXtreme Scale events. To receive additional event notifications, you can implement the following interfaces. These sub-interfaces are included in the ObjectGridEventGroup interface:

- ShardEvents interface
- ShardLifecycle interface
- TransactionEvents interface

For more information about these interfaces, see the API documentation.

Shard events

When the catalog service places partition primary or replica shards in a Java virtual machine (JVM), a new ObjectGrid instance is created in that JVM to host that shard. Some applications that need to start threads on the JVM host the primary need notification of these events. The ObjectGridEventGroup.ShardEvents interface declares the shardActivate and shardDeactivate methods. These methods are called only when a shard is activated as a primary and when the shard is deactivated from a primary. These two events allow the application to start additional threads when the shard is a primary and stop the threads when the shard returns to being a replica or is taken out of service.

An application can determine which partition has been activated by looking up a specific BackingMap in the ObjectGrid reference that is provided to the shardActivate method using the ObjectGrid#getMap method. The application can then see the partition number using the BackingMap#getPartitionId() method. The partitions are numbered from 0 to the number of partitions in the deployment descriptor minus one.

Shard life-cycle events

ObjectGridEventListener.initialize and ObjectGridEventListener.destroy method events are delivered using the ObjectGridEventGroup.ShardLifecycle interface.

Transaction events

ObjectGridEventListener.transactionBegin and ObjectGridEventListener.transactionEnd methods are delivered through the ObjectGridEventGroup.TransactionEvents interface.
If an ObjectGridEventListener plug-in implements the ObjectGridEventListener and ShardLifecycle interfaces, then shard life-cycle events are the only events that are delivered to the listener. After you implement any of the new ObjectGridEventGroup inner interfaces, eXtreme Scale only delivers those specific events by the new interfaces. With this implementation, code can be backwards compatible. If you are using the new inner interfaces, it can now receive just the specific events that are needed.

Using the ObjectGridEventListener plug-in

To use a custom ObjectGridEventListener plug-in, first create a class that implements the ObjectGridEventListener interface and any optional ObjectGridEventGroup sub-interfaces. Add the custom listener to an ObjectGrid to receive notification of significant events. You have two approaches to add an ObjectGridEventListener plug-in into the eXtreme Scale configuration: programmatic configuration and XML configuration.

Configure an ObjectGridEventListener plug-in programmatically

Assume that the class name of the eXtreme Scale event listener is the com.company.org.MyObjectGridEventListener class. This class implements the ObjectGridEventListener interface. The following code snippet creates the custom ObjectGridEventListener and adds it to an ObjectGrid.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid myGrid = objectGridManager.createObjectGrid("myGrid", false);
MyObjectGridEventListener myListener = new MyObjectGridEventListener();
myGrid.addEventListener(myListener);
```

Configure an ObjectGridEventListener plug-in with XML

You can also configure an ObjectGridEventListener plug-in using XML. The following XML creates a configuration that is equivalent to the described programmatically created ObjectGrid event listener. The following text must be in the myGrid.xml file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsobjectgrideventlistplugin_ObjectGr
idEventListener"
                                                    className="com.company.org.MyObjectGridEventListener" />
            <backingMap name="Book"/>
        </objectGrid>
```

```
    </objectGrids>
</objectGridConfig>
```

Notice the bean declarations come before the backingMap declarations. Provide this file to the ObjectGridManager plug-in to facilitate the creation of this configuration. The following code snippet demonstrates how to create an ObjectGrid instance using this XML file. The ObjectGrid instance that is created has an ObjectGridEventListener listener set on the myGrid ObjectGrid.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid myGrid = objectGridManager.createObjectGrid("myGrid",
        new URL("file:etc/test/myGrid.xml"), true, false);
```

ObjectGridEventListener interface

BackingMapLifecycleListener plug-in

A BackingMapLifecycleListener plug-in receives notification of WebSphere® eXtreme Scale life cycle state change events for the backing map.

The BackingMapLifecycleListener plug-in receives an event containing a BackingMapLifecycleListener.State object for each state change of the backing map. Any BackingMap plug-in that also implements the BackingMapLifecycleListener interface will automatically be added as a listener for the BackingMap instance where the plug-in is registered.

Overview

A BackingMapLifecycleListener plug-in is useful when an existing BackingMap plug-in needs to perform activities relative to activities in a related plugin. As an example, a loader plug-in might need to retrieve configuration from a cooperating MapIndexPlugin or DataSerializer plug-in.

By implementing the BackingMapLifecycleListener interface, and detecting the BackingMapLifecycleListener.State.INITIALIZED event, the loader can know about the state of other plug-ins in the BackingMap instance. The loader can safely retrieve information from the cooperating MapIndexPlugin or DataSerializer plug-in, since the BackingMap is in the INITIALIZED state, which means that the other plug-in has had its initialize() method called.

A BackingMapLifecycleListener can be added or removed at any time, either before or after the ObjectGrid and its BackingMaps are initialized.

Write a BackingMapLifecycleListener plug-in

A BackingMapLifecycleListener plug-in must implement the BackingMapLifecycleListener interface to receive notifications about significant eXtreme Scale events. Any BackingMap plug-in can implement the BackingMapLifecycleListener interface and be automatically added as a listener when it is also added to the backing map.

For more information about these interfaces, see the API documentation.

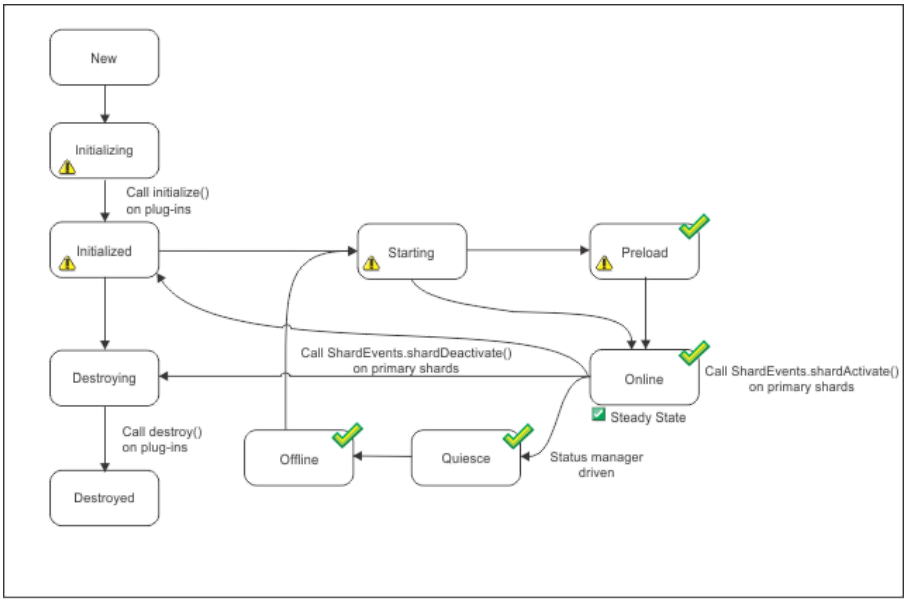
Life cycle event and plug-in relationships

The BackingMapLifecycleListener retrieves the life cycle state from the event in the backingMapStateChanged method; for example:

```
public void backingMapStateChanged(BackingMap map,
                                   LifecycleEvent event)
throws LifecycleFailedException {
  switch(event.getState()) {
    case INITIALIZED: // All other plug-ins are initialized.
      // Retrieve reference to plug-in X for use from map.
      break;
    case DESTROYING:  // Destroy phase is starting
      // Eliminate reference to plug-in X it may be destroyed before this plug-in
      break;
  }
}
```

The following illustration summarizes the states of the BackingMap objects as life cycle events occur and are sent to a BackingMapLifecycleListener plug-in.

Figure 1. BackingMap state summary



The following table describes the relationship between life cycle events sent to a BackingMapLifecycleListener plug-in and the states of the BackingMap and other plug-in objects.

BackingMapLifecycleListener.State value	**Description**
INITIALIZING	The BackingMap initialization phase is starting. The BackingMap and BackingMap plug-ins are about to be initialized.
INITIALIZED	The BackingMap initialization phase is complete. All BackingMap plug-ins are initialized. The INITIALIZED state might recur when shard placement activities (promotion or demotion) occur.
STARTING	The BackingMap instance is being activated for use as a local instance, client instance or as an instance in a primary or replica shard on the server. All ObjectGrid plug-ins in the ObjectGrid instance owning this BackingMap instance have been initialized. The STARTING state might recur when shard placement activities (promotion or demotion) occur.
PRELOAD	The BackingMap instance is set to the PRELOAD state by the StateManager API for preloading, or the configured loader is preloading data into the backing map.
ONLINE	The BackingMap instance is ready for work as a local instance, client instance, or as an instance in a primary or replica shard on the server. All ObjectGrid plug-ins in the ObjectGrid instance owning this BackingMap instance have been initialized. This steady state is typical of the BackingMap. The ONLINE state might recur when shard placement activities (promotion or demotion) occur.
QUIESCE	Work is stopping on the BackingMap as a result of the StateManager API or other event. No new work is allowed. Your plug-in ends any existing work as soon as possible.
OFFLINE	All work is stopped on the BackingMap as a result of the StateManager API or another event. No new work is allowed.
DESTROYING	The BackingMap instance is starting the destroy phase. BackingMap plug-ins for the instance are about to be destroyed.
DESTROYED	The BackingMap instance and all BackingMap plug-ins have been destroyed.

Configure a BackingMapLifecycleListener plug-in with XML

Assume that the class name of the eXtreme Scale event listener is the com.company.org.MyBackingMapLifecycleListener class. This class implements the BackingMapLifecycleListener interface.

You can configure a BackingMapLifecycleListener plug-in using XML. The following text must be in the object grid XML file:

```
<?xml version="1.0" encoding="UTF-8" ?>
<objectGridconfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xsi:schemaLocation="http://ibm.com/ws/objectgrid/config../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <backingMap name="myMap" pluginCollectionRef="myPlugins" />
        </objectGrid>
    </objectGrids>
    <backingMapPluginCollections>
        <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsconfigbacklife_myPlugins">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsconfigbacklife_BackingMapLifecycle
Listener"
                  className="com.company.org.MyBackingMapLifecycleListener" />
        </backingMapPluginCollection>
```

```
    </backingMapPluginCollections>
</objectGridConfig>
```

Provide this file to the ObjectGridManager plug-in to facilitate the creation of this configuration. The BackingMap instance that is created has a BackingMapLifecycleListener listener set on the myGrid ObjectGrid.

Like the BackingMapLifecycleListener, other BackingMap plug-ins, such as Loader or MapIndexPlugin, that you specify using XML that also implement the BackingMapLifecycleListener interface, will automatically be added as life cycle listeners.

ObjectGridLifecycleListener plug-in

ObjectGridLifecycleListener plug-in

An ObjectGridLifecycleListener plug-in receives notification of WebSphere® eXtreme Scale life cycle, state change events for the data grid.

The ObjectGridLifecycleListener plug-in receives an event containing an ObjectGridLifecycleListener.State object for each state change of the ObjectGrid. Any ObjectGrid plug-in that also implements the ObjectGridLifecycleListener interface will automatically be added as a listener for the ObjectGrid instance where the plug-in is registered.

Overview

An ObjectGridLifecycleListener plug-in is useful when an existing ObjectGrid plug-in needs to perform activities relative to activities in a related plug-in. As an example, a TransactionCallback plug-in might need to retrieve the configuration from a cooperating ObjectGridEventListener or ShardListener plug-in.

By implementing the ObjectGridLifecycleListener interface, and detecting the ObjectGridLifecycleListener.State.INITIALIZED event, the TransactionCallback plug-in can detect the state of other plug-ins in the ObjectGrid instance. The TransactionCallback plug-in can safely retrieve information from the cooperating ObjectGridEventListener plug-in or ShardListener plug-in, since the ObjectGrid is in the INITIALIZED state, which means that the other plug-in has had its initialize() method called.

You can add an ObjectGridLifecycleListener plug-in at any time, either before or after the ObjectGrid is initialized.

Write an ObjectGridLifecycleListener plug-in

An ObjectGridLifecycleListener plug-in must implement the ObjectGridLifecycleListener interface to receive notifications about significant eXtreme Scale events. Any ObjectGrid plug-in can implement the ObjectGridLifecycleListener interface and be automatically added as a listener when it is also added to the ObjectGrid.

For more information about these interfaces, see the API documentation.

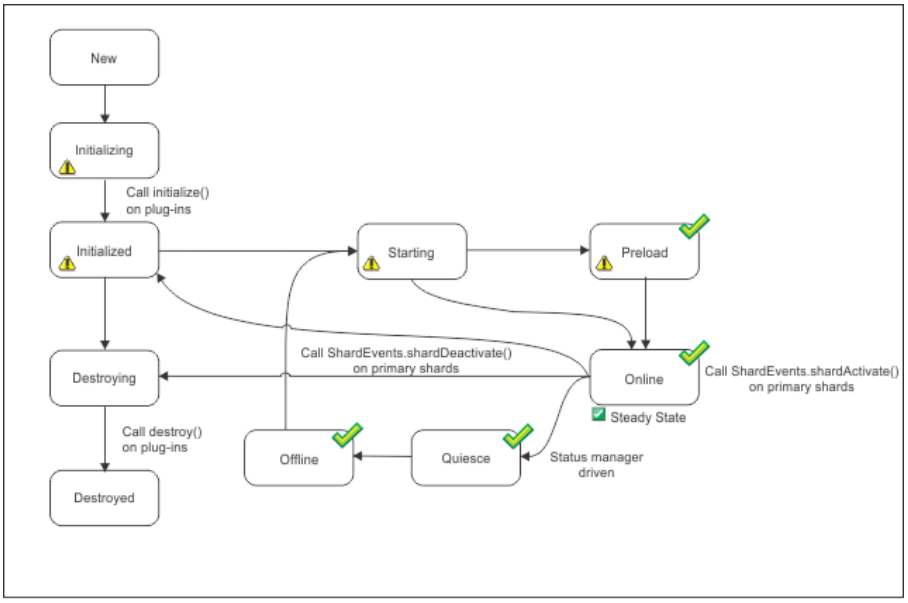
Life cycle event and plug-in relationships

The ObjectGridLifecycleListener retrieves the life cycle state from the event in the objectgridStateChanged method; for example:

```
public void objectGridStateChanged(ObjectGrid grid,
                                   LifecycleEvent event)
throws LifecycleFailedException {
  switch(event.getState()) {
    case INITIALIZED: // All other plug-ins are initialized.
      // Retrieve reference to plug-in X for use from grid.
      break;
    case DESTROYING:  // Destroy phase is starting
      // Eliminate reference to plug-in X it may be destroyed before this plug-in
      break;
  }
```

The following illustration summarizes the states of the ObjectGrid objects as life cycle events occur and are sent to a ObjectGridLifecycleListener plug-in.

Figure 1. ObjectGrid state summary



The following table further describes the relationship between life cycle events sent to a ObjectGridLifecycleListener and the states of the ObjectGrid and other plug-in objects.

ObjectGridLifecycleListener.State value	**Description**
INITIALIZING	The ObjectGrid initialization phase is starting. The ObjectGrid and ObjectGrid plug-ins are about to be initialized.
INITIALIZED	The ObjectGrid initialization phase is complete. All ObjectGrid plug-ins are initialized. The INITIALIZED state might recur when shard placement activities (promotion or demotion) occur. All BackingMap plug-ins in the BackingMap instances owned by this ObjectGrid instance have been initialized.
STARTING	The ObjectGrid instance is being activated for use as a local instance, client instance, or as an instance in a primary or replica shard on the server. The STARTING state might recur when shard placement activities (promotion or demotion) occur.
PRELOAD	The ObjectGrid instance is set to the PRELOAD state by the StateManager API or other configuration.
ONLINE	The ObjectGrid instance is ready for work as a local instance, client instance, or as an instance in a primary or replica shard on the server. This steady state is typical of the ObjectGrid. The ONLINE state might recur when shard placement activities (promotion or demotion) occur.
QUIESCE	Work is stopping on the ObjectGrid as a result of the StateManager API or other event. No new work is allowed. End any existing work as soon as possible.
OFFLINE	All work is stopped on the ObjectGrid as a result of the StateManager API or other event. No new work is allowed.
DESTROYING	The ObjectGrid instance is starting the destroy phase. ObjectGrid plug-ins for the instance are about to be destroyed. During the destroy phase, all BackingMap instances owned by this ObjectGrid instance are also destroyed.
DESTROYED	The ObjectGrid instance, its BackingMap instances, and all ObjectGrid plug-ins have been destroyed.

Configure an ObjectGridLifecycleListener plug-in with XML

Assume that the class name of the eXtreme Scale event listener is the com.company.org.MyObjectGridLifecycleListener class. This class implements the ObjectGridLifecycleListener interface.

You can configure an ObjectGridLifecycleListener plug-in using XML. The following XML creates a configuration using the ObjectGridLifecycleListener. The following text must be in the object grid xml file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsobjgridlifelist_ObjectGridLifecycl
eListener"
                  className="com.company.org.MyObjectGridLifecycleListener" />
            <backingMap name="Book"/>
        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

Notice the bean declarations come before the backingMap declarations. Provide this file to the ObjectGridManager plug-in to facilitate the creation of this configuration.

Like the registered ObjectGridLifecycleListener in the previous example, other ObjectGrid plug-ins, CollisionArbiter or TransactionCallback for example, that you specify using XML that also implement the ObjectGridLifecycleListener interface, will automatically be added as life cycle listeners.

Plug-ins for indexing data

Depending on the type of indexes you want to build, WebSphere® eXtreme Scale provides built-in plug-ins that you can add to the BackingMap to build an index.

HashIndex

The built-in HashIndex, the com.ibm.websphere.objectgrid.plugins.index.HashIndex class, is a MapIndexPlugin plug-in that you can add into BackingMap to build static or dynamic indexes. This class supports both the MapIndex and MapRangeIndex interfaces. Defining and implementing indexes can significantly improve query performance.

- Configuring the HashIndex plug-in
  You can configure the built-in HashIndex, the com.ibm.websphere.objectgrid.plugins.index.HashIndex class, with an XML file, programmatically or with an entity annotation on an entity map.

Configuring the HashIndex plug-in

You can configure the built-in HashIndex, the com.ibm.websphere.objectgrid.plugins.index.HashIndex class, with an XML file, programmatically or with an entity annotation on an entity map.

About this task

Configuring a composite index is the same as configuring a regular index with XML, except for the attributeName property value. In a composite index, the value of attributeName property is a comma-delimited list of attributes. For example, the value class `Address` has three attributes: `city`, `state`, and `zipcode`. A composite index can be defined with the attributeName property value as `"city,state,zipcode"` indicating that `city`, `state`, and `zipcode` are included in the composite index.

The composite HashIndexes do not support range lookups and therefore cannot have the RangeIndex property set to true.

Procedure

- Configure a composite index in the ObjectGrid descriptor XML file.
  Use the backingMapPluginCollections element to define the plug-in:

```
<bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txshashconf_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
        <property name="Name" type="java.lang.String" value="Address.CityStateZip"/>
        <property name="AttributeName" type="java.lang.String" value="city,state,zipcode"/>
</bean>
```

- Configure a composite index programmatically.
  The following example code creates the same composite index:

```
          HashIndex mapIndex = new HashIndex();
    mapIndex.setName("Address.CityStateZip");
    mapIndex.setAttributeName(("city,state,zipcode"));
    mapIndex.setRangeIndex(false);

    BackingMap bm = objectGrid.defineMap("mymap");
    bm.addMapIndexPlugin(mapIndex);
```

- Configure a composite index with entity notations.

If you are using entity maps, you can use an annotation approach to define a composite index. You can define a list of CompositeIndex within the CompositeIndexes annotation on the entity class level. The CompositeIndex has a name and attributeNames property. Each CompositeIndex is associated with a HashIndex instance applied to the backing map that is associated with the entity. The HashIndex is configured as a non-range index.

```
@Entity
@CompositeIndexes({
    @CompositeIndex(name="CityStateZip", attributeNames="city,state,zipcode"),
    @CompositeIndex(name="lastnameBirthday", attributeNames="lastname,birthday")
 })
public class Address {
    @Id int id;
    String street;
    String city;
    String state;
    String zipcode;
    String lastname;
    Date birthday;
}
```

The name property for each composite index must be unique within the entity and backing map. If the name is not specified, a generated name is used. The attributeName property is used to populate the HashIndex attributeName with the comma-delimited list of attributes. The attribute names coincide with the persistent field names when the entities are configured to use field-access, or the property name as defined for the JavaBeans naming conventions for property-access entities. For example: If the attribute name is `street`, the property getter method is named getStreet.

Example: Adding a HashIndex class into a BackingMap instance

In the following example, you configure the HashIndex plug-in by adding static index plug-ins to the XML file:

```
<backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txshashconf_person">
   <bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txshashconf_MapIndexPlugin"
      className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
         <property name="Name" type="java.lang.String" value="CODE"
            description="index name" />
         <property name="RangeIndex" type="boolean" value="true"
            description="true for MapRangeIndex" />
         <property name="AttributeName" type="java.lang.String" value="employeeCode"
            description="attribute name" />
   </bean>
</backingMapPluginCollection>
```

In this XML configuration example, the built-in HashIndex class is used as the index plug-in. The HashIndex supports properties that users can configure, such as Name, RangeIndex, and AttributeName.

- The Name property is configured as `CODE`, a string that identifies this index plug-in. The Name property value must be unique within the scope of the backing map. The name can be used to retrieve the index object by name from the ObjectMap instance for the BackingMap.
- The RangeIndex property is configured as `true`, which means the application can cast the retrieved index object to the MapRangeIndex interface. If the RangeIndex property is configured as `false`, the application can only cast the retrieved index object to the MapIndex interface. A MapRangeIndex supports functions to find data using range functions such as greater than, less than, or both, while a MapIndex supports equals functions only. If the index is to be used by query, the RangeIndex property must be configured to `true` on single-attribute indexes or `false` on relationship or composite indexes. For a relationship index and composite index, the RangeIndex property must be configured to `false`.
- The AttributeName property is configured as `employeeCode`, which means the employeeCode attribute of the cached object is used to build a single-attribute index. If an application must search for cached objects with multiple attributes, the AttributeName property can be set to a comma-delimited list of attributes, yielding a composite index.

In summary, the previous example defines a single-attribute range HashIndex. It is a single-attribute HashIndex because the AttributeName property value is `employeeCode` that includes only one attribute name. It also is a range HashIndex.

- HashIndex plug-in attributes
  You can use the following attributes to configure the HashIndex plug-in.
- Plug-ins for custom indexing of cache objects
  With a MapIndexPlugin plug-in, or index, you can write custom indexing strategies that are beyond the built-in indexes that eXtreme Scale provides.
- Using a composite index
  The composite HashIndex improves query performance and avoids expensive map scanning. The feature also provides a convenient way for the HashIndex API to find cached objects when search criteria involve many attributes.

HashIndex plug-in attributes

HashIndex plug-in attributes

You can use the following attributes to configure the HashIndex plug-in.

Attributes

Name
: Specifies the name of the index. The name must be unique for each map. The name is used to retrieve the index object from the object map instance for the backing map.

AttributeName
: Specifies the comma-delimited names of the attributes to index. For field-access indexes, the attribute names are equivalent to the field names. For property-access indexes, the attribute names are the JavaBean compatible property names. If only one attribute name exists, the HashIndex is a single attribute index. If this attribute is a relationship, it is also a relationship index. If multiple attribute names are included in the attribute names, the HashIndex is a composite index.

FieldAccessAttribute
: Used for non-entity maps. If `true`, the object is accessed using the fields directly. If not specified or `false`, the getter method for the attribute is used to access the data.

POJOKeyIndex
: Used for non-entity maps. If `true`, the index introspects the object in the key part of the map. This setting is useful when the key is a composite key and the value does not have the key embedded within it. If not specified or `false`, then the index introspects the object in the value part of the map.

RangeIndex
: If `true`, range indexing is enabled and the application can cast the retrieved index object to the MapRangeIndex interface. If the RangeIndex property is configured as `false`, the application can cast the retrieved index object to the MapIndex interface only.

Single-attribute HashIndex versus composite HashIndex

When the AttributeName property of HashIndex includes multiple attribute names, the HashIndex is a composite index. Otherwise, if it includes only one attribute name, it is a single-attribute index. For example, the AttributeName property value of a composite HashIndex might be `city,state,zipcode`. It includes three attributes delimited by commas. If the AttributeName property value is only `zipcode` that only has one attribute, it is a single-attribute HashIndex.

Composite HashIndex provides an efficient way to look up cached objects when search criteria involve many attributes. However, it does not support range index and its RangeIndex property must set to `false`.
Restriction: A composite index cannot be created if GlobalIndexEnabled is set to true.
For more information, see Using a composite index.

Relationship HashIndex

If the indexed attribute of single-attribute HashIndex is a relationship, either single- or multi-valued, the HashIndex is a relationship HashIndex. For relationship HashIndex, the RangeIndex property of HashIndex must set to “false”.

Relationship HashIndex can speed up queries that use cyclical references or use the IS NULL, IS EMPTY, SIZE, and MEMBER OF query filters. For more information, see Query optimization using indexes.

Key HashIndex

For non-entity maps, when the POJOKeyIndex property of HashIndex is set to `true`, the HashIndex is a key HashIndex and the key part of entry are used for indexing. When the AttributeName property of HashIndex is not specified, the whole key is indexed; otherwise, the key HashIndex can only be a single-attribute HashIndex.

For example, adding the following property into the preceding sample causes the HashIndex to become key HashIndex because the POJOKeyIndex property value is `true`.

```
<property name="POJOKeyIndex" type="boolean" value="true"
description="indicates if POJO key HashIndex" />
```

In the preceding key index example, because the AttributeName property value is specified as `employeeCode`, the indexed attribute is the employeeCode field of the key part of map entry. If you want to build key index on the whole key part of map entry, remove the AttributeName property.

Range HashIndex

When the RangeIndex property of HashIndex is set to `true`, the HashIndex is a range index and can support the MapRangeIndex interface. A MapRangeIndex implementation supports functions to find data using range functions, such as greater than, less than, or both, while a MapIndex supports equals functions only. For a single-attribute index, the RangeIndex property can be set to `true` only if the indexed attribute is of type Comparable. If the single-attribute index will be used by query, the RangeIndex property must set to `true` and the indexed attribute must be of type Comparable. For relationship HashIndex and composite HashIndex, the RangeIndex property must set to `false`.

The preceding sample is a range HashIndex because the RangeIndex property value is `true`.

The following table provides a summary for using range index.

Table 1. Support for range index. States whether HashIndex types support range index.

HashIndex type	Supports range index
Single-attribute HashIndex: indexed key or attribute is of type Comparable	Yes
Single-attribute HashIndex: indexed key or attribute is not of type Comparable	No

HashIndex type	Supports range index
Composite HashIndex	No
Relationship HashIndex	No

Query optimization with HashIndex plug-ins

Defining indexes can significantly improve query performance.WebSphere® eXtreme Scale queries can use built-in HashIndex plug-ins to improve performance of queries. Although using indexes can significantly improve query performance, it might have a performance impact on transactional map operations.

Plug-ins for custom indexing of cache objects

With a MapIndexPlugin plug-in, or index, you can write custom indexing strategies that are beyond the built-in indexes that eXtreme Scale provides.

MapIndexPlugin implementations must use the MapIndexPlugin interface and follow the common eXtreme Scale plug-in conventions.

The following sections include some of the important methods of the index interface.

setProperties method

Use the setProperties method to initialize the index plug-in programmatically. The Properties object parameter that is passed into the method should contain required configuration information to initialize the index plug-in properly. The setProperties method implementation, along with the getProperties method implementation, are required in a distributed environment because the index plug-in configuration moves between client and server processes. An implementation example of this method follows.

```
setProperties(Properties properties)

// setProperties method sample code
    public void setProperties(Properties properties) {
        ivIndexProperties = properties;

        String ivRangeIndexString = properties.getProperty("rangeIndex");
        if (ivRangeIndexString != null && ivRangeIndexString.equals("true")) {
            setRangeIndex(true);
        }
        setName(properties.getProperty("indexName"));
        setAttributeName(properties.getProperty("attributeName"));

        String ivFieldAccessAttributeString = properties.getProperty("fieldAccessAttribute");
        if (ivFieldAccessAttributeString != null && ivFieldAccessAttributeString.equals("true")) {
            setFieldAccessAttribute(true);
        }

        String ivPOJOKeyIndexString = properties.getProperty("POJOKeyIndex");
        if (ivPOJOKeyIndexString != null && ivPOJOKeyIndexString.equals("true")) {
            setPOJOKeyIndex(true);
        }
    }
```

getProperties method

The getProperties method extracts the index plug-in configuration from a MapIndexPlugin instance. You can use the extracted properties to initialize another MapIndexPlugin instance to have the same internal states. The getProperties method and setProperties method implementations are required in a distributed environment. An implementation example of the getProperties method follows.

```
getProperties()

// getProperties method sample code
    public Properties getProperties() {
        Properties p = new Properties();
        p.put("indexName", indexName);
        p.put("attributeName", attributeName);
        p.put("rangeIndex", ivRangeIndex ? "true" : "false");
        p.put("fieldAccessAttribute", ivFieldAccessAttribute ? "true" : "false");
        p.put("POJOKeyIndex", ivPOJOKeyIndex ? "true" : "false");
        return p;
    }
```

setEntityMetadata method

The setEntityMetadata method is called by the WebSphere® eXtreme Scale run time during initialization to set the EntityMetadata of the associated BackingMap on the MapIndexPlugin instance. The EntityMetadata is required for supporting indexing of tuple objects. A tuple is a data set that represents an entity object or its key. If the BackingMap is for an entity, then you must implement this method.

The following code sample implements the setEntityMetadata method.

```
setEntityMetadata(EntityMetadata entityMetadata)
```

```
// setEntityMetadata method sample code
    public void setEntityMetadata(EntityMetadata entityMetadata) {
        ivEntityMetadata = entityMetadata;
        if (ivEntityMetadata != null) {
            // this is a tuple map
            TupleMetadata valueMetadata = ivEntityMetadata.getValueMetadata();
            int numAttributes = valueMetadata.getNumAttributes();
            for (int i = 0; i < numAttributes; i++) {
                String tupleAttributeName = valueMetadata.getAttribute(i).getName();
                if (attributeName.equals(tupleAttributeName)) {
                    ivTupleValueIndex = i;
                    break;
                }
            }

            if (ivTupleValueIndex == -1) {
                // did not find the attribute in value tuple, try to find it on key tuple.
                // if found on key tuple, implies key indexing on one of tuple key attributes.
                TupleMetadata keyMetadata = ivEntityMetadata.getKeyMetadata();
                numAttributes = keyMetadata.getNumAttributes();
                for (int i = 0; i < numAttributes; i++) {
                    String tupleAttributeName = keyMetadata.getAttribute(i).getName();
                    if (attributeName.equals(tupleAttributeName)) {
                        ivTupleValueIndex = i;
                        ivKeyTupleAttributeIndex = true;
                        break;
                    }
                }
            }

            if (ivTupleValueIndex == -1) {
                // if entityMetadata is not null and we could not find the
                                                    // attributeName in entityMetadata, this is an
                // error
                throw new ObjectGridRuntimeException("Invalid attributeName.  Entity: " +
                                                        ivEntityMetadata.getName());
            }
        }
    }
```

Attribute name methods

The setAttributeName method sets the name of the attribute to be indexed. The cached object class must provide the get method for the indexed attribute. For example, if the object has an employeeName or EmployeeName attribute, the index calls the getEmployeeName method on the object to extract the attribute value. The attribute name must be the same as the name in the get method, and the attribute must implement the Comparable interface. If the attribute is boolean type, you can also use the isAttributeName method pattern.

The getAttributeName method returns the name of the indexed attribute.

getAttribute method

The getAttribute method returns the indexed attribute value from the specified object. For example, if an Employee object has an attribute called employeeName that is indexed, you can use the getAttribute method to extract the employeeName attribute value from a specified Employee object. This method is required in a distributed WebSphere eXtreme Scale environment.

```
getAttribute(Object value)
```

```
// getAttribute method sample code
    public Object getAttribute(Object value) throws ObjectGridRuntimeException {
        if (ivPOJOKeyIndex) {
            // In the POJO key indexing case, no need to get attribute from value object.
            // The key itself is the attribute value used to build the index.
            return null;
        }

        try {
            Object attribute = null;
            if (value != null) {
                // handle Tuple value if ivTupleValueIndex != -1
                if (ivTupleValueIndex == -1) {
                    // regular value
                    if (ivFieldAccessAttribute) {
                        attribute = this.getAttributeField(value).get(value);
                    } else {
                        attribute = getAttributeMethod(value).invoke(value, emptyArray);
```

```
                    }
                } else {
                    // Tuple value
                    attribute = extractValueFromTuple(value);
                }
            }
            return attribute;
        } catch (InvocationTargetException e) {
             throw new ObjectGridRuntimeException(
                    "Caught unexpected Throwable during index update processing,
                                                                                index name = " + indexName + ":
" + t,
                    t);
        } catch (Throwable t) {
             throw new ObjectGridRuntimeException(
                    "Caught unexpected Throwable during index update processing,
                                                                            index name = " + indexName + ": " + t,
                    t);
        }
    }
```

HashIndex plug-in attributes

Using a composite index

The composite HashIndex improves query performance and avoids expensive map scanning. The feature also provides a convenient way for the HashIndex API to find cached objects when search criteria involve many attributes.

Improved performance

A composite HashIndex provides a fast and convenient way to search for cached objects with multiple attributes in match-searching criteria. The composite index supports full attribute-match searches, but does not support range searches.

Note: Composite indexes do not support the BETWEEN operator in the ObjectGrid query language because BETWEEN would require range support. The greater than (>) and less than (<) conditionals also do not work because they require range indexes.
A composite index can improve performance of queries if the appropriate composite index is available for the WHERE condition. This means that the composite index has exactly the same attributes as involved in the WHERE condition with full attributes matched.

A query might have many attributes involved in a condition as in the following example.

```
SELECT a FROM Address a WHERE a.city='Rochester' AND a.state='MN' AND a.zipcode='55901'
```

Composite index can improve query performance by avoiding scanning map or joining multiple single-attribute index results. In the example, if a composite index is defined with attributes (city,state,zipcode), the query engine can use the composite index to find the entry with `city='Rochester'`, `state='MN'`, and `zipcode='55901'`. Without composite index and attribute index on city, state, and zipcode attributes, the query engine must scan the map or join multiple single-attribute searches, which usually have expensive overhead. Also, querying for the composite index supports a full-matched pattern only.

Configuring a composite index

You can configure composite indexing in three ways: using XML, programmatically, and with entity annotations only for entity maps.

Programmatic configuration

The following example creates the a composite index.

```
        HashIndex mapIndex = new HashIndex();
    mapIndex.setName("Address.CityStateZip");
    mapIndex.setAttributeName(("city,state,zipcode"));
    mapIndex.setRangeIndex(false);
    BackingMap bm = objectGrid.defineMap("mymap");
    bm.addMapIndexPlugin(mapIndex);
```

Note that configuring a composite index is the same as configuring a regular index with XML except for the attributeName property value. In a composite index case, the value of attributeName is a comma-delimited list of attributes. For example, the value class Address has 3 attributes: city, state, and zipcode. A composite index can be defined with the attributeName property value as `"city,state,zipcode"` indicating that city, state, and zipcode are included in the composite index.

Composite HashIndexes do not support range lookups and therefore cannot have the RangeIndex property set to true.

Using XML

To configure a composite index with XML, include the following configuration in the backingMapPluginCollections element in the ObjectGrid descriptor XML file.

```
Composite index - XML configuration approach
<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxscompindx_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
<property name="Name" type="java.lang.String" value="Address.CityStateZip"/>
<property name="AttributeName" type="java.lang.String" value="city,state,zipcode"/>
</bean>
```

With entity annotations

In the entity map case, annotation approach can be used to define a composite index. You can define a list of CompositeIndex within CompositeIndexes annotation on the entity class level. The CompositeIndex has a name and attributeNames property. Each CompositeIndex is associated with a HashIndex instance applied to the backing map that is associated with the entity. The HashIndex is configured as a non-range index.

```
@Entity
@CompositeIndexes({
    @CompositeIndex(name="CityStateZip", attributeNames="city,state,zipcode"),
    @CompositeIndex(name="lastnameBirthday", attributeNames="lastname,birthday")
 })
public class Address {
    @Id int id;
    String street;
    String city;
    String state;
    String zipcode;
    String lastname;
    Date birthday;
}
```

The name property for each composite index must be unique within the entity and BackingMap. If the name is not specified, a generated name is used. The attributeNames property is used to populate the HashIndex attributeName with the comma-delimited list of attributes. The attribute names coincide with the persistent field names when the entities are configured to use field-access, or the property name as defined for the JavaBeans naming conventions for property-access entities. For example: If the attribute name is "street", the property getter method is named getStreet.

Performing composite index lookups

After a composite index is configured, an application can use the findAll(Object) method of the MapIndex interface to perform lookups.

```
Session sess = objectgrid.getSession();
ObjectMap map = sess.getMap("MAP_NAME");
MapIndex codeIndex = (MapIndex) map.getIndex("INDEX_NAME");
Object[] compositeValue = new Object[]{ MapIndex.EMPTY_VALUE,
                        "MN", "55901"};
Iterator iter = mapIndex.findAll(compositeValue);
// Close the session (optional in Version 7.1.1 and later) for improved performance
sess.close();
```

The MapIndex.EMPTY_VALUE is assigned to the compositeValue[0] which indicates that the city attribute is excluded from evaluation. Only objects with state attribute equal to "MN" and zipcode attribute equal to "55901" are included in the result.

The following queries benefit from the previous composite index configuration:

```
SELECT a FROM Address a WHERE a.city='Rochester' AND a.state='MN' AND a.zipcode='55901'

SELECT a FROM Address a WHERE a.state='MN' AND a.zipcode='55901'
```

The query engine finds the appropriate composite index and use it to improve query performance in full attribute-match cases.

In some scenarios, the application might need to define multiple composite indexes with overlapped attributes in order to satisfy all queries with full attributes matched. A disadvantage of increasing the number of indexes is the possible performance overhead on map operations.

Configuring a global composite index

A global composite index is a type of global index used to index multiple attributes of a cached object which is in the form of a composite index. You can configure a global composite index in two ways, either programmatically or using XML.

Programmatic configuration

The following example creates the a composite index.

```
          HashIndex mapIndex = new HashIndex();
    mapIndex.setName("Address.CityStateZip");
    mapIndex.setAttributeName(("city,state,zipcode"));
    mapIndex.setRangeIndex(false);
    mapIndex.setGlobalIndexEnabled(true);
    BackingMap bm = objectGrid.defineMap("mymap");
    bm.addMapIndexPlugin(mapIndex);
```

Using XML

To configure a global composite index with XML, include the following configuration in the backingMapPluginCollections element in the ObjectGrid descriptor XML file.

```
Global composite index - XML configuration approach
<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxscompindx_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
<property name="Name" type="java.lang.String" value="Address.CityStateZip"/>
<property name="AttributeName" type="java.lang.String" value="city,state,zipcode"/>
<property name="GlobalIndexEnabled" type="boolean" value="true" description="required"/>
</bean>
```

After a global composite index is configured, an application can use the findAll(Object) method of the MapIndex interface to perform lookups.

```
Session sess = objectgrid.getSession();
ObjectMap map = sess.getMap("MAP_NAME");
globalIndex = (MapGlobalIndex)map.getIndex("IndexName");
Object values = new Object[]{ "MN" , "55901" } ;
//  OR :
//  Object[] values =  new Object[] { new Object[] {  "MN" , "55901"  } };
Set keys = mapIndex.findKeys (values);
sess.close();
```

The MapGlobalIndex.EMPTY_VALUE is assigned to the compositeValue[0] which indicates that the city attribute is excluded from evaluation. Only objects with state attribute equal to "MN" and zipcode attribute equal to "55901" are included in the result.

The following queries benefit from the previous composite index configuration:

```
SELECT a FROM Address a WHERE a.city='Rochester' AND a.state='MN' AND a.zipcode='55901'
```

```
SELECT a FROM Address a WHERE a.state='MN' AND a.zipcode='55901'
```

The query engine finds the appropriate composite index and use it to improve query performance in full attribute-match cases.

In some scenarios, the application might need to define multiple composite indexes with overlapped attributes in order to satisfy all queries with full attributes matched. A disadvantage of increasing the number of indexes is the possible performance overhead on map operations.

Migration and interoperability

The only constraint for the use of a composite index is that an application cannot configure it in a distributed environment with heterogeneous containers. Old and new container servers cannot be mixed, since older container servers do not recognize a composite index configuration. The composite index is just like the existing regular attribute index, except that the former allows indexing over multiple attributes. When using only the regular attribute index, a mixed-container environment is still viable.

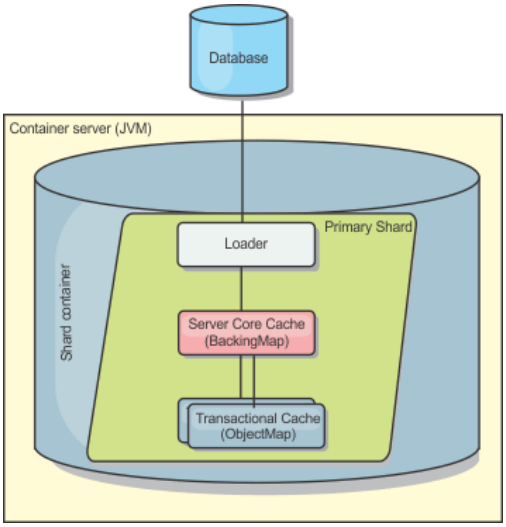
Plug-ins for communicating with databases

With a Loader plug-in, an ObjectGrid map can behave as a memory cache for data that is typically kept in a persistent store on either the same system or some other system. Typically, a database or file system is used as the persistent store. A remote Java™ virtual machine (JVM) can also be used as the source of data, allowing hub-based caches to be built using ObjectGrid. A loader has the logic for reading and writing data to and from a persistent store.

Loaders are backing map plug-ins that are invoked when changes are made to the backing map or when the backing map is unable to satisfy a data request (a cache miss).

Figure 1. Loader



WebSphere® eXtreme Scale includes two built-in loaders to integrate with relational database back ends. The Java Persistence API (JPA) loaders use the Object-Relational Mapping (ORM) capabilities of both the OpenJPA and Hibernate implementations of the JPA specification.

Using a loader

To add a loader into the BackingMap configuration, you can use programmatic configuration or XML configuration. A loader has the following relationship with a backing map:

- A backing map can have only one loader.
- A client backing map (near cache) cannot have a loader.
- A loader definition can be applied to multiple backing maps, but each backing map has its own loader instance.

Restriction: BackMaps that are configured with a Loader plug-in can read but cannot write to the map in a multi-partition transaction.

Loaders in multi-master configurations

For considerations about using loaders in multi-master configurations, see Loader considerations in a multi-master topology.

Programmatically plug in a Loader

The following snippet of code demonstrates how to plug an application-provided Loader into the backing map for map1 using the ObjectGrid API:

```
import com.ibm.websphere.objectgrid.ObjectGridManagerFactory;
import com.ibm.websphere.objectgrid.ObjectGridManager;
import com.ibm.websphere.objectgrid.ObjectGrid;
import com.ibm.websphere.objectgrid.BackingMap;
ObjectGridManager ogManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid og = ogManager.createObjectGrid( "grid" );
BackingMap bm = og.defineMap( "map1" );
MyLoader loader = new MyLoader();
loader.setDataBaseName("testdb");
loader.setIsolationLevel("read committed");
bm.setLoader( loader );
```

This snippet assumes that the MyLoader class is the application-provided class that implements the com.ibm.websphere.objectgrid.plugins.Loader interface. Because the association of a Loader with a backing map cannot be changed after ObjectGrid is initialized, the code must be run before invoking the initialize method of the ObjectGrid interface that is being called. An IllegalStateException exception occurs on a setLoader method call if it is called after initialization has occurred.

The application-provided Loader can have set properties. In the example, the MyLoader loader is used to read and write data from a table in a relational database. The loader must specify the name of the database and the SQL isolation level. The MyLoader loader has the setDataBaseName and setIsolationLevel methods that allow the application to set these two Loader properties.

XML configuration approach to plug in a Loader

An application-provided Loader can also be plugged in by using an XML file. The following example demonstrates how to plug the MyLoader loader into the map1 backing map with the same database name and isolation level Loader properties. You must specify the className for your loader, the database name and connection details, and the isolation level properties. You can use the same XML structure if you are only using a preloader by specifying the preloader classname instead of a complete loader classname.:

```
<?xml version="1.0" encoding="UTF-8" ?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
<objectGrids>
    <objectGrid name="grid">
        <backingMap name="map1" pluginCollectionRef="map1" lockStrategy="OPTIMISTIC" />
```

```
    </objectGrid>
</objectGrids>
<backingMapPluginCollections>
    <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsuseloaders_map1">
        <bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsuseloaders_Loader"
className="com.myapplication.MyLoader">
            <property name="dataBaseName"
                      type="java.lang.String"
                      value="testdb"
                      description="database name" />
            <property name="isolationLevel"
                      type="java.lang.String"
                      value="read committed"
                      description="iso level" />
        </bean>
    </backingMapPluginCollection>
</backingMapPluginCollections>
</objectGridConfig>
```

- Configuring database loaders
  Loaders are backing map plug-ins that are invoked when changes are made to the backing map or when the backing map is unable to satisfy a data request (a cache miss).
- Writing a loader
  You can write your own loader plug-in implementation in your applications, which must follow the common WebSphere eXtreme Scale plug-in conventions.
- Map pre-loading
  Maps can be associated with Loaders. A loader is used to fetch objects when they cannot be found in the map (a cache miss) and also to write changes to a back-end when a transaction commits. Loaders can also be used for pre-loading data into a map. The preloadMap method of the Loader interface is called on each map when its corresponding partition in the map set becomes a primary. The preloadMap method is not called on replicas. It attempts to load all the intended referenced data from the back-end into the map using the provided session. The relevant map is identified by the BackingMap argument that is passed to the preloadMap method.
- Configuring write-behind loader support
  You can enable write-behind support with the ObjectGrid descriptor XML file or programmatically with the BackingMap interface.
- JPA loader programming considerations
  A Java Persistence API (JPA) Loader is a loader plug-in implementation that uses JPA to interact with the database. Use the following considerations when you develop an application that uses a JPA loader.
- Using a loader with entity maps and tuples
  The entity manager converts all entity objects into tuple objects before they are stored in an WebSphere eXtreme Scale map. Every entity has a key tuple and a value tuple. This key-value pair is stored in the associated eXtreme Scale map for the entity. When you are using an eXtreme Scale map with a loader, the loader must interact with the tuple objects.
- Writing a loader with a replica preload controller
  A Loader with a replica preload controller is a Loader that implements the ReplicaPreloadController interface in addition to the Loader interface.

Configuring database loaders

Loaders are backing map plug-ins that are invoked when changes are made to the backing map or when the backing map is unable to satisfy a data request (a cache miss).

Preload considerations

Loaders are backing map plug-ins that are invoked when changes are made to the backing map or when the backing map is unable to satisfy a data request (a cache miss). For an overview of how eXtreme Scale interacts with a loader, see In-line cache.

Each backing map has a boolean preloadMode attribute that is set to indicate if preload of a map runs asynchronously. By default, the preloadMode attribute is set to false, which indicates that the backing map initialization does not complete until the preload of the map is complete. For example, backing map initialization is not complete until the preloadMap method returns. If the preloadMap method reads a large amount of data from its back end and loads it into the map, it might take a relatively long time to complete. In this case, you can configure a backing map to use asynchronous preload of the map by setting the preloadMode attribute to true. This setting causes the backing map initialization code to start a thread that invokes the preloadMap method, allowing initialization of a backing map to complete while the preload of the map is still in progress.

In a distributed eXtreme Scale scenario, one of the preload patterns is client preload. In the client preload pattern, an eXtreme Scale client is responsible for retrieving data from the backend and then inserting the data into the distributed container server using DataGrid agents. Furthermore, client preload could be executed in the Loader.preloadMap method in one and only one specific partition. In this case, asynchronously loading the data to the grid becomes very important. If the client preload were executed in the same thread, the backing map would never be initialized, so the partition it resides in would never become ONLINE. Therefore, the eXtreme Scale client could not send the request to the partition, and eventually it would cause an exception.

If an eXtreme Scale client is used in the preloadMap method, you should set the preloadMode attribute to true. The alternative is to start a thread in the client preload code.

The following snippet of code illustrates how the preloadMode attribute is set to enable asynchronous preload:

```
BackingMap bm = og.defineMap( "map1" );
bm.setPreloadMode( true );
```

The preloadMode attribute can also be set by using a XML file as illustrated in the following example:

```
<backingMap name="map1" preloadMode="true" pluginCollectionRef="map1"
        lockStrategy="OPTIMISTIC" />
```

TxID and use of the TransactionCallback interface

Both the get method and batchUpdate methods on the Loader interface are passed a TxID object that represents the Session transaction that requires the get or batchUpdate operation to be performed. The get and batchUpdate methods can be called more than once per transaction. Therefore, transaction-scoped objects that are needed by the Loader are typically kept in a slot of the TxID object. A Java™ database connectivity (JDBC) Loader is used to illustrate how a Loader uses the TxID and TransactionCallback interfaces.

Several ObjectGrid maps can be stored in the same database. Each map has its own loader, and each loader might need to connect to the same database. When the loaders connect to the database, they should use the same JDBC connection. Using the same connection commits the changes to each table as part of the same database transaction. Typically, the same person who writes the Loader implementation also writes the TransactionCallback implementation.

The Loader plug-in can fail when it is unable to communicate to the database back end. This failure can happen if the database server or the network connection is down. The write-behind loader queues the updates and tries to push the data changes to the loader periodically. The loader must notify the ObjectGrid runtime that there is a database connectivity problem by throwing a LoaderNotAvailableException exception. It is not necessary to connect to the database in write-behind mode. However, your TransactionCallback implementation, (*MyTransactionCallback*), must be aware that the database is down and consequently, the database is not run failing database operations. Use the Loader interface and the LoaderNotAvailableException exception to tell WebSphere® eXtreme Scale that the database is down. Do not use your TransactionCallback implementation to communication outages to the server.

A correctly implemented combination of the Loader interface and your TransactionCallback implementation typically does *lazy* instantiation of the SQL connection at the time of the Loader.batchUpdate() call. So instead of programming *MyTransactionCallback*.begin() to create a connection, the Loader.batchUpdate() method calls a private method on the *MyTransactionCallback* object to instantiate the database connection. If this operation fails, then the Loader can immediately throw the LoaderNotAvailableException exception because the database is down. The operations will be intermittently retried until a connection is reestablished.

The best method is when the TransactionCallback interface is extended to add methods that the Loader needs for getting a database connection and for caching prepared statements. The reason for this methodology becomes apparent as you see how the TransactionCallback and TxID interfaces are used by the loader.

As an example, the loader might need the TransactionCallback interface to be extended as follows:

```
import java.sql.Connection;
import java.sql.PreparedStatement;
import java.sql.SQLException;
import com.ibm.websphere.objectgrid.TxID;
public interface MyTransactionCallback extends TransactionCallback
{
    Connection getAutoCommitConnection(TxID tx, String databaseName) throws SQLException;
    Connection getConnection(TxID tx, String databaseName, int isolationLevel ) throws SQLException;
    PreparedStatement getPreparedStatement(TxID tx, Connection conn, String tableName, String sql)
                      throws SQLException;
    Collection getPreparedStatementCollection( TxID tx, Connection conn,        String tableName );
}
```

Using these new methods, the Loader get and batchUpdate methods can get a connection as follows:

```
import java.sql.Connection;
import java.sql.PreparedStatement;
import java.sql.SQLException;
import com.ibm.websphere.objectgrid.TxID;
private Connection getConnection(TxID tx, int isolationLevel)
{
    Connection conn = ivTcb.getConnection(tx, databaseName, isolationLevel );
    return conn;
}
```

In the previous example and in the examples that follow, ivTcb and ivOcb are Loader instance variables that were initialized as described in the Preload considerations section. The ivTcb variable is a reference to the MyTransactionCallback instance and the ivOcb is a reference to the MyOptimisticCallback instance. The databaseName variable is an instance variable of the Loader that was set as a Loader property during the initialization of the backing map. The isolationLevel argument is one of the JDBC Connection constants that are defined for the various isolation levels that JDBC supports. If the Loader is using an optimistic implementation, the get method typically uses a JDBC auto–commit connection to fetch the data from the database. In that case, the Loader might have a getAutoCommitConnection method that is implemented as follows:

```
import java.sql.Connection;
import java.sql.PreparedStatement;
import java.sql.SQLException;
```

```
import com.ibm.websphere.objectgrid.TxID;
private Connection getAutoCommitConnection(TxID tx)
{
    Connection conn = ivTcb.getAutoCommitConnection(tx, databaseName);
    return conn;
}
```

Recall that the batchUpdate method has the following switch statement:

```
switch ( logElement.getType().getCode() )
{
    case LogElement.CODE_INSERT:
        buildBatchSQLInsert( tx, key, value, conn );
        break;
    case LogElement.CODE_UPDATE:
        buildBatchSQLUpdate( tx, key, value, conn );
        break;
    case LogElement.CODE_DELETE:
        buildBatchSQLDelete( tx, key, conn );
        break;
}
```

Each of the buildBatchSQL methods uses the MyTransactionCallback interface to get a prepared statement. Following is a snippet of code that shows the buildBatchSQLUpdate method building an SQL update statement for updating an EmployeeRecord entry and adding it for the batch update:

```
private void buildBatchSQLUpdate( TxID tx, Object key, Object value,
        Connection conn )
throws SQLException, LoaderException
{
    String sql = "update EMPLOYEE set LASTNAME = ?, FIRSTNAME = ?, DEPTNO = ?,
    SEQNO = ?, MGRNO = ? where EMPNO = ?";
    PreparedStatement sqlUpdate = ivTcb.getPreparedStatement( tx, conn,
                        "employee", sql );
    EmployeeRecord emp = (EmployeeRecord) value;
    sqlUpdate.setString(1, emp.getLastName());
    sqlUpdate.setString(2, emp.getFirstName());
    sqlUpdate.setString(3, emp.getDepartmentName());
    sqlUpdate.setLong(4, emp.getSequenceNumber());
    sqlUpdate.setInt(5, emp.getManagerNumber());
    sqlUpdate.setInt(6, key);
    sqlUpdate.addBatch();
}
```

After the batchUpdate loop has built all of the prepared statements, it calls the getPreparedStatementCollection method. This method is implemented as follows:

```
private Collection getPreparedStatementCollection( TxID tx, Connection conn )
{
    return ( ivTcb.getPreparedStatementCollection( tx, conn, "employee" ) );
}
```

When the application invokes the commit method on the Session, the Session code calls the commit method on the TransactionCallback method after it has pushed all the changes made by the transaction out to the Loader for each map that was changed by the transaction. Because all of the Loaders used the MyTransactionCallback method to get any connection and prepared statements they needed, the TransactionCallback method knows which connection to use to request that the back end commits the changes. So, extending the TransactionCallback interface with methods that are needed by each of the Loaders has the following advantages:

- The TransactionCallback object encapsulates the use of TxID slots for transaction-scoped data, and the Loader does not require information about the TxID slots. The Loader only needs to know about the methods that are added to TransactionCallback using the MyTransactionCallback interface for the supporting functions needed by the Loader.
- The TransactionCallback object can ensure that connection sharing occurs between each Loader that connects to the same backend so that a two phase commit protocol can be avoided.
- The TransactionCallback object can ensure that connecting to the backend is driven to completion through a commit or rollback invoked on the connection when appropriate.
- TransactionCallback ensures that the cleanup of database resources occurs when a transaction completes.
- TransactionCallback hides if it is obtaining a managed connection from a managed environment such as WebSphere Application Server or some other Java 2 Platform, Enterprise Edition (J2EE) compliant application server. This advantage allows the same Loader code to be used in both a managed and unmanaged environments. Only the TransactionCallback plug-in must be changed.
- For detailed information about how the TransactionCallback implementation uses the TxID slots for transaction-scoped data, see TransactionCallback plug-in.

OptimisticCallback

As mentioned earlier, the Loader might use an optimistic approach for concurrency control. In this case, the buildBatchSQLUpdate method example must be modified slightly for implementing an optimistic approach. Several possible ways exist for using an optimistic approach. A typical way is to have either a timestamp column or sequence number counter column for versioning each update of the row. Assume that the employee table has a sequence number column that increments each time the row is updated. You then modify the signature of the buildBatchSQLUpdate method so that it is passed the LogElement object instead of the key and value pair. It also needs to use the OptimisticCallback object that is plugged into the backing map for getting both the initial version object and for updating the version object. The following is an example of a modified buildBatchSQLUpdate method that uses the ivOcb instance variable that was initialized as described in the preloadMap section:

```
modified batch-update method code example
private void buildBatchSQLUpdate( TxID tx, LogElement le, Connection conn )
        throws SQLException, LoaderException
```

```
{
    // Get the initial version object when this map entry was last read
    // or updated in the database.
    Employee emp = (Employee) le.getCurrentValue();
    long initialVersion = ((Long) le.getVersionedValue()).longValue();
    // Get the version object from the updated Employee for the SQL update
    //operation.
    Long currentVersion = (Long)ivOcb.getVersionedObjectForValue( emp );
    long nextVersion = currentVersion.longValue();
    // Now build SQL update that includes the version object in where clause
    // for optimistic checking.
    String sql = "update EMPLOYEE set LASTNAME = ?, FIRSTNAME = ?,
    DEPTNO = ?,SEQNO = ?, MGRNO = ? where EMPNO = ? and SEQNO = ?";
    PreparedStatement sqlUpdate = ivTcb.getPreparedStatement( tx, conn,
                        "employee", sql );
    sqlUpdate.setString(1, emp.getLastName());
    sqlUpdate.setString(2, emp.getFirstName());
    sqlUpdate.setString(3, emp.getDepartmentName());
    sqlUpdate.setLong(4, nextVersion );
    sqlUpdate.setInt(5, emp.getManagerNumber());
    sqlUpdate.setInt(6, key);
    sqlUpdate.setLong(7, initialVersion);
    sqlUpdate.addBatch();
}
```

The example shows that the LogElement is used to obtain the initial version value. When the transaction first accesses the map entry, a LogElement is created with the initial Employee object that is obtained from the map. The initial Employee object is also passed to the getVersionedObjectForValue method on the OptimisticCallback interface and the result is saved in the LogElement. This processing occurs before an application is given a reference to the initial Employee object and has a chance to call some method that changes the state of the initial Employee object.

The example shows that the Loader uses the getVersiondObjectForValue method to obtain the version object for the current updated Employee object. Before calling the batchUpdate method on the Loader interface, eXtreme Scale calls the updateVersionedObjectForValue method on the OptimisticCallback interface to cause a new version object to be generated for the updated Employee object. After the batchUpdate method returns to the ObjectGrid, the LogElement is updated with the current version object and becomes the new initial version object. This step is necessary because the application might have called the flush method on the map instead of the commit method on the Session. It is possible for the Loader to be called multiple times by a single transaction for the same key. For that reason, eXtreme Scale ensures that the LogElement is updated with the new version object each time the row is updated in the employee table.

Now that the Loader has both the initial version object and the next version object, it can run an SQL update statement that sets the SEQNO column to the next version object value and uses the initial version object value in the where clause. This approach is sometimes referred to as an overqualified update statement. The use of the overqualified update statement allows the relational database to verify that the row was not changed by some other transaction between the time that this transaction read the data from the database and the time that this transaction updates the database. If another transaction modified the row, then the count array that is returned by the batch update indicates that zero rows were updated for this key. The Loader is responsible for verifying that the SQL update operation did update the row. If it does not, the Loader displays a com.ibm.websphere.objectgrid.plugins.OptimisticCollisionException exception to inform the Session that the batchUpdate method failed due to more than one concurrent transaction trying to update the same row in the database table. This exception causes the Session to roll back and the application must retry the entire transaction. The rationale is that the retry will be successful, which is why this approach is called optimistic. The optimistic approach performs better if data is infrequently changed or concurrent transactions rarely try to update the same row.

It is important for the Loader to use the key parameter of the OptimisticCollisionException constructor to identify which key or set of keys caused the optimistic batchUpdate method to fail. The key parameter can either be the key object itself or an array of key objects if more than one key resulted in optimistic update failure. And eXtreme Scale uses the getKey method of the OptimisticCollisionException constructor to determine which map entries contain stale data and caused the exception to result. Part of the rollback processing is to evict each stale map entry from the map. Evicting stale entries is necessary so that any subsequent transaction that accesses the same key or keys results in the get method of the Loader interface being called to refresh the map entries with the current data from the database.

Other ways for a Loader to implement an optimistic approach include:

- No timestamp or sequence number column exists. In this case, the getVersionObjectForValue method on the OptimisticCallback interface simply returns the value object itself as the version. With this approach, the Loader needs to build a where clause that includes each of the fields of the initial version object. This approach is not efficient, and not all column types are eligible to be used in the where clause of an overqualified SQL update statement. This approach is typically not used.
- No timestamp or sequence number column exists. However, unlike the prior approach, the where clause only contains the value fields that were modified by the transaction. One method to detect which fields are modified is to set the copy mode on the backing map to be CopyMode.COPY_ON_WRITE mode. This copy mode requires that a value interface be passed to the setCopyMode method on the BackingMap interface. The BackingMap creates dynamic proxy objects that implement the provided value interface. With this copy mode, the Loader can cast each value to a com.ibm.websphere.objectgrid.plugins.ValueProxyInfo object. The ValueProxyInfo interface has a method that allows the Loader to obtain the List of attribute names that were changed by the transaction. This method enables the Loader to call the get methods on the value interface for the attribute names to obtain the changed data and to build an SQL update statement that only sets the changed attributes. The where clause can now be built to have the primary key column plus each of the changed attribute columns. This approach is more efficient than the prior approach, but it requires more code to be written in the Loader and leads to the possibility that the prepared statement cache needs to be larger to handle the different permutations. However, if transactions typically only modify a few of the attributes, this limitation might not be a problem.
- Some relational databases might have an API to assist in automatically maintaining column data that is useful for optimistic versioning. Consult your database documentation to determine if this possibility exists.

Writing a loader

You can write your own loader plug-in implementation in your applications, which must follow the common WebSphere® eXtreme Scale plug-in conventions.

Including a loader plug-in

The Loader interface has the following definition:

```
public interface Loader
{
    static final SpecialValue KEY_NOT_FOUND;
    List get(TxID txid, List keyList, boolean forUpdate) throws LoaderException;
    void batchUpdate(TxID txid, LogSequence sequence) throws
                              LoaderException, OptimisticCollisionException;
    void preloadMap(Session session, BackingMap backingMap) throws LoaderException;
}
```

See Loaders for more information.

get method

The backing map calls the Loader get method to get the values that are associated with a key list that is passed as the keyList argument. The get method is required to return a java.lang.util.List list of values, one value for each key that is in the key list. The first value that is returned in the value list corresponds to the first key in the key list, the second value returned in the value list corresponds to the second key in the key list, and so on. If the loader does not find the value for a key in the key list, the Loader is required to return the special KEY_NOT_FOUND value object that is defined in the Loader interface. Because a backing map can be configured to allow `null` as a valid value, it is very important for the Loader to return the special KEY_NOT_FOUND object when the Loader cannot find the key. This special value allows the backing map to distinguish between a null value and a value that does not exist because the key was not found. If a backing map does not support null values, a Loader that returns a null value instead of the KEY_NOT_FOUND object for a key that does not exist results in an exception.

The forUpdate argument tells the Loader if the application called a get method on the map or a getForUpdate method on the map. See the ObjectMap interface for more information. The Loader is responsible for implementing a concurrency control policy that controls concurrent access to the persistent store. For example, many relational database management systems support the for update syntax on the SQL select statement that is used to read data from a relational table. The Loader can choose to use the for update syntax on the SQL select statement based on whether `boolean true` is passed as the argument value for the forUpdate parameter of this method. Typically, the Loader uses the for update syntax only when the pessimistic concurrency control policy is used. For an optimistic concurrency control, the Loader never uses `for update` syntax on the SQL select statement. The Loader is responsible to decide to use the forUpdate argument based on the concurrency control policy that is being used by the Loader.

For an explanation of the txid parameter, see Plug-ins for managing transaction life cycle events.

batchUpdate method

The batchUpdate method is important on the Loader interface. This method is called whenever the eXtreme Scale needs to apply all the current changes to the Loader. The Loader is given a list of changes for the selected Map. The changes are iterated and applied to the backend. The method receives the current TxID value and the changes to apply. The following sample iterates over the set of changes and batches three Java database connectivity (JDBC) statements, one with insert, another with update, and one with delete.

```
import java.util.Collection;
import java.util.Map;
import java.sql.PreparedStatement;
import java.sql.SQLException;
import com.ibm.websphere.objectgrid.TxID;
import com.ibm.websphere.objectgrid.plugins.Loader;
import com.ibm.websphere.objectgrid.plugins.LoaderException;
import com.ibm.websphere.objectgrid.plugins.LogElement;
import com.ibm.websphere.objectgrid.plugins.LogSequence;

    public void batchUpdate(TxID tx, LogSequence sequence) throws LoaderException {
        // Get a SQL connection to use.
        Connection conn = getConnection(tx);
        try {
            // Process the list of changes and build a set of prepared
            // statements for executing a batch update, insert, or delete
            // SQL operation.
            Iterator iter = sequence.getPendingChanges();
            while (iter.hasNext()) {
                LogElement logElement = (LogElement) iter.next();
                Object key = logElement.getKey();
                Object value = logElement.getCurrentValue();
                switch (logElement.getType().getCode()) {
                case LogElement.CODE_INSERT:
                    buildBatchSQLInsert(tx, key, value, conn);
                    break;
                case LogElement.CODE_UPDATE:
                    buildBatchSQLUpdate(tx, key, value, conn);
                    break;
                case LogElement.CODE_DELETE:
                    buildBatchSQLDelete(tx, key, conn);
                    break;
                }
            }
            // Execute the batch statements that were built by above loop.
            Collection statements = getPreparedStatementCollection(tx, conn);
            iter = statements.iterator();
            while (iter.hasNext()) {
                PreparedStatement pstmt = (PreparedStatement) iter.next();
                pstmt.executeBatch();
            }
```

```
        } catch (SQLException e) {
            LoaderException ex = new LoaderException(e);
            throw ex;
        }
    }
```

The preceding sample illustrates the high level logic of processing the LogSequence argument, but the details of how a SQL insert, update, or delete statement is built are not illustrated. Some of the key points that are illustrated include:

- The getPendingChanges method is called on the LogSequence argument to obtain an iterator over the list of LogElements that the Loader needs to process.
- The LogElement.getType().getCode() method is used to determine if the LogElement is for a SQL insert, update, or delete operation.
- An SQLException exception is caught and is chained to a LoaderException exception that prints to report that an exception occurred during the batch update.
- JDBC batch update support is used to minimize the number of queries to the backend that must be made.

preloadMap method

During the eXtreme Scale initialization, each backing map that is defined is initialized. If a Loader is plugged into a backing map, the backing map invokes the preloadMap method on the Loader interface to allow the loader to prefetch data from its back end and load the data into the map. The following sample assumes the first 100 rows of an Employee table is read from the database and is loaded into the map. The EmployeeRecord class is an application-provided class that holds the employee data that is read from the employee table.

Note: This sample fetches all the data from database and then insert them into the base map of one partition. In a real-world distributed eXtreme Scale deployment scenario, data should be distributed into all the partitions. Refer to Developing client-based JPA loaders for more information.

```
import java.sql.PreparedStatement;
import java.sql.SQLException;
import com.ibm.websphere.objectgrid.Session;
import com.ibm.websphere.objectgrid.TxID;
import com.ibm.websphere.objectgrid.plugins.Loader;
import com.ibm.websphere.objectgrid.plugins.LoaderException
```

```
    public void preloadMap(Session session, BackingMap backingMap) throws LoaderException {
        boolean tranActive = false;
        ResultSet results = null;
        Statement stmt = null;
        Connection conn = null;
        try {
            session.beginNoWriteThrough();
            tranActive = true;
            ObjectMap map = session.getMap(backingMap.getName());
            TxID tx = session.getTxID();
            // Get a auto-commit connection to use that is set to
            // a read committed isolation level.
            conn = getAutoCommitConnection(tx);
            // Preload the Employee Map with EmployeeRecord
            // objects. Read all Employees from table, but
            // limit preload to first 100 rows.
            stmt = conn.createStatement();
            results = stmt.executeQuery(SELECT_ALL);
            int rows = 0;
            while (results.next() && rows < 100) {
                int key = results.getInt(EMPNO_INDEX);
                EmployeeRecord emp = new EmployeeRecord(key);
                emp.setLastName(results.getString(LASTNAME_INDEX));
                emp.setFirstName(results.getString(FIRSTNAME_INDEX));
                emp.setDepartmentName(results.getString(DEPTNAME_INDEX));
                emp.updateSequenceNumber(results.getLong(SEQNO_INDEX));
                emp.setManagerNumber(results.getInt(MGRNO_INDEX));
                map.put(new Integer(key), emp);
                ++rows;
            }
            // Commit the transaction.
            session.commit();
            tranActive = false;
        } catch (Throwable t) {
            throw new LoaderException("preload failure: " + t, t);
        } finally {
            if (tranActive) {
                try {
                    session.rollback();
                } catch (Throwable t2) {
                    // Tolerate any rollback failures and
                    // allow original Throwable to be thrown.
                }
            }
            // Be sure to clean up other databases resources here
            // as well such a closing statements, result sets, etc.
        }
    }
```

This sample illustrates the following key points:

- The preloadMap backing map uses the Session object that is passed to it as the session argument.
- The Session.beginNoWriteThrough method is used to begin the transaction instead of the begin method.

- The Loader cannot be called for each put operation that occurs in this method for loading the map.
- The Loader can map columns of the employee table to a field in the EmployeeRecord Java object. The Loader catches all throwable exceptions that occur and throws a LoaderException exception with the caught throwable exception chained to it.
- The finally block ensures that any throwable exception that occurs between the time the beginNoWriteThrough method is called and the commit method is called cause the finally block to roll back the active transaction. This action is critical to ensure that any transaction that has been started by the preloadMap method is completed before returning to the caller. The finally block is a good place to perform other cleanup actions that might be needed, like closing the JDBC connection and other JDBC objects.

The preloadMap sample is using a SQL select statement that selects all rows of the table. In your application-provided Loader, you might need to set one or more Loader properties to control how much of the table needs to be preloaded into the map.

Because the preloadMap method is only called one time during the BackingMap initialization, it is also a good place to run the one time Loader initialization code. Even if a Loader chooses not to prefetch data from the backend and load the data into the map, it probably needs to perform some other one time initialization to make other methods of the Loader more efficient. The following example illustrates caching the TransactionCallback object and OptimisticCallback object as instance variables of the Loader so that the other methods of the Loader do not have to make method calls to get access to these objects. This caching of the ObjectGrid plug-in values can be performed because after the BackingMap is initialized, the TransactionCallback and the OptimisticCallback objects cannot be changed or replaced. It is acceptable to cache these object references as instance variables of the Loader.

```
import com.ibm.websphere.objectgrid.Session;
import com.ibm.websphere.objectgrid.BackingMap;
import com.ibm.websphere.objectgrid.plugins.OptimisticCallback;
import com.ibm.websphere.objectgrid.plugins.TransactionCallback;

    // Loader instance variables.
    MyTransactionCallback ivTcb; // MyTransactionCallback

    // extends TransactionCallback
    MyOptimisticCallback ivOcb; // MyOptimisticCallback

    // implements OptimisticCallback
    // ...
    public void preloadMap(Session session, BackingMap backingMap) throws LoaderException
                  [Replication programming]
        // Cache TransactionCallback and OptimisticCallback objects
        // in instance variables of this Loader.
        ivTcb = (MyTransactionCallback) session.getObjectGrid().getTransactionCallback();
        ivOcb = (MyOptimisticCallback) backingMap.getOptimisticCallback();
        // The remainder of preloadMap code (such as shown in prior example).
    }
```

For information about preloading and recoverable preloading as it pertains to replication failover, see Replication for availabilitythe information about replication in the *Product Overview*.

Loaders with entity maps

If the loader is plugged into an entity map, the loader must handle tuple objects. Tuple objects are a special entity data format. The loader must conversion data between tuple and other data formats. For example, the get method returns a list of values that correspond to the set of keys that are passed in to the method. The passed-in keys are in the type of Tuple, says key tuples. Assuming that the loader persists the map with a database using JDBC, the get method must convert each key tuple into a list of attribute values that correspond to the primary key columns of the table that is mapped to the entity map, run the SELECT statement with the WHERE clause that uses converted attribute values as criteria to fetch data from database, and then convert the returned data into value tuples. The get method gets data from the database and converts the data into value tuples for passed-in key tuples, and then returns a list of value tuples correspond to the set of tuple keys that are passed in to the caller. The get method can perform one SELECT statement to fetch all data at one time, or run a SELECT statement for each key tuple. For programming details that show how to use the Loader when the data is store using an entity manager, see Using a loader with entity maps and tuples.

JPA loader programming considerations

Map pre-loading

Maps can be associated with Loaders. A loader is used to fetch objects when they cannot be found in the map (a cache miss) and also to write changes to a back-end when a transaction commits. Loaders can also be used for pre-loading data into a map. The preloadMap method of the Loader interface is called on each map when its corresponding partition in the map set becomes a primary. The preloadMap method is not called on replicas. It attempts to load all the intended referenced data from the back-end into the map using the provided session. The relevant map is identified by the BackingMap argument that is passed to the preloadMap method.

```
void preloadMap(Session session, BackingMap backingMap) throws LoaderException;
```

Pre-loading in partitioned map set

Maps can be partitioned into N partitions. Maps can therefore be striped across multiple servers, with each entry identified by a key that is stored only on one of those servers. Very large maps can be held in a data grid because the application is no longer limited by the heap size of a single Java™ virtual machine (JVM) to

hold all the entries of a Map. Applications that want to preload with the preloadMap method of the Loader interface must identify the subset of the data that it preloads. A fixed number of partitions always exists. You can determine this number by using the following code example:

```
int numPartitions = backingMap.getPartitionManager().getNumOfPartitions();
int myPartition = backingMap.getPartitionId();
```

This code example shows how an application can identify the subset of the data to preload from the database. Applications must always use these methods even when the map is not initially partitioned. These methods allow flexibility: If the map is later partitioned by the administrators, then the loader continues to work correctly.
The application must issue queries to retrieve the *myPartition* subset from the backend. If a database is used, then it might be easier to have a column with the partition identifier for a given record unless there is some natural query that allows the data in the table to partition easily.

See Writing a loader with a replica preload controller for an example on how to implement a Loader for a replicated data grid.

Performance

The preload implementation copies data from the back-end into the map by storing multiple objects in the map in a single transaction. The optimal number of records to store per transaction depends on several factors, including complexity and size. For example, after the transaction includes blocks of more than 100 entries, the performance benefit decreases as you increase the number of entries. To determine the optimal number, begin with 100 entries and then increase the number until the performance benefit decreases to none. Larger transactions result in better replication performance. Remember, only the primary runs the preload code. The preloaded data is replicated from the primary to any replicas that are online.

Pre-loading map set

If the application uses a map set with multiple maps then each map has its own loader. Each loader has a preload method. Each map is loaded serially by the data grid. It might be more efficient to preload all the maps by designating a single map as the pre-loading map. This process is an application convention. For example, two maps, department and employee, might use the department Loader to preload both the department and the employee maps. This procedure ensures that, transactionally, if an application wants a department then the employees for that department are in the cache. When the department Loader preloads a department from the back-end, it also fetches the employees for that department. The department object and its associated employee objects are then added to the map using a single transaction.

Recoverable pre-loading

Some customers have very large data sets that need caching. Pre-loading this data can be very time consuming. Sometimes, the pre-loading must complete before the application can go online. You can benefit from making pre-loading recoverable. Suppose there are a million records to preload. The primary is pre-loading them and fails at the 800,000th record. Normally, the replica chosen to be the new primary clears any replicated state and starts from the beginning. eXtreme Scale can use a ReplicaPreloadController interface. The loader for the application would also need to implement the ReplicaPreloadController interface. This example adds a single method to the Loader: `Status checkPreloadStatus(Session session, BackingMap bmap);`. This method is called by the eXtreme Scale run time before the preload method of the Loader interface is normally called. The eXtreme Scale tests the result of this method (Status) to determine its behavior whenever a replica is promoted to a primary.

Table 1. Status value and response

Returned status value	eXtreme Scale response
`Status.PRELOADED_ALREADY`	eXtreme Scale does not call the preload method at all because this status value indicates that the map is fully preloaded.
`Status.FULL_PRELOAD_NEEDED`	eXtreme Scale clears the map and calls the preload method normally.
`Status.PARTIAL_PRELOAD_NEEDED`	eXtreme Scale leaves the map as-is and calls preload. This strategy allows the application loader to continue pre-loading from that point onwards.

Clearly, while a primary is pre-loading the map, it must leave some state in a map in the MapSet that is being replicated so that the replica determines what status to return. You can use an extra map named, for example, RecoveryMap map. This RecoveryMap map must be part of the same MapSet map set that is being preloaded to ensure that the map is replicated consistently with the data being preloaded. A suggested implementation follows.

As the preload commits each block of records, the process also updates a counter or value in the RecoveryMap map as part of that transaction. The preloaded data and the RecoveryMap map data are replicated atomically to the replicas. When the replica is promoted to primary, it can now check the RecoveryMap map to see what has happened.

The RecoveryMap map can hold a single entry with the state key. If no object exists for this key then you need a full preload (checkPreloadStatus returns FULL_PRELOAD_NEEDED). If an object exists for this state key and the value is COMPLETE, the preload completes, and the checkPreloadStatus method returns `PRELOADED_ALREADY`. Otherwise, the value object indicates where the preload restarts and the checkPreloadStatus method returns `PARTIAL_PRELOAD_NEEDED`. The loader can store the recovery point in an instance variable for the loader so that when preload is called, the loader knows the starting point. The RecoveryMap map can also hold an entry per map if each map is preloaded independently.

Handling recovery in synchronous replication mode with a Loader

The eXtreme Scale run time is designed not to lose committed data when the primary fails. The following section shows the algorithms used. These algorithms apply only when a replication group uses synchronous replication. A loader is optional.

The eXtreme Scale run time can be configured to replicate all changes from a primary to the replicas synchronously. When a synchronous replica is placed, it receives a copy of the existing data on the primary shard. During this time, the primary continues to receives transactions and copies them to the replica asynchronously. The replica is not considered to be online at this time.

After the replica catches up the primary, the replica enters peer mode and synchronous replication begins. Every transaction committed on the primary is sent to the synchronous replicas and the primary waits for a response from each replica. A synchronous commit sequence with a Loader on the primary looks like the following set of steps:

Table 2. Commit sequence on the primary

Step with loader	Step without loader

Step with loader	Step without loader
Get locks for entries	same
Flush changes to the loader	no-op
Save changes to the cache	same
Send changes to replicas and wait for acknowledgement	same
Commit to the loader through the TransactionCallback plug-in	plug-in commit called, but does nothing
Release locks for entries	same

Notice that the changes are sent to the replica before they are committed to the loader. To determine when the changes are committed on the replica, revise this sequence: At initialize time, initialize the tx lists on the primary as below.

```
CommitedTx = {}, RolledBackTx = {}
```

During synchronous commit processing, use the following sequence:

Table 3. Synchronous commit processing

Step with loader	Step without loader
Get locks for entries	same
Flush changes to the loader	no-op
Save changes to the cache	same
Send changes with a committed transaction, roll back transaction to replica, and wait for acknowledgement	same
Clear list of committed transactions and rolled back transactions	same
Commit the loader through the TransactionCallBack plug-in	TransactionCallBack plug-in commit is still called, but typically does not do anything
If commit succeeds, add the transaction to the committed transactions, otherwise add to the rolled back transactions	no-op
Release locks for entries	same

For replica processing, use the following sequence:

1. Receive changes
2. Commit all received transactions in the committed transaction list
3. Roll back all received transactions in the rolled back transaction list
4. Start a transaction or session
5. Apply changes to the transaction or session
6. Save the transaction or session to the pending list
7. Send back reply

Notice that on the replica, no loader interactions occur while the replica is in replica mode. The primary must push all changes through the Loader. The replica does not change data. A side effect of this algorithm is that the replica always has the transactions, but they are not committed until the next primary transaction sends the commit status of those transactions. The transactions are then committed or rolled back on the replica. Until then, the transactions are not committed. You can add a timer on the primary that sends the transaction outcome after a small time period (a few seconds). This timer limits, but does not eliminate, any staleness to that time window. This staleness is only a problem when using replica read mode. Otherwise, the staleness does not have an impact on the application.

When the primary fails, it is likely that a few transactions were committed or rolled back on the primary, but the message never made it to the replica with these outcomes. When a replica is promoted to the new primary, one of the first actions is to handle this condition. Each pending transaction is reprocessed against the new primary's set of maps. If there is a Loader, then each transaction is given to the Loader. These transactions are applied in strict first in first out (FIFO) order. If a transaction fails, it is ignored. If three transactions are pending, A, B, and C, then A might commit, B might rollback, and C might also commit. No one transaction has any impact on the others. Assume that they are independent.

A loader might want to use slightly different logic when it is in failover recovery mode versus normal mode. The loader can easily know when it is in failover recovery mode by implementing the ReplicaPreloadController interface. The checkPreloadStatus method is only called when failover recovery completes. Therefore, if the apply method of the Loader interface is called before the checkPreloadStatus method, then it is a recovery transaction. After the checkPreloadStatus method is called, the failover recovery is complete.

Configuring write-behind loader support

You can enable write-behind support with the ObjectGrid descriptor XML file or programmatically with the BackingMap interface.

Use either the ObjectGrid descriptor XML file to enable write-behind support, or programmatically by using the BackingMap interface.

ObjectGrid descriptor XML file

When you configure an ObjectGrid with an ObjectGrid descriptor XML file, the write-behind loader is enabled by setting the writeBehind attribute on the backingMap tag. An example follows:

```
<objectGrid name="library" >
     <backingMap name="book" writeBehind="T300;C900" pluginCollectionRef="bookPlugins"/>
```

In the previous example, write-behind support of the book backing map is enabled with parameter T300;C900. The write-behind attribute specifies the maximum update time, maximum key update count, or both. The format of the write-behind parameter is:

```
write-behind attribute ::=<defaults> | <update time> | <update key count> | <update time> ";" <update key count>

update time ::= "T" <positive integer>
update key count ::= "C" <positive integer>
defaults ::= "" {table}
```

Updates to the loader occur when one of the following events occurs:

1. The maximum update time in seconds has elapsed since the last update.
2. The number of updated keys in the queue map has reached the update key count.

These parameters are only hints. The real update count and update time will be within close range of the parameters. However, we do not guarantee that the actual update count or update time are the same as defined in the parameters. Also, to prevent all partitions from accessing the database simultaneously, the ObjectGrid randomizes the update starting time. For example, the first update can occur after up to twice as long as the real update time.

In the previous example T300;C900, the loader writes the data to the back-end when 300 seconds have passed since the last update or when 900 keys are pending to be updated. The default update time is 300 seconds and the default update key count is 1000.

Table 1. Some write-behind options

Attribute value	Time
T100	The update time is 100 seconds, and the update key count is 1000 (the default value)
C2000	The update time is 300 seconds (the default value), and the update key count is 2000.
T300;C900	The update time is 300 seconds and the update key count is 900.
""	The update time is 300 second (the default value), and the update key count is 1000 (the default value). Note: If you configure the write-behind loader as an empty string: `writeBehind=""`, the write-behind loader is enabled with the default values. Therefore, do not specify the writeBehind attribute if you do not want write-behind support enabled.

Programmatically enabling write-behind support

When you are creating a backing map programmatically for a local, in-memory eXtreme Scale, you can use the following method on the BackingMap interface to enable and disable write-behind support.

```
public void setWriteBehind(String writeBehindParam);
```

For more details about how to use the setWriteBehind method, see BackingMap interface.

- Write-behind caching
  You can use write-behind caching to reduce the overhead that occurs when updating a database you are using as a back end.
- Write-behind loader application design considerations
  When you implement a write-behind loaders, you must consider several issues such as integrity constraints, locking behavior, and performance.
- Handling failed write-behind updates
  Because the WebSphere® eXtreme Scale transaction finishes before the back-end transaction starts, the transaction could have false success.

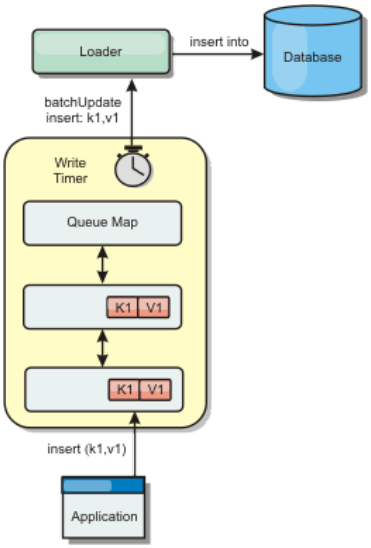
Write-behind caching

You can use write-behind caching to reduce the overhead that occurs when updating a database you are using as a back end.

Write-behind caching overview

Write-behind caching asynchronously queues updates to the Loader plug-in. You can improve performance by disconnecting updates, inserts, and removes for a map, the overhead of updating the back-end database. The asynchronous update is performed after a time-based delay (for example, five minutes) or an entry-based delay (1000 entries).

Figure 1. Write-behind caching



The write-behind configuration on a BackingMap creates a thread between the loader and the map. The loader then delegates data requests through the thread according to the configuration settings in the BackingMap.setWriteBehind method. When an eXtreme Scale transaction inserts, updates, or removes an entry from a map, a LogElement object is created for each of these records. These elements are sent to the write-behind loader and queued in a special ObjectMap called a queue map. Each backing map with the write-behind setting enabled has its own queue maps. A write-behind thread periodically removes the queued data from the queue maps and pushes them to the real back-end loader.

The write-behind loader only sends insert, update, and delete types of LogElement objects to the real loader. All other types of LogElement objects, for example, EVICT type, are ignored.

Write-behind support *is* an extension of the Loader plug-in, which you use to integrate eXtreme Scale with the database. For example, consult the Configuring JPA loaders information about configuring a JPA loader.

Benefits

Enabling write-behind support has the following benefits:

- **Back end failure isolation:** Write-behind caching provides an isolation layer from back end failures. When the back-end database fails, updates are queued in the queue map. The applications can continue driving transactions to eXtreme Scale. When the back end recovers, the data in the queue map is pushed to the back-end.
- **Reduced back end load:** The write-behind loader merges the updates on a key basis so only one merged update per key exists in the queue map. This merge decreases the number of updates to the back-end database.
- **Improved transaction performance:** Individual eXtreme Scale transaction times are reduced because the transaction does not need to wait for the data to be synchronized with the back-end.

Write-behind loader application design considerations

When you implement a write-behind loaders, you must consider several issues such as integrity constraints, locking behavior, and performance.

Application design considerations

Enabling write-behind support is simple, but designing an application to work with write-behind support needs careful consideration. Without write-behind support, the ObjectGrid transaction encloses the back-end transaction. The ObjectGrid transaction starts before the back-end transaction starts, and it ends after the back-end transaction ends.

With write-behind support enabled, the ObjectGrid transaction finishes before the back-end transaction starts. The ObjectGrid transaction and back-end transaction are de-coupled.

Referential integrity constraints

Each backing map that is configured with write-behind support has its own write-behind thread to push the data to the back-end. Therefore, the data that updated to different maps in one ObjectGrid transaction are updated to the back-end in different back-end transactions. For example, transaction T1 updates key key1 in map Map1 and key key2 in map Map2. The key1 update to map Map1 is updated to the back-end in one back-end transaction, and the key2 updated to map Map2 is updated to the back-end in another back-end transaction by different write-behind threads. If data stored in Map1 and Map2 have relations, such as foreign key constraints in the back-end, the updates might fail.

When designing the referential integrity constraints in your back-end database, ensure that out-of-order updates are allowed.

Queue map locking behavior

Another major transaction behavior difference is the locking behavior. ObjectGrid supports three different locking strategies: PESSIMISTIC, OPTIMISITIC, and NONE. The write-behind queue maps uses pessimistic locking strategy no matter which lock strategy is configured for its backing map. Two different types of operations exist that acquire a lock on the queue map:

- When an ObjectGrid transaction commits, or a flush (map flush or session flush) happens, the transaction reads the key in the queue map and places an S lock on the key.
- When an ObjectGrid transaction commits, the transaction tries to upgrade the S lock to X lock on the key.

Because of this extra queue map behavior, you can see some locking behavior differences.

- If the user map is configured as PESSIMISTIC locking strategy, there isn't much locking behavior difference. Every time a flush or commit is called, an S lock is placed on the same key in the queue map. During the commit time, not only is an X lock acquired for key in the user map, it is also acquired for the key in the queue map.
- If the user map is configured as OPTIMISTIC or NONE locking strategy, the user transaction will follow the PESSIMISTIC locking strategy pattern. Every time a flush or commit is called, an S lock is acquired for the same key in the queue map. During the commit time, an X lock is acquired for the key in the queue map using the same transaction.

Loader transaction retries

ObjectGrid does not support 2-phase or XA transactions. The write-behind thread removes records from the queue map and updates the records to the back-end. If the server fails in the middle of the transaction, some back-end updates can be lost.

The write-behind loader will automatically retry to write failed transactions and will send an in-doubt LogSequence to the back-end to avoid data loss. This action requires the loader to be idempotent, which means when the Loader.batchUpdate(TxId, LogSequence) is called twice with the same value, it gives the same result as if it were applied one time. Loader implementations must implement the RetryableLoader interface to enable this feature. See the API documentation for more details.

Write-behind caching performance considerations

Write-behind caching support improves response time by removing the loader update from the transaction. It also increases database throughput because database updates are combined. It is important to understand the overhead introduced by write-behind thread, which pulls the data out of the queue map and pushed to the loader.

The maximum update count or the maximum update time need to be adjusted based on the expected usage patterns and environment. If the value of the maximum update count or the maximum update time is too small, the overhead of the write-behind thread may exceed the benefits. Setting a large value for these two parameters could also increase the memory usage for queuing the data and increase the stale time of the database records.

For best performance, tune the write-behind parameters based on the following factors:

- Ratio of read and write transactions
- Same record update frequency
- Database update latency.

Example: Writing a write-behind dumper class

Handling failed write-behind updates

Because the WebSphere® eXtreme Scale transaction finishes before the back-end transaction starts, the transaction could have false success.

If you try to insert an entry in an eXtreme Scale transaction that does not exist in the backing map but exists in the backend database, causing a duplicate key, the eXtreme Scale transaction succeeds. However, the transaction in which the write-behind thread inserts the object into the backend database fails with a duplicate key exception.

Handling failed write-behind updates: client side

Such an update, or any other failed back-end update, is a failed write-behind update. Failed write-behind updates are stored in a failed write-behind update map. This map serves as an event queue for failed updates. The key of the update is a unique Integer object, and the value is an instance of FailedUpdateElement. The failed write-behind update map is configured with an evictor, which evicts the records one hour after it has been inserted. So the failed-update records are lost if they are not retrieved within one hour.

The ObjectMap API can be used to retrieve the failed write-behind update map entries. The failed write-behind update map name is: `IBM_WB_FAILED_UPDATES_<map name>`. See the WriteBehindLoaderConstants API documentation for the prefix names of each of the write-behind system maps. The following is an example.

```
process failed - example code
ObjectMap failedMap = session.getMap(
    WriteBehindLoaderConstants.WRITE_BEHIND_FAILED_UPDATES_MAP_PREFIX + "Employee");
Object key = null;

session.begin();
while(key = failedMap.getNextKey(ObjectMap.QUEUE_TIMEOUT_NONE)) {
    FailedUpdateElement element = (FailedUpdateElement) failedMap.get(key);
    Throwable throwable = element.getThrowable();
    Object failedKey = element.getKey();
    Object failedValue = element.getAfterImage();
    failedMap.remove(key);
    // Do something interesting with the key, value, or exception.

}
session.commit();
```

A getNextKey method call works with a specific partition for each eXtreme Scale transaction. In a distributed environment, to get keys from all partitions, you must start multiple transactions, as shown in the following example:

```
getting keys from all partitions - example code
ObjectMap failedMap = session.getMap(
    WriteBehindLoaderConstants.WRITE_BEHIND_FAILED_UPDATES_MAP_PREFIX + "Employee");
while (true) {
    session.begin();
    Object key = null;
    while(( key = failedMap.getNextKey(5000) )!= null ) {
        FailedUpdateElement element = (FailedUpdateElement) failedMap.get(key);
    Throwable throwable = element.getThrowable();
        Object failedKey = element.getKey();
        Object failedValue = element.getAfterImage();
        failedMap.remove(key);
        // Do something interesting with the key, value, or exception.

    }
    Session.commit();
}
```

Note: The failed update map provides a way to monitor the application health. If a system produces many records in the failed update map, it is a sign that you need to revise the application or architecture to use the write-behind support. You can use the **xscmd -showMapSizes** command to see the failed update map entry size.

Handling failed write-behind updates: shard listener

It is important to detect and log when a write-behind transaction fails. Every application using write-behind needs to implement a watcher to handle failed write-behind updates. This avoids potentially running out of memory as records in the bad update Map are not evicted because the application is expected to handle them.

The following code shows how to plug in such a watcher, or "dumper," which must be added to the ObjectGrid descriptor XML as in the snippet.

```
        <objectGrid name="Grid">
                <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsfailupdate_ObjectGridEventListener
" className="utils.WriteBehindDumper"/>
```

You can see the ObjectGridEventListener bean that has been added, which is the write-behind watcher referred to above. The watcher interacts over the Maps for all primary shards in a JVM looking for ones with write-behind enabled. If it finds one then it tries to log up to 100 bad updates. It keeps watching a primary shard until the shard is moved to a different JVM. All applications using write-behind must use a watcher similar to this one. Otherwise, the Java™ virtual machines run out of memory because this error map is never evicted

See Example: Writing a write-behind dumper class for more information.

/**
 * Write behind expects transactions to the Loader to succeed. If a transaction for a key fails then
 * it inserts an entry in a Map called PREFIX + mapName. The application should be checking this
 * map for entries to dump out write behind transaction failures. The application is responsible for
 * analyzing and then removing these entries. These entries can be large as they include the key, before
 * and after images of the value and the exception itself. Exceptions can easily be 20k on their own.
 *
 * The class is registered with the grid and an instance is created per primary shard in a JVM. It creates
 * a single thread
 * and that thread then checks each write behind error map for the shard, prints out the problem and
 * then removes the entry.
 *
 * This means there will be one thread per shard. If the shard is moved to another JVM then the deactivate
 * method stops the thread.

                                                continue;
                                        }
                                        // try to dump out up to N records at once
                                        session.begin();
                                        for(int counter = 0; counter < 100; ++counter)
                                        {
                                                Integer seqKey = (Integer)errorMap.getNextKey(1L);
                                                if(seqKey != null)
                                                {
                                                        foundErrors = true;
                                                        FailedUpdateElement elem =
(FailedUpdateElement)errorMap.get(seqKey);
                                                        //
                                                        // Your application should log the problem here
                                                        logger.info("WriteBehindDumper ( " + origName + ") for key (" +
elem.getKey() + ") Exception: " +
                                                                elem.getThrowable().toString());
                                                        //
                                                        //
```

```
                                                errorMap.remove(seqKey);
                                        }
                                        else
                                                break;
                                }
                                session.commit();
                        }
                } // do next map
                // loop faster if there are errors
                if(isShardActive)
                {
                        // reschedule after one second if there were bad records
                        // otherwise, wait 20 seconds.
                        if(foundErrors)
                                future = pool.schedule(this, 1L, TimeUnit.SECONDS);
                        else
                                future = pool.schedule(this, BLOCKTIME_SECS, TimeUnit.SECONDS);
                }
        }
        catch(ObjectGridException e)
        {
                logger.fine("Exception in WriteBehindDumper" + e.toString());
                e.printStackTrace();

                //don't leave a transaction on the session.
                if(session.isTransactionActive())
                {
                        try { session.rollback(); } catch(Exception e2) {}
                }
        }
        return true;
    }

    public void destroy() {
            // TODO Auto-generated method stub

    }

    public void initialize(Session arg0) {
            // TODO Auto-generated method stub

    }

JPA loader programming considerations

A Java™ Persistence API (JPA) Loader is a loader plug-in implementation that uses JPA to interact with the database. Use the following considerations when you develop an application that uses a JPA loader.

eXtreme Scale entity and JPA entity

You can designate any POJO class as an eXtreme Scale entity using eXtreme Scale entity annotations, XML configuration, or both. You can also designate the same POJO class as a JPA entity using JPA entity annotations, XML configuration, or both.

eXtreme Scale entity: An eXtreme Scale entity represents persistent data that is stored in ObjectGrid maps. An entity object is transformed into a key tuple and a value tuple, which are then stored as key-value pairs in the maps. A tuple is an array of primitive attributes.

JPA entity: A JPA entity represents persistent data that is stored in a relational database automatically using container-managed persistence. The data is persisted in some form of a data storage system in the appropriate form, such as database tuples in a database.

When an eXtreme Scale entity is persisted, its relations are stored in other entity maps. For example, when you are persisting a Consumer entity with a one-to-many relation to a ShippingAddress entity, if cascade-persist is enabled, the ShippingAddress entity is stored in the shippingAddress map in tuple format. If you

are persisting a JPA entity, the related JPA entities are also persisted to database tables if cascade-persist is enabled. When a POJO class is designated as both an eXtreme Scale entity and a JPA entity, the data can be persisted to both ObjectGrid entity maps and databases. Common uses follow:

- **Preload scenario**: An entity is loaded from a database using a JPA provider and persists it into ObjectGrid entity maps.
- **Loader scenario**: A Loader implementation is plugged in for the ObjectGrid entity maps so an entity stored in ObjectGrid entity maps can be persisted into or loaded from a database using JPA providers.

It is also common that a POJO class is designated as a JPA entity only. In that case, what is stored in the ObjectGrid maps are the POJO instances, versus the entity tuples in the ObjectGrid entity case.

Application design considerations for entity maps

When you are plugging in a JPALoader interface, the object instances are directly stored in the ObjectGrid maps.

However, you are when plugging in a JPAEntityLoader, the entity class is designated as both an eXtreme Scale entity and a JPA entity. In that case, treat this entity as if it has two persistent stores: the ObjectGrid entity maps and the JPA persistence store. The architecture becomes more complicated than the JPALoader case.

For more information about the JPAEntityLoader plug-in and application design considerations, see JPAEntityLoader plug-in. This information can also help if you plan to implement your own loader for the entity maps.

Performance considerations

Ensure that you set the proper eager or lazy fetch type for relationships. For example, a bidirectional one-to-many relationship Consumer to ShippingAddress, with OpenJPA to help explain the performance differences. In this example, a JPA query attempts `select o from Consumer o where . . .` to do a bulk load, and also load all related ShippingAddress objects. A one-to-many relationship defined in the Consumer class follows:

```
@Entity
public class Consumer implements Serializable {

    @OneToMany(mappedBy="consumer",cascade=CascadeType.ALL, fetch =FetchType.EAGER)
    ArrayList <ShippingAddress> addresses;
```

The many-to-one relation consumer defined in the ShippingAddress class follows:

```
@Entity
public class ShippingAddress implements Serializable{

    @ManyToOne(fetch=FetchType.EAGER)
    Consumer consumer;
}
```

If the fetch types of both relationships are configured as `eager`, OpenJPA uses N+1+1 queries to get all the Consumer objects and ShippingAddress objects, where N is the number of ShippingAddress objects. However if the ShippingAddress is changed to use lazy fetch type as follows, it only takes two queries to get all the data.

```
@Entity
public class ShippingAddress implements Serializable{

    @ManyToOne(fetch=FetchType.LAZY)
    Consumer consumer;
}
```

Although the query returns the same results, having a lower number of queries significantly decreases interaction with the database, which can increase application performance.

- JPAEntityLoader plug-in
  The JPAEntityLoader plug-in is a built-in Loader implementation that uses Java Persistence API (JPA) to communicate with the database when you are using the EntityManager API. When you are using the ObjectMap API, use the JPALoader loader.

JPAEntityLoader plug-in

The JPAEntityLoader plug-in is a built-in Loader implementation that uses Java™ Persistence API (JPA) to communicate with the database when you are using the EntityManager API. When you are using the ObjectMap API, use the JPALoader loader.

Loader details

Use the JPALoader plug-in when you are storing data using the ObjectMap API. Use the JPAEntityLoader plug-in when you are storing data using the EntityManager API.

Loaders provide two main functions:

1. **get**: In the get method, the JPAEntityLoader plug-in first calls the javax.persistence.EntityManager.find(Class entityClass, Object key) method to find the JPA entity. Then the plug-in projects this JPA entity into entity tuples. During the projection, both the tuple attributes and the association keys are stored in the value tuple. After processing each key, the get method returns a list of entity value tuples.
2. **batchUpdate**: The batchUpdate method takes a LogSequence object that contains a list of LogElement objects. Each LogElement object contains a key tuple and a value tuple. To interact with the JPA provider, you must first find the eXtreme Scale entity based on the key tuple. Based on the LogElement type, you run the following JPA calls:
   - **insert**: javax.persistence.EntityManager.persist(Object o)
   - **update**: javax.persistence.EntityManager.merge(Object o)
   - **remove**: javax.persistence.EntityManager.remove(Object o)

A LogElement with type **update** makes the JPAEntityLoader call the javax.persistence.EntityManager.merge(Object o) method to merge the entity. However, an **update** type LogElement might be the result of either a com.ibm.websphere.objectgrid.em.EntityManager.merge(object o) call or an attribute change of the eXtreme Scale EntityManager managed-instance. See the following example:

```
com.ibm.websphere.objectgrid.em.EntityManager em = og.getSession().getEntityManager();
em.getTransaction().begin();
Consumer c1 = (Consumer) em.find(Consumer.class, c.getConsumerId());
c1.setName("New Name");
em.getTransaction().commit();
```

In this example, an update type LogElement is sent to the JPAEntityLoader of the map consumer. The javax.persistence.EntityManager.merge(Object o) method is called to the JPA entity manager instead of an attribute update to the JPA-managed entity. Because of this changed behavior, some limitations exist with using this programming model.

Application design rules

Entities have relationships with other entities. Designing an application with relationships involved and with JPAEntityLoader plugged in requires additional considerations. The application should follow the following four rules, described in the following sections.

Limited relationship depth support

The JPAEntityLoader is only supported when using entities without any relationships or entities with single-level relationships. Relationships with more than one level, such as `Company > Department > Employee` are not supported.

One loader per map

Using the Consumer-ShippingAddress entity relationships as an example, when you load a consumer with eager fetch enabled, you could load all the related ShippingAddress objects. When you persist or merge a Consumer object, you could persist or merge related ShippingAddress objects if cascade-persist or cascade-merge is enabled.

You cannot plug in a loader for the root entity map which stores the Consumer entity tuples. You must configure a loader for each entity map.

Same cascade type for JPA and eXtreme Scale

Reconsider the scenario where the entity Consumer has a one-to-many relationship with ShippingAddress. You can look at the scenario where cascade-persist is enabled for this relationship. When a Consumer object is persisted into eXtreme Scale, the associated N number of ShippingAddress objects are also persisted into eXtreme Scale.

A persist call of the Consumer object with a cascade-persist relationship to ShippingAddress translates to one javax.persistence.EntityManager.persist(consumer) method call and *N* javax.persistence.EntityManager.persist(shippingAddress) method calls by the JPAEntityLoader layer. However, these N extra persist calls to ShippingAddress objects are unnecessary because of the cascade-persist setting from the JPA provider point of view. To solve this problem, eXtreme Scale provides a new method isCascaded on the LogElement interface. The isCascaded method indicates whether the LogElement is a result of an eXtreme Scale EntityManager cascade operation. In this example, the JPAEntityLoader of the ShippingAddress map receives *N* LogElement objects because of the cascade persist calls. The JPAEntityLoader finds out that the isCascaded method returns true and then ignores them without making any JPA calls. Therefore, from a JPA point of view, only one javax.persistence.EntityManager.persist(consumer) method call is received.

The same behavior is exhibited if you merge an entity or remove an entity with cascade enabled. The cascaded operations are ignored by the JPAEntityLoader plug-in.

The design of the cascade support is to replay the eXtreme Scale EntityManager operations to the JPA providers. These operations include persist, merge, and remove operations. To enable cascade support, verify that the cascade setting for the JPA and the eXtreme Scale EntityManager are the same.

Use entity update with caution

As previously described, the design of the cascade support is to replay eXtreme Scale EntityManager operations to the JPA providers. If your application calls the ogEM.persist(consumer) method to the eXtreme Scale EntityManager, even the associated ShippingAddress objects are persisted because of the cascade-persist setting, and the JPAEntityLoader only calls the jpAEM.persist(consumer) method to the JPA providers.

However, if your application updates a managed entity, this update translates to a JPA merge call by the JPAEntityLoader plug-in. In this scenario, support for multiple levels of relationships and key associations is not guaranteed. In this case, the best practice is to use the javax.persistence.EntityManager.merge(o) method instead of updating a managed entity.

Using a loader with entity maps and tuples

The entity manager converts all entity objects into tuple objects before they are stored in an WebSphere® eXtreme Scale map. Every entity has a key tuple and a value tuple. This key-value pair is stored in the associated eXtreme Scale map for the entity. When you are using an eXtreme Scale map with a loader, the loader must interact with the tuple objects.

eXtreme Scale includes loader plug-ins that simplify integration with relational databases. The Java™ Persistence API (JPA) Loaders use a Java Persistence API to interact with the database and create the entity objects. The JPA loaders are compatible with eXtreme Scale entities.

Tuples

A tuple contains information about the attributes and associations of an entity. Primitive values are stored using their primitive wrappers. Other supported object types are stored in their native format. Associations to other entities are stored as a collection of key tuple objects that represent the keys of the target entities.

Each attribute or association is stored using a zero-based index. You can retrieve the index of each attribute using the getAttributePosition or getAssociationPosition methods. After the position is retrieved, it remains unchanged for the duration of the eXtreme Scale life cycle. The position can change when the eXtreme Scale is restarted. The setAttribute, setAssociation and setAssociations methods are used to update the elements in the tuple.

Attention: When you are creating or updating tuple objects, update every primitive field with a non-null value. Primitive values such as `int` should not be null. If you do not change the value to a default, poor performance issues can result, also affecting fields marked with the @Version annotation or version attribute in the entity descriptor XML file.
The following example further explains how to process tuples. For more information about defining entities for this example, see Entity manager tutorial: Order Entity Schema. WebSphere eXtreme Scale is configured for using loaders with each of the entities. Additionally, only the Order entity is taken, and this specific entity has a many-to-one relationship with the Customer entity. The attribute name is `customer`, and it has a one-to-many relationship with the OrderLine entity.

Use the Projector to build Tuple objects automatically from entities. Using the Projector can simplify loaders when you are using an object-relational mapping utility such as Hibernate or JPA.

order.java

```
@Entity
public class Order
{
    @Id  String orderNumber;
    java.util.Date date;
    @OneToOne(cascade=CascadeType.PERSIST) Customer customer;
    @OneToMany(cascade=CascadeType.ALL, mappedBy="order") @OrderBy("lineNumber") List<OrderLine> lines;
}
```

customer.java

```
@Entity
public class Customer {
    @Id String id;
    String firstName;
    String surname;
    String address;
    String phoneNumber;
}
```

orderLine.java

```
@Entity
public class OrderLine
{
    @Id @ManyToOne(cascade=CascadeType.PERSIST) Order order;
    @Id int lineNumber;
    @OneToOne(cascade=CascadeType.PERSIST) Item item;
    int quantity;
    double price;
}
```

A OrderLoader class that implements the Loader interface is shown in the following code. The following example assumes that an associated TransactionCallback plug-in is defined.

orderLoader.java

```
public class OrderLoader implements com.ibm.websphere.objectgrid.plugins.Loader {

        private EntityMetadata entityMetaData;
        public void batchUpdate(TxID txid, LogSequence sequence)
            throws LoaderException, OptimisticCollisionException {
        ...
        }
        public List get(TxID txid, List keyList, boolean forUpdate)
            throws LoaderException {
        ...
        }
        public void preloadMap(Session session, BackingMap backingMap)
            throws LoaderException {
                this.entityMetaData=backingMap.getEntityMetadata();
        }

}
```

The instance variable entityMetaData is initialized during the preLoadMap method call from the eXtreme Scale. The *entityMetaData* variable is not null if the Map is configured to use entities. Otherwise, the value is null.

batchUpdate method

The batchUpdate method provides the ability to know what action the application intended to perform. Based on an insert, update or a delete operation, a connection can be opened to the database and the work performed. Because the key and values are of type Tuple, they must be transformed so the values make sense on the SQL statement.

The ORDER table was created with the following Data Definition Language (DDL) definition, as shown in the following code:

```
CREATE TABLE ORDER (ORDERNUMBER VARCHAR(250) NOT NULL, DATE TIMESTAMP, CUSTOMER_ID VARCHAR(250))
ALTER TABLE ORDER ADD CONSTRAINT PK_ORDER PRIMARY KEY (ORDERNUMBER)
```

The following code demonstrates how to convert a Tuple to an Object:

```
public void batchUpdate(TxID txid, LogSequence sequence)
            throws LoaderException, OptimisticCollisionException {
        Iterator iter = sequence.getPendingChanges();
        while (iter.hasNext()) {
            LogElement logElement = (LogElement) iter.next();
            Object key = logElement.getKey();
            Object value = logElement.getCurrentValue();

            switch (logElement.getType().getCode()) {
            case LogElement.CODE_INSERT:

1)              if (entityMetaData!=null) {

// The order has just one key orderNumber
2)                  String ORDERNUMBER=(String) getKeyAttribute("orderNumber", (Tuple) key);
// Get the value of date
3)                  java.util.Date unFormattedDate = (java.util.Date) getValueAttribute("date",(Tuple)value);
// The values are 2 associations. Lets process customer because
// the our table contains customer.id as primary key
4)                  Object[] keys= getForeignKeyForValueAssociation("customer","id",(Tuple) value);
                    //Order to Customer is M to 1. There can only be 1 key
5)                  String CUSTOMER_ID=(String)keys[0];
// parse variable unFormattedDate and format it for the database as formattedDate
6)                   String formattedDate = "2007-05-08-14.01.59.780272"; // formatted for DB2
// Finally, the following SQL statement to insert the record
7) //INSERT INTO ORDER (ORDERNUMBER, DATE, CUSTOMER_ID) VALUES(ORDERNUMBER,formattedDate, CUSTOMER_ID)
                }
                break;
            case LogElement.CODE_UPDATE:
                break;
            case LogElement.CODE_DELETE:
                break;
            }
        }

    }
// returns the value to attribute as stored in the key Tuple
 private Object getKeyAttribute(String attr, Tuple key) {
        //get key metadata
        TupleMetadata keyMD = entityMetaData.getKeyMetadata();
        //get position of the attribute
        int keyAt = keyMD.getAttributePosition(attr);
        if (keyAt > -1) {
            return key.getAttribute(keyAt);
        } else { // attribute undefined
            throw new IllegalArgumentException("Invalid position index for  "+attr);
        }

    }
// returns the value to attribute as stored in the value Tuple
    private Object getValueAttribute(String attr, Tuple value) {
        //similar to above, except we work with value metadata instead
        TupleMetadata valueMD = entityMetaData.getValueMetadata();
```

```
        int keyAt = valueMD.getAttributePosition(attr);
        if (keyAt > -1) {
            return value.getAttribute(keyAt);
        } else {
            throw new IllegalArgumentException("Invalid position index for  "+attr);
        }
    }
// returns an array of keys that refer to association.
    private Object[] getForeignKeyForValueAssociation(String attr, String fk_attr, Tuple value) {
        TupleMetadata valueMD = entityMetaData.getValueMetadata();
        Object[] ro;

        int customerAssociation = valueMD.getAssociationPosition(attr);
        TupleAssociation tupleAssociation = valueMD.getAssociation(customerAssociation);

        EntityMetadata targetEntityMetaData = tupleAssociation.getTargetEntityMetadata();

        Tuple[] customerKeyTuple = ((Tuple) value).getAssociations(customerAssociation);

        int numberOfKeys = customerKeyTuple.length;
        ro = new Object[numberOfKeys];

        TupleMetadata keyMD = targetEntityMetaData.getKeyMetadata();
        int keyAt = keyMD.getAttributePosition(fk_attr);
        if (keyAt < 0) {
            throw new IllegalArgumentException("Invalid position index for  " + attr);
        }
        for (int i = 0; i < numberOfKeys; ++i) {
            ro[i] = customerKeyTuple[i].getAttribute(keyAt);
        }

        return ro;

    }
```

1. Ensure that entityMetaData is not null, which implies that the key and value cache entries are of type Tuple. From the entityMetaData, Key TupleMetaData is retrieved, which really reflects only the key part of Order metadata.
2. Process the KeyTuple and get the value of Key Attribute orderNumber
3. Process the ValueTuple and get the value of attribute date
4. Process the ValueTuple and get the value of Keys from association customer
5. Extract CUSTOMER_ID. Based on relationship, an Order can only have one customer, we will only have one key. Hence the size of keys is 1. For simplicity, we skipped parsing of date to correct format.
6. Because this is an insert operation, the SQL statement is passed onto the data source connection to complete the insert operation.

Transaction demarcation and access to database is covered in Writing a loader.

get method

If the key is not found in the cache, call the get method in the Loader plug-in to find the key.

The key is a Tuple. The first step is to convert the Tuple to primitive values that can be passed onto the SELECT SQL statement. After all the attributes are retrieved from the database, you must convert into Tuples. The following code demonstrates the Order class.

```
public List get(TxID txid, List keyList, boolean forUpdate)     throws LoaderException {
                System.out.println("OrderLoader: Get called");
                ArrayList returnList = new ArrayList();

1)              if (entityMetaData != null) {
                        int index=0;
                        for (Iterator iter = keyList.iterator(); iter.hasNext();) {
2)                              Tuple orderKeyTuple=(Tuple) iter.next();

                                // The order has just one key orderNumber
3)                              String ORDERNUMBERKEY = (String) getKeyAttribute("orderNumber",orderKeyTuple);
                                //We need to run a query to get values of
4)                              // SELECT CUSTOMER_ID, date FROM ORDER WHERE ORDERNUMBER='ORDERNUMBERKEY'

5)                              //1) Foreign key: CUSTOMER_ID
6)                              //2) date
                                // Assuming those two are returned as
7)                              String  CUSTOMER_ID = "C001"; // Assuming Retrieved and initialized
8)                              java.util.Date retrievedDate = new java.util.Date();
                                // Assuming this date reflects the one in database

                                // We now need to convert this data into a tuple before returning

                                //create a value tuple
9)                              TupleMetadata valueMD = entityMetaData.getValueMetadata();
                                Tuple valueTuple=valueMD.createTuple();

                                //add retrievedDate object to Tuple
                                int datePosition = valueMD.getAttributePosition("date");
10)                             valueTuple.setAttribute(datePosition, retrievedDate);

                                //Next need to add the Association
11)                             int customerPosition=valueMD.getAssociationPosition("customer");
```

```
                                TupleAssociation customerTupleAssociation =
                                  valueMD.getAssociation(customerPosition);
                                EntityMetadata customerEMD = customerTupleAssociation.getTargetEntityMetadata();
                                TupleMetadata customerTupleMDForKEY=customerEMD.getKeyMetadata();
12)                             int customerKeyAt=customerTupleMDForKEY.getAttributePosition("id");

                                Tuple customerKeyTuple=customerTupleMDForKEY.createTuple();
                                customerKeyTuple.setAttribute(customerKeyAt, CUSTOMER_ID);
13)                             valueTuple.addAssociationKeys(customerPosition, new Tuple[] {customerKeyTuple});

14)                             int linesPosition = valueMD.getAssociationPosition("lines");
                                TupleAssociation linesTupleAssociation = valueMD.getAssociation(linesPosition);
                                EntityMetadata orderLineEMD = linesTupleAssociation.getTargetEntityMetadata();
                                TupleMetadata orderLineTupleMDForKEY = orderLineEMD.getKeyMetadata();
                                int lineNumberAt = orderLineTupleMDForKEY.getAttributePosition("lineNumber");
                                int orderAt = orderLineTupleMDForKEY.getAssociationPosition("order");

                                if (lineNumberAt < 0 || orderAt < 0) {
                                        throw new IllegalArgumentException(
                                        "Invalid position index for lineNumber or order "+
                                        lineNumberAt + " " + orderAt);
                                }
15) // SELECT LINENUMBER FROM ORDERLINE WHERE ORDERNUMBER='ORDERNUMBERKEY'
                                // Assuming two rows of line number are returned with values 1 and 2

                                Tuple orderLineKeyTuple1 = orderLineTupleMDForKEY.createTuple();
                                orderLineKeyTuple1.setAttribute(lineNumberAt, new Integer(1));// set Key
                                orderLineKeyTuple1.addAssociationKey(orderAt, orderKeyTuple);

                                Tuple orderLineKeyTuple2 = orderLineTupleMDForKEY.createTuple();
                                orderLineKeyTuple2.setAttribute(lineNumberAt, new Integer(2));// Init Key
                                orderLineKeyTuple2.addAssociationKey(orderAt, orderKeyTuple);

16)                             valueTuple.addAssociationKeys(linesPosition, new Tuple[]
                                    {orderLineKeyTuple1, orderLineKeyTuple2 });

                                returnList.add(index, valueTuple);

                                index++;

                        }
                }else {
                        // does not support tuples
                }
                return returnList;
        }
```

1. The get method is called when the ObjectGrid cache could not find the key and requests the loader to fetch. Test for entityMetaData value and proceed if not null.
2. The keyList contains Tuples.
3. Retrieve value of attribute orderNumber.
4. Run query to retrieve date (value) and customer ID (foreign key).
5. CUSTOMER_ID is a foreign key that must be set in the association tuple.
6. The date is a value and should already be set.
7. Since this example does not perform JDBC calls, CUSTOMER_ID is assumed.
8. Since this example does not perform JDBC calls, date is assumed.
9. Create value Tuple.
10. Set the value of date into the Tuple, based on its position.
11. Order has two associations. Start with the attribute customer which refers to the customer entity. You must have the value of ID to set in the Tuple.
12. Find the position of ID on the customer entity.
13. Set the values of the association keys only.
14. Also, lines is an association that must be set up as a group of association keys, in the same way as you did for customer association.
15. Since you must set up keys for the lineNumber associated with this order, run the SQL to retrieve lineNumber values.
16. Set up the association keys in the valueTuple. This completes the creation of the Tuple that is returned to the BackingMap.

This topic offers the steps create tuples, and a description of the Order entity only. Complete similar steps for the other entities, and the entire process that is tied together with the TransactionCallback plug-in. See Plug-ins for managing transaction life cycle events for details.

Writing a loader with a replica preload controller

A Loader with a replica preload controller is a Loader that implements the ReplicaPreloadController interface in addition to the Loader interface.

The ReplicaPreloadController interface is designed to provide a way for a replica that becomes the primary shard to know whether the previous primary shard has completed the preload process. If the preload is partially completed, the information to pick up where the previous primary left is provided. With the ReplicaPreloadController interface implementation, a replica that becomes the primary continues the preload process where the previous primary left and continues to finish the overall preload.

In a distributed WebSphere® eXtreme Scale environment, a map can have replicas and might preload large volume of data during initialization. The preload is a Loader activity and only occurs in the primary map during initialization. The preload might take a long time to complete if a large volume of data is preloaded. If the primary map has completed large portion of preload data, but is stopped for unknown reason during initialization, a replica becomes the primary. In this situation, the preloaded data that was completed by the previous primary is lost because the new primary normally performs an unconditional preload. With an unconditional preload, the new primary starts the preload process from the beginning and the previous preloaded data is ignored. If you want the new primary to pick up where the previous primary left during preload process, provide a Loader that implements the ReplicaPreloadController interface. For more information see the API documentation.

For information about Loaders, see Loaders. If you are interested in writing a regular Loader plug-in, see Writing a loader.

The ReplicaPreloadController interface has the following definition:

```
public interface ReplicaPreloadController
{
    public static final class Status
    {
        static public final Status PRELOADED_ALREADY =
                                                    new Status(K_PRELOADED_ALREADY);
        static public final Status FULL_PRELOAD_NEEDED =
                                                    new Status(K_FULL_PRELOAD_NEEDED);
        static public final Status PARTIAL_PRELOAD_NEEDED =
                                                    new Status(K_PARTIAL_PRELOAD_NEEDED);
    }

    Status checkPreloadStatus(Session session,
                              BackingMap bmap);
}
```

The following sections discuss some of the methods of the Loader and ReplicaPreloadController interface.

checkPreloadStatus method

When a Loader implements ReplicaPreloadController interface, the checkPreloadStatus method is called before the preloadMap method during map initialization. The return status of this method determines if the preloadMap method is called. If this method returns `Status#PRELOADED_ALREADY`, the preload method is not called. Otherwise, the preload method runs. Because of this behavior, this method should serve as the Loader initialization method. You must initialize the Loader properties in this method. This method must return the correct status, or the preload might not work as expected.

```
public Status checkPreloadStatus(Session session,
                                                    BackingMap backingMap) {
        // When a loader implements ReplicaPreloadController interface,
                        //     this method will be called before preloadMap method during
                        // map initialization. Whether the preloadMap method will be
                        //     called depends on teh returned status of this method. So, this
                        // method also serve as Loader's initialization method. This method
                        // has to return the right staus, otherwise the preload may not
                        // work as expected.

        // Note: must initialize this loader instance here.
        ivOptimisticCallback = backingMap.getOptimisticCallback();
        ivBackingMapName = backingMap.getName();
        ivPartitionId = backingMap.getPartitionId();
        ivPartitionManager = backingMap.getPartitionManager();
        ivTransformer = backingMap.getObjectTransformer();
        preloadStatusKey = ivBackingMapName + "_" + ivPartitionId;

        try {
            // get the preloadStatusMap to retrieve preload status that
                                    // could be set by other JVMs.
            ObjectMap preloadStatusMap = session.getMap(ivPreloadStatusMapName);

            // retrieve last recorded preload data chunk index.
            Integer lastPreloadedDataChunk = (Integer) preloadStatusMap
                                                                    .get(preloadStatusKey);

            if (lastPreloadedDataChunk == null) {
                preloadStatus = Status.FULL_PRELOAD_NEEDED;
            } else {
                preloadedLastDataChunkIndex = lastPreloadedDataChunk.intValue();
                if (preloadedLastDataChunkIndex == preloadCompleteMark) {
                    preloadStatus = Status.PRELOADED_ALREADY;
                } else {
                    preloadStatus = Status.PARTIAL_PRELOAD_NEEDED;
                }
            }
```

```
            System.out.println("TupleHeapCacheWithReplicaPreloadControllerLoader.
                                                                checkPreloadStatus()
                                        -> map = " + ivBackingMapName + ", preloadStatusKey = " + preloadStatusKey
                    + ", retrieved lastPreloadedDataChunk =" + lastPreloadedDataChunk + ",
                                                                determined preloadStatus = "
                    + getStatusString(preloadStatus));

        } catch (Throwable t) {
            t.printStackTrace();
        }

        return preloadStatus;
    }
```

preloadMap method

Running the preloadMap method depends on the returned result from checkPreloadStatus method. If the preloadMap method is called, it typically must retrieve preload status information from designated preload status map and determine how to proceed. Ideally, the preloadMap method should know if the preload is partially complete and exactly where to start. During the data preload, the preloadMap method should first check the preload status (stored in the preload status map), and then update the preload status whenever data is pushed into the cache. The preload status (that is stored in the preload status map) is retrieved by the checkPreloadStatus method when it needs to check the preload status.

```
public void preloadMap(Session session, BackingMap backingMap)
                                        throws LoaderException {
        EntityMetadata emd = backingMap.getEntityMetadata();
        if (emd != null && tupleHeapPreloadData != null) {
            // The getPreLoadData method is similar to fetching data
                                         // from database. These data will be push into cache as
                                         // preload process.
            ivPreloadData = tupleHeapPreloadData.getPreLoadData(emd);

            ivOptimisticCallback = backingMap.getOptimisticCallback();
            ivBackingMapName = backingMap.getName();
            ivPartitionId = backingMap.getPartitionId();
            ivPartitionManager = backingMap.getPartitionManager();
            ivTransformer = backingMap.getObjectTransformer();
            Map preloadMap;

            if (ivPreloadData != null) {
                try {
                    ObjectMap map = session.getMap(ivBackingMapName);

                    // get the preloadStatusMap to record preload status.
                    ObjectMap preloadStatusMap = session.
                                                                                getMap(ivPreloadStatusMapName);

                    // Note: when this preloadMap method is invoked, the
                                                                    // checkPreloadStatus has been called, Both
preloadStatus
                                                                    // and preloadedLastDataChunkIndex have been
set. And the
                                                                    // preloadStatus must be either
PARTIAL_PRELOAD_NEEDED
                                                                    // or FULL_PRELOAD_NEEDED that will require a
preload again.

                    // If large amount of data will be preloaded, the data usually
                                                                    // is divided into few chunks and the preload
process will
                                                                    // process each chunk within its own tran. This
sample only
                                                                    // preload few entries and assuming each entry
represent a chunk.
                    // so that the preload process an entry in a tran to simulate
                                                                    // chunk preloading.

                    Set entrySet = ivPreloadData.entrySet();
                    preloadMap = new HashMap();
                    ivMap = preloadMap;

                    // The dataChunkIndex represent the data chunk that is in
                                                                    // processing
                    int dataChunkIndex = -1;
                    boolean shouldRecordPreloadStatus = false;
                    int numberOfDataChunk = entrySet.size();
                    System.out.println("    numberOfDataChunk to be preloaded = "
                                                                            + numberOfDataChunk);

                    Iterator it = entrySet.iterator();
                    int whileCounter = 0;
                    while (it.hasNext()) {
                        whileCounter++;
                        System.out.println("preloadStatusKey = " + preloadStatusKey
                                                                                                    + " ,
                                                                                whileCounter = " +
whileCounter);
```

```
                        dataChunkIndex++;

                        // if the current dataChunkIndex <= preloadedLastDataChunkIndex
                        // no need to process, becasue it has been preloaded by
                                                                                // other JVM before. only need
to process dataChunkIndex
                                                                                // > preloadedLastDataChunkIndex
                        if (dataChunkIndex <= preloadedLastDataChunkIndex) {
                            System.out.println("ignore current dataChunkIndex =

" + dataChunkIndex + " that has been previously

preloaded.");
                            continue;
                        }

                        // Note: This sample simulate data chunk as an entry.
                        // each key represent a data chunk for simplicity.
                        // If the primary server or shard stopped for unknown
                                                                        // reason, the preload status that
indicates the progress
                                                                        // of preload should be available in
preloadStatusMap. A
                                                                        // replica that become a primary
can get the preload status
                                                                        // and determine how to preload
again.
                        // Note: recording preload status should be in the same
                                                                        // tran as putting data into cache; so
that if tran
                                                                        // rollback or error, the
recorded preload status is the
                                                                        // actual status.

                        Map.Entry entry = (Entry) it.next();
                        Object key = entry.getKey();

                    // otherwise, it will be insert.
                    preloadStatusMap.put(preloadStatusKey, new Integer(preloadCompleteMark));
                    session.commit();
                    ivMap = preloadMap;
                } catch (Throwable e) {
                    e.printStackTrace();
                    throw new LoaderException("preload failed with exception: " + e, e);
                }
            }
        }
    }
```

Preload status map

You must use a preload status map to support the ReplicaPreloadController interface implementation. The preloadMap method should always check the preload status stored in the preload status map first and update the preload status in the preload status map whenever it pushes data into the cache. The

checkPreloadStatus method can retrieve the preload status from preload status map, determine the preload status, and return the status to its caller. The preload status map should be in the same mapSet as other maps that have replica preload controller Loaders.

Plug-ins for managing transaction life cycle events

Use the TransactionCallback plug-in to customize versioning and comparison operations of cache objects when you are using the optimistic locking strategy.

You can provide a pluggable optimistic callback object that implements the com.ibm.websphere.objectgrid.plugins.OptimisticCallback interface. For entity maps, a high performance OptimisticCallback plug-in is automatically configured.

Purpose

Use the OptimisticCallback interface to provide optimistic comparison operations for the values of a map. An OptimisticCallback implementation is required when you use the optimistic locking strategy. WebSphere® eXtreme Scale provides a default OptimisticCallback implementation. However, usually the application must plug in its own implementation of the OptimisticCallback interface. See Locking strategies for more information.

Default implementation

The eXtreme Scale framework provides a default implementation of the OptimisticCallback interface that is used if the application does not plug in an application-provided OptimisticCallback object, as demonstrated in the previous section. The default implementation always returns the special value of NULL_OPTIMISTIC_VERSION as the version object for the value and never updates the version object. This action makes optimistic comparison a no operation function. In most cases, you do not want the no operation function to occur when you are using the optimistic locking strategy. Your applications must implement the OptimisticCallback interface and plug in their own OptimisticCallback implementations so that the default implementation is not used. However, at least one scenario exists where the default provided OptimisticCallback implementation is useful. Consider the following situation:

- A loader is plugged for the backing map.
- The loader knows how to perform the optimistic comparison without assistance from an OptimisticCallback plug-in.

How can the loader know how to deal with optimistic versioning without assistance from an OptimisticCallback object? The loader has knowledge of the value class object and knows which field of the value object is used as an optimistic versioning value. For example, suppose the following interface is used for the value object for the employees map:

```
public interface Employee
{
    // Sequential sequence number used for optimistic versioning.
    public long getSequenceNumber();
    public void setSequenceNumber(long newSequenceNumber);
    // Other get/set methods for other fields of Employee object.
}
```

In this case, the loader knows that it can use the getSequenceNumber method to get the current version information for an Employee value object. The loader increments the returned value to generate a new version number before updating the persistent storage with the new Employee value. For a Java™ database connectivity (JDBC) loader, the current sequence number in the where clause of an overqualified SQL update statement is used, and it uses the new generated sequence number to set the sequence number column to the new sequence number value.

Another possibility is that the loader makes use of some backend-provided function that automatically updates a hidden column that can be used for optimistic versioning. In some cases, a stored procedure or trigger can possibly be used to help maintain a column that holds versioning information. If the loader is using one of these techniques for maintaining optimistic versioning information, then the application does not need to provide an OptimisticCallback implementation. You can use the default OptimisticCallback implementation because the loader is able to handle optimistic versioning without any assistance from an OptimisticCallback object.

Default implementation for entities

Entities are stored in the ObjectGrid using tuple objects. The default OptimisticCallback implementation behaves similarly to the behavior for non-entity maps. However, the version field in the entity is identified using the @Version annotation or the version attribute in the entity descriptor XML file.

The version attribute can be of the following types: int, Integer, short, Short, long, Long or java.sql.Timestamp. An entity should have only one version attribute defined. The version attribute should be set only during construction. After the entity is persisted, the value of the version attribute should not be modified.

If a version attribute is not configured and the optimistic locking strategy is used, then the entire tuple is implicitly versioned using the entire state of the tuple.

In the following example, the Employee entity has a long version attribute named SequenceNumber:

```
@Entity
public class Employee
{
private long sequence;
    // Sequential sequence number used for optimistic versioning.
    @Version
    public long getSequenceNumber() {
        return sequence;
    }
    public void setSequenceNumber(long newSequenceNumber) {
        this.sequence = newSequenceNumber;
    }
    // Other get/set methods for other fields of Employee object.
}
```

Writing an OptimisticCallback implementation

An OptimisticCallback implementation must implement the OptimisticCallback interface and follow the common ObjectGrid plug-in conventions

The following list provides a description or consideration for each of the methods in the OptimisticCallback interface:

NULL_OPTIMISTIC_VERSION

This special value is returned by getVersionedObjectForValue method if the default OptimisticCallback implementation is used instead of an application-provided OptimisticCallback implementation.

getVersionedObjectForValue method

The getVersionedObjectForValue method might return a copy of the value or it might return an attribute of the value that can be used for versioning purposes. This method is called whenever an object is associated with a transaction. When no Loader is set into a backing map, the backing map uses this value at commit time to perform an optimistic version comparison. The optimistic version comparison is used by the backing map to ensure that the version has not changed since this transaction first accessed the map entry that was modified by this transaction. If another transaction had already modified the version for this map entry, the version comparison fails and the backing map displays an OptimisticCollisionException exception to force rollback of the transaction. If a Loader is plugged in, the backing map does not use the optimistic versioning information. Instead, the Loader is responsible for performing the optimistic versioning comparison and updating the versioning information when necessary. The Loader typically gets the initial versioning object from the LogElement passed to the batchUpdate method on the Loader, which is called when a flush operation occurs or a transaction is committed.

The following code shows the implementation used by the EmployeeOptimisticCallbackImpl object:

```
public Object getVersionedObjectForValue(Object value)
{
    if (value == null)
    {
        return null;
    }
    else
    {
        Employee emp = (Employee) value;
        return new Long( emp.getSequenceNumber() );
    }
}
```

As demonstrated in the previous example, the sequenceNumber attribute is returned in a java.lang.Long object as expected by the Loader, which implies that the same person that wrote the Loader either wrote the EmployeeOptimisticCallbackImpl implementation or worked closely with the person that implemented the EmployeeOptimisticCallbackImpl implementation. For example, these people agreed on the value that is returned by the getVersionedObjectForValue method. As previously described, the default OptimisticCallback implementation returns the special value NULL_OPTIMISTIC_VERSION as the version object.

updateVersionedObjectForValue method

The updateVersionedObjectForValue method is called when a transaction has updated a value and a new versioned object is needed. If the getVersionedObjectForValue method returns an attribute of the value, this method typically updates the attribute value with a new version object. If the getVersionedObjectForValue method returns a copy of the value, this method typically would not update. The default OptimisticCallback does not update because the default implementation of the getVersionedObjectForValue method always returns the special value NULL_OPTIMISTIC_VERSION as the version object. The following example shows the implementation used by the EmployeeOptimisticCallbackImpl object that is used in the OptimisticCallback section:

```
public void updateVersionedObjectForValue(Object value)
{
    if ( value != null )
    {
        Employee emp = (Employee) value;
        long next = emp.getSequenceNumber() + 1;
        emp.updateSequenceNumber( next );
    }
}
```

As demonstrated in the previous example, the sequenceNumber attribute is increments by one so that the next time the getVersionedObjectForValue method is called, the java.lang.Long value that is returned has a long value that is the original sequence number value. Plus one, for example, is the next version value for this employee instance. Again, this example implies that the same person that wrote the Loader either wrote EmployeeOptimisticCallbackImpl implementation or worked closely with the person that implemented the EmployeeOptimisticCallbackImpl implementation.

serializeVersionedValue method

This method writes the versioned value to the specified stream. Depending on the implementation, the versioned value can be used to identify optimistic update collisions. In some implementations, the versioned value is a copy of the original value. Other implementations might have a sequence number or some other object to indicate the version of the value. Because the actual implementation is unknown, this method is provided to perform the proper serialization. The default implementation calls the writeObject method.

inflateVersionedValue method

This method takes the serialized version of the versioned value and returns the actual versioned value object. Depending on the implementation, the versioned value can be used to identify optimistic update collisions. In some implementations, the versioned value is a copy of the original value. Other implementations might have a sequence number or some other object to indicate the version of the value. Because the actual implementation is unknown, this method is provided to perform the proper deserialization. The default implementation calls the readObject method.

Using an application-provided OptimisticCallback implementation

You have two approaches to add an application-provided OptimisticCallback into the BackingMap configuration: programmatic configuration and XML configuration.

Programmatically plug in an OptimisticCallback implementation

The following example demonstrates how an application can programmatically plug in an OptimisticCallback object for the employee backing map in the grid1 ObjectGrid instance:

```
import com.ibm.websphere.objectgrid.ObjectGridManagerFactory;
import com.ibm.websphere.objectgrid.ObjectGridManager;
import com.ibm.websphere.objectgrid.ObjectGrid;
import com.ibm.websphere.objectgrid.BackingMap;
ObjectGridManager ogManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid og = ogManager.createObjectGrid( "grid1" );
BackingMap bm = dg.defineMap("employees");
EmployeeOptimisticCallbackImpl cb = new EmployeeOptimisticCallbackImpl();
bm.setOptimisticCallback( cb );
```

XML configuration approach to plug in an OptimisticCallback implementation

The EmployeeOptimisticCallbackImpl object in the preceding example must implement the OptimisticCallback interface. The application can also use an XML file to plug in its OptimisticCallback object as shown in the following example:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
<objectGrids>
    <objectGrid name="grid1">
        <backingMap name="employees" pluginCollectionRef="employees" lockStrategy="OPTIMISTIC" />
    </objectGrid>
</objectGrids>

<backingMapPluginCollections>
    <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugtrans_employees">
        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugtrans_OptimisticCallback"
className="com.xyz.EmployeeOptimisticCallbackImpl" />
    </backingMapPluginCollection>
</backingMapPluginCollections>
</objectGridConfig>
```

- Transaction processing overview
  WebSphere eXtreme Scale uses transactions as its mechanism for interaction with data.
- Introduction to plug-in slots
  A plug-in slot is a transactional storage space that is reserved for plug-ins that share transactional context. These slots provide a way for eXtreme Scale plug-ins to communicate with each other, share transactional context, and ensure that transactional resources are used correctly and consistently within a transaction.
- External transaction managers
  Typically, eXtreme Scale transactions begin with the Session.begin method and end with the Session.commit method. However, when an ObjectGrid is embedded, an external transaction coordinator can start and end transactions. In this case, you do not need to call the begin or commit methods.
- WebSphereTransactionCallback plug-in
  When you use the WebSphereTransactionCallback plug-in, enterprise applications that are running in a WebSphere Application Server environment can manage ObjectGrid transactions. This plug-in is deprecated. Use the WebSphere eXtreme Scale resource adapter instead.

Transaction processing overview

WebSphere® eXtreme Scale uses transactions as its mechanism for interaction with data.

Transaction processing in Java applications

To interact with data, the thread in your application needs its own session. When the application wants to use the ObjectGrid on a thread, call one of the ObjectGrid.getSession methods to obtain a session. With the session, the application can work with data that is stored in the ObjectGrid maps.

When an application uses a Session object, the session must be in the context of a transaction. A transaction begins and commits or begins and rolls back with the begin, commit, and rollback methods on the Session object. Applications can also work in auto-commit mode, in which the Session automatically begins and commits a transaction whenever an operation runs on the map. Auto-commit mode cannot group multiple operations into a single transaction. Auto-commit mode is the slower option if you are creating a batch of multiple operations into a single transaction. However, for transactions that contain only one operation, auto-commit is the faster option.

When your application is finished with the Session, use the optional Session.close() method to close the session. Closing the Session releases it from the heap and allows subsequent calls to the getSession() method to be reused, improving performance.

- Transactions
  Transactions have many advantages for data storage and manipulation. You can use transactions to protect the data grid from concurrent changes, to apply multiple changes as a concurrent unit, to replicate data, and to implement a lifecycle for locks on changes.
- CopyMode attribute
  You can tune the number of copies by defining the CopyMode attribute of the BackingMap or ObjectMap objects in the ObjectGrid descriptor XML file.
- Locking strategies
  Locking strategies include pessimistic, optimistic, and none. To choose a locking strategy, you must consider issues such as the percentage of each type of operations you have, whether you use a loader, and so on.
- Lock types
  When you are using pessimistic and optimistic locking, shared (S), upgradeable (U) and exclusive (X) locks are used to maintain consistency. Understanding locking and its behavior is important when you have pessimistic locking enabled. With optimistic locking, the locks are not held. Different types of locks are compatible with others in various ways. Locks must be handled in the correct order to avoid deadlock scenarios.
- Deadlocks
  Deadlocks can occur when two transactions try to update the same cache entry.
- Data access and transactions
  WebSphere eXtreme Scale uses transactions. After an application has a connection to a data grid, you can access and interact with data in the data grid.
- Transaction isolation
  You can use one of three transaction isolation levels to tune the locking semantics that maintain consistency in each cache map: repeatable read, read committed and read uncommitted.
- Single-partition and cross-data-grid transactions
  The major distinction between WebSphere eXtreme Scale and traditional data storage solutions like relational databases or in-memory databases is the use of partitioning, which allows the cache to scale linearly. The important types of transactions to consider are single-partition and every-partition (cross-data-grid) transactions.
- JMS for distributed transaction changes
  Use Java™ Message Service (JMS) for distributed transaction changes between different tiers or in environments on mixed platforms.

Introduction to plug-in slots

A plug-in slot is a transactional storage space that is reserved for plug-ins that share transactional context. These slots provide a way for eXtreme Scale plug-ins to communicate with each other, share transactional context, and ensure that transactional resources are used correctly and consistently within a transaction.

A plug-in can store transactional context, such as database connection, Java™ Message Service (JMS) connection, and so on, in a plug-in slot. The stored transactional context can be retrieved by any plug-in that knows the plug-in slot number, which serves as the key to retrieve transactional context.

Using plug-in slots

Plug-in slots are part of the TxID Interface. See the API documentation for more information about the interface.The slots are entries on an ArrayList array. Plug-ins can reserve an entry in the ArrayList array by calling the ObjectGrid.reserveSlot method and indicating that it wants a slot on all TxID objects. After the slots are reserved, plug-ins can put transactional context into slots of each TxID object and retrieve the context later. The put and get operations are coordinated by slot numbers that are returned by the ObjectGrid.reserveSlot method.

A plug-in typically has a life cycle. Using plug-in slots has to fit into the life cycle of plug-in. Typically, the plug-in must reserve plug-in slots during the initialization stage and obtain slot numbers for each slot. During normal run time, the plug-in puts transactional context into the reserved slot in the TxID object at the appropriate point. This appropriate point is typically at the beginning of the transaction. The plug-in or other plug-ins can then get the stored transactional context by the slot number from the TxID within the transaction.

The plug-in typically performs a clean up by removing transactional context and the slots. The following snippet of code illustrates how to use plug-in slots in a TransactionCallback plug-in:

```
public class DatabaseTransactionCallback implements TransactionCallback {
    int connectionSlot;
    int autoCommitConnectionSlot;
    int psCacheSlot;
    Properties ivProperties = new Properties();

    public void initialize(ObjectGrid objectGrid) throws TransactionCallbackException {
        // In initialization stage, reserve desired plug-in slots by calling the
        //reserveSlot method of ObjectGrid and
```

```
        // passing in the designated slot name, TxID.SLOT_NAME.
        // Note: you have to pass in this TxID.SLOT_NAME that is designated
        // for application.
        try {
            // cache the returned slot numbers
            connectionSlot = objectGrid.reserveSlot(TxID.SLOT_NAME);
            psCacheSlot = objectGrid.reserveSlot(TxID.SLOT_NAME);
            autoCommitConnectionSlot = objectGrid.reserveSlot(TxID.SLOT_NAME);
        } catch (Exception e) {
        }
    }

    public void begin(TxID tx) throws TransactionCallbackException {
        // put transactional contexts into the reserved slots at the
        // beginning of the transaction.
        try {
            Connection conn = null;
            conn = DriverManager.getConnection(ivDriverUrl, ivProperties);
            tx.putSlot(connectionSlot, conn);
            conn = DriverManager.getConnection(ivDriverUrl, ivProperties);
            conn.setAutoCommit(true);
            tx.putSlot(autoCommitConnectionSlot, conn);
            tx.putSlot(psCacheSlot, new HashMap());
        } catch (SQLException e) {
            SQLException ex = getLastSQLException(e);
            throw new TransactionCallbackException("unable to get connection", ex);
        }
    }

    public void commit(TxID id) throws TransactionCallbackException {
        // get the stored transactional contexts and use them
        // then, clean up all transactional resources.
        try {
            Connection conn = (Connection) id.getSlot(connectionSlot);
            conn.commit();
            cleanUpSlots(id);
        } catch (SQLException e) {
            SQLException ex = getLastSQLException(e);
            throw new TransactionCallbackException("commit failure", ex);
        }
    }

    void cleanUpSlots(TxID tx) throws TransactionCallbackException {
        closePreparedStatements((Map) tx.getSlot(psCacheSlot));
        closeConnection((Connection) tx.getSlot(connectionSlot));
        closeConnection((Connection) tx.getSlot(autoCommitConnectionSlot));
    }

    /**
     * @param map
     */
    private void closePreparedStatements(Map psCache) {
        try {
            Collection statements = psCache.values();
            Iterator iter = statements.iterator();
            while (iter.hasNext()) {
                PreparedStatement stmt = (PreparedStatement) iter.next();
                stmt.close();
            }
        } catch (Throwable e) {
        }

    }

    /**
     * Close connection and swallow any Throwable that occurs.
     *
     * @param connection
     */
    private void closeConnection(Connection connection) {
        try {
            connection.close();
        } catch (Throwable e1) {
        }
    }

    public void rollback(TxID id) throws TransactionCallbackException
        // get the stored transactional contexts and use them
        // then, clean up all transactional resources.
        try {
            Connection conn = (Connection) id.getSlot(connectionSlot);
            conn.rollback();
            cleanUpSlots(id);
        } catch (SQLException e) {
        }
    }

    public boolean isExternalTransactionActive(Session session) {
        return false;
    }
```

```
    // Getter methods for the slot numbers, other plug-in can obtain the slot numbers
    // from these getter methods.

    public int getConnectionSlot() {
        return connectionSlot;
    }
    public int getAutoCommitConnectionSlot() {
        return autoCommitConnectionSlot;
    }
    public int getPreparedStatementSlot() {
        return psCacheSlot;
    }
```

The following snippet of code illustrates how a Loader can get the stored transactional context that is put by previous TransactionCallback plug-in example:

```
public class DatabaseLoader implements Loader
{
    DatabaseTransactionCallback tcb;
    public void preloadMap(Session session, BackingMap backingMap) throws LoaderException
    {
        // The preload method is the initialization method of the Loader.
        // Obtain interested plug-in from Session or ObjectGrid instance.
        tcb =
                        (DatabaseTransactionCallback)session.getObjectGrid().getTransactionCallback();
    }
    public List get(TxID txid, List keyList, boolean forUpdate) throws LoaderException
    {
        // get the stored transactional contexts that is put by tcb's begin method.
        Connection conn = (Connection)txid.getSlot(tcb.getConnectionSlot());
        // implement get here
        return null;
    }
    public void batchUpdate(TxID txid, LogSequence sequence) throws LoaderException,
                        OptimisticCollisionException
    {
        // get the stored transactional contexts that is put by tcb's begin method.
        Connection conn = (Connection)txid.getSlot(tcb.getConnectionSlot());
        // implement batch update here ...
    }
}
```

External transaction managers

Typically, eXtreme Scale transactions begin with the Session.begin method and end with the Session.commit method. However, when an ObjectGrid is embedded, an external transaction coordinator can start and end transactions. In this case, you do not need to call the begin or commit methods.

External transaction coordination

The TransactionCallback plug-in is extended with the isExternalTransactionActive(Session session) method that associates the eXtreme Scale session with an external transaction. The method header follows:

```
public synchronized boolean isExternalTransactionActive(Session session)
```

For example, eXtreme Scale can be set up to integrate with WebSphere® Application Server and WebSphere Extended Deployment.

Also, eXtreme Scale provides a built in plug-in called the WebSphere Plug-ins for managing transaction life cycle events, which describes how to build the plug-in for WebSphere Application Server environments, but you can adapt the plug-in for other frameworks.

The key to this seamless integration is the exploitation of the ExtendedJTATransaction API in WebSphere Application Server Version 6.1 . However, if you are using WebSphere Application Server Version 6.1, you must apply APAR PK07848 to support this method. Use the following sample code to associate an ObjectGrid session with a WebSphere Application Server transaction ID:

```
/**
* This method is required to associate an objectGrid session with a WebSphere
* Application Server transaction ID.
*/
Map/**/ localIdToSession;
public synchronized boolean isExternalTransactionActive(Session session)
{
    // remember that this localid means this session is saved for later.
    localIdToSession.put(new Integer(jta.getLocalId()), session);
    return true;
}
```

Retrieve an external transaction

Sometimes you might need to retrieve an external transaction service object for the TransactionCallback plug-in to use. In the WebSphere Application Server server, look up the ExtendedJTATransaction object from its namespace as shown in the following example:

```
public J2EETransactionCallback() {
    super();
    localIdToSession = new HashMap();
```

```
    String lookupName="java:comp/websphere/ExtendedJTATransaction";
    try
    {
        InitialContext ic = new InitialContext();
        jta = (ExtendedJTATransaction)ic.lookup(lookupName);
        jta.registerSynchronizationCallback(this);
    }
    catch(NotSupportedException e)
    {
        throw new RuntimeException("Cannot register jta callback", e);
    }
    catch(NamingException e){
        throw new RuntimeException("Cannot get transaction object");
    }
}
```

For other products, you can use a similar approach to retrieve the transaction service object.

Control commit by external callback

The TransactionCallback plug-in must receive an external signal to commit or roll back the eXtreme Scale session. To receive this external signal, use the callback from the external transaction service. Implement the external callback interface and register it with the external transaction service. For example, with WebSphere Application Server, implement the SynchronizationCallback interface, as shown in the following example:

```
public class J2EETransactionCallback implements
        com.ibm.websphere.objectgrid.plugins.TransactionCallback, SynchronizationCallback {
   public J2EETransactionCallback() {
      super();
      String lookupName="java:comp/websphere/ExtendedJTATransaction";
      localIdToSession = new HashMap();
      try {
         InitialContext ic = new InitialContext();
         jta = (ExtendedJTATransaction)ic.lookup(lookupName);
         jta.registerSynchronizationCallback(this);
      } catch(NotSupportedException e) {
         throw new RuntimeException("Cannot register jta callback", e);
      }
      catch(NamingException e) {
         throw new RuntimeException("Cannot get transaction object");
      }
   }

   public synchronized void afterCompletion(int localId, byte[] arg1,boolean didCommit) {
      Integer lid = new Integer(localId);
      // find the Session for the localId
      Session session = (Session)localIdToSession.get(lid);
      if(session != null) {
                try {
            // if WebSphere Application Server is committed when
            // hardening the transaction to backingMap.
            // We already did a flush in beforeCompletion
            if(didCommit) {
               session.commit();
            } else {
               // otherwise rollback
               session.rollback();
            }
         } catch(NoActiveTransactionException e) {
            // impossible in theory
         } catch(TransactionException e) {
            // given that we already did a flush, this should not fail
         } finally {
            // always clear the session from the mapping map.
            localIdToSession.remove(lid);
         }
      }
   }

   public synchronized void beforeCompletion(int localId, byte[] arg1) {
      Session session = (Session)localIdToSession.get(new Integer(localId));
      if(session != null) {
         try {
            session.flush();
         } catch(TransactionException e) {
            // WebSphere Application Server  does not formally define
            // a way to signal the
            // transaction has failed so do this
            throw new RuntimeException("Cache flush failed", e);
         }
      }
   }
}
```

Use eXtreme Scale APIs with the TransactionCallback plug-in

The TransactionCallback plug-in disables autocommit in eXtreme Scale. The normal usage pattern for an eXtreme Scale follows:

```
Session ogSession = ...;
ObjectMap myMap = ogSession.getMap("MyMap");
ogSession.begin();
MyObject v = myMap.get("key");
v.setAttribute("newValue");
myMap.update("key", v);
ogSession.commit();
```

When this TransactionCallback plug-in is in use, eXtreme Scale assumes that the application uses the eXtreme Scale when a container-managed transaction is present. The previous code snippet changes the following code in this environment:

```
public void myMethod() {
   UserTransaction tx = ...;
   tx.begin();
   Session ogSession = ...;
   ObjectMap myMap = ogSession.getMap("MyMap");
   yObject v = myMap.get("key");
   v.setAttribute("newValue");
   myMap.update("key", v);
   tx.commit();
}
```

The myMethod method is similar to a Web application scenario. The application uses the normal UserTransaction interface to begin, commit, and roll back transactions. The eXtreme Scale automatically begins and commits around the container transaction. If the method is an Enterprise JavaBeans (EJB) method that uses the TX_REQUIRES attribute, then remove the UserTransaction reference and the calls to begin and commit transactions and the method works the same way. In this case, the container is responsible for starting and ending the transaction.

WebSphereTransactionCallback plug-in

When you use the WebSphereTransactionCallback plug-in, enterprise applications that are running in a WebSphere® Application Server environment can manage ObjectGrid transactions. This plug-in is deprecated. Use the WebSphere eXtreme Scale resource adapter instead.

8.5+ The WebSphereTransactionCallback interface has been replaced by the WebSphere eXtreme Scale resource adapter, which enables Java Transaction API (JTA) transaction management. You can install this resource adapter on WebSphere Application Server or other Java Platform, Enterprise Edition (Java EE) application servers. The WebSphereTransactionCallback plug-in is not an enlisted JTA API, and therefore, is not designed to roll back the JTA transaction if the commit fails.

When you are using an ObjectGrid session within a method that is configured to use container-managed transactions, the enterprise container automatically begins, commits or rolls back the ObjectGrid transaction. When you are using Java™ Transaction API (JTA) UserTransaction objects, the ObjectGrid transaction is managed by the UserTransaction object automatically.

For a detailed discussion of the implementation of this plug-in, see External transaction managers.

Note: The ObjectGrid does not support 2-phase, XA transactions. This plug-in does not enlist the ObjectGrid transaction with the transaction manager. Therefore, if the ObjectGrid fails to commit, any other resources that are managed by the XA transaction do not roll back.

Programmatically plug in the WebSphereTransactionCallback object

You can enable the WebSphereTransactionCallback into the ObjectGrid configuration with programmatic configuration or XML configuration. The following code snippet uses the application to create the WebSphereTransactionCallback object and add it to an ObjectGrid:

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid myGrid = objectGridManager.createObjectGrid("myGrid", false);
WebSphereTransactionCallback wsTxCallback= new WebSphereTransactionCallback ();
myGrid.setTransactionCallback(wsTxCallback);
```

XML configuration approach to plug in the WebSphereTransactionCallback object

The following XML configuration creates the WebSphereTransactionCallback object and adds it to an ObjectGrid. The following text must be in the myGrid.xml file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="myGrid">
            <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsplugweb_TransactionCallback"
classNam=
        "com.ibm.websphere.objectgrid.plugins.builtins.WebSphereTransactionCallback" />

        </objectGrid>
    </objectGrids>
</objectGridConfig>
```

Programming to use the OSGi framework

You can start eXtreme Scale servers and clients in an OSGi container, which allows you to dynamically add and update eXtreme Scale plug-ins to the runtime environment.

- Building eXtreme Scale dynamic plug-ins
  WebSphere® eXtreme Scale includes ObjectGrid and BackingMap plug-ins. These plug-ins are implemented in Java™ and are configured using the ObjectGrid descriptor XML file. To create a dynamic plug-in that can be dynamically upgraded, they need to be aware of ObjectGrid and BackingMap life cycle events because they might need to complete some actions during an update. Enhancing a plug-in bundle with life cycle callback methods, event listeners, or both allows the plug-in to complete those actions at the appropriate times.
- Upgrading agents and data models dynamically from OSGi bundles in the Liberty profile
  Upgrade your OSGi bundles without interruption in the Liberty profile.

Building eXtreme Scale dynamic plug-ins

WebSphere® eXtreme Scale includes ObjectGrid and BackingMap plug-ins. These plug-ins are implemented in Java™ and are configured using the ObjectGrid descriptor XML file. To create a dynamic plug-in that can be dynamically upgraded, they need to be aware of ObjectGrid and BackingMap life cycle events because they might need to complete some actions during an update. Enhancing a plug-in bundle with life cycle callback methods, event listeners, or both allows the plug-in to complete those actions at the appropriate times.

Before you begin

This topic assumes that you have built the appropriate plug-in. For more information about developing eXtreme Scale plug-ins, see the System APIs and plug-ins topic.

About this task

All eXtreme Scale plug-ins apply to either a BackingMap or ObjectGrid instance. Many plug-ins also interact with other plug-ins. For example, a Loader and TransactionCallback plug-in work together to properly interact with a database transaction and the various database JDBC calls. Some plug-ins might also need to cache configuration data from other plug-ins to improve performance.

The BackingMapLifecycleListener and ObjectGridLifecycleListener plug-ins provide life cycle operations for the respective BackingMap and ObjectGrid instances. This process allows plug-ins to be notified when the parent BackingMap or ObjectGrid and their respective plug-ins might be changed. BackingMap plug-ins implement the BackingMapLifecyleListener interface, and ObjectGrid plug-ins implement the ObjectGridLifecycleListener interface. These plug-ins are automatically invoked when the life cycle of the parent BackingMap or ObjectGrid changes. For more information about life cycle plug-ins, see the Managing plug-in life cycles topic.

You can expect to enhance bundles using the life cycle methods or event listeners in the following common tasks:

- Starting and stopping resources, such as threads or messaging subscribers.
- Specifying that a notification occur when peer plug-ins have been updated, allowing direct access to the plug-in and detecting any changes.

Whenever you access another plug-in directly, access that plug-in through the OSGi container to ensure that all parts of the system reference the correct plug-in. If, for example, some component in the application directly references, or caches, an instance of a plug-in, it will maintain its reference to that version of the plug-in, even after that plug-in has been dynamically updated. This behavior can cause application-related problems as well as memory leaks. Therefore, write code that depends on dynamic plug-ins that obtain its reference using OSGi, getService() semantics. If the application must cache one or more plug-ins, it listens for life cycle events using ObjectGridLifecycleListener and BackingMapLifecycleListener interfaces. The application must also be able to refresh its cache when necessary, in a thread safe manner.

All eXtreme Scale plug-ins used with OSGi must also implement the respective BackingMapPlugin or ObjectGridPlugin interfaces. New plug-ins such as the MapSerializerPlugin interface enforce this practice. These interfaces provide the eXtreme Scale runtime environment and OSGi a consistent interface for injecting state into the plug-in and controlling its life cycle.

Use this task to specify that a notification occurs when peer plug-ins are updated, you might create a listener factory that produces a listener instance.

Procedure

- Update the ObjectGrid plug-in class to implement the ObjectGridPlugin interface. This interface includes methods that allow eXtreme Scale to initialize, set the ObjectGrid instance and destroy the plug-in. See the following code example:

```
package com.mycompany;
import com.ibm.websphere.objectgrid.plugins.ObjectGridPlugin;
...
```

```
public class MyTranCallback implements TransactionCallback, ObjectGridPlugin {

    private ObjectGrid og = null;

    private enum State {
        NEW, INITIALIZED, DESTROYED
    }

    private State state = State.NEW;

    public void setObjectGrid(ObjectGrid grid) {
        this.og = grid;
    }

    public ObjectGrid getObjectGrid() {
        return this.og;
    }
    void initialize() {
        // Handle any plug-in initialization here.  This is called by
        // eXtreme Scale, and not the OSGi bean manager.
        state = State.INITIALIZED;
    }
    boolean isInitialized() {
        return state == State.INITIALIZED;
    }

    public void destroy() {
        // Destroy the plug-in and release any resources.  This
        // can be callsed by the OSGi Bean Manager or by eXtreme Scale.
        state = State.DESTROYED;
    }

    public boolean isDestroyed() {
        return state == State.DESTROYED;
    }
}
```

- Update the ObjectGrid plug-in class to implement the ObjectGridLifecycleListener interface. See the following code example:

```
package com.mycompany;
import com.ibm.websphere.objectgrid.plugins.ObjectGridLifecycleListener;
      import com.ibm.websphere.objectgrid.plugins.ObjectGridLifecycleListener.LifecycleEvent;
      ...

      public class MyTranCallback implements TransactionCallback, ObjectGridPlugin, ObjectGridLifecycleListener{
          public void objectGridStateChanged(LifecycleEvent event) {
              switch(event.getState()) {
              case NEW:
              case DESTROYED:
              case DESTROYING:
              case INITIALIZING:
                  break;
              case INITIALIZED:
                  // Lookup a Loader or MapSerializerPlugin using
                  // OSGi or directly from the ObjectGrid instance.
                  lookupOtherPlugins()
                  break;
              case STARTING:
              case PRELOAD:
                  break;
              case ONLINE:
                  if (event.isWritable()) {
                      startupProcessingForPrimary();
                  } else {
                      startupProcessingForReplica();
                  }
                  break;
              case QUIESCE:
                  if (event.isWritable()) {
                      quiesceProcessingForPrimary();
                  } else {
                      quiesceProcessingForReplica();
                  }
                  break;
              case OFFLINE:
                  shutdownShardComponents();
                  break;
              }
          }
          ...
      }
```

- Update a BackingMap plug-in. Update the BackingMap plug-in class to implement the BackingMap plu-in interface. This interface includes methods that allow eXtreme Scale to initialize, set the BackingMap instance, and destroy the plug-in. See the following code example:

```
package com.mycompany;
import com.ibm.websphere.objectgrid.plugins.BackingMapPlugin;
...

public class MyLoader implements Loader, BackingMapPlugin {
```

```
    private BackingMap bmap = null;

    private enum State {
        NEW, INITIALIZED, DESTROYED
    }

    private State state = State.NEW;

    public void setBackingMap(BackingMap map) {
        this.bmap = map;
    }

    public BackingMap getBackingMap() {
        return this.bmap;
    }
    void initialize() {
        // Handle any plug-in initialization here.  This is called by
        // eXtreme Scale, and not the OSGi bean manager.
        state = State.INITIALIZED;
    }
    boolean isInitialized() {
        return state == State.INITIALIZED;
    }

    public void destroy() {
        // Destroy the plug-in and release any resources.  This
        // can be callsed by the OSGi Bean Manager or by eXtreme Scale.
        state = State.DESTROYED;
    }

    public boolean isDestroyed() {
        return state == State.DESTROYED;
    }
}
```

- Update the BackingMap plug-in class to implement the BackingMapLifecycleListener interface. See the following code example:

```
package com.mycompany;

      import com.ibm.websphere.objectgrid.plugins.BackingMapLifecycleListener;
      import com.ibm.websphere.objectgrid.plugins.BackingMapLifecycleListener.LifecycleEvent;
      ...

      public class MyLoader implements Loader, ObjectGridPlugin, ObjectGridLifecycleListener{
          ...

              }
          }
          ...
      }
```

Results

By implementing the ObjectGridPlugin or BackingMapPlugin interface, eXtreme Scale can control the life cycle of your plug-in at the right times.

By implementing the ObjectGridLifecycleListener or BackingMapLifecycleListener interface, the plug-in is automatically registered as a listener of the associated ObjectGrid or BackingMap life cycle events. The INITIALIZING event is used to signal that all of the ObjectGrid and BackingMap plug-ins have been initialized

and are available for lookup and use. The ONLINE event is used to signal that the ObjectGrid is online and ready to start processing events.

JPA Loaders

The Java™ Persistence API (JPA) is a specification that allows mapping Java objects to relational databases. JPA contains a full object-relational mapping (ORM) specification using Java language metadata annotations, XML descriptors, or both to define the mapping between Java objects and a relational database. A number of open-source and commercial implementations are available.

You can use a Java Persistence API (JPA) loader plug-in implementation with eXtreme Scale to interact with any database supported by your chosen loader. To use JPA, you must have a supported JPA provider, such as OpenJPA or Hibernate, JAR files, and a META-INF/persistence.xml file in your class path.

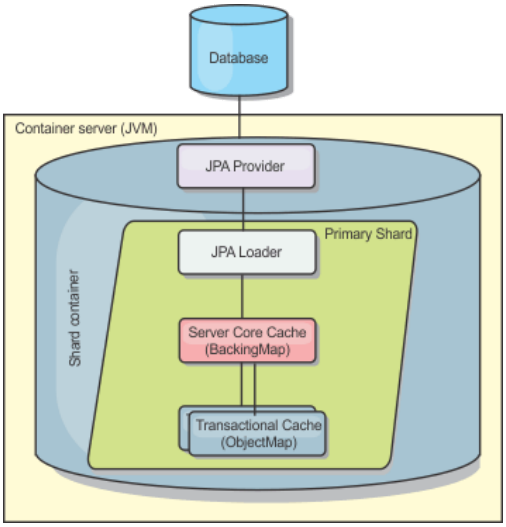
The JPALoader com.ibm.websphere.objectgrid.jpa.JPALoader and the JPAEntityLoader com.ibm.websphere.objectgrid.jpa.JPAEntityLoader plug-ins are two built-in JPA loader plug-ins that are used to synchronize the ObjectGrid maps with a database. You must have a JPA implementation, such as Hibernate or OpenJPA, to use this feature. The database can be any back end that is supported by the chosen JPA provider.

You can use the JPALoader plug-in when you are storing data using the ObjectMap API. Use the JPAEntityLoader plug-in when you are storing data using the EntityManager API.

JPA loader architecture

The JPA Loader is used for eXtreme Scale maps that store plain old Java objects (POJO).

Figure 1. JPA Loader architecture



When an ObjectMap.get(Object key) method is called, the eXtreme Scale run time first checks whether the entry is contained in the ObjectMap layer. If not, the run time delegates the request to the JPA Loader. Upon request of loading the key, the JPALoader calls the JPA EntityManager.find(Object key) method to find the data from the JPA layer. If the data is contained in the JPA entity manager, it is returned; otherwise, the JPA provider interacts with the database to get the value.

When an update to ObjectMap occurs, for example, using the ObjectMap.update(Object key, Object value) method, the eXtreme Scale run time creates a LogElement for this update and sends it to the JPALoader. The JPALoader calls the JPA EntityManager.merge(Object value) method to update the value to the database.

For the JPAEntityLoader, the same four layers are involved. However, because the JPAEntityLoader plug-in is used for maps that store eXtreme Scale entities, relations among entities could complicate the usage scenario. An eXtreme Scale entity is distinguished from JPA entity. For more details, see JPAEntityLoader plug-in.For more information, see JPAEntityLoader plug-in.For more information, see the information about the JPAEntityLoader plug-in in the *Programming Guide*.

Methods

Loaders provide three main methods:

1. get: Returns a list of values that correspond to the list of keys that are passed in by retrieving the data using JPA. The method uses JPA to find the entities in the database. For the JPALoader plug-in, the returned list contains a list of JPA entities directly from the find operation. For the JPAEntityLoader plug-in, the returned list contains eXtreme Scale entity value tuples that are converted from the JPA entities.
2. batchUpdate: Writes the data from ObjectGrid maps to the database. Depending on different operation types (insert, update, or delete), the loader uses the JPA persist, merge, and remove operations to update the data to the database. For the JPALoader, the objects in the map are directly used as JPA entities. For the JPAEntityLoader, the entity tuples in the map are converted into objects which are used as JPA entities.
3. preloadMap: Preloads the map using the ClientLoader.load client loader method. For partitioned maps, the preloadMap method is only called in one partition. The partition is specified the preloadPartition property of the JPALoader or JPAEntityLoader class. If the preloadPartition value is set to less than zero, or greater than (*total_number_of_partitions* - 1), preload is disabled.

Both JPALoader and JPAEntityLoader plug-ins work with the JPATxCallback class to coordinate the eXtreme Scale transactions and JPA transactions. JPATxCallback must be configured in the ObjectGrid instance to use these two loaders.

Configuration and programming

If you are using JPA loaders in a multi-master environment, see Loader considerations in a multi-master topology. For more information about configuring JPA loaders, see Configuring JPA loaders. For more information about programming JPA loaders, see JPA loader programming considerations.

Developing client-based JPA loaders

You can implement preloading and reloading of data in your application with a Java Persistence API (JPA) utility. This capability can simplify loading the maps when the queries to the database cannot be partitioned.

Before you begin

- You must be using a JPA provider with a supported database.
- Before you preload or reload maps, you must set the availability state of the ObjectGrid to `PRELOAD`. You can set the availability state with the setObjectGridState method of the StateManager interface. The StateManager interface prevents other clients from accessing the ObjectGrid when it is not yet online. After you preload or reload the map, you can set the state back to ONLINE.

- When you are preloading different maps in one ObjectGrid, set the ObjectGrid state to `PRELOAD` one time and set the value back to `ONLINE` after all maps finish data loading. This coordination can be done by the ClientLoadCallback interface. Set the ObjectGrid state to `PRELOAD` after the first preStart notification from the ObjectGrid instance, and set it back to `ONLINE` after the last postFinish notification.
- If you need to preload maps from different Java™ virtual machines, you have to coordinate between multiple Java virtual machines. Set the ObjectGrid state to `PRELOAD` one time before the first map is being preloaded in any of the Java virtual machines, and set the value back to `ONLINE` after all maps finish data loading in all the Java virtual machines. For more information, see Managing ObjectGrid availability.

About this task

When you run a preload or reload operation on your map, the following actions occur:

1. The initial action that is taken depends on if you are running a preload or reload operation.
   - **Preload operation:** The map to be preloaded is cleared. For an entity map, if any relation is configured as cascade-remove, any related maps are cleared.
   - **Reload operation:** The provided query is run on the map and the results are invalidated. For an entity map, if any relation is configured with the CascadeType.INVALIDATE option, the related entities are also invalidated from their maps.
2. Run the query to JPA for the entities in a batch.
3. For each batch, a key list and value list for each partition is built.
4. For each partition, the data grid agent is called to insert or update the data on the server side directly if it is an eXtreme Scale client. If the data grid is a local instance, the data in the maps is directly inserted or updated.

- Client-based JPA preload utility overview
  The client-based Java Persistence API (JPA) preload utility loads data into eXtreme Scale backing maps using a client connection to the ObjectGrid.
- Example: Preloading a map with the ClientLoader interface
  You can preload a map to populate the map data before clients begin accessing the map.
- Example: Reloading a map with the ClientLoader interface
  Reloading a map is the same as preloading a map, except that the isPreload argument is set to false in the ClientLoader.load method.
- Example: Calling a client loader
  You can use the preload method in the Loader interface to call a client loader.
- Example: Creating a custom client-based JPA loader
  The ClientLoader.load method in the Loader interface provides a client load function that satisfies most scenarios. However, if you want to load data without the ClientLoader.load method, you can implement your own preload utility.
- Developing a client-based JPA loader with a DataGrid agent
  When loading from the client side, using a DataGrid agent could increase performance. By using a DataGrid agent, all the data reads and writes occur in the server process. You can also design your application to make sure that DataGrid agents on multiple partitions run in parallel to further boost performance.

Client-based JPA preload utility overview

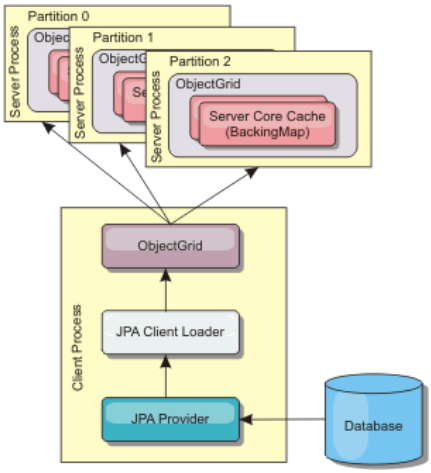
The client-based Java™ Persistence API (JPA) preload utility loads data into eXtreme Scale backing maps using a client connection to the ObjectGrid.

This capability can simplify loading the maps when the queries to the database cannot be partitioned. A loader, such as a JPA Loader can also be used and is ideal when the data can be loaded in parallel.

The client-based JPA preload utility can use either the OpenJPA or Hibernate JPA implementations to load the ObjectGrid from a database. Because WebSphere® eXtreme Scale does not directly interact with the database or Java Database Connectivity (JDBC), any database that OpenJPA or Hibernate supports can be used to load the ObjectGrid.

Figure 1. Client loader that uses JPA implementation to load the ObjectGrid



Typically, a user application provides a persistence unit name, an entity class name, and a JPA query to the client loader. The client loader retrieves the JPA entity manager based on the persistence unit name, uses the entity manager to query data from the database with the provided entity class and JPA query, and finally loads the data into the distributed ObjectGrid maps. When multi-level relations are involved in the query, can use a custom query string to optimize the performance. Optionally, a persistence property map could be provided to override the configured persistence properties.

A client loader can load data in two different modes, as displayed in the following table:

Table 1. Client loader modes

Mode	Description
Preload	Clears and loads all entries into the backing map. If the map is an entity map, any related entity maps will also be cleared if the ObjectGrid CascadeType.REMOVE option is enabled.
Reload	The JPA query is executed against the ObjectGrid to invalidate all the entities in the map that match the query. If the map is an entity map, any related entity maps will also be cleared if the ObjectGrid CascadeType.INVALIDATE option is enabled.

In either case, a JPA query is used to select and load the desired entities from the database and to store them in the ObjectGrid maps. If the ObjectGrid map is a non-entity map, the JPA entities will be detached and stored directly. If the ObjectGrid map is an entity map, the JPA entities are stored as ObjectGrid entity tuples. You can provide a JPA query or use the default query `select o from EntityName o`.

Example: Preloading a map with the ClientLoader interface

You can preload a map to populate the map data before clients begin accessing the map.

Client-based preload example

The following sample code snippet shows a simple client loading. In this example, the CUSTOMER map is configured as an entity map. The Customer entity class, which is configured in the ObjectGrid entity metadata descriptor XML file, has a one-to-many relation with Order entities. The Customer entity has the CascadeType.ALL option enabled on the relation to the Order entity. Before the ClientLoader.load method is called, the ObjectGrid state is set to PRELOAD. The isPreload parameter on the load method is set to `true`.

```
// Get the StateManager
StateManager stateMgr = StateManagerFactory.getStateManager();

// Set ObjectGrid state to PRELOAD before calling ClientLoader.loader
stateMgr.setObjectGridState(AvailabilityState.PRELOAD, objectGrid);

ClientLoader c = ClientLoaderFactory.getClientLoader();

// Load the data
c.load(objectGrid, "CUSTOMER", "customerPU", null,
```

```
    null, null, null, true, null);

// Set ObjectGrid state back to ONLINE
stateMgr.setObjectGridState(AvailabilityState.ONLINE, objectGrid);
```

Example: Reloading a map with the ClientLoader interface

Reloading a map is the same as preloading a map, except that the isPreload argument is set to false in the ClientLoader.load method.

Client-based reload example

The following sample shows how to reload maps. Compared to the preload sample, the main difference is that a loadSql and parameters are provided. This sample only reloads the Customer data with an ID between `1000` and `2000`. The isPreload parameter on the load method is set to `false`.

```
// Get the StateManager
StateManager stateMgr = StateManagerFactory.getStateManager();

// Set ObjectGrid state to PRELOAD before calling ClientLoader.loader
stateMgr.setObjectGridState(AvailabilityState.PRELOAD, objectGrid);

ClientLoader c = ClientLoaderFactory.getClientLoader();

// Load the data
String loadSql = "select c from CUSTOMER c
    where c.custId >= :startCustId and c.custId < :endCustId ";
Map<String, Long> params = new HashMap<String, Long>();
params.put("startCustId", 1000L);
params.put("endCustId", 2000L);

c.load(objectGrid, "CUSTOMER", "customerPU", null, null,
    loadSql, params, false, null);

// Set ObjectGrid state back to ONLINE
stateMgr.setObjectGridState(AvailabilityState.ONLINE, objectGrid);
```

Remember: This query string observes both JPA query syntax and eXtreme Scale entity query syntax. This query string is important because it runs twice: to invalidate the matched ObjectGrid entities and to load the matched JPA entities.

Example: Preloading a map with the ClientLoader interface
Example: Calling a client loader
Example: Creating a custom client-based JPA loader
Related information:
Interface ClientLoader
Interface StateManager

Example: Calling a client loader

You can use the preload method in the Loader interface to call a client loader.

Use the preload method in the Loader interface to call a client loader:

```
void preloadMap(Session session, BackingMap backingMap) throws LoaderException;
```

This method signals the loader to preload the data into the map. A loader implementation can use a client loader to preload the data to all its partitions. For example, the JPA loader uses the client loader to preload data into the map. See Client-based JPA preload utility overview for more information.

Example: Calling a client loader with the preloadMap method

An example of how to preload the map using the client loader in the preloadMap method follows. The example first checks whether the current partition number is the same as the preload partition. If the partition number is not the same as the preload partition, no action occurs. If the partition numbers match, the client loader is called to load data into the maps. You must call the client loader in one and only one partition.

```
void preloadMap (Session session, BackingMap backingMap) throws LoaderException {

....
        ObjectGrid objectGrid = session.getObjectGrid();
        int partitionId = backingMap.getPartitionId();
        int numPartitions = backingMap.getPartitionManager().getNumOfPartitions();

        // Only call client loader data in one partition
        if (partitionId == preloadPartition) {
          ClientLoader c = ClientLoaderFactory.getClientLoader();
    // Call the client loader to load the data
    try {
        c.load(objectGrid, "CUSTOMER", "customerPU",
                                        null, entityClass, null, null, true, null);
    } catch (ObjectGridException e) {
        LoaderException le = new LoaderException("Exception caught in ObjectMap " +
                                        ogName + "." + mapName);
        le.initCause(e);
        throw le;
    }
        }
}
```

Remember: Configure the backingMap attribute "preloadMode" to `true`, so the preload method runs asynchronously. Otherwise, the preload method blocks the ObjectGrid instance from being activated.

Example: Creating a custom client-based JPA loader

The ClientLoader.load method in the Loader interface provides a client load function that satisfies most scenarios. However, if you want to load data without the ClientLoader.load method, you can implement your own preload utility.

Custom loader template

Use the following template to develop your loader:

```
// Get the StateManager
StateManager stateMgr = StateManagerFactory.getStateManager();

// Set ObjectGrid state to PRELOAD before calling ClientLoader.loader
stateMgr.setObjectGridState(AvailabilityState.PRELOAD, objectGrid);

// Load the data
...<your preload utility implementation>...

// Set ObjectGrid state back to ONLINE
stateMgr.setObjectGridState(AvailabilityState.ONLINE, objectGrid);
```

Developing a client-based JPA loader with a DataGrid agent

When loading from the client side, using a DataGrid agent could increase performance. By using a DataGrid agent, all the data reads and writes occur in the server process. You can also design your application to make sure that DataGrid agents on multiple partitions run in parallel to further boost performance.

About this task

For more information about the DataGrid agent, see DataGrid APIs and partitioning.
After you create the data preload implementation, you can create a generic Loader to complete the following tasks:

- Query the data from database in batches.
- Build a key list and value list for each partition.
- For each partition, call the agentMgr.callReduceAgent(agent, aKey) method to run the agent in the server in a thread. By running in a thread, you can run agents concurrently on multiple partitions.

Example

The following snippet of code is an example of how to load using a DataGrid agent:

```
import java.io.Externalizable;
import java.io.IOException;
import java.io.ObjectInput;
import java.io.ObjectOutput;

    }

    public void writeExternal(ObjectOutput out) throws IOException {
        out.write(1);
        out.writeBoolean(isEntityMap);

        writeList(out, vals);
        if (!isEntityMap) {
            writeList(out, keys);
        }

    }

    public void setData(List ks, List vs) {
        vals = vs;
        if (!isEntityMap) {
            keys = ks;
        }
    }
```

```
    /**
     * @return Returns the isEntityMap.
     */
    public boolean isEntityMap() {
        return isEntityMap;
    }

    static public void writeList(ObjectOutput oo, Collection l)
      throws IOException {
        int size = l == null ? -1 : l.size();
        oo.writeInt(size);
        if (size > 0) {
            Iterator iter = l.iterator();
            while (iter.hasNext()) {
                Object o = iter.next();
                oo.writeObject(o);
            }
        }
    }

    public static List readList(ObjectInput oi)
      throws IOException, ClassNotFoundException {
        int size = oi.readInt();
        if (size == -1) {
            return null;
        }

        ArrayList list = new ArrayList(size);
        for (int i = 0; i < size; ++i) {
            Object o = oi.readObject();
            list.add(o);
        }
        return list;
    }
}
```

Client-based JPA preload utility overview
Related reference:
Example: Preloading a map with the ClientLoader interface
Example: Reloading a map with the ClientLoader interface
Example: Calling a client loader
Example: Creating a custom client-based JPA loader

Example: Using the Hibernate plug-in to preload data into the ObjectGrid cache

You can use the preload method of the ObjectGridHibernateCacheProvider class to preload data into the ObjectGrid cache for an entity class.

Example: Using the EntityManagerFactory class

```
EntityManagerFactory emf = Persistence.createEntityManagerFactory("testPU");
ObjectGridHibernateCacheProvider.preload("objectGridName", emf, TargetEntity.class, 100, 100);
```

Important: By default, entities are not part of the second level cache. In the Entity classes that need caching, add the @cache annotation. An example follows:

```
import org.hibernate.annotations.Cache;
import org.hibernate.annotations.CacheConcurrencyStrategy;
@Entity
@Cache(usage=CacheConcurrencyStrategy.TRANSACTIONAL)
public class HibernateCacheTest { ... }
```

You can override this default by setting the shared-cache-mode element in your persistence.xml file or by using the javax.persistence.sharedCache.mode property.

Example: Using the SessionFactory class

```
org.hibernate.cfg.Configuration cfg = new Configuration();
// use addResource, addClass, and setProperty method of Configuration to prepare
// configuration required to create SessionFactor
SessionFactory sessionFactory= cfg.buildSessionFactory();
ObjectGridHibernateCacheProvider.preload("objectGridName", sessionFactory,
TargetEntity.class, 100, 100);
```

Note:

1. In a distributed system, this preload mechanism can only be invoked from one Java™ virtual machine. The preload mechanism cannot run simultaneously from multiple Java virtual machines.
2. Before running the preload, you must initialize the eXtreme Scale cache by creating EntityManager using EntityManagerFactory to have all corresponding BackingMaps created; otherwise, the preload forces the cache to be initialized with only one default BackingMap to support all entities. This means a single BackingMap is shared by all entities.

Developing client-based JPA loaders
Starting the JPA time-based updater

Starting the JPA time-based updater

When you start the Java™ Persistence API (JPA) time-based updater, the ObjectGrid maps are updated with the latest changes in the database.

Before you begin

Configure the time-based updater. See Configuring a JPA time-based data updater.

About this task

For more information about how the Java Persistence API (JPA) time-based data updater works, see JPA time-based data updater.

Procedure

- Start a time-based database updater.
  - **Automatically for distributed eXtreme Scale:**
    If you create the timeBasedDBUpdate configuration for the backing map, the time-based database updater is automatically started when a distributed ObjectGrid primary shard is activated. For an ObjectGrid that has multiple partitions, the time-based database updater only starts at partition 0.

  - **Automatically for local eXtreme Scale:**
    If you create the timeBasedDBUpdate configuration for the backing map, the time-based database updater is automatically started when the local map is activated.

  - **Manually:**
    You can also manually start or stop a time-based database updater using the TimeBasedDBUpdater API.

    ```
    public synchronized void startDBUpdate(ObjectGrid objectGrid, String mapName,
            String punitName, Class entityClass, String timestampField, DBUpdateMode mode) {
    ```

    1. **ObjectGrid**: the ObjectGrid instance (local or client).
    2. **mapName**: the name of the backing map for which the time-based database updater is started.
    3. **punitName**: the JPA persistence unit name for creating a JPA entity manager factory; the default value is the name of the first persistence unit defined in the persistence.xml file.
    4. **entityClass**: The entity class name used to interact with the Java Persistence API (JPA) provider; the entity class name is used to get JPA entities using entity queries.
    5. **timestampField**: A timestamp field of the entity class to identify the time or sequence when a database back end record was last updated or inserted.
    6. **mode**: The time-based database update mode; an INVALIDATE_ONLY type causes it to invalidate the entries in the ObjectGrid map if the corresponding records in the database have changed; an UPDATE_ONLY type indicates to update the existing entries in the ObjectGrid map with the latest values from the database; however, all the newly inserted records to the database are ignored; an INSERT_UPDATE type indicates to update the existing entries in the ObjectGrid map with the latest values from the database; also, all the newly inserted records to the database are inserted into the ObjectGrid map.

    If you want to stop the time-based database updater, you can call the following method to stop the updater:

    ```
    public synchronized void stopDBUpdate(ObjectGrid objectGrid, String mapName)
    ```

    The ObjectGrid and mapName parameters should be the same as those passed in the startDBUpdate method.

- Create the timestamp field in your database.
  - **DB2®**
    As a part of the optimistic locking feature, DB2 9.5 provides a row change timestamp feature. You can define a column ROWCHGTS using the ROW CHANGE TIMESTAMP format as follows:

    ```
    ROWCHGTS TIMESTAMP NOT NULL
         GENERATED ALWAYS
         FOR EACH ROW ON UPDATE AS
         ROW CHANGE TIMESTAMP
    ```

    Then you can indicate the entity field which corresponds to this column as the timestamp field by either annotation or configuration. An example follows:

    ```
    @Entity(name = "USER_DB2")
    @Table(name = "USER1")
    public class User_DB2 implements Serializable {

        private static final long serialVersionUID = 1L;

        public User_DB2() {
        }
    ```

```
    public User_DB2(int id, String firstName, String lastName) {
        this.id = id;
        this.firstName = firstName;
        this.lastName = lastName;
    }

    @Id
    @Column(name = "ID")
    public int id;

    @Column(name = "FIRSTNAME")
    public String firstName;

    @Column(name = "LASTNAME")
    public String lastName;

    @com.ibm.websphere.objectgrid.jpa.dbupdate.annotation.Timestamp
    @Column(name = "ROWCHGTS", updatable = false, insertable = false)
    public Timestamp rowChgTs;
}
```

- **Oracle**
  In Oracle, there is a pseudo-column `ora_rowscn` for the system change number of the record. You can use this column for the same purpose. An example of the entity that uses the ora_rowscn field as the time-based database update timestamp field follows:

```
@Entity(name = "USER_ORA")
@Table(name = "USER1")
public class User_ORA implements Serializable  {

    private static final long serialVersionUID = 1L;

    public User_ORA() {
    }

    public User_ORA(int id, String firstName, String lastName) {
        this.id = id;
        this.firstName = firstName;
        this.lastName = lastName;
    }

    @Id
    @Column(name = "ID")
    public int id;

    @Column(name = "FIRSTNAME")
    public String firstName;

    @Column(name = "LASTNAME")
    public String lastName;

    @com.ibm.websphere.objectgrid.jpa.dbupdate.annotation.Timestamp
    @Column(name = "ora_rowscn", updatable = false, insertable = false)
    public long rowChgTs;
}
```

- **Other databases**
  For other types of databases, you can create a table column to track the changes. The column values have to be manually managed by the application that updates the table.

  Take an Apache Derby database as an example: You can create a column "ROWCHGTS" to track the change numbers. Also, a latest change number is tracked for this table. Every time a record is inserted or updated, the latest change number for the table is incremented, and the ROWCHGTS column value for the record is updated with this incremented number.

```
@Entity(name = "USER_DER")
@Table(name = "USER1")
public class User_DER implements Serializable {

    private static final long serialVersionUID = 1L;

    public User_DER() {
    }

    public User_DER(int id, String firstName, String lastName) {
        this.id = id;
        this.firstName = firstName;
        this.lastName = lastName;
    }

    @Id
    @Column(name = "ID")
    public int id;

    @Column(name = "FIRSTNAME")
    public String firstName;

    @Column(name = "LASTNAME")
    public String lastName;
```

```
    @com.ibm.websphere.objectgrid.jpa.dbupdate.annotation.Timestamp
    @Column(name = "ROWCHGTS", updatable = true, insertable = true)
    public long rowChgTs;
}
```

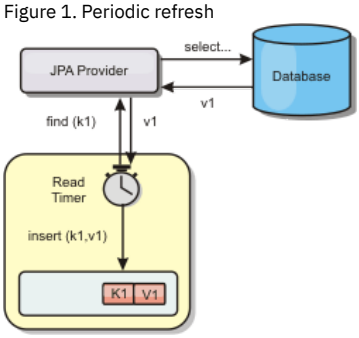
JPA time-based data updater

A Java™ Persistence API (JPA) time-based database updater updates the ObjectGrid maps with the latest changes in the database.

When changes are made directly to a database that is being fronted by WebSphere® eXtreme Scale, those changes are not concurrently reflected in the eXtreme Scale grid. To properly implement eXtreme Scale as an in-memory database processing space, take into consideration that your grid can get out of sync with the database. Time-based database updater uses the System Change Number (SCN) capability in Oracle 10g and row change timestamp in DB2® 9.5 to monitor changes in the database for invalidation and update. The updater also allows applications to have a user-defined field for the same purpose.

Figure 1. Periodic refresh



The time-based database updater periodically queries the database using JPA interfaces to get the JPA entities that represent the newly inserted and updated records in the database. To periodically update the records, every record in the database should have a timestamp to identify the time or sequence in which the record was last updated or inserted. It is not required that the timestamp be in a timestamp format. The timestamp value can be in an integer or long format, if it generates a unique, increasing value.

Several commercial databases have provided this capability.

For example, in DB2 9.5, you can define a column using the ROW CHANGE TIMESTAMP format as follows:

```
ROWCHGTS TIMESTAMP NOT NULL
      GENERATED ALWAYS
      FOR EACH ROW ON UPDATE AS
      ROW CHANGE TIMESTAMP
```

In Oracle, you can use the pseudo-column **ora_rowscn**, which represents the system change number of the record.

The time-based database updater updates the ObjectGrid maps in three different ways:

1. INVALIDATE_ONLY. Invalidate the entries in the ObjectGrid map if the corresponding records in the database have changed.
2. UPDATE_ONLY. Update the entries in the ObjectGrid map if the corresponding records in the database have changed. However, all the newly inserted records to the database are ignored.
3. INSERT_UPDATE. Update the existing entries in the ObjectGrid map with the latest values from the database. Also, all the newly inserted records to the database are inserted into the ObjectGrid map.

For more information about configuring the JPA time-based data updater, see Configuring a JPA time-based data updater.

Developing applications with the Spring framework

Spring framework overview

Spring is a framework for developing Java™ applications. WebSphere® eXtreme Scale provides support to allow Spring to manage transactions and configure the clients and servers comprising your deployed in-memory data grid.

8.5+

Spring cache provider

Spring Framework Version 3.1 introduced a new cache abstraction. With this new abstraction, you can transparently add caching to an existing Spring application. You can use WebSphere eXtreme Scale as the cache provider for the cache abstraction. For more information, see Configuring a Spring cache provider.

Spring managed native transactions

Spring provides container-managed transactions that are similar to a Java Platform, Enterprise Edition application server. However, the Spring mechanism can use different implementations. WebSphere eXtreme Scale provides transaction manager integration which allows Spring to manage the ObjectGrid transaction life cycles. For more information, see Managing transactions with Spring.

Spring managed extension beans and namespace support

Also, eXtreme Scale integrates with Spring to allow Spring-style beans defined for extension points or plug-ins. This feature provides more sophisticated configurations and more flexibility for configuring the extension points.

In addition to Spring managed extension beans, eXtreme Scale provides a Spring namespace called "objectgrid". Beans and built-in implementations are pre-defined in this namespace, which makes it easier for users to configure eXtreme Scale. See Spring extension beans and namespace support for more details on these topics and a sample of how to start an eXtreme Scale container server using Spring configurations.

Shard scope support

With the traditional style Spring configuration, an ObjectGrid bean can either be a singleton type or prototype type. ObjectGrid also supports a new scope called the "shard" scope. If a bean is defined as shard scope, then only one bean is created per shard. All requests for beans with an ID or IDs matching that bean definition in the same shard results in that one specific bean instance being returned by the Spring container.

The following example shows that a com.ibm.ws.objectgrid.jpa.plugins.JPAPropFactoryImpl bean is defined with scope set to shard. Therefore, only one instance of the JPAPropFactoryImpl class is created per shard.

```
<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprgfrmwk_2_jpaPropFactory"
class="com.ibm.ws.objectgrid.jpa.plugins.JPAPropFactoryImpl" scope="shard" />
```

Spring Web Flow

Spring Web Flow stores its session state in an HTTP session by default. If a web application uses eXtreme Scale for session management, then Spring automatically stores state with eXtreme Scale. Also, fault tolerance is enabled in the same manner as the session.

For more information, see HTTP session management.

Packaging

The eXtreme Scale Spring extensions are in the ogspring.jar file. This Java archive (JAR) file must be on the class path for Spring support to work. If a Java EE application that is running in a WebSphere Extended Deployment augmented WebSphere Application Server Network Deployment, put the spring.jar file and its associated files in the enterprise archive (EAR) modules. You must also place the ogspring.jar file in the same location.

Managing transactions with Spring

Spring is a popular framework for developing Java™ applications. WebSphere® eXtreme Scale provides support to allow Spring to manage eXtreme Scale transactions and configure eXtreme Scale clients and servers.

About this task

The Spring Framework is highly integrable with eXtreme Scale, as discussed in the following sections.

Procedure

- **Native transactions:** Spring provides container-managed transactions along the style of a Java Platform, Enterprise Edition application server but has the advantage that Springs mechanism can have different implementations plugged in. This topic describes an eXtreme Scale Platform Transaction manager that can be used with Spring. This allows programmers to annotate their POJOs (plain old Java objects) and then have Spring automatically acquire Sessions from eXtreme Scale and begin, commit, rollback, suspend, and resume eXtreme Scale transactions. Spring transactions are described more fully in Chapter 10 of the official Spring reference documentation. The following explains how to create an eXtreme Scale transaction manager and use it with annotated POJOs. It also explains how to use this approach with client or local eXtreme Scale as well as a collocated Data Grid style application.
- **Transaction manager:** To work with Spring,, eXtreme Scale provides an implementation of a Spring PlatformTransactionManager. This manager can provide managed eXtreme Scale sessions to POJOs managed by Spring. Through the use of annotations, Spring manages those sessions for the POJOs in terms of transaction life cycle. The following XML snippet shows how to create a transaction Manager:

```
<aop:aspectj-autoproxy/>
        <tx:annotation-driven transaction-manager="transactionManager"/>

        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txspringint_ObjectGridManager"
                                class="com.ibm.websphere.objectgrid.ObjectGridManagerFactory"
                                factory-method="getObjectGridManager"/>

        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txspringint_ObjectGrid"
                                factory-bean="ObjectGridManager"
                                factory-method="createObjectGrid"/>

        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txspringint_transactionManager"
                                class="com.ibm.websphere.objectgrid.spring.ObjectGridSpringFactory"
                                factory-method="getLocalPlatformTransactionManager"/>
        </bean>

        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txspringint_Service"
class="com.ibm.websphere.objectgrid.spring.test.TestService">
                <property name="txManager" ref+"transactionManager"/>
        </bean>
```

  This shows the transactionManager bean being declared and wired in to the Service bean that will use Spring transactions. We will demonstrate this using annotations and this is the reason for the tx:annotation clause at the beginning.
- **Obtaining an ObjectGrid session:** A POJO that has methods managed by Spring can now obtain the ObjectGrid session for the current transaction using

```
Session s = txManager.getSession();
```

  This returns the session for the POJO to use. Beans participating in the same transaction will receive the same session when they call this method. Spring will automatically handle begin for the Session and also automatically invoke commit or rollback when necessary. You can obtain an ObjectGrid EntityManager also by simply calling getEntityManager from the Session object.
- **Setting the ObjectGrid instance for a thread:** A single Java Virtual Machine (JVM) can host many ObjectGrid instances. Each primary shard placed in a JVM has its own ObjectGrid instance. A JVM acting as a client to a remote ObjectGrid uses an ObjectGrid instance returned from the connect method's ClientClusterContext to interact with that Grid. Before invoking a method on a POJO using Spring transactions for ObjectGrid, the thread must be primed with the ObjectGrid instance to use. The TransactionManager instance has a method allowing a specific ObjectGrid instance to be specified. Once specified then any subsequent txManager.getSession calls will returns Sessions for that ObjectGrid instance.
  The following example shows a sample main for exercising this capability:

```
ClassPathXmlApplicationContext ctx = new ClassPathXmlApplicationContext(new String[]
            {"applicationContext.xml"});
    SpringLocalTxManager txManager = (SpringLocalTxManager)ctx.getBean("transactionManager");
    txManager.setObjectGridForThread(og);

    ITestService s = (ITestService)ctx.getBean("Service");
    s.initialize();
    assertEquals(s.query(), "Billy");
    s.update("Bobby");
    assertEquals(s.query(), "Bobby");
    System.out.println("Requires new test");
    s.testRequiresNew(s);
    assertEquals(s.query(), "1");
```

Here we use a Spring ApplicationContext. The ApplicationContext is used to obtain a reference to the txManager and specify an ObjectGrid to use on this thread. The code then obtains a reference to the service and invokes methods on it. Each method call at this level causes Spring to create a Session and do begin/commit calls around the method call. Any exceptions will cause a rollback.

- **SpringLocalTxManager interface:** The SpringLocalTxManager interface is implemented by the ObjectGrid Platform Transaction Manager and has all public interfaces. The methods on this interface are for selecting the ObjectGrid instance to use on a thread and obtaining a Session for the thread. Any POJOs using ObjectGrid local transactions should be injected with a reference to this manager instance and only a single instance need be created, that is, its scope should be singleton. This instance is created using a static method on ObjectGridSpringFactory. getLocalPlatformTransactionManager(). Restriction: WebSphere eXtreme Scale does not support JTA or two-phase commit for various reasons mainly to do with scalability. Thus, except at a last single-phase participant, ObjectGrid does not interact in XA or JTA type global transactions. This platform manager is intended to make using local ObjectGrid transactions as easy as possible for Spring developers.

Spring managed extension beans

You can declare plain old Java objects (POJOs) to use as extension points in the objectgrid.xml file. If you name the beans and then specify the class name, eXtreme Scale normally creates instances of the specified class and uses those instances as the plug-in. WebSphere® eXtreme Scale can now delegate to Spring to act as the bean factory for obtaining instances of these plug-in objects.

If an application uses Spring, POJOs have a requirement to be accessible to the rest of the application.
An application can register a Spring Bean Factory instance to use for an ObjectGrid specified by name. The application creates an instance of BeanFactory or a Spring application context and then registers it with ObjectGrid using the following static method:

```
void registerSpringBeanFactoryAdapter(String objectGridName, Object springBeanFactory)
```

The previous method applies to the case when eXtreme Scale finds an extension bean whose className begins with the prefix {spring}. Such an extension bean, which could be an ObjectTransformer, Loader, TransactionCallback, and so on, uses the remainder of the name as a Spring Bean name. Then it obtains the bean instance using the Spring Bean Factory.

The eXtreme Scale deployment environment can also create a Spring bean factory from a default Spring XML configuration file. If no bean factory was registered for a given ObjectGrid, then your deployment searches for an XML file called "/<ObjectGridName>_spring.xml" automatically. For example, if your data grid is called GRID, then the XML file is called "/GRID_spring.xml' and appears in the class path in the root package. ObjectGrid constructs an ApplicationContext using the "/<ObjectGridName>_spring.xml file and constructs beans from that bean factory.

The following is an example class name:

```
"{spring}MyLoaderBean"
```

Using the previous class name allows eXtreme Scale to use Spring to search for a bean named "MyLoaderBean". You can specify Spring-managed POJOs for any extension point if the bean factory has been registered. The Spring extensions are in the ogspring.jar file. This JAR file must be on the class path for Spring support. If a J2EE application runs in WebSphere Application Server Network Deployment augmented with WebSphere Extended Deployment, then you must place the applicaitonhe application should place the spring.jar file and its associated files in the EAR modules. The ogspring.jar must also be placed in the same location.

Spring extension beans and namespace support

WebSphere® eXtreme Scale provides a feature to declare plain old Java™ objects (POJOs) to use as extension points in the objectgrid.xml file and a way to name the beans and then specify the class name. Normally, instances of the specified class are created, and those objects are used as the plug-ins. Now, eXtreme

Scale can delegate to Spring to obtain instances of these plug-in objects. If an application uses Spring then typically such POJOs have a requirement to be wired in to the rest of the application.

In some scenarios, you must use Spring to configure a plug-in, as in the following example:

```
<objectGrid name="Grid">
    <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_TransactionCallback"
className="com.ibm.websphere.objectgrid.jpa.JPATxCallback">
        <property name="persistenceUnitName" type="java.lang.String"  value="employeePU" />
    </bean>
    ...
</objectGrid>
```

The built-in TransactionCallback implementation, the com.ibm.websphere.objectgrid.jpa.JPATxCallback class, is configured as the TransactionCallback class. This class is configured with the persistenceUnitName property as shown in the previous example. The JPATxCallback class also has the JPAPropertyFactory attribute, which is of type java.lang.Object. The ObjectGrid XML configuration cannot support this type of configuration.

The eXtreme Scale Spring integration solves this problem by delegating the bean creation to the Spring framework. The revised configuration follows:

```
<objectGrid name="Grid">
    <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_TransactionCallback"
className="{spring}jpaTxCallback"/>
    ...
</objectGrid>
```

The spring file for the "Grid" object contains the following information:

```
<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_jpaTxCallback"
class="com.ibm.websphere.objectgrid.jpa.JPATxCallback" scope="shard">
    <property name="persistenceUnitName" value="employeeEMPU"/>
    <property name="JPAPropertyFactory" ref ="jpaPropFactory"/>
</bean>

<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_jpaPropFactory"
class="com.ibm.ws.objectgrid.jpa.plugins.
JPAPropFactoryImpl" scope="shard">
</bean>
```

Here, the TransactionCallback is specified as `{spring}jpaTxCallback`, and the jpaTxCallback and jpaPropFactory bean are configured in the spring file as shown in the previous example. The Spring configuration makes it possible to configure a JPAPropertyFactory bean as a parameter of the JPATxCallback object.

Default Spring bean factory

When eXtreme Scale finds a plug-in or an extension bean (such as an ObjectTransformer, Loader, TransactionCallback, and so on) with a classname value that begins with the prefix `{spring}`, then eXtreme Scale uses the remainder of the name as a Spring Bean name and obtain the bean instance using the Spring Bean Factory.

By default, if no bean factory was registered for a given ObjectGrid, then it tries to find an ObjectGridName_spring.xml file. For example, if your data grid is called "Grid" then the XML file is called /Grid_spring.xml. This file should be in the class path or in a META-INF directory which is in the class path. If this file is found, then eXtreme Scale constructs an ApplicationContext using that file and constructs beans from that bean factory.

Custom Spring bean factory

WebSphere eXtreme Scale also provides an ObjectGridSpringFactory API to register a Spring Bean Factory instance to use for a specific named ObjectGrid. This API registers an instance of BeanFactory with eXtreme Scale using the following static method:

```
void registerSpringBeanFactoryAdapter(String objectGridName, Object springBeanFactory)
```

Namespace support

Since version 2.0, Spring has a mechanism for schema-based extensions to the basic Spring XML format for defining and configuring beans. ObjectGrid uses this new feature to define and configure ObjectGrid beans. With Spring XML schema extension, some of the built-in implementations of eXtreme Scale plug-ins and some ObjectGrid beans are predefined in the "objectgrid" namespace. When writing the Spring configuration files, you do not have to specify the full class name of the built-in implementations. Instead, you can reference the predefined beans.

Also, with the attributes of the beans defined in the XML schema, you are less likely to provide a wrong attribute name. XML validation based on the XML schema can catch these kind of errors earlier in the development cycle.

These beans defined in the XML schema extensions are:

- transactionManager
- register
- server
- catalog
- catalogServerProperties
- container
- JPALoader
- JPATxCallback
- JPAEntityLoader
- LRUEvictor
- LFUEvictor

- HashIndex

These beans are defined in the objectgrid.xsd XML schema. This XSD file is shipped as com/ibm/ws/objectgrid/spring/namespace/objectgrid.xsd file in the ogspring.jar file . For detailed descriptions of the XSD file and the beans defined in the XSD file, see Spring descriptor XML file.

Use the JPATxCallback example from the previous section. In the previous section, the JPATxCallback bean is configured as the following:

```
<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_jpaTxCallback"
class="com.ibm.websphere.objectgrid.jpa.JPATxCallback" scope="shard">
    <property name="persistenceUnitName" value="employeeEMPU"/>
    <property name="JPAPropertyFactory" ref ="jpaPropFactory"/>
</bean>

<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_jpaPropFactory"
class="com.ibm.ws.objectgrid.jpa.plugins.JPAPropFactoryImpl" scope="shard">
</bean>
```

Using this namespace feature, the spring XML configuration can be written as the following:

```
<objectgrid:JPATxCallback
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_jpaTxCallback"
persistenceUnitName="employeeEMPU"
        jpaPropertyFactory="jpaPropFactory" />

<bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxssprngxbns_jpaPropFactory"
class="com.ibm.ws.objectgrid.jpa.plugins.JPAPropFactoryImpl"
        scope="shard">
</bean>
```

Notice here that instead of specifying the com.ibm.websphere.objectgrid.jpa.JPATxCallback class as in the previous example, we directly use the pre-defined objectgrid:JPATxCallback bean. As you can see, this configuration is less verbose and more friendly to error checking.

For a description of working with Spring beans, consult Starting a container server with Spring.

Starting a container server with Spring

You can start a container server using Spring managed extension beans and namespace support.

About this task

With several XML files configured for Spring, you can start basic eXtreme Scale container servers.

Procedure

1. **ObjectGrid XML file:**
   First of all, define a very simple ObjectGrid XML file which contains one ObjectGrid "Grid" and one map "Test". The ObjectGrid has an ObjectGridEventListener plug-in called "partitionListener", and the map "Test" has an Evictor plugged in called "testLRUEvictor". Notice both the ObjectGridEventListener plug-in and Evictor plug-in are configured using Spring as their names contain "{spring}".

   ```
   <?xml version="1.0" encoding="UTF-8"?>
   <objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
    xmlns="http://ibm.com/ws/objectgrid/config">
       <objectGrids>
           <objectGrid name="Grid">
               <bean
   id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_ObjectGridEventList
   ener" className="{spring}partitionListener" />
               <backingMap name="Test" pluginCollectionRef="test" />
           </objectGrid>
       </objectGrids>

       <backingMapPluginCollections>
           <backingMapPluginCollection
   id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_test">
               <bean
   id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_Evictor"
   className="{spring}testLRUEvictor"/>
           </backingMapPluginCollection>
       </backingMapPluginCollections>
   </objectGridConfig>
   ```

2. **ObjectGrid deployment XML file:**
   Now, create a simple ObjectGrid deployment XML file as follows. It partitions the ObjectGrid into 5 partitions, and no replica is required.

```
<?xml version="1.0" encoding="UTF-8"?>
<deploymentPolicy xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/deploymentPolicy ../deploymentPolicy.xsd"
 xmlns="http://ibm.com/ws/objectgrid/deploymentPolicy">
    <objectgridDeployment objectgridName="Grid">
        <mapSet name="mapSet" numInitialContainers="1" numberOfPartitions="5" minSyncReplicas="0"
            maxSyncReplicas="1" maxAsyncReplicas="0">
            <map ref="Test"/>
        </mapSet>
    </objectgridDeployment>
</deploymentPolicy>
```

3. **ObjectGrid Spring XML file:**
   Now we will use both ObjectGrid Spring managed extension beans and namespace support features to configure the ObjectGrid beans. The spring xml file is named Grid_spring.xml. Notice two schemas are included in the XML file: spring-beans-2.0.xsd is for using the Spring managed beans, and objectgrid.xsd is for using the beans predefined in the objectgrid namespace.

```
<beans xmlns="http://www.springframework.org/schema/beans"
       xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
       xmlns:aop="http://www.springframework.org/schema/aop"
       xmlns:tx="http://www.springframework.org/schema/tx"

xmlns:objectgrid="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_http:
//www.ibm.com/schema/objectgrid"
       xsi:schemaLocation="
       http://www.ibm.com/schema/objectgrid
                        http://www.ibm.com/schema/objectgrid/objectgrid.xsd
       http://www.springframework.org/schema/beans
                        http://www.springframework.org/schema/beans/spring-beans-2.0.xsd">

    <objectgrid:register
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_ogregister"
gridname="Grid"/>

    <objectgrid:server
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_server"
isCatalog="true" name="server">
        <objectgrid:catalog host="localhost" port="2809"/>
    </objectgrid:server>

    <objectgrid:container
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_container"
                        objectgridxml="com/ibm/ws/objectgrid/test/springshard/objectgrid.xml"
       deploymentxml="com/ibm/ws/objectgrid/test/springshard/deployment.xml"
                        server="server"/>

    <objectgrid:LRUEvictor
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_testLRUEvictor"
numberOfLRUQueues="31"/>

    <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txssprngcont_partitionListener"
                        class="com.ibm.websphere.objectgrid.springshard.ShardListener" scope="shard"/>
</beans>
```

   There were six beans defined in this spring XML file:

   a. *objectgrid:register*: This register the default bean factory for the ObjectGrid "Grid".
   b. *objectgrid:server*: This defines an ObjectGrid server with name "server". This server will also provide catalog service since it has an objectgrid:catalog bean nested in it.
   c. *objectgrid:catalog*: This defines an ObjectGrid catalog service endpoint, which is set to "localhost:2809".
   d. *objectgrid:container*: This defines an ObjectGrid container with specified objectgrid XML file and deployment XML file as we discussed before. The server property specifies which server this container is hosted in.
   e. *objectgrid:LRUEvictor*: This defines an LRUEvictor with the number of LRU queues to use set to 31.
   f. *bean partitionListener*: This defines a ShardListener plug-in. You must provide an implementation for this plug-in, so it cannot use the pre-defined beans. Also this scope of the bean is set to "shard", which means there is only one instance of this ShardListener per ObjectGrid shard.

4. **Starting the server:**
   The snippet below starts the ObjectGrid server, which hosts both the container service and the catalog service. As we can see, the only method we need to call to start the server is to get a bean "container" from the bean factory. This simplifies the programming complexity by moving most of the logic into Spring configuration.

```
public class ShardServer extends TestCase
{
    Container container;
    org.springframework.beans.factory.BeanFactory bf;

    public void startServer(String cep)
    {
        try
        {
            bf = new org.springframework.context.support.ClassPathXmlApplicationContext(
                "/com/ibm/ws/objectgrid/test/springshard/Grid_spring.xml", ShardServer.class);
            container = (Container)bf.getBean("container");
        }
```

```
        catch(Exception e)
        {
            throw new ObjectGridRuntimeException("Cannot start OG container", e);
        }
    }

    public void stopServer()
    {
        if(container != null)
            container.teardown();
    }
}
```

Configuring clients in the Spring framework

You can override client-side ObjectGrid settings with the Spring Framework.

About this task

The following example XML file shows how to build an ObjectGridConfiguration element, and use it to override some client side settings. You can create a similar configuration using programmatic configuration or by configuring the ObjectGrid descriptor XML file.
8.5+ For information about how to use the ObjectGridClientBean and ObjectGridCatalogServiceDomainBean beans to support the Spring Framework Version 3.1 cache abstraction, see Configuring a Spring cache provider.

Procedure

1. Create an XML file to configure clients with the Spring framework.

```
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE beans PUBLIC "-//SPRING//DTD BEAN//EN"
                "http://www.springframework.org/dtd/spring-beans.dtd">
<beans>
  <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txscliconfigspring_companyGrid"
factory-bean="manager" factory-method="getObjectGrid"
    singleton="true">
    <constructor-arg type="com.ibm.websphere.objectgrid.ClientClusterContext">
      <ref bean="client" />
    </constructor-arg>
    <constructor-arg type="java.lang.String" value="CompanyGrid" />
</bean>

  <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txscliconfigspring_manager"
class="com.ibm.websphere.objectgrid.ObjectGridManagerFactory"
    factory-method="getObjectGridManager" singleton="true">
    <property name="overrideObjectGridConfigurations">
      <map>
        <entry key="DefaultDomain">
          <list>
            <ref bean="ogConfig" />
          </list>
        </entry>
      </map>
    </property>
  </bean>

  <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txscliconfigspring_ogConfig"
    class="com.ibm.websphere.objectgrid.config.ObjectGridConfigFactory"
    factory-method="createObjectGridConfiguration">
    <constructor-arg type="java.lang.String">
      <value>CompanyGrid</value>
    </constructor-arg>
    <property name="plugins">
      <list>
          <bean class="com.ibm.websphere.objectgrid.config.ObjectGridConfigFactory"
          factory-method="createPlugin">
          <constructor-arg type="com.ibm.websphere.objectgrid.config.PluginType"
            value="TRANSACTION_CALLBACK" />
          <constructor-arg type="java.lang.String"
            value="com.company.MyClientTxCallback" />
        </bean>
        <bean class="com.ibm.websphere.objectgrid.config.ObjectGridConfigFactory"
```

```
          factory-method="createPlugin">
          <constructor-arg type="com.ibm.websphere.objectgrid.config.PluginType"
            value="OBJECTGRID_EVENT_LISTENER" />
          <constructor-arg type="java.lang.String" value="" />
        </bean>
      </list>
        </property>
      <property name="backingMapConfigurations">
        <list>
            <bean class="com.ibm.websphere.objectgrid.config.ObjectGridConfigFactory"
            factory-method="createBackingMapConfiguration">
            <constructor-arg type="java.lang.String" value="Customer" />
              <property name="plugins">
                    <bean class="com.ibm.websphere.objectgrid.config.ObjectGridConfigFactory"
                factory-method="createPlugin">
                <constructor-arg type="com.ibm.websphere.objectgrid.config.PluginType"
                        value="EVICTOR" />
                    <constructor-arg type="java.lang.String"
                value="com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor" />
              </bean>
            </property>
            <property name="numberOfBuckets" value="1429" />
            </bean>
            <bean class="com.ibm.websphere.objectgrid.config.ObjectGridConfigFactory"
              factory-method="createBackingMapConfiguration">
                <constructor-arg type="java.lang.String" value="OrderLine" />
                  <property name="numberOfBuckets" value="701" />                        <property name="timeToLive"
value="800" />
                    <property name="ttlEvictorType">
                  <value type="com.ibm.websphere.objectgrid.

TTLType">LAST_ACCESS_TIME</value>
                    </property>
            </bean>
          </list>
        </property>
      </bean>

      <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txscliconfigspring_client"
factory-bean="manager" factory-method="connect"
        singleton="true">
        <constructor-arg type="java.lang.String">
            <value>localhost:2809</value>
        </constructor-arg>
          <constructor-arg
          type="com.ibm.websphere.objectgrid.security.
                                              config.ClientSecurityConfiguration">
          <null />
        </constructor-arg>
          <constructor-arg type="java.net.URL">
            <null />
        </constructor-arg>
      </bean>
</beans>
```

2. Load the XML file you created and build the ObjectGrid.

```
BeanFactory beanFactory = new XmlBeanFactory(newUrlResource
                ("file:test/companyGridSpring.xml"));
ObjectGrid companyGrid = (ObjectGrid) beanFactory.getBean("companyGrid");
```

Monitoring

You can use the included monitoring console, APIs, MBeans, logs, and utilities to monitor the performance of your application environment.

- Statistics overview
  Statistics in WebSphere® eXtreme Scale are built on an internal statistics tree. The StatsAccessor API, Performance Monitoring Infrastructure (PMI) modules, and MBean API are built from the internal tree.
- Monitoring with the web console
  With the web console, you can chart current and historical statistics. This console provides some preconfigured charts for high-level overviews, and has a

custom reports page that you can use to build charts from the available statistics. You can use the charting capabilities in the monitoring console of WebSphere eXtreme Scale to view the overall performance of the data grids in your environment.

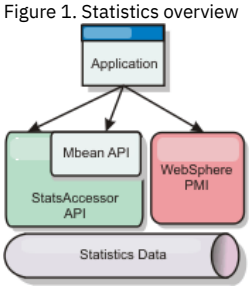
- Monitoring with CSV files
  You can enable monitoring data collected for a container server to be written to comma-separated values (CSV) files. These CSV files can contain information about the Java virtual machine (JVM), map, or ObjectGrid instance.
- Enabling statistics
  WebSphere eXtreme Scale uses an internal statistics model to track and filter data, which is the underlying structure that all data views use to gather snapshots of statistics. You can use several methods to retrieve the information from the statistics modules.
- Monitoring with the xscmd utility
  The **xscmd** utility replaces the **xsadmin** sample utility as a fully supported monitoring and administration tool. With the **xscmd** utility, you can display textual information about your WebSphere eXtreme Scale topology.
- Monitoring with WebSphere Application Server PMI
  WebSphere eXtreme Scale supports Performance Monitoring Infrastructure (PMI) when running in a WebSphere Application Server or WebSphere Extended Deployment application server. PMI collects performance data on runtime applications and provides interfaces that support external applications to monitor performance data. You can use the administrative console or the wsadmin tool to access monitoring data.
- Monitoring server statistics with managed beans (MBeans)
  You can used managed beans (MBeans) to track statistics in your environment.
- Monitoring with vendor tools
  WebSphere eXtreme Scale can be monitored using several popular enterprise monitoring solutions. Plug-in agents are included for IBM® Tivoli® Monitoring and Hyperic HQ, which monitor WebSphere eXtreme Scale using publicly accessible management beans. CA Wily Introscope uses Java™ method instrumentation to capture statistics.
- Monitoring eXtreme Scale information in DB2
  When the JPALoader or JPAEntityLoader is used with DB2® as the back-end database, eXtreme Scale-specific information can be passed to DB2. You can view this information by a performance monitor tool such as DB2 Performance Expert to monitor the eXtreme Scale applications that are accessing the database.

Statistics overview

Statistics in WebSphere® eXtreme Scale are built on an internal statistics tree. The StatsAccessor API, Performance Monitoring Infrastructure (PMI) modules, and MBean API are built from the internal tree.

The following figure shows the general setup of statistics for WebSphere eXtreme Scale.

Figure 1. Statistics overview



Each of these APIs offer a view into the statistics tree, but are used for different reasons:

- **Statistics API**: The Statistics API allows developers direct access to statistics for flexible and customizable statistics integration solutions, such as custom MBeans or logging.
- **MBean API**: The MBean API is a specification-based mechanism for monitoring. The MBean API uses the Statistics API and runs local to the server Java™ Virtual Machine (JVM). The API and MBean structures are designed to readily integrate with other vendor utilities. Use the MBean API when you are running a distributed object grid.
- **WebSphere Application Server Performance Monitoring Infrastructure (PMI) modules**: Use PMI if you are running WebSphere eXtreme Scale within WebSphere Application Server. These modules provide a view of the internal statistics tree.

Statistics API

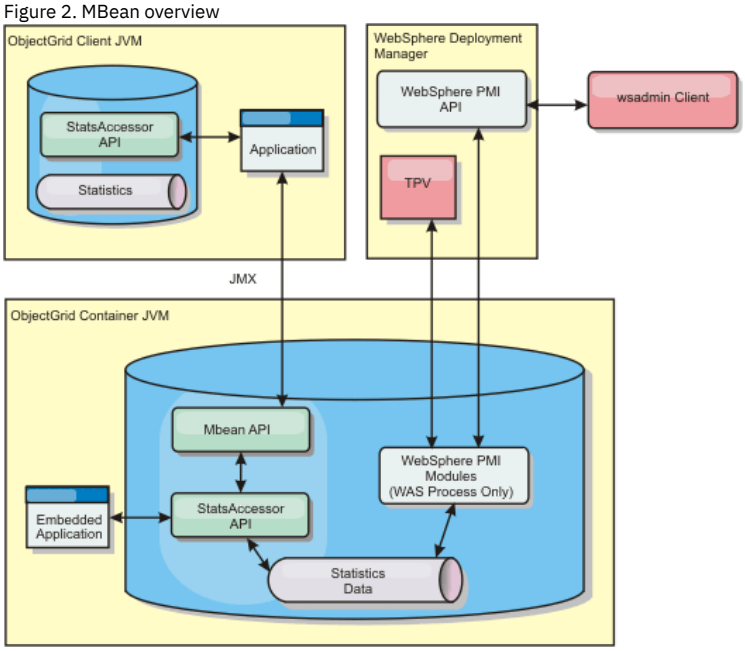
Much like a tree map, there is a corresponding path and key used to retrieve a specific module, or in this case granularity or aggregation level. For example, assume there is always an arbitrary root node in the tree and that statistics are being gathered for a map named "payroll," belonging to an ObjectGrid named "accounting." For example, to access the module for a map's aggregation level or granularity, you could pass in a String[] of the paths. In this case that would equate to String[] {root, "accounting", "payroll"}, as each String would represent the node's path. The advantage of this structure is that a user can specify the array to any node in the path and get the aggregation level for that node. So passing in String[] {root, "accounting"} would give you map statistics, but for the entire grid of "accounting." This leaves the user with both the ability to specify types of statistics to monitor, and at whatever level of aggregation is required for the application.

WebSphere Application Server PMI modules

WebSphere eXtreme Scale includes statistics modules for use with the WebSphere Application Server PMI. When a WebSphere Application Server profile is augmented with WebSphere eXtreme Scale, the augment scripts automatically integrate the WebSphere eXtreme Scale modules into the WebSphere Application Server configuration files. With PMI, you can enable and disable statistics modules, automatically aggregate statistics at various granularity, and even graph the data using the built-in Tivoli® Performance Viewer. See Monitoring with WebSphere Application Server PMI for more information.

Vendor product integration with Managed Beans (MBean)

The eXtreme Scale APIs and Managed Beans are designed to allow for easy integration with third party monitoring applications. JConsole or MC4J are some examples of lightweight Java Management Extensions (JMX) consoles that can be used to analyze information about an eXtreme Scale topology. You can also use the programmatic APIs to write adapter implementations to snapshot or track eXtreme Scale performance. WebSphere eXtreme Scale includes a sample monitoring application that allows out-of-the box monitoring capabilities, and can be used as a template for writing more advanced custom monitoring utilities.
Figure 2. MBean overview



See Sample: xsadmin utility for more information. For more information about integrating with specific vendor applications, see the following topics:

- Monitoring eXtreme Scale with IBM® Tivoli Monitoring agent
- Monitoring eXtreme Scale with Hyperic HQ
- Monitoring eXtreme Scale applications with CA Wily Introscope

Monitoring with the web console

With the web console, you can chart current and historical statistics. This console provides some preconfigured charts for high-level overviews, and has a custom reports page that you can use to build charts from the available statistics. You can use the charting capabilities in the monitoring console of WebSphere® eXtreme Scale to view the overall performance of the data grids in your environment.

1. Starting and logging on to the web console
   Start the console server by running the **startConsoleServer** command and logging on to the server with the default user ID and password.
2. Connecting the web console to catalog servers
   To start viewing statistics in the web console, you must first connect to catalog servers that you want to monitor. Additional steps are required if your catalog servers have security enabled.
3. Viewing statistics with the web console
   You can monitor statistics and other performance information with the web console.
4. Monitoring with custom reports
   You can build custom reports to save various charts that contain statistics about the catalog service domains, data grids, and container servers in your

environment. You can save the custom reports and load them to view again later.

Getting started tutorial lesson 4: Monitor your environment

Starting and logging on to the web console

Start the console server by running the **startConsoleServer** command and logging on to the server with the default user ID and password.

Before you begin

- **Web browser requirements**
  Use one of the following browsers with the web console:
  - Mozilla Firefox, version 3.5.x and later
  - Mozilla Firefox, version 3.6.x and later
  - Microsoft Internet Explorer, version 7 or 8

About this task

If your catalog servers are running in a stand-alone environment, with a Java™ security manager, then the user ID that you use to log in must correspond to a principal that has the following permissions in the Java security policy file:

```
grant principal javax.security.auth.x500.X500Principal "CN=manager,O=acme,OU=OGSample"
     {
        permission javax.management.MBeanPermission "*",
"getAttribute,setAttribute,invoke,queryNames,addNotificationListener,removeNotificationListener";
     };
```

Procedure

1. Optional: If you want to run your console server on a port other than the default port, edit the web console configuration. Click Settings > Configuration > System. The default port for the console server is `7080` for HTTP and `7443` for HTTPS. If you edit these values after the console server is already started, restart the server to use the new port numbers.
2. Start the console server. The **startConsoleServer.bat|sh** script for starting the console server is in the *wxs_install_root*/ObjectGrid/bin directory of your installation.
3. Log on to the console.
   a. From your web browser, go to `https://your.console.host:7443`, replacing `your.console.host` with the host name of the server onto which you installed the console. If you had changed the port number, remember to update the port number in the URL.
   b. Log on to the console.
      - **User ID:** `admin`
      - **Password:** `admin`

      The console welcome page is displayed.
4. Edit the console configuration. Click Settings > Configuration to review the console configuration. The console configuration includes information such as:
   - Trace string for the WebSphere® eXtreme Scale client, such as `*=all=disabled`
   - The Administrator name and password
   - The Administrator e-mail address

What to do next

- Connect your catalog servers to the web console to start tracking statistics. See Connecting the web console to catalog servers for more information.
- If you need to stop the web console server, run the **stopConsoleServer.bat|sh** script. This script is in the *wxs_install_root*/ObjectGrid/bin directory of your installation.

Getting started tutorial lesson 4: Monitor your environment

Connecting the web console to catalog servers

To start viewing statistics in the web console, you must first connect to catalog servers that you want to monitor. Additional steps are required if your catalog servers have security enabled.

Before you begin

- The web console server must be running. See Starting and logging on to the web console for more information.
- You must have at least one catalog server running to which you want to connect. See Starting a stand-alone catalog service for more information.

Procedure

1. If your catalog servers have Secure Sockets Layer (SSL) enabled, you must configure a keystore and a truststore in the client properties file. You can enable SSL for a catalog server by setting the transportType attribute to `SSL-Required` or `SSL-Supported` in the server properties file. For more information about the SSL properties you can set on the server, see the Server properties file.
   a. Configure a keystore and truststore, and then exchange, or cross-import the public certificates. For example, you might copy the truststore and keystore to a location on the server that is running the web console.
   b. Edit the client properties file on the web console server to include the properties for SSL configuration. For more information about the SSL properties you can set for the client, see the Client properties file. For example, you can make a copy of the client properties file located in the*wxs_install_root*/ObjectGridProperties/sampleclient.properties and edit that file. The following properties are required for outbound SSL connections from the web console:

```
#-------------------------------------------------------------------------------
# SSL Configuration
#
# - contextProvider     (IBMJSSE2, IBMJSSE, IBMJSSEFIPS, etc.)
# - protocol            (SSL, SSLv2, SSLv3, TLS, TLSv1, etc.)
# - keyStoreType        (JKS, JCEK, PKCS12, etc.)
# - trustStoreType      (JKS, JCEK, PKCS12, etc.)
# - keyStore            (fully qualified path to key store file)
# - trustStore          (fully qualified path to trust store file)
# - alias               (string specifying ssl certificate alias to use from keyStore)
# - keyStorePassword    (string specifying password to the key store - encoded or not)
# - trustStorePassword  (string specifying password to the trust store - encoded or not)
#
# Uncomment these properties to set the SSL configuration.
#-------------------------------------------------------------------------------
#alias=clientprivate
#contextProvider=IBMJSSE
#protocol=SSL
#keyStoreType=JKS
#keyStore=etc/test/security/client.private
#keyStorePassword={xor}PDM2OjErLyg\=
#trustStoreType=JKS
#trustStore=etc/test/security/server.public
#trustStorePassword={xor}Lyo9MzY8
```

   Windows Important: If you are using Windows, you must escape any backslash (\ ) characters in the path. For example, if you want to use the path C:\opt\ibm, enter C:\\opt\\ibm in the properties file. Windows directories with spaces are not supported.
2. Establish and maintain connections to catalog servers that you want to monitor. Repeat the following steps to add each catalog server to the configuration.
   a. Click Settings > eXtreme Scale Catalog Servers.
   b. Add a new catalog server.
      i. Click the add icon () to register an existing catalog server.
      ii. Provide information, such as the host name and listener port. See Planning for network ports for more information about port configuration and defaults.
      iii. Click OK.
      iv. Verify that the catalog server has been added to the navigation tree.
3. Group the catalog servers that you created into a catalog service domain. You must create a catalog service domain when security is enabled in your catalog servers because security settings are configured in the catalog service domain.
   a. Click Settings > eXtreme Scale Domains page.
   b. Add a new catalog service domain.
      i. Click the add icon () to register a catalog service domain. Enter a name for the catalog service domain.
      ii. After you create the catalog service domain, you can edit the properties. The catalog service domain properties follow:

      Name
      : Indicates the host name of the domain, as assigned by the administrator.

      Catalog servers
      : Lists one or more catalog servers that belong to the selected domain. You can add the catalog servers that you created in the previous step.

      Generator class
      : Specifies the name of the class that implements the CredentialGenerator interface. This class is used to get credentials for clients. If you specify a value in this field, the value overrides the crendentialGeneratorClass property in the client.properties file.

      Generator properties
      : Specifies the properties for the CredentialGenerator implementation class. The properties are set to the object with the setProperties(String) method. The credentialGeneratorprops value is used only if the value of the credentialGeneratorClass property is not null. If you specify a value in this field, the value overrides the credentialGeneratorProps property in the client.properties file.

eXtreme Scale client properties path
Specifies the path to the client properties file that you edited to include SSL properties. For example, you might indicate the /ObjectGridProperties/sampleclient.properties file. If you want to stop the console from trying to use SSL connections, you can delete the value in this field. After you set the path, the console uses an unsecured connection.

iii. Click OK.
iv. Verify that the domain has been added to the navigation tree.

To view information about an existing catalog service domain, click the name of the catalog service domain in the navigation tree on the Settings > eXtreme Scale Domains page.

4. View the connection status. The Current domain field indicates the name of the catalog service domain that is currently being used to display information in the web console. The connection status displays next to the name of the catalog service domain.

Viewing statistics with the web console

You can monitor statistics and other performance information with the web console.

Before you begin

Before you can view statistics with the web console, you must complete the following tasks:

1. Start the web console server. See Starting and logging on to the web console for more information.
2. Connect your catalog servers to the web console server. See Connecting the web console to catalog servers for more information.
3. Run active data grids and applications within the servers that are managed by your catalog service domain.

About this task

After you create your data grids and configure your applications to use the data grids, allow some time to pass for the statistics to become available. For example, with a dynamic cache data grid, statistics are not available until a WebSphere® Application Server that is running a dynamic cache connects to the dynamic cache. In general, wait up to one minute after a major configuration change to see the changes in your statistics.

Tip: To view more specific information about any data point in a chart, you can move the mouse pointer over the data point.

Procedure

- To view the current server statistics, click Monitor > Server Overview.
- To view the performance of all of your data grids, click Monitor > Data grid domain overview.
- To view individual data grids, click Monitor > Data grid overview > *data_grid_name*. This page shows a summary that includes the number of cache entries, the average transaction time, and average throughput.
- To view further details about a specific data grid, click Monitor > Data grid details. A tree displays with all of the data grids in your configuration. You can drill down into a specific data grid to view the maps that are a part of that data grid. You can either click a data grid name or a map for further information.
- To choose which statistics you would like your custom report to contain, click Monitor > Custom reports.
  Use this view to construct detailed data charts of the various statistics. Use the tree to explore the available data grids and servers and their associated statistics. A menu opens when you click or press enter on a node that references data that can be charted. Create a new chart containing the statistics, or add the statistics into an existing chart with compatible statistics. See Monitoring with custom reports for more information.

- Web console statistics
  Depending on the view you are using in the web console, you can view different statistics about your configuration. These statistics include the used memory, the top used data grids, and the number of cache entries.

  - Custom reports: Data grid statistics
  - Custom reports: Map statistics

Data grid domain overview

Data grid domain overview statistics are displayed on the Monitor > Data Grid Domain Overview page. Click one of the following tabs for more information about the data grid domain:

Used Capacity tab
: In the Current Data Grid Used Capacity Distribution chart, a picture of the Total Pool, and the Largest Used Capacity Consumers are displayed. Only the top 25 data grids are displayed. In the Used Capacity Over Time chart, the number of bytes that are consumed by the data grid is displayed.

Average Throughput tab
: The 5 Most Active Data Grids by Average Transaction Time in Milliseconds chart contains a list of the top five data caches, organized by the average transaction time. The Average Throughput Over time chart displays the average, maximum, and minimum throughput within the last hour, day, and week.

Average Transaction Time tab
: The 5 Slowest Data Grids chart displays data about the slowest data grids. The Average Transaction Time Over Time chart displays the average , maximum, and minimum transaction time within the last hour, day, and week.

Data grid overview

To view statistics for an individual data grid, click Monitor > Data Grid Overview > *data_grid_name*.

Current summary over last 30 seconds
: Displays the current number of cache entries, average transaction time, average throughput, and cache hit rate for the selected data grid.

Used Capacity tab
: The Current summary over last 30 seconds chart displays the number of cache entries and used capacity in bytes over a specified time range.

Cache Usage tab
: The Cache Usage chart helps to visualize the number of successful queries to the cache, and displays cache attempts, cache hits, and the cache hit rate over a specified time range.

Average Throughput tab
: The Average Throughput vs. Average Transaction Time chart displays the transaction time and throughput over a specified time range.

Data grid details

Data grid statistics are displayed on the Monitor > Data Grid Details page. You can look at data for a selected grid and the maps that are within that grid.

Current summary over last 30 seconds
: Displays the current used capacity, number of cache entries, average throughput, and average transaction time for the selected data grid.

Current eXtreme Scale Object Grid Map Used Capacity Distribution
: View a total pool, which includes the capacity by zone and the total capacity in each zone. Only the top 25 ObjectGrid maps are displayed. You can also view the largest used capacity consumers by each map.

Current Zone Used Capacity Distribution
: View a total pool, which includes the total pool and the top used capacity consumers in the zone of the selected data grid. You can also view the largest used capacity consumers by each zone.

Map statistics:

Current summary over last 30 seconds
: Displays the current used capacity, number of cache entries, average throughput, and average transaction time for the selected map.

Current Partition Used Capacity Distribution
: View a partition, which includes the total pool and the top used capacity consumers. Only the top 25 partitions are displayed. You can also view the largest used capacity consumers by each partition.

Server overview

Server statistics are displayed on the Monitor > Server Overview page.

Current Server Used Memory Distribution
: This chart is composed of two views. Total Pool displays the current amount of used (real) memory in the server run time. Largest Used memory Consumers breaks down the used memory by server; however only the top 25 servers that are using the most memory are displayed.

Total Memory Over Time
: Displays the real memory usage in the server run time.

Used Memory Over Time
: Displays the amount of used memory in the server run time.

Custom reports: Catalog service domain statistics

You can view catalog service domain statistics by creating a custom report. Click Monitor > Custom Reports.

Average Transaction Time (ms)
: Displays the average time required to complete a transaction in this domain.

Average Transaction Throughput (trans/sec)
: Displays the average number of transactions per second in this domain.

Maximum Transaction Time (ms)
: Displays the time spent by the *most* time-consuming transaction in this domain.

Minimum Transaction Time (ms)
: Displays the time spent by the *least* time-consuming transaction in this domain.

Total Transaction Time (ms)
: Displays total time spent on transactions in this domain, since the time the domain was initialized.

Custom reports: Container server statistics

You can view container server statistics by creating a custom report. Click Monitor > Custom Reports.

Average Transaction Time (ms)
: Displays the average time required to complete a transaction for this catalog server.

Average Transaction Throughput (trans/sec)
: Displays the average number of transactions per second for this catalog server.

Maximum Transaction Time (ms)
: Displays the time spent by the *most* time-consuming transaction for this catalog server.

Minimum Transaction Time (ms)
: Displays the time spent by the *least* time-consuming transaction for this catalog server.

Total Transaction Time (ms)
: Displays total time spent on transactions for this catalog server, since the time for this catalog server was initialized.

Total Entries in Cache
: Displays the current number of objects cached in the grids overseen by this catalog server.

Hit rate (percentage)
: Displays the hit rate (hit ratio) for the selected data grid. A high hit rate is desirable. The hit rate indicates how well the grid is helping to avoid accessing the persistent store.

Used Bytes
: Displays memory consumption by this map. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

Minimum Used Bytes
: Displays the low point in memory consumption by this catalog service and its maps. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

Maximum Used Bytes
: Displays the high point in memory consumption by this catalog service and its maps. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

Total Number of Hits
: Displays the total number of times the requested data was found in the map, avoiding the need to access persistent store.

Total Number of Gets
: Displays the total number of times the map had to access the persistent store to obtain data.

Free Heap (MB)
: Displays the actual amount of heap available to the JVM being used by the catalog server.

Total Heap
: Displays the amount of heap available to the JVM being used by this catalog server.

Number of Available Processors
: Displays the number of processors that are available to this catalog service and its maps. For the highest stability, run your servers at 60% processor loading and JVM heaps at 60% heap loading. Spikes can then drive the processor usage to 80–90%, but do not regularly run your servers higher than these levels

Maximum Heap Size (MB)
: Displays the maximum amount of heap available to the JVM being used by this catalog server.

Used Memory
: Displays the used memory in the JVM being used by this catalog server.

Custom reports: Data grid statistics

You can view data grid statistics by creating a custom report. Click Monitor > Custom Reports.

Average Transaction Time (ms)
: Displays the average time required to complete transactions involving this grid.

Average Transaction Throughput (trans/sec)
: Displays the average number of transactions per second completed by this grid.

Maximum Transaction Time (ms)
: Displays the time spent by the *most* time-consuming transaction completed by this grid.

Minimum Transaction time (ms)
: Displays the time spent by the *least* time-consuming transaction completed by this grid.

Total Transaction Time (ms)
: Displays the total amount of transaction processing time for this grid.

Custom reports: Map statistics

You can view map statistics by creating a custom report. Click Monitor > Custom Reports.

Total Entries in Cache
: Displays the current number of objects cached in this map.

Hit Rate (percentage)
: Displays the hit rate (hit ratio) for the selected map. A high hit rate is desirable. The hit rate indicates how well the map is helping to avoid accessing the persistent store.

Used Bytes
: Displays memory consumption by this map. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

Minimum Used Bytes
: Displays the minimum consumption (in Bytes) for this map. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

Maximum Used Bytes
: Displays the maximum consumption (in Bytes) for this map. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

Total Number of Hits
: Displays the total number of times the requested data was found in the map, avoiding the need to access persistent store.

Total Number of Gets
: Displays the total number of times the map had to access the persistent store to obtain data.

Free Heap (MB)
: Displays the current amount of heap available to this map, in the JVM being used by the catalog server.

Total Heap (MB)
: Displays the total amount of heap available to this map, in the JVM being used by the catalog server. For the highest stability, run your servers at 60% processor loading and JVM heaps at 60% heap loading. Spikes can then drive the processor usage to 80–90%, but do not regularly run your servers higher than these levels

Number of Available Processors
: Displays the number of processors available to this map. For the highest stability, run your servers at 60% processor loading and JVM heaps at 60% heap loading. Spikes can then drive the processor usage to 80–90%, but do not regularly run your servers higher than these levels

Maximum Heap Size (MB)
: Displays the maximum amount of heap available to this map, in the JVM being used by the catalog server.

Used Memory (MB)
: Displays the used amount of memory in this map.

Monitoring with custom reports

You can build custom reports to save various charts that contain statistics about the catalog service domains, data grids, and container servers in your environment. You can save the custom reports and load them to view again later.

Before you begin

Before you can view statistics with the web console, you must complete the following tasks:

1. Start the web console server. See Starting and logging on to the web console for more information.
2. Connect your catalog servers to the web console server. See Connecting the web console to catalog servers for more information.
3. Run active data grids and applications within the servers that are managed by your catalog service domain.

Procedure

- Create a custom report.
    1. Click Monitor > Custom Reports. A list of the eXtreme Scale domains that you have defined are listed in a tree format. You can expand each of these domains to display the available statistics that you can add to the custom report.
    2. Add charts with the statistics you want to track. Available statistics are indicated by the chart icon (). Click one of the statistics that you want to track. Choose Add to new chart or Add to existing chart. Depending on your selection, the selected statistic either displays in a new chart tab or in the selected existing chart. You can only add a metric to an existing chart if the metrics already on the chart and the new metric use the same units.
- Save a custom report. Saving the custom report saves the statistics in all of the tabs you have created. To save the report, click Save.
- Load a custom report. Click Load and choose the saved custom report that you want to view.

Previous topic: Viewing statistics with the web console

Monitoring with CSV files

You can enable monitoring data collected for a container server to be written to comma-separated values (CSV) files. These CSV files can contain information about the Java virtual machine (JVM), map, or ObjectGrid instance.

About this task

By enabling monitoring data to be written to CSV files, you can download and analyze historical data for individual container servers. Data begins being collected when you start the server with the server properties that enable the CSV files. You can then download the CSV files at any time and use the files as you choose.

Procedure

1. Update the server properties file with the following properties that are related to enabling the CSV files.

```
parameter=default value
jvmStatsLoggingEnabled=true
maxJVMStatsFiles=5
maxJVMStatsFileSize=100
jvmStatsFileName=jvmstats
jvmStatsWriteRate=10

mapStatsLoggingEnabled=true
maxMapStatsFiles=5
maxMapStatsFileSize=100
mapStatsFileName=mapstats
mapStatsWriteRate=10

ogStatsLoggingEnabled=true
maxOGStatsFiles=5
maxOGStatsFileSize=100
ogStatsFileName=ogstats
ogStatsWriteRate=10
```

   For more information about these properties, see Server properties file.
2. Restart the server to pick up the changes to the server properties file.
3. Import the CSV file into the program that you are using to process the data, such as a spreadsheet.

What to do next

For more information about the data that is contained in the CSV files, see CSV file statistics definitions.

- CSV file statistics definitions
  The CSV files that you can download for a server include statistics that you can use to build historical charts or other information.

CSV file statistics definitions

The CSV files that you can download for a server include statistics that you can use to build historical charts or other information.

Java virtual machine (JVM) statistics log

TimeStamp (column 1)
: Specifies the date and time of the statistics snapshot that was taken for the Java virtual machine (JVM).

ServerName (column 2)
: Specifies the server name of the JVM.

Hostname (column 3)
: Specifies the host name of the JVM.

FreeMemory (column 4)
: Specifies the number of available bytes for the JVM.

MaxMemory (column 5)
: Specifies the maximum number of bytes that can be allocated for the JVM.

TotalMemory (column 6)
: Displays the real memory usage in the server run time.

AvailProcs (column 7)
: Displays the number of processors that are available to this catalog service and its maps. For the highest stability, run your servers at 60% processor loading and JVM heaps at 60% heap loading. Spikes can then drive the processor usage to 80–90%, but do not regularly run your servers higher than these levels

Map statistics log

TimeStamp (column 1)
: Specifies the date and time of the statistics snapshot that was taken for the map.

MapName (column 2)
: Specifies the name of the map.

OgName (column 3)
: Specifies the name of the data grid to which this map belongs.

PartitionId (column 4)
: Specifies the ID of the partition.

MapSetName (column 5)
: Specifies the map set to which this map belongs.

HitRate (column 6)
: Displays the hit rate (hit ratio) for the selected map. A high hit rate is desirable. The hit rate indicates how well the data grid is helping to avoid accessing the persistent store.

Count (column 7)
: Indicates the number of entries in the data grid since the server started. For example, a value of 100 indicates that the entry is the 100th sample entry that has been gathered since the server started.

TotalGetCount (column 8)
: Displays the total number of times the map had to access the persistent store to obtain data.

TotalHitCount (column 9)
: Displays the total number of times the requested data was found in the map, avoiding the need to access persistent store.

StartTime (column 10)
: Specifies the time that the counters began from last reset call. The resets occur when the server starts or restarts.

LastCount (column 11)
: Specifies the amount of time since the last data sample was taken.

LastTotalGetCount (column 12)
: Indicates the current total number of get operations from the cache minus the number of get operations in the previous time period.

LastTotalHitCount (column 13)
: Indicates the current total number of hits from the cache minus the number of hits in the previous time period.

UsedBytes (column 14)
: Displays memory consumption by this map. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

MinUsedBytes (column 15)
: Displays the low point in memory consumption by this catalog service and its maps. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

MaxUsedBytes (column 16)
: Displays the high point in memory consumption by this catalog service and its maps. The used bytes statistics are accurate only when you are using simple objects or the COPY_TO_BYTES copy mode.

LastUsedBytes (column 17)
: Indicates the current UsedBytes value minus the UsedBytes value from the previous statistics collection period.

SampleLen (column 18)
: Indicates the length, in milliseconds, of the time period during with the data was sampled.

ObjectGrid statistics log

TimeStamp (column 1)
: Specifies the date and time of the statistics snapshot that was taken for the data grid.

OgName (column 2)
: Specifies the name of the data grid.

PartitionId (column 3)
: Specifies the partition ID.

Count (column 4)
: Indicates a count of the entries in the data grid that have been gathered since the server started. For example, a value of 100 indicates that the entry is the 100th sample entry that has been gathered since the server started.

Hostname (column 5)
: Specifies the host name.

DomainName (column 6)
: Specifies the catalog service domain to which this data grid belongs.

MaxTime (column 7)
: Displays the time spent by the *most* time-consuming transaction for this server.

MinTime (column 8)
: Displays the time spent by the *least* time-consuming transaction for this server.

MeanTime (column 9)
: Specifies the average time spent on a transaction.

TotalTime (column 10)
: Displays total time spent on transactions for this server, since the time for this server was initialized.

AvgTransTime (column 11)
: Displays the average time required to complete a transaction for this server.

AvgThroughPut (column 12)
Displays the average number of transactions per second for this server.
SumOfSquares (column 13)
Specifies the sum of squares value for the transaction time. This value measures the deviation from the mean at the given point in time.
SampleLen (column 14)
Indicates the length, in milliseconds, of the time period during with the data was sampled.
LastDataSample (column 15)
Specifies the time since the last sample was taken.
LastTotalTime (column 16)
Specifies the current total time minus the previous total time for the data sample.
StartTime (column 17)
Indicates the time that the statistics began to be collected since the last reset of the data. The data is reset when the server restarts.

Enabling statistics

WebSphere® eXtreme Scale uses an internal statistics model to track and filter data, which is the underlying structure that all data views use to gather snapshots of statistics. You can use several methods to retrieve the information from the statistics modules.

About this task

For a list of all of the modules on which you can enable statistics, see StatsSpec class.

Procedure

- Enable statistics with the server properties file. You can use the statsSpec property in the server properties file for the container server to set the statistics specification when you start the server. For more information, see Server properties file.
- Enable statistics with the **xscmd** utility. You can use the **-c setStatsSpec** command to set the statistics specification at run time. For more information, see Administering with the xscmd utility.
- Enable statistics programmatically with the StatsSpec interface. For more information, see Monitoring with the statistics API.
- Enable statistics with JMX with the setStatsSpec operation on the DynamicServerMBean. For more information, see Interface DynamicServerMBean.

Example

Some examples of statsSpec strings that you might specify using the properties file, **xscmd** utility, or StatsSpec interface follow:

Enable all statistics for all modules:

```
all=enabled
```

Disable all statistics for all modules:

```
all=disabled
```

Enable statistics for all statistics in the OGStatsModule:

```
og.all=enabled
```

Enable statistics for all statistics in the OGStatsModule and MapStatsModule:

```
og.all=enabled;map.all=enabled
```

Enable statistics for only Map Used bytes statistic, and disable everything else:

```
all=disabled;map.usedbytes=enabled
```

- Statistics modules
  WebSphere eXtreme Scale uses an internal statistics model to track and filter data, which is the underlying structure that all data views use to gather snapshots of statistics.
- Monitoring with the statistics API
  The Statistics API is the direct interface to the internal statistics tree. Statistics are disabled by default, but can be enabled by setting a StatsSpec interface. A StatsSpec interface defines how WebSphere eXtreme Scale should monitor statistics.

Statistics modules

WebSphere® eXtreme Scale uses an internal statistics model to track and filter data, which is the underlying structure that all data views use to gather snapshots of statistics.

Overview

Statistics in WebSphere eXtreme Scale are tracked and contained within StatsModules components. Within the statistics model, several types of statistics modules exist:

OGStatsModule
: Provides statistics for an ObjectGrid instance, including transaction response times.

MapStatsModule
: Provides statistics for a single map, including the number of entries and hit rate.

QueryStatsModule
: Provides statistics for queries, including plan creation and run times.

AgentStatsModule
: Provides statistics for DataGrid API agents, including serialization times and run times.

HashIndexStatsModule
: Provides statistics for HashIndex query and maintenance run times.

SessionStatsModule
: Provides statistics for the HTTP session manager plug-in.

For details about the statistics modules, see the Statistics API.

Statistics in a local environment

The model is organized like an n-ary tree (a tree structure with the same degree for all nodes) comprised of all of the StatsModule types mentioned in the previous list. Because of this organization structure, every node in the tree is represented by the StatsFact interface. The StatsFact interface can represent an individual module or a group of modules for aggregation purposes. For example, if several leaf nodes in the tree represent particular MapStatsModule objects, the parent StatsFact node to these nodes contains aggregated statistics for all of the children modules. After you fetch a StatsFact object, you can then use interface to retrieve the corresponding StatsModule.

Much like a tree map, you use a corresponding path or key to retrieve a specific StatsFact. The path is a String[] value that consists of every node that is along the path to the requested fact. For example, you created an ObjectGrid called ObjectGridA, which contains two Maps: MapA and MapB. The path to the StatsModule for MapA would look like `[ObjectGridA, MapA]`. The path to the aggregated statistics for both maps would be: `[ObjectGridA]`.

Statistics in a distributed environment

In a distributed environment, the statistics modules are retrieved using a different path. Because a server can contain multiple partitions, the statistics tree needs to track the partition to which each module belongs. As a result, the path to look up a particular StatsFact object is different. Using the previous example, but adding in that the maps exist within partition 1, the path is `[1, ObjectGridA, MapA]` for retrieving that StatsFact object for MapA.

Monitoring with the statistics API

The Statistics API is the direct interface to the internal statistics tree. Statistics are disabled by default, but can be enabled by setting a StatsSpec interface. A StatsSpec interface defines how WebSphere® eXtreme Scale should monitor statistics.

About this task

You can use the local StatsAccessor API to query data and access statistics on any ObjectGrid instance that is in the same Java™ virtual machine (JVM) as the running code. For more information about the specific interfaces, see the API documentation. Use the following steps to enable monitoring of the internal statistics tree.

Procedure

1. Retrieve the StatsAccessor object. The StatsAccessor interface follows the singleton pattern. So, apart from problems related to the classloader, one StatsAccessor instance should exist for each JVM. This class serves as the main interface for all local statistics operations. The following code is an example of how to retrieve the accessor class. Call this operation before any other ObjectGrid calls.

```
public class LocalClient
{

   public static void main(String[] args) {

      // retrieve a handle to the StatsAccessor
      StatsAccessor accessor = StatsAccessorFactory.getStatsAccessor();

   }

}
```

2. Set the data grid StatsSpec interface. Set this JVM to collect all statistics at the ObjectGrid level only. You must ensure that an application enables all statistics that might be needed before you begin any transactions. The following example sets the StatsSpec interface using both a static constant field and using a spec String. Using a static constant field is simpler because the field has already defined the specification. However, by using a spec String, you can enable any combination of statistics that are required.

```
public static void main(String[] args) {

      // retrieve a handle to the StatsAccessor
      StatsAccessor accessor = StatsAccessorFactory.getStatsAccessor();

      // Set the spec via the static field
      StatsSpec spec = new StatsSpec(StatsSpec.OG_ALL);
      accessor.setStatsSpec(spec);

      // Set the spec via the spec String
      StatsSpec spec = new StatsSpec("og.all=enabled");
      accessor.setStatsSpec(spec);

}
```

3. Send transactions to the grid to force data to be collected for monitoring. To collect useful data for statistics, you must send transactions to the data grid. The following code excerpt inserts a record into MapA, which is in ObjectGridA. Because the statistics are at the ObjectGrid level, any map within the ObjectGrid yields the same results.

```
public static void main(String[] args) {

      // retrieve a handle to the StatsAccessor
      StatsAccessor accessor = StatsAccessorFactory.getStatsAccessor();

      // Set the spec via the static field
      StatsSpec spec = new StatsSpec(StatsSpec.OG_ALL);
      accessor.setStatsSpec(spec);

      ObjectGridManager manager =
                                ObjectGridmanagerFactory.getObjectGridManager();
      ObjectGrid grid = manager.getObjectGrid("ObjectGridA");
      Session session = grid.getSession();
      Map map = session.getMap("MapA");

      // Drive insert
      session.begin();
      map.insert("SomeKey", "SomeValue");
      session.commit();
}
```

4. Query a StatsFact by using the StatsAccessor API. Every statistics path is associated with a StatsFact interface. The StatsFact interface is a generic placeholder that is used to organize and contain a StatsModule object. Before you can access the actual statistics module, the StatsFact object must be retrieved.

```
public static void main(String[] args)
{

      // retrieve a handle to the StatsAccessor
      StatsAccessor accessor = StatsAccessorFactory.getStatsAccessor();

      // Set the spec via the static field
      StatsSpec spec = new StatsSpec(StatsSpec.OG_ALL);
      accessor.setStatsSpec(spec);

      ObjectGridManager manager =
                                ObjectGridManagerFactory.getObjectGridManager();
      ObjectGrid grid = manager.getObjectGrid("ObjectGridA");
      Session session = grid.getSession();
      Map map = session.getMap("MapA");

      // Drive insert
      session.begin();
      map.insert("SomeKey", "SomeValue");
      session.commit();
```

```
        // Retrieve StatsFact

        StatsFact fact = accessor.getStatsFact(new String[] {"EmployeeGrid"},
                                    StatsModule.MODULE_TYPE_OBJECT_GRID);

    }
```

5. Interact with the StatsModule object. The StatsModule object is contained within the StatsFact interface. You can obtain a reference to the module by using the StatsFact interface. Since the StatsFact interface is a generic interface, you must cast the returned module to the expected StatsModule type. Because this task collects eXtreme Scale statistics, the returned StatsModule object is cast to an OGStatsModule type. After the module is cast, you have access to all of the available statistics.

```
public static void main(String[] args) {

        // retrieve a handle to the StatsAccessor
        StatsAccessor accessor = StatsAccessorFactory.getStatsAccessor();

        // Set the spec via the static field
        StatsSpec spec = new StatsSpec(StatsSpec.OG_ALL);
        accessor.setStatsSpec(spec);

        ObjectGridManager manager =
                                    ObjectGridmanagerFactory.getObjectGridManager();
        ObjectGrid grid = manager.getObjectGrid("ObjectGridA");
        Session session = grid.getSession();
        Map map = session.getMap("MapA");

        // Drive insert
        session.begin();
        map.insert("SomeKey", "SomeValue");
        session.commit();

        // Retrieve StatsFact
        StatsFact fact = accessor.getStatsFact(new String[] {"EmployeeGrid"},
                                    StatsModule.MODULE_TYPE_OBJECT_GRID);

        // Retrieve module and time
        OGStatsModule module = (OGStatsModule)fact.getStatsModule();
        ActiveTimeStatistic timeStat =
                                    module.getTransactionTime("Default", true);
        double time = timeStat.getMeanTime();

    }
```

Monitoring with the xscmd utility

The **xscmd** utility replaces the **xsadmin** sample utility as a fully supported monitoring and administration tool. With the **xscmd** utility, you can display textual information about your WebSphere® eXtreme Scale topology.

Before you begin

- For the **xscmd** utility to display results, you must have created your data grid topology. Your catalog servers and container servers must be started. See Starting and stopping stand-alone servers for more information.
- See Administering with the xscmd utility for more information about starting the **xscmd** utility.

About this task

You can use the **xscmd** utility to view the current layout and specific state of the data grid, such as map content. In this example, the layout of the data grid in this task consists of a single *ObjectGridA* data grid with one *MapA* map that belongs to the *MapSetA* map set. This example demonstrates how you can display all active containers within a data grid and print out filtered metrics regarding the map size of the *MapA* map. To see all possible command options, run the **xscmd** utility without any arguments or with the -help option.

Procedure

Monitor the environment with the **xscmd** utility.

- To enable statistics for all of the servers, run the following command:
  - UNIX `./xscmd.sh -c setStatsSpec -spec ALL=enabled`
  - Windows `xscmd.bat -c setStatsSpec -spec ALL=enabled`
- To display all online container servers for a data grid, run the following command:

- UNIX `./xscmd.sh -c showPlacement -g ObjectGridA -ms MapSetA`
- Windows `xscmd.bat -c showPlacement -g ObjectGridA -ms MapSetA`

All container information is displayed.

Attention: To obtain this information when Transport Layer Security/Secure Sockets Layer (TLS/SSL) is enabled, you must start the catalog and container servers with the JMX service port set. To set the JMX service port, you can either use the -JMXServicePort option on the **startOgServer** script or you can call the setJMXServicePort method on the ServerProperties interface.

- To display information about the maps for the ObjectGridA data grid, run the following command:
  - UNIX `./xscmd.sh -c showMapSizes -g ObjectGridA -ms MapSetA`
  - Windows `xscmd.bat -c showMapSizes -g ObjectGridA -ms MapSetA`
- To connect to the catalog service and display information about the MapA map for the entire catalog service domain, run the following command:
  - UNIX `./xscmd.sh -c showMapSizes -g ObjectGridA -ms MapSetA -m MapA -cep CatalogMachine:6645`
  - Windows `xscmd.bat -c showMapSizes -g ObjectGridA -ms MapSetA -m MapA -cep CatalogMachine:6645`

  The **xscmd** utility connects to the MBean server that is running on a catalog server. By connecting to a single catalog server, you can retrieve information about the entire catalog service domain. A catalog server can run as a stand-alone process, WebSphere Application Server process, or embedded within a custom application process. Use the -cep option to specify the catalog service host name and port. If you include a list of catalog servers for the -cep option, the catalog servers must be within the same catalog service domain. You can retrieve statistics for one catalog service domain at a time.

- To display the configured and runtime placement of your configuration, run one of the following commands:
  - `xscmd -c placementServiceStatus`
  - `xscmd -c placementServiceStatus -g ObjectGridA -ms MapSetA`
  - `xscmd -c placementServiceStatus -ms MapSetA`
  - `xscmd -c placementServiceStatus -g ObjectGridA`

  You can scope the command to display placement information for the entire configuration, a single data grid, a single map set, or a combination of a data grid and map set.

Monitoring with WebSphere Application Server PMI

WebSphere® eXtreme Scale supports Performance Monitoring Infrastructure (PMI) when running in a WebSphere Application Server or WebSphere Extended Deployment application server. PMI collects performance data on runtime applications and provides interfaces that support external applications to monitor performance data. You can use the administrative console or the wsadmin tool to access monitoring data.

Before you begin

You can use PMI to monitor your environment when you are using WebSphere eXtreme Scale combined with WebSphere Application Server.

About this task

WebSphere eXtreme Scale uses the custom PMI feature of WebSphere Application Server to add its own PMI instrumentation. With this approach, you can enable and disable WebSphere eXtreme Scale PMI with the administrative console or with Java™ Management Extensions (JMX) interfaces in the wsadmin tool. In addition, you can access WebSphere eXtreme Scale statistics with the standard PMI and JMX interfaces that are used by monitoring tools, including the Tivoli® Performance Viewer.

Procedure

1. Enable eXtreme Scale PMI. You must enable PMI to view the PMI statistics. See Enabling PMI for more information.
2. Retrieve eXtreme Scale PMI statistics. View the performance of your eXtreme Scale applications with the Tivoli Performance Viewer. See Retrieving PMI statistics for more information.

What to do next

For more information about the wsadmin tool, see Accessing Managed Beans (MBeans) using the wsadmin tool.

- Enabling PMI
  You can use WebSphere Application Server Performance Monitoring Infrastructure (PMI) to enable or disable statistics at any level. For example, you can choose to enable the map hit rate statistic for a particular map, but not the number of entry statistic or the loader batch update time statistic. You can enable PMI in the administrative console or with scripting.
- Retrieving PMI statistics
  By retrieving PMI statistics, you can see the performance of your eXtreme Scale applications.
- PMI modules
  You can monitor the performance of your applications with the performance monitoring infrastructure (PMI) modules.
- Accessing Managed Beans (MBeans) using the wsadmin tool
  You can use the wsadmin utility provided in WebSphere Application Server to access managed bean (MBean) information.

Enabling PMI

You can use WebSphere® Application Server Performance Monitoring Infrastructure (PMI) to enable or disable statistics at any level. For example, you can choose to enable the map hit rate statistic for a particular map, but not the number of entry statistic or the loader batch update time statistic. You can enable PMI in the administrative console or with scripting.

Before you begin

- Your application server must be started and have an eXtreme Scale-enabled application installed.
- To enable PMI with wsadmin scripting, you also must be able to log in and use the wsadmin tool. For more information about the wsadmin tool, see WebSphere Application Server Information Center: Scripting the application serving environment (wsadmin).

About this task

Use WebSphere Application Server PMI to provide a granular mechanism with which you can enable or disable statistics at any level. For example, you can choose to enable the map hit rate statistic for a particular map, but not the number of entry or the loader batch update time statistics. This section shows how to use the administrative console and wsadmin scripts to enable ObjectGrid PMI.

Procedure

- **Enable PMI in the administrative console.**
  1. In the administrative console, click Monitoring and Tuning > Performance Monitoring Infrastructure > *server_name*.
  2. Verify that Enable Performance Monitoring Infrastructure (PMI) is selected. This setting is enabled by default. If the setting is not enabled, select the check box, then restart the server.
  3. Click Custom. In the configuration tree, select the ObjectGrid and ObjectGrid Maps module. Enable the statistics for each module.

  The transaction type category for ObjectGrid statistics is created at runtime. You can see only the subcategories of the ObjectGrid and Map statistics on the Runtime tab.
- **Enable PMI with scripting.**
  1. Open a command line prompt. Navigate to the *was_root*/bin directory. Type **wsadmin** to start the wsadmin command line tool.
  2. Modify the eXtreme Scale PMI runtime configuration. Verify that PMI is enabled for the server using the following commands:

     ```
     wsadmin>set s1 [$AdminConfig getid /Cell:CELL_NAME/Node:NODE_NAME/
                                    Server:APPLICATION_SERVER_NAME/]
     wsadmin>set pmi [$AdminConfig list PMIService $s1]
     wsadmin>$AdminConfig show $pmi.
     ```

     If PMI is not enabled, run the following commands to enable PMI:

     ```
     wsadmin>$AdminConfig modify $pmi {{enable true}}
     wsadmin>$AdminConfig save
     ```

     If you need to enable PMI, restart the server.
  3. Set variables for changing the statistic set to a custom set using the following commands:

```
wsadmin>set perfName [$AdminControl completeObjectName type=Perf,
process=APPLICATION_SERVER_NAME,*]
wsadmin>set perfOName [$AdminControl makeObjectName $perfName]
wsadmin>set params [java::new {java.lang.Object[]} 1]
wsadmin>$params set 0 [java::new java.lang.String custom]
wsadmin>set sigs [java::new {java.lang.String[]} 1]
wsadmin>$sigs set 0 java.lang.String
```

4. Set statistic set to custom using the following command:

```
wsadmin>$AdminControl invoke_jmx $perfOName setStatisticSet $params $sigs
```

5. Set variables to enable the objectGridModule PMI statistic using the following commands:

```
wsadmin>set params [java::new {java.lang.Object[]} 2]
wsadmin>$params set 0 [java::new java.lang.String objectGridModule=1]
wsadmin>$params set 1 [java::new java.lang.Boolean false]
wsadmin>set sigs [java::new {java.lang.String[]} 2]
wsadmin>$sigs set 0 java.lang.String
wsadmin>$sigs set 1 java.lang.Boolean
```

6. Set the statistics string using the following command:

```
wsadmin>set params2 [java::new {java.lang.Object[]} 2]
wsadmin>$params2 set 0 [java::new java.lang.String mapModule=*]
wsadmin>$params2 set 1 [java::new java.lang.Boolean false]
wsadmin>set sigs2 [java::new {java.lang.String[]} 2]
wsadmin>$sigs2 set 0 java.lang.String
wsadmin>$sigs2 set 1 java.lang.Boolean
```

7. Set the statistics string using the following command:

```
wsadmin>$AdminControl invoke_jmx $perfOName setCustomSetString $params2 $sigs2
```

These steps enable eXtreme Scale runtime PMI, but do not modify the PMI configuration. If you restart the application server, the PMI settings are lost except for the main PMI enablement.

Example

You can perform the following steps to enable PMI statistics for the sample application:

1. Launch the application using the `http://host:port/ObjectGridSample` Web address, where host and port are the host name and HTTP port number of the server where the sample is installed.
2. In the sample application, click ObjectGridCreationServlet, and then click action buttons 1, 2, 3, 4, and 5 to generate actions to the ObjectGrid and maps. Do not close this servlet page right now.
3. In the administrative console, click Monitoring and Tuning > Performance Monitoring Infrastructure > *server_name* Click the Runtime tab.
4. Click the Custom radio button.
5. Expand the ObjectGrid Maps module in the runtime tree, then click the clusterObjectGrid link. Under the ObjectGrid Maps group, there is an ObjectGrid instance called clusterObjectGrid, and under the clusterObjectGrid group four maps exist: counters, employees, offices, and sites. In the ObjectGrids instance, there is the clusterObjectGrid instance, and under that instance is a transaction type called DEFAULT.
6. You can enable the statistics of interest to you. For example, you can enable number of map entries for employees map, and transaction response time for the DEFAULT transaction type.

What to do next

After PMI is enabled, you can view PMI statistics with the administrative console or through scripting.

Retrieving PMI statistics

By retrieving PMI statistics, you can see the performance of your eXtreme Scale applications.

Before you begin

- Enable PMI statistics tracking for your environment. See Enabling PMI for more information.
- The paths in this task are assuming you are retrieving statistics for the sample application, but you can use these statistics for any other application with similar steps.
- If you are using the administrative console to retrieve statistics, you must be able to log in to the administrative console. If you are using scripting, you must be able to log in to wsadmin.

About this task

You can retrieve PMI statistics to view in Tivoli® Performance Viewer by completing steps in the administrative console or with scripting.For more information about the statistics that can be retrieved, see PMI modules.

Procedure

- Retrieve PMI statistics in the administrative console.
  1. In the administrative console, click Monitoring and tuning > Performance viewer > Current activity
  2. Select the server that you want to monitor using Tivoli Performance Viewer, then enable the monitoring.
  3. Click the server to view the Performance viewer page.
  4. Expand the configuration tree. Click ObjectGrid Maps > clusterObjectGrid select employees. Expand ObjectGrids > clusterObjectGrid and select DEFAULT.
  5. In the ObjectGrid sample application, go to the ObjectGridCreationServlet servlet , click button 1, then populate maps. You can view the statistics in the viewer.
- Retrieve PMI statistics with scripting.
  1. On a command line prompt, navigate to the *was_root*/bin directory. Type `wsadmin` to start the wsadmin tool.
  2. Set variables for the environment using the following commands:

```
wsadmin>set perfName [$AdminControl completeObjectName type=Perf,*]
wsadmin>set perfOName [$AdminControl makeObjectName $perfName]
wsadmin>set mySrvName [$AdminControl completeObjectName type=Server,
        name=APPLICATION_SERVER_NAME,*]
```

  3. Set variables to get mapModule statistics using the following commands:

```
wsadmin>set params [java::new {java.lang.Object[]} 3]
wsadmin>$params set 0 [$AdminControl makeObjectName $mySrvName]
wsadmin>$params set 1 [java::new java.lang.String mapModule]
wsadmin>$params set 2 [java::new java.lang.Boolean true]
wsadmin>set sigs [java::new {java.lang.String[]} 3]
wsadmin>$sigs set 0 javax.management.ObjectName
wsadmin>$sigs set 1 java.lang.String
wsadmin>$sigs set 2 java.lang.Boolean
```

  4. Get mapModule statistics using the following command:

```
wsadmin>$AdminControl invoke_jmx $perfOName getStatsString $params $sigs
```

  5. Set variables to get objectGridModule statistics using the following commands:

```
wsadmin>set params2 [java::new {java.lang.Object[]} 3]
wsadmin>$params2 set 0 [$AdminControl makeObjectName $mySrvName]
wsadmin>$params2 set 1 [java::new java.lang.String objectGridModule]
wsadmin>$params2 set 2 [java::new java.lang.Boolean true]
wsadmin>set sigs2 [java::new {java.lang.String[]} 3]
wsadmin>$sigs2 set 0 javax.management.ObjectName
wsadmin>$sigs2 set 1 java.lang.String
wsadmin>$sigs2 set 2 java.lang.Boolean
```

  6. Get objectGridModule statistics using the following command:

```
wsadmin>$AdminControl invoke_jmx $perfOName getStatsString $params2 $sigs2
```

Results

You can view statistics in the Tivoli Performance Viewer.

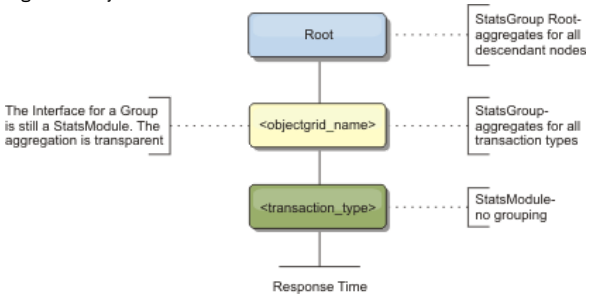
PMI modules

You can monitor the performance of your applications with the performance monitoring infrastructure (PMI) modules.

objectGridModule

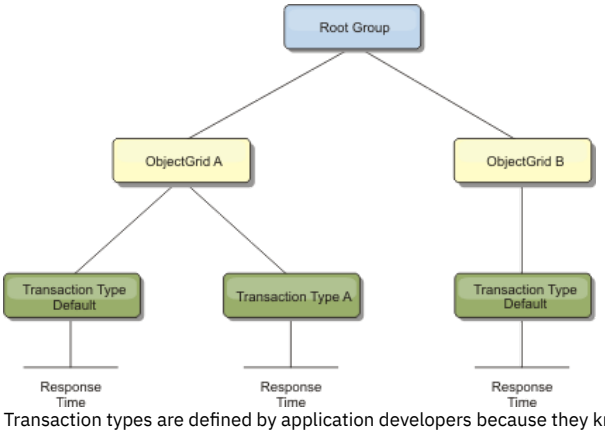
The objectGridModule contains a time statistic: transaction response time. A transaction is defined as the duration between the Session.begin method call and the Session.commit method call. This duration is tracked as the transaction response time. The root element of the objectGridModule, "root", serves as the entry point to the WebSphere® eXtreme Scale statistics. This root element has ObjectGrids as its child elements, which have transaction types as their child elements. The response time statistic is associated with each transaction type.

Figure 1. ObjectGridModule module structure



The following diagram shows an example of the ObjectGridModule structure. In this example, two ObjectGrid instances exist in the system: ObjectGrid A and ObjectGrid B. The ObjectGrid A instance has two types of transactions: A and default. The ObjectGrid B instance has only the default transaction type.

Figure 2. ObjectGridModule module structure example



Transaction types are defined by application developers because they know what types of transactions their applications use. The transaction type is set using the following Session.setTransactionType(String) method:

```
/**
* Sets the transaction type for future transactions.
*
* After this method is called, all of the future transactions have the
* same type until another transaction type is set. If  no transaction
* type is set, the default  TRANSACTION_TYPE_DEFAULT transaction type
* is used.
*
* Transaction types are used mainly for statistical data tracking purpose.
* Users can predefine types of transactions that run in an
* application. The idea is to categorize transactions with the same characteristics
* to one category (type), so one transaction response time statistic can be
* used to track each transaction type.
*
* This tracking is useful when your application has different types of
* transactions.
* Among them, some types of transactions, such as update transactions, process
* longer than other transactions, such as read-only transactions. By using the
* transaction type, different transactions are tracked by different statistics,
* so the statistics can be more useful.
*
* @param tranType the transaction type for future transactions.
*/
void setTransactionType(String tranType);
```

The following example sets transaction type to `updatePrice`:

```
// Set the transaction type to updatePrice
// The time between session.begin() and session.commit() will be
// tracked in the time statistic for "updatePrice".
session.setTransactionType("updatePrice");
session.begin();
map.update(stockId, new Integer(100));
session.commit();
```

The first line indicates that the subsequent transaction type is updatePrice. An updatePrice statistic exists under the ObjectGrid instance that corresponds to the session in the example. Using Java™ Management Extensions (JMX) interfaces, you can get the transaction response time for updatePrice transactions. You can also get the aggregated statistic for all types of transactions on the specified ObjectGrid instance.

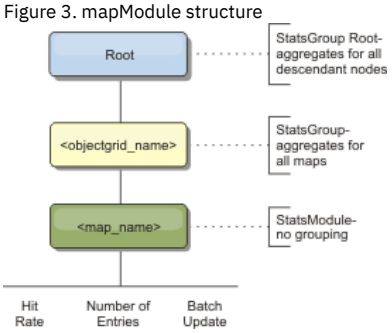
mapModule

The mapModule contains three statistics that are related to eXtreme Scale maps:

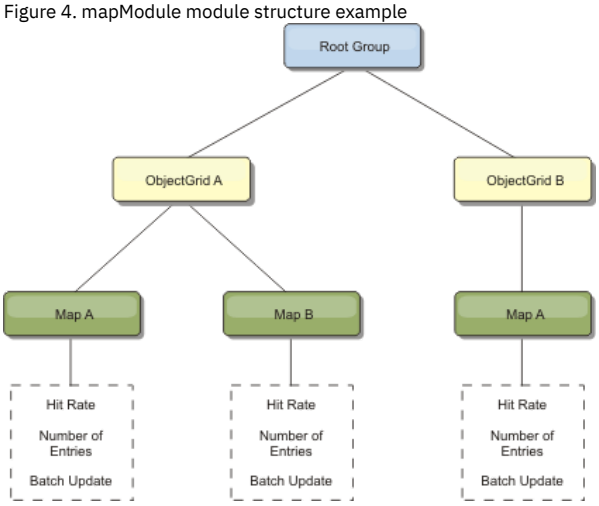
- **Map hit rate** - *BoundedRangeStatistic*: Tracks the hit rate of a map. Hit rate is a float value between 0 and 100 inclusively, which represents the percentage of map hits in relation to map get operations.
- **Number of entries**-*CountStatistic*: Tracks the number of entries in the map.
- **Loader batch update response time**-*TimeStatistic*: Tracks the response time that is used for the loader batch-update operation.

The root element of the mapModule, "root", serves as the entry point to the ObjectGrid Map statistics. This root element has ObjectGrids as its child elements, which have maps as their child elements. Every map instance has the three listed statistics. The mapModule structure is shown in the following diagram:

Figure 3. mapModule structure



The following diagram shows an example of the mapModule structure:
Figure 4. mapModule module structure example

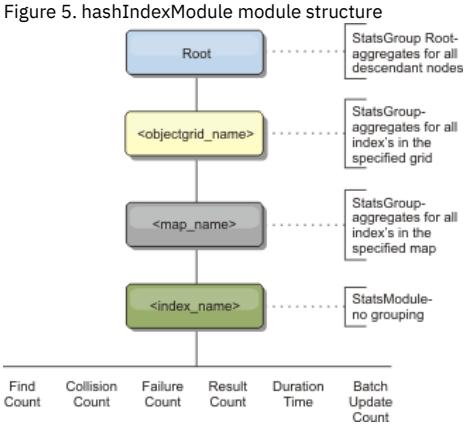


hashIndexModule

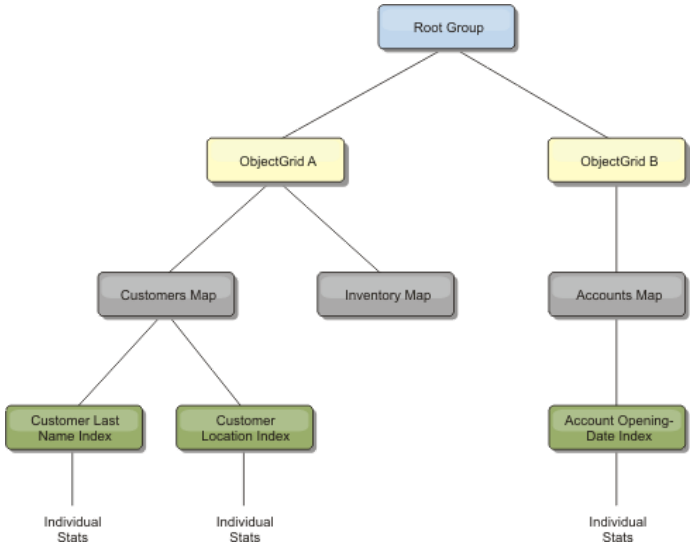
The hashIndexModule contains the following statistics that are related to Map-level indexes:

- **Find Count**-*CountStatistic*: The number of invocations for the index find operation.
- **Collision Count**-*CountStatistic*: The number of collisions for the find operation.
- **Failure Count**-*CountStatistic*: The number of failures for the find operation.
- **Result Count**-*CountStatistic*: The number of keys returned from the find operation.
- **BatchUpdate Count**-*CountStatistic*: The number of batch updates against this index. When the corresponding map is changed in any manner, the index will have its doBatchUpdate() method called. This statistic will tell you how frequently your index is changing or being updated.
- **Find Operation Duration Time**-*TimeStatistic*: The amount of time the find operation takes to complete

The root element of the hashIndexModule, "root", serves as the entry point to the HashIndex statistics. This root element has ObjectGrid instances as its child elements, ObjectGrid instances have maps as their child elements, which have HashIndexes as their child elements and leaf nodes in the tree. Every HashIndex instance has the three listed statistics. The hashIndexModule structure is shown in the following diagram:
Figure 5. hashIndexModule module structure



The following diagram shows an example of the hashIndexModule structure:
Figure 6. hashIndexModule module structure example



agentManagerModule

The agentManagerModule contains statistics that are related to map-level agents:

- **Reduce Time**: *TimeStatistic* - The amount of time for the agent to finish the reduce operation.
- **Total Duration Time**: *TimeStatistic* - The total amount of time for the agent to complete all operations.
- **Agent Serialization Time**: *TimeStatistic* - The amount of time to serialize the agent.
- **Agent Inflation Time**: *TimeStatistic* - The amount of time it takes to inflate the agent on the server.
- **Result Serialization Time**: *TimeStatistic* - The amount of time to serialize the results from the agent.
- **Result Inflation Time**: *TimeStatistic* - The amount of time to inflate the results from the agent.
- **Failure Count**: *CountStatistic* - The number of times that the agent failed.
- **Invocation Count**: *CountStatistic* - The number of times the AgentManager has been invoked.
- **Partition Count**: *CountStatistic* - The number of partitions to which the agent is sent.

The root element of the agentManagerModule, "root", serves as the entry point to the AgentManager statistics. This root element has ObjectGrids as its child elements, ObjectGrids have maps as their child elements, which finally have AgentManager instances as their child elements and leaf nodes of the tree. Every AgentManager instance has statistics.

Figure 7. agentManagerModule structure

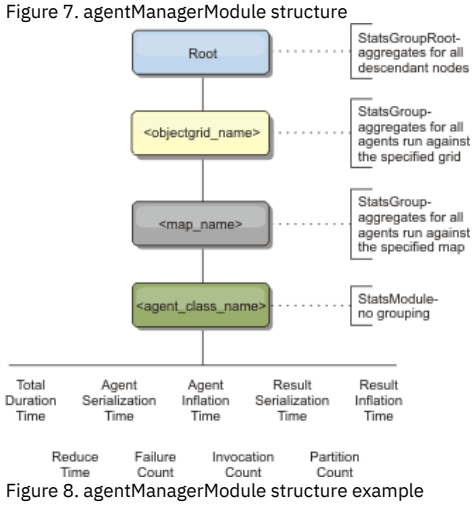


Figure 8. agentManagerModule structure example

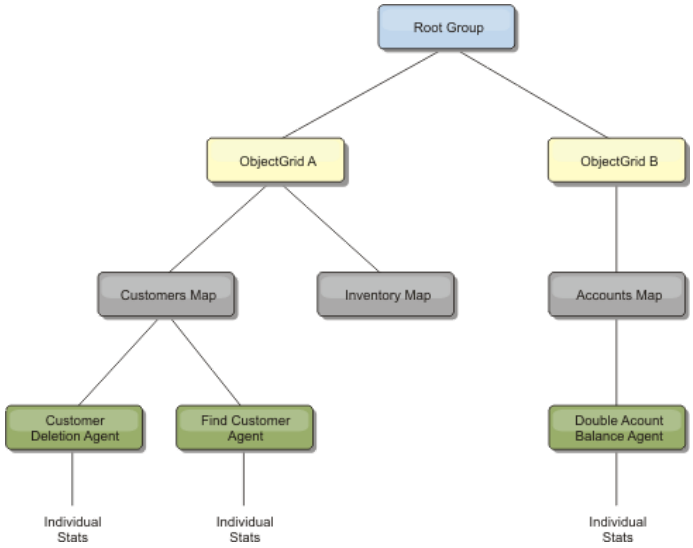

queryModule

The queryModule contains statistics that are related to eXtreme Scale queries:

- **Plan Creation Time**: *TimeStatistic* - The amount of time to create the query plan.
- **Execution Time**: *TimeStatistic* - The amount of time to run the query.
- **Execution Count**: *CountStatistic* - The number of times the query has been run.
- **Result Count**: *CountStatistic* - The count for each the result set of each query run.
- **FailureCount**: *CountStatistic* - The number of times the query has failed.

The root element of the queryModule, "root", serves as the entry point to the Query Statistics. This root element has ObjectGrids as its child elements, which have Query objects as their child elements and leaf nodes of the tree. Every Query instance has the three listed statistics.

Figure 9. queryModule structure

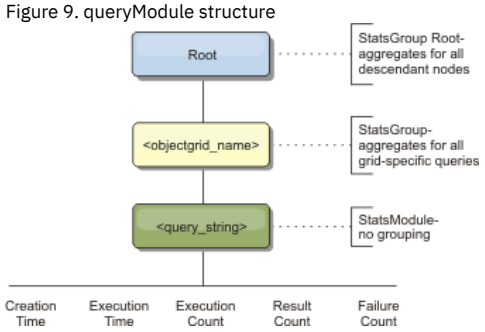

Figure 10. QueryStats.jpg queryModule structure example

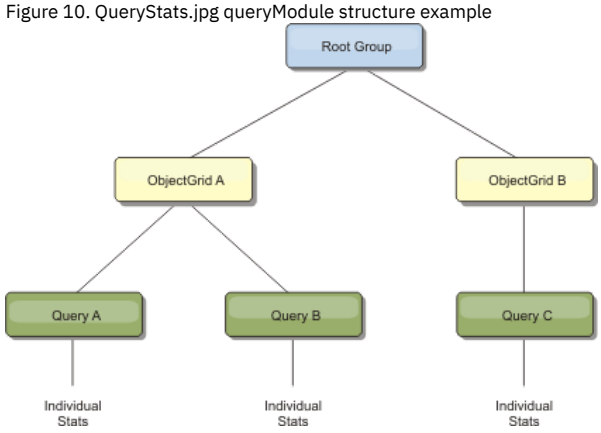

Accessing Managed Beans (MBeans) using the wsadmin tool

You can use the wsadmin utility provided in WebSphere® Application Server to access managed bean (MBean) information.

Procedure

Run the wsadmin tool from the bin directory in your WebSphere Application Server installation. The following example retrieves a view of the current shard placement in a dynamic eXtreme Scale. You can run the wsadmin tool from any installation where eXtreme Scale is running. You do not have to run the wsadmin tool on the catalog service.

```
$ wsadmin.sh -lang jython
wsadmin>placementService = AdminControl.queryNames
        ("com.ibm.websphere.objectgrid:*,type=PlacementService")
wsadmin>print AdminControl.invoke(placementService,
        "listObjectGridPlacement","library ms1")

<objectGrid name="library" mapSetName="ms1">
  <container name="container-0" zoneName="DefaultDomain"
               hostName="host1.company.org" serverName="server1">
     <shard type="Primary" partitionName="0"/>
     <shard type="SynchronousReplica" partitionName="1"/>
  </container>
  <container name="container-1" zoneName="DefaultDomain"
               hostName="host2.company.org" serverName="server2">
     <shard type="SynchronousReplica" partitionName="0"/>
     <shard type="Primary" partitionName="1"/>
  </container>
  <container name="UNASSIGNED" zoneName="_ibm_SYSTEM"
               hostName="UNASSIGNED" serverName="UNNAMED">
    <shard type="SynchronousReplica" partitionName="0"/>
    <shard type="AsynchronousReplica" partitionName="0"/>
  </container>
</objectGrid>
```

Monitoring server statistics with managed beans (MBeans)

You can used managed beans (MBeans) to track statistics in your environment.

Before you begin

For the attributes to be recorded, you must enable statistics. You can enable statistics on the server, or enable HTTP session statistics to track attributes on your client application. For more information on how to enable HTTP session statistics, see xref.

You can enable statistics in one of the following ways:

- **With the server properties file:**
  You can enable statistics in the server properties file with a key-value entry of `statsSpec=<StatsSpec>`. Some examples of possible settings follow:
  - To enable all statistics, use `statsSpec=all=enabled`
  - To enable only ObjectGrid statistics, use `statsSpec=og.all=enabled`. To see a description of all possible statistics specifications, see the StatsSpec API.

  For more information about the server properties file, see Server properties file.
- **With a managed bean:**
  You can enable statistics using the StatsSpec attribute on the ObjectGrid MBean. For more information, see the StatsSpec API.
- **Programmatically:**
  You can also enable statistics programmatically with the StatsAccessor interface, which is retrieved with the StatsAccessorFactory class. Use this interface in a client environment or when you need to monitor a data grid that is running in the current process.

Procedure

- **Access MBean statistics using the wsadmin tool.**
  For more information, see Accessing Managed Beans (MBeans) using the wsadmin tool.
- **Access MBean statistics programmatically.**
  For more information, see Accessing Managed Beans (MBeans) programmatically.

Example

For an example of how to use managed beans, see Sample: xsadmin utility.

Monitoring with vendor tools

WebSphere® eXtreme Scale can be monitored using several popular enterprise monitoring solutions. Plug-in agents are included for IBM® Tivoli® Monitoring and Hyperic HQ, which monitor WebSphere eXtreme Scale using publicly accessible management beans. CA Wily Introscope uses Java™ method instrumentation to capture statistics.

- Monitoring with the WebSphere eXtreme Scale Agent for IBM Tivoli Monitoring
  IBM Tivoli Monitoring is a feature-rich monitoring solution that you can use to monitor databases, operating systems and servers in distributed and host environments. WebSphere eXtreme Scale includes a customized agent that you can use to introspect eXtreme Scale management beans. This solution works effectively for eXtreme Scale in a stand-alone environment and a WebSphere Application Server deployment.
- Monitoring eXtreme Scale applications with CA Wily Introscope
  CA Wily Introscope is a third-party management product that you can use to detect and diagnose performance problems in enterprise application environments. eXtreme Scale includes details on configuring CA Wily Introscope to introspect select portions of the eXtreme Scale run time to quickly view and validate eXtreme Scale applications. CA Wily Introscope works effectively for both stand-alone and WebSphere Application Server deployments.
- Monitoring eXtreme Scale with Hyperic HQ
  Hyperic HQ is a third-party monitoring solution that is available freely as an open source solution or as an enterprise product. WebSphere eXtreme Scale includes a plug-in that allows Hyperic HQ agents to discover eXtreme Scale container servers and to report and aggregate statistics using eXtreme Scale management beans. You can use Hyperic HQ to monitor stand-alone eXtreme Scale deployments.

Monitoring with the WebSphere eXtreme Scale Agent for IBM Tivoli Monitoring

IBM® Tivoli® Monitoring is a feature-rich monitoring solution that you can use to monitor databases, operating systems and servers in distributed and host environments. WebSphere® eXtreme Scale includes a customized agent that you can use to introspect eXtreme Scale management beans. This solution works effectively for eXtreme Scale in a stand-alone environment and a WebSphere Application Server deployment.

Before you begin

- Install WebSphere eXtreme Scale Version 7.0.0 or later.
  Also, statistics must be enabled in order to collect statistical data from WebSphere eXtreme Scale servers. Various options for enabling statistics are described in Monitoring server statistics with managed beans (MBeans) and Sample: xsadmin utility

- Install IBM Tivoli Monitoring Version 6.2.1 with fix pack 2 or later.
- Install the Tivoli OS agent on each server or host on which eXtreme Scale servers run.
- Install the monitoring agent for eXtreme Scale, which you can download for free from the IBM Integrated Service Management Library.

Complete the following steps to install and configure the monitoring agent for eXtreme Scale for IBM Tivoli Monitoring:

Procedure

1. Install WebSphere eXtreme Scale Agent for IBM Tivoli Monitoring.
   Download the installation image and extract its files to a temporary directory.

2. Install the monitoring agent for application support files.
   Install the monitoring agent for WebSphere eXtreme Scale application support on each of the following deployments.

   - Tivoli Enterprise Portal Server (TEPS)
   - Tivoli Enterprise Desktop Client (TEPD)
   - Tivoli Enterprise Monitoring Server (TEMS)

   a. From the temporary directory that you created, start a new command window and run the appropriate executable file for your platform. The installation script automatically detects your Tivoli deployment type (TEMS, TEPD, or TEPS). You can install any type on a single host or on multiple hosts; and all of the three deployment types require the installation of **Monitoring Agent for WebSphere eXtreme Scale** application support files.
   b. In the Installer window, verify that the selections for the Tivoli Components deployed are correct. Click Next.
   c. If you are prompted, submit your administrative credentials followed by the hostname. Click Next.
   d. Select the **Monitoring Agent for WebSphere eXtreme Scale**. Click Next.
   e. You are notified of what installation actions are to be performed. Click Next, and you can see the progress of the installation until completion.

   After completing the procedure, all application support files are installed.
3. Install the agent on each of the eXtreme Scale nodes.
   You install a Tivoli OS agent on each of the computers. You do not need to configure or start this agent. Use the same installation image from the previous step to run the platform specific executable file.

   As a guideline, you need to install only one agent per host. Each agent is capable of supporting many instances of eXtreme Scale servers. For best performance, use one agent instance for monitoring about 50 eXtreme Scale servers.

   a. From the installation wizard welcome screen, click **Next** to open the screen to specify installation path information.
   b. For the Tivoli Monitoring installation directory field, enter or browse to C:\IBM\ITM (or /opt/IBM/ITM). Then for the Enter the location where your installable media... field, verify that the displayed value is correct and click Next.
   c. Select the components you want to add, such as Perform a local install of the solution... and click Next.
   d. Select the applications for which to add support for by selecting the application, such as **Monitoring Agent for WebSphere eXtreme Scale**, and click Next.
   e. You can see the progress until application support is added successfully.

   Note: Repeat these steps on each of the eXtreme Scale nodes. You can also use silent installation. See the IBM Tivoli Monitoring Information Center for more information about silent installation.
4. Configure the monitoring agent for eXtreme Scale.
   Each of the agents installed need to be configured to monitor any catalog server, eXtreme Scale server, or both.

   The steps to configure Windows and UNIX platforms are different. Configuration for the Windows platform is completed with the **Manage Tivoli Monitoring Services** user interface. Configuration for UNIX platforms is command-line based.

   Windows Use the following steps to initially configure the agent on Windows

   a. From the **Manage Tivoli Enterprise Monitoring Services** window, click Start > All Programs > IBM Tivoli Monitoring > Manage Tivoli Monitoring Services.
   b. Right click on **Monitoring Agent for WebSphere eXtreme Scale** and select Configure using defaults, which opens a window to create a unique instance of the agent.
   c. Choose a unique name: for example, `instance1`, and click Next.

   - If you plan to monitor stand-alone eXtreme Scale servers, complete the following steps:
     - Update the Java™ parameters, ensure that the Java Home value is correct. JVM arguments can be left empty. Click Next.
     - Select the type of MBean server connection type, Use `JSR-160-Complaint Server` for stand-alone eXtreme Scale servers. Click Next.
     - If security is enabled, update User ID and Password values. Leave the JMX service URL value as is. You override this value later. Leave the JMX Class Path Information field as it is. Click Next.

     To configure the servers for the agent on Windows, complete the following steps:
     - Set up subnode instances of eXtreme Scale servers in the **WebSphere eXtreme Scale Grid Servers** pane. If no container servers exist on your computer, click **Next** to proceed to the catalog service pane.
     - If multiple eXtreme Scale container servers exist on your computer, configure the agent to monitor each one server.
     - You can add as many eXtreme Scale servers as you require, if their names and ports are unique, by clicking New. (When an eXtreme Scale server is started, a JMXPort value must be specified.)
     - After you configure the container servers, click **Next**, which brings you to the **WebSphere eXtreme Scale Catalog Servers** pane.
     - If you have no catalog servers, click OK. If you have catalog servers, add a new configuration for each server, as you did with the container servers. Again, choose a unique name, preferably the same name that is used when starting the catalog service. Click OK to finish.
   - If you plan to monitor servers for the agent on eXtreme Scale servers that are embedded within a WebSphere Application Server process, complete the following steps:
     - Update the Java parameters, ensure that the Java Home value is correct. JVM arguments can be left empty. Click Next.
     - Select the MBean server connection type. Select the WebSphere Application Server version that is appropriate for your environment. Click Next.
     - Ensure that the WebSphere Application Server information in the panel is correct. Click Next.
     - Add only one subnode definition. Give the subnode definition a name, but do not update the port definition. Within WebSphere Application Server environment, data can be collected from all the application server that are managed by the node agent that is running on the computer. Click Next.

- If there no catalog servers exist in the environment, click OK. If you have catalog servers, add a new configuration for each catalog server, similarly to the container servers. Choose a unique name for the catalog service, preferably the same name that you use when starting the catalog service. Click OK to finish.

Note: The container servers do not need to be collocated with the catalog service.
Now that the agent and servers are configured and ready, on the next window, right click on `instance1` to start the agent.

UNIX To configure the agent on the UNIX platform on the command line, complete the following steps:

An example follows for stand-alone servers that uses a JSR160 Compliant connection type. The example shows three eXtreme Scale containers on the single host (rhea00b02) and the JMX listener addresses are 15000,15001 and 15002 respectively. There are no catalog servers.

Output from the configuration utility displays in *`monospace italics`*, while the user response is in **`monospace bold`**. (If no user response was required, the default was selected by pressing the enter key.)

```

Will this agent connect to a TEMS? [1=YES, 2=NO] (Default is: 1):
TEMS Host Name (Default is: rhea00b00):

Network Protocol [ip, sna, ip.pipe or ip.spipe] (Default is: ip.pipe):

     Now choose the next protocol number from one of these:
     - ip
     - sna
     - ip.spipe
     - 0 for none
Network Protocol 2 (Default is: 0):
IP.PIPE Port Number (Default is: 1918):
Enter name of KDC_PARTITION (Default is: null):

Configure connection for a secondary TEMS? [1=YES, 2=NO] (Default is: 2):
Enter Optional Primary Network Name or 0 for "none" (Default is: 0):
Agent configuration completed...
```

The previous example creates an agent instance called “inst1”, and updates the Java Home settings. The eXtreme Scale container servers are configured, but the catalog service is not configured.

Note: The previous procedure creates a text file of the following format in the directory: <ITM_install>/config/<host>_xt_<instance name>.cfg.
Example: rhea00b02_xt_inst1.cfg

It is best to edit this file with your choice of plain text editor. An example of the content of such the file follows:

```
INSTANCE=inst2 [SECTION=KQZ_JAVA [ { JAVA_HOME=/opt/OG61/java }  { JAVA_TRACE_LEVEL=ERROR }  ]
SECTION=KQZ_JMX_CONNECTION_SECTION [ { KQZ_JMX_CONNECTION_PROPERTY=KQZ_JMX_JSR160_JSR160 }  ]
SECTION=KQZ_JMX_JSR160_JSR160 [ { KQZ_JMX_JSR160_JSR160_CLASS_PATH_TITLE= }
```

```
{ KQZ_JMX_JSR160_JSR160_SERVICE_URL=service:jmx:rmi:///jndi/rmi://localho
st:port/objectgrid/MBeanServer }  { KQZ_JMX_JSR160_JSR160_CLASS_PATH_SEPARATOR= }  ]
SECTION=OGS:rhea00b02_c1 [ { KQZ_JMX_JSR160_JSR160_SERVICE_URL=service:jmx:
rmi:///jndi/rmi://localhost:15001/objectgrid/MBeanServer }  ]
SECTION=OGS:rhea00b02_c0 [ { KQZ_JMX_JSR160_JSR160_SERVICE_URL=service:jmx:
rmi:///jndi/rmi://localhost:15002/objectgrid/MBeanServer }  ]

rhea00b02 #
```

For WebSphere Application Server deployments, you do not need to create multiple sub nodes. The monitoring agent for eXtreme Scale connects to the node agent to gather all the information from application servers for which it is responsible.
`SECTION=CAT` signifies a catalog service line whereas `SECTION=OGS` signifies an eXtreme Scale server configuration line.

5. Configure the JMX port for all eXtreme Scalecontainer servers.
When eXtreme Scale container servers are started, without specifying the -JMXServicePort argument, an MBean server is assigned a dynamic port. The agent needs to know in advance with which JMX port to communicate. The agent does not work with dynamic ports.

   When you start the servers, you must specify the `-JMXServicePort <port_number>` argument when you start the eXtreme Scale server using the start server command. Running this command ensures that the JMX server within the process listens to a static pre-defined port.

   For the previous examples in a UNIX installation, two eXtreme Scale servers need to be started with ports set:
   a. "-JMXServicePort" "15000" (for rhea00b02_c0)
   b. "-JMXServicePort" "15001" (for rhea00b02_c1)
   a. Start the eXtreme Scale agent.
      Assuming the `inst1` instance was created, as in the previous example, issue the following commands.

      i. `cd <ITM_install>/bin`
      ii. `itmcmd agent -o inst1 start xt`
   b. Stop the eXtreme Scale agent.
      Assuming “inst1” was the instance created, as in the previous example, issue the following commands.

      i. `cd <ITM_install>/bin`

ii. `itmcmd agent -o inst1 stop xt`

6. Enable Statistics for all eXtreme Scale container servers.
   The agent uses the eXtreme Scale statistics MBeans to record statistics. The eXtreme Scale statistics specification must be enabled using one of the following methods.
   - Configure server properties to enable all statistics when the container servers are started: all=enabled.
   - Use the xsadmin sample utility to enable statistics for all active containers using the -setstatsspec all=enabled parameters.

Results

After all servers are configured and started, MBeans data is displayed on the IBM Tivoli Portal console. Predefined workspaces show graphs and data metrics at each node level.

The following workspaces are defined: **eXtreme Scale Grid Servers** node for all nodes monitored.

- eXtreme Scale Transactions View
- eXtreme Scale Primary Shard View
- eXtreme Scale Memory View
- eXtreme Scale ObjectMap View

You can also configure your own workspace. For more information, see the information about customizing workspaces in the IBM Tivoli Monitoring Information Center.

Monitoring eXtreme Scale applications with CA Wily Introscope

CA Wily Introscope is a third-party management product that you can use to detect and diagnose performance problems in enterprise application environments. eXtreme Scale includes details on configuring CA Wily Introscope to introspect select portions of the eXtreme Scale run time to quickly view and validate eXtreme Scale applications. CA Wily Introscope works effectively for both stand-alone and WebSphere® Application Server deployments.

Overview

To monitor eXtreme Scale applications with CA Wily Introscope, you must put settings into the ProbeBuilderDirective (PBD) files that give you access to the monitoring information for eXtreme Scale.
Attention: The instrumentation points for Introscope might change with each fix pack or release. When you install a new fix pack or release, check the documentation for any changes in the instrumentation points.
You can configure CA Wily Introscope ProbeBuilderDirective (PBD) files to monitor your eXtreme Scale applications. CA Wily Introscope is an application management product with which you can proactively detect, triage, and diagnose performance problems in your complex, composite, and web application environments. You can use one or more of the following settings in your PBD file to monitor the catalog service.

Catalog

HAControllerImpl
: The HAControllerImpl class handles core group lifecycle and feedback events. You can monitor this class to get an indication of the core group structure and changes.

CatalogServiceImpl
: The CatalogServiceImpl class handles the catalog routing events. You can monitor this class to get an indication of route changes and updates.

PlacementServiceImpl
: The PlacementServiceImpl class coordinates the containers. You can use the methods on this class to monitor server join and placement events.

BalanceGridEventListener
: The BalanceGridEventListener class controls the catalog leadership. You can monitor this class to get an indication of which catalog service is acting as the leader.

Container

ServerAgent
: The ServerAgent class is responsible for communicating core group events with the catalog service. You can monitor various heartbeat calls to spot major events.

ShardImpl
: The ShardImpl class has the processMessage method. The processMessage method is the method for client requests. With this method, you can get server-side response time and request counts. By watching the counts across all the servers and monitoring heap utilization, you can determine if the grid is balanced.

ObjectGridImpl
: The ObjectGridImpl class has the queryRevision and applyRevision methods. The queryRevision method is used by primaries to build an updated revision package to send to its replicas. The applyRevision method is used by the replicas to apply the updated revisions to their ObjectGrid.

BaseMap
: The BaseMap class has the evictMapEntries method that is called when the evictor wants to remove entries from the map.

Client

ORBClientCoreMessageHandler

The ORBClientCoreMessageHandler class is responsible for sending application requests to the containers. You can monitor the sendMessage method for client response time and number of requests.

ClusterStore
: The ClusterStore class holds the routing information on the client side.

BaseMap
: The BaseMap class has the evictMapEntries method that is called when the evictor wants to remove entries from the map.

SelectionServiceImpl
: The SelectionServiceImpl class makes the routing decisions. If the client is making failover decisions, you can use this class to see the actions that are completed from the decisions.

SessionImpl
: The SessionImpl class has the getMap method. The getMap method is called by most of client applications and can be monitored for response time and number of requests.

ObjectGridImpl
: The ObjectGridImpl class has the getSession method that you can monitor to see the number of requests to this method.

Monitoring eXtreme Scale with Hyperic HQ

Hyperic HQ is a third-party monitoring solution that is available freely as an open source solution or as an enterprise product. WebSphere® eXtreme Scale includes a plug-in that allows Hyperic HQ agents to discover eXtreme Scale container servers and to report and aggregate statistics using eXtreme Scale management beans. You can use Hyperic HQ to monitor stand-alone eXtreme Scale deployments.

Before you begin

- This set of instructions is for Hyperic Version 4.0. If you have a newer version of Hyperic, see the Hyperic documentation for information such as the path names and how to start agents and servers.
- Download the Hyperic server and agent installations. One server installation must be running. To detect all of the eXtreme Scale servers, a Hyperic agent must be running on each machine on which an eXtreme Scale server is running. See the Hyperic website for download information and documentation support.
- You must have access to the objectgrid-plugin.xml and hqplugin.jar files. These files are in the *wxs_install_root*/hyperic/etc directory.

About this task

By integrating eXtreme Scale with Hyperic HQ monitoring software, you can graphically monitor and display metrics about the performance of your environment. You set up this integration by using a plug-in implementation on each agent.

Procedure

1. Start your eXtreme Scale servers. The Hyperic plug-in looks at the local processes to attach to the Java™ virtual machines that are running eXtreme Scale. To properly attach to the Java virtual machines, each server must be started with the -jmxServicePort option. For information about starting servers with the -jmxServicePort option, see Starting and stopping stand-alone servers.
2. Put the extremescale-plugin.xml file and the wxshyperic.jar file in the appropriate server and agent plug-in directories in your Hyperic configuration. To integrate with Hyperic, both the agent and server installations must have access to the plug-in and Java archive (JAR) files. Although the server can dynamically swap configurations, you should complete the integration before you start any of the agents.
    a. Place the extremescale-plugin.xml file in the server plugin directory, which is at the following location:

    ***hyperic_home*/server_home/hq-engine/server/default/deploy/hq.ear/hq-plugins**

    b. Place the extremescale-plugin.xml file in the agent plugin directory, which is at the following location:

    ***agent_home*/bundles/gent-4.0.2-939/pdk/plugins**

    c. Put the wshyperic.jar file in the agent lib directory, which is at the following location

    ***agent_home*/bundles/gent-4.0.2-939/pdk/lib**

3. Configure the agent. The agent.properties file serves as a configuration point for the agent runtime. This property is in the *agent_home*/conf directory. The following keys are optional, but of importance to the eXtreme Scale plug-in:

    - **autoinventory.defaultScan.interval.millis=*<time_in_milliseconds>***

      Sets the interval in milliseconds between Agent discoveries.

    - **log4j.logger.org.hyperic.hq.plugin.extremescale.XSServerDetector=DEBUG**

      : Enables verbose debug statements from the eXtreme Scale plug-in.
    - `username=<username>`: Sets the Java Management Extensions (JMX) user name if security is enabled.
    - `password=<password>`: Sets the JMX password if security is enabled.
    - `sslEnabled=<true|false>`: Tells the plug-in whether or not to use Secure Sockets Layer (SSL). The value is `false` by default.
    - `trustPath=<path>`: Sets the trust path for the SSL connection.
    - `trustType=<type>`: Sets the trust type for the SSL connection.
    - `trustPass=<password>`: Sets the trust password for the SSL connection.
4. Start the agent discovery. The Hyperic agents send discoveries and metrics information to the server. Use the server to customize data views and group logical inventory objects to generate useful information. After the server is available, you must run the launch script or start the Windows service for the agent:
    - Linux *agent_home*/bin/hq-agent.sh start
    - Windows Start the agent with the Windows service.

    After you start the agents, the servers are detected and groups are configured. You can log into the server console and choose which resources to add to the inventory database for the server. The server console is at the following URL by default: `http://<server_host_name>:7080/`
5. Statistics must be enabled for Hyperic to collect statistical data.
    Use the SetStatsSpec control action on the Hyperic console for eXtreme Scale. Navigate to the resource, then use the Control Action drop-down list on the Control tabbed page to specify a `SetStatsSpec` setting with `ALL=enabled` in the Control Arguments text box.

    Catalog servers are not detected by the filter set in the Hyperic console. See the information about the statsSpec property in Server properties file, which enable statistics as soon as the containers start. Various options for enabling statistics are described in Monitoring server statistics with managed beans (MBeans) and Sample: xsadmin utility

6. Monitor servers with the Hyperic console. After the servers are added to the inventory model, their services are no longer needed.
    - **Dashboard view**: When you viewed the resource detection events, you logged into the main dashboard view. The dashboard view is a generic view that acts as a message center that you can customize. You can export graphs or inventory objects to this main dashboard.
    - **Resources view**: You can query and view the entire inventory model from this page. After the services have been added, you can see every eXtreme Scale server properly labeled and listed together under the servers section. You can click on the individual servers to see the basic metrics.
7. View the entire server inventory on the Resource View page. On this page, you can then select multiple ObjectGrid servers and group them together. After you group a set of resources, their common metrics can be graphed to show overlays and differences among group members. To display an overlay, select

the metrics on the display of your Server Group. The metric then displays in the charting area. To display an overlay for all group members, click the underlined metric name. You can export any of the charts, node views, and comparative overlays to the main dashboard with the Tools menu.

Monitoring eXtreme Scale information in DB2

When the JPALoader or JPAEntityLoader is used with DB2® as the back-end database, eXtreme Scale-specific information can be passed to DB2. You can view this information by a performance monitor tool such as DB2 Performance Expert to monitor the eXtreme Scale applications that are accessing the database.

Before you begin

See Collecting trace for more information about the different methods for setting trace that you can use.

About this task

When the loader is configured to use DB2 as the back-end database, the following eXtreme Scale information can be passed to DB2 for monitoring purposes:

- **User:** Specifies the name of the user that authenticates to eXtreme Scale. When basic authentication is not used, the principals from the authentication are used.
- **Workstation Name:** Specifies the host name, IP of the eXtreme Scale container server.
- **Application Name:** Specifies the name of the ObjectGrid, Persistence Unit name (if set).
- **Accounting Information:** Specifies the thread ID, transaction type, transaction id, and the connection string.

Read about the DB2 Performance Expert to learn how to monitor database access.

Procedure

- To enable all eXtreme Scale client information, set the following trace strings:

  `ObjectGridClientInfo*=event=enabled`

- To enable all but user information, use one of the following settings:
  - `ObjectGridClientInfo*=event=enabled,ObjectGridClientInfoUser=event=disabled`

    or

  - `ObjectGridClientInfo=event=enabled`

Results

After you turn on the trace function, data displays in the performance monitor tool such as DB2 Performance Expert.

Example

In the following example, user `bob` is authenticated as an eXtreme Scale user. The application is accessing the `mygrid` data grid using the `DB2Hibernate` persistence unit. The container server is named `XS_Server1`. The resulting information follows:

- **User**=`bob`
- **Workstation Name**=`XS_Server1,192.168.1.101`
- **Application Name**=`mygrid,DB2Hibernate`
- **Accounting Information**=`1, DEFAULT,FE7954BD-0126-4000-E000-2298094151DB,com.ibm.db2.jcc.t4.b@71787178`

In the following example, user `bob` is authenticated using a WebSphere® Application Server token. The application is accessing the `mygrid` data grid using the `DB2OpenJPA` persistence unit name. The container server is named `XS_Server2`. The resulting information follows:

- **User**

  `=acme.principal.UserPrincipal[Bob],acme.principal.GroupPrincipal[admin]`

- **Workstation Name**=`XS_Server2,192.168.1.102`
- **Application Name**=`mygrid,DB2OpenJPA`
- **Accounting Information**=`188,DEFAULT,FE72BC63-0126-4000-E000-851C092A4E33,com.ibm.ws.rsadapter.jdbc.WSJccSQLJConnection@2b432b43`

Tuning performance

You can tune settings in your environment to increase the overall performance of your WebSphere® eXtreme Scale environment.

- Tuning operating systems and network settings
  Network tuning can reduce Transmission Control Protocol (TCP) stack delay by changing connection settings and can improve throughput by changing TCP buffers.
- ORB properties
  Object Request Broker (ORB) properties modify the transport behavior of the data grid. These properties can be set with an orb.properties file, as settings in the WebSphere Application Server administrative console, or as custom properties on the ORB in the WebSphere Application Server administrative console.
- Tuning Java virtual machines
  You must take into account several specific aspects of Java™ virtual machine (JVM) tuning for WebSphere eXtreme Scale best performance. In most cases, few or no special JVM settings are required. If many objects are being stored in the data grid, adjust the heap size to an appropriate level to avoid running out of memory.
- Tuning the heartbeat interval setting for failover detection
  You can configure the amount of time between system checks for failed servers with the heartbeat interval setting. This setting applies to catalog servers only.
- Tuning garbage collection with WebSphere Real Time
  Using WebSphere eXtreme Scale with WebSphere Real Time increases consistency and predictability at a cost of performance throughput in comparison to the default garbage collection policy employed in the standard IBM® Java™ SE Runtime Environment (JRE). The cost versus benefit proposition can vary. WebSphere eXtreme Scale creates many temporary objects that are associated with each transaction. These temporary objects deal with requests, responses, log sequences, and sessions. Without WebSphere Real Time, transaction response time can go up to hundreds of milliseconds. However, using WebSphere Real Time with WebSphere eXtreme Scale can increase the efficiency of garbage collection and reduce response time to 10% of the stand-alone configuration response time.
- Tuning the dynamic cache provider
  The WebSphere eXtreme Scale dynamic cache provider supports the following configuration parameters for performance tuning.
- Tuning the cache sizing agent for accurate memory consumption estimates
  WebSphere eXtreme Scale supports sizing the memory consumption of BackingMap instances in distributed data grids. Memory consumption sizing is not supported for local data grid instances. The value that is reported by WebSphere eXtreme Scale for a given map is very close to the value that is reported by heap dump analysis. If map object is complex, the sizings might be less accurate. The CWOBJ4543 message is displayed in the log for any cache entry object that cannot be accurately sized because it is overly complex. You can get a more accurate measurement by avoiding unnecessary map complexity.
- Tuning and performance for application development
  To improve performance for your in-memory data grid or database processing space, you can investigate several considerations such using the best practices for product features such as locking, serialization, and query performance.

Tuning operating systems and network settings

Network tuning can reduce Transmission Control Protocol (TCP) stack delay by changing connection settings and can improve throughput by changing TCP buffers.

Operating systems

The tuning settings might improve WebSphere® eXtreme Scale performance. Tune according to your network and application load.

Windows:

```
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\
Tcpip\Parameters
MaxFreeTcbs = dword:00011940
MaxHashTableSize = dword:00010000
MaxUserPort = dword:0000fffe
TcpTimedWaitDelay = dword:0000001e
```

Solaris:

```
ndd -set /dev/tcp tcp_time_wait_interval 60000
fndd -set /dev/tcp tcp_keepalive_interval 15000
ndd -set /dev/tcp tcp_fin_wait_2_flush_interval 67500
ndd -set /dev/tcp tcp_conn_req_max_q 16384
ndd -set /dev/tcp tcp_conn_req_max_q0 16384
ndd -set /dev/tcp tcp_xmit_hiwat 400000
ndd -set /dev/tcp tcp_recv_hiwat 400000
ndd -set /dev/tcp tcp_cwnd_max 2097152
```

```
ndd -set /dev/tcp tcp_ip_abort_interval 20000
ndd -set /dev/tcp tcp_rexmit_interval_initial 4000
ndd -set /dev/tcp tcp_rexmit_interval_max 10000
ndd -set /dev/tcp tcp_rexmit_interval_min 3000
ndd -set /dev/tcp tcp_max_buf 4194304
```

AIX®:

```
/usr/sbin/no -o tcp_sendspace=65536
/usr/sbin/no -o tcp_recvspace=65536
/usr/sbin/no -o udp_sendspace=65536
/usr/sbin/no -o udp_recvspace=65536
/usr/sbin/no -o somaxconn=10000
/usr/sbin/no -o tcp_nodelayack=1
/usr/sbin/no -o tcp_keepinit=40
/usr/sbin/no -o tcp_keepintvl=10
```

Linux:

```
sysctl -w net.ipv4.tcp_timestamps=0
sysctl -w net.ipv4.tcp_tw_reuse=1
sysctl -w net.ipv4.tcp_tw_recycle=1
sysctl -w net.ipv4.tcp_fin_timeout=30
sysctl -w net.ipv4.tcp_keepalive_time=1800
sysctl -w net.ipv4.tcp_rmem="4096 87380 8388608"
sysctl -w net.ipv4.tcp_wmem="4096 87380 8388608"
sysctl -w net.ipv4.tcp_max_syn_backlog=4096
```

HP-UX:

```
ndd -set /dev/tcp tcp_ip_abort_cinterval 20000
```

Jumbo frames

For Ethernet networks, enabling jumbo frames (frame size or Maximum Transmission Unit (MTU) of 9000 bytes) on all systems (hosts and switches) can provide a significant performance improvement, especially when the application uses large payload sizes. Check the operating instructions for the particular host and switches in your network for information about how to enable jumbo frames. The steps to configure jumbo frames are particular to each equipment type.
Note: Enabling jumbo frames on some hosts in the configuration and not others can cause the switch to become a bottleneck point. The switch must convert between frame sizes on different ports. Therefore, it is best to enable jumbo frames on all hosts in the configuration or none of the hosts in the configuration.

ORB properties

Object Request Broker (ORB) properties modify the transport behavior of the data grid. These properties can be set with an orb.properties file, as settings in the WebSphere® Application Server administrative console, or as custom properties on the ORB in the WebSphere Application Server administrative console.

orb.properties

The orb.properties file is in the java/jre/lib directory. When you modify the orb.properties file in a WebSphere Application Server java/jre/lib directory, the ORB properties are updated on the node agent and any other Java virtual machines (JVM) that are using the Java runtime environment (JRE). If you do not want this behavior, use custom properties or the ORB settings WebSphere Application Server administrative console.

Default WebSphere Application Server settings

WebSphere Application Server has some properties defined on the ORB by default. These settings are on the application server container services and the deployment manger. These default settings override any settings that you create in the orb.properties file. For each described property, see the **Where to specify** section to determine the location to define the suggested value.

File descriptor settings

For UNIX and Linux systems, a limit exists for the number of open files that are allowed per process. The operating system specifies the number of open files permitted. If this value is set too low, a memory allocation error occurs on AIX®, and too many files opened are logged.

In the UNIX system terminal window, set this value higher than the default system value. For large SMP machines with clones, set to unlimited.

For AIX configurations set this value to unlimited with the command: `ulimit -n unlimited`.

For Solaris configurations set this value to `16384` with the command: `ulimit -n 16384`.

To display the current value use the command: `ulimit -a`.

Baseline settings

The following settings are a good baseline but not necessarily the best settings for every environment. Understand the settings to help make a good decision on what values are appropriate in your environment.

```
com.ibm.CORBA.RequestTimeout=30
com.ibm.CORBA.ConnectTimeout=10
com.ibm.CORBA.FragmentTimeout=30
com.ibm.CORBA.LocateRequestTimeout=10
com.ibm.CORBA.ThreadPool.MinimumSize=256
com.ibm.CORBA.ThreadPool.MaximumSize=256
com.ibm.CORBA.ThreadPool.IsGrowable=false
com.ibm.CORBA.ConnectionMultiplicity=1
com.ibm.CORBA.MinOpenConnections=1024
com.ibm.CORBA.MaxOpenConnections=1024
com.ibm.CORBA.ServerSocketQueueDepth=1024
com.ibm.CORBA.FragmentSize=0
com.ibm.CORBA.iiop.NoLocalCopies=true
com.ibm.CORBA.NoLocalInterceptors=true
com.ibm.CORBA.SocketWriteTimeout=30
```

Property descriptions

Timeout Settings

The following settings relate to the amount of time that the ORB waits before giving up on request operations. Use these settings to prevent excess threads from being created in an abnormal situation.

Request timeout

Property name: com.ibm.CORBA.RequestTimeout

Valid value: Integer value for number of seconds.

Suggested value: 30

Where to specify: WebSphere Application Server administrative console

Description: Indicates how many seconds any request waits for a response before giving up. This property influences the amount of time a client takes to fail over if a network outage failure occurs. If you set this property too low, requests might time out inadvertently. Carefully consider the value of this property to prevent inadvertent timeouts.

Connect timeout

Property name: com.ibm.CORBA.ConnectTimeout

Valid value: Integer value for number of seconds.

Suggested value: 10

Where to specify: orb.properties file

Description: Indicates how many seconds a socket connection attempt waits before giving up. This property, like the request timeout, can influence the time a client takes to fail over if a network outage failure occurs. In general, set this property to a smaller value than the request timeout value because the amount of time to establish connections is relatively constant.

Fragment timeout

Property name: com.ibm.CORBA.FragmentTimeout

Valid value: Integer value for number of seconds.

Suggested value: 30

Where to specify: orb.properties file

Description: Indicates how many seconds a fragment request waits before giving up. This property is similar to the request timeout property.

Socket write timeout

Property name: com.ibm.CORBA.SocketWriteTimeout

Valid value: Integer value for number of seconds.

Suggested value: 30

Where to specify: orb.properties file

Description: Indicates how many seconds a socket write waits before giving up. This property is similar to the request timeout property.

Thread Pool Settings

These properties constrain the thread pool size to a specific number of threads. The threads are used by the ORB to spin off the server requests after they are received on the socket. Setting these property values too low results in an increased socket queue depth and possibly timeouts.

Connection multiplicity

Property name: com.ibm.CORBA.ConnectionMultiplicity

Valid value: Integer value for the number of connections between the client and server. The default value is 1. Setting a larger value sets multiplexing across multiple connections.

Suggested value: 1

Where to specify: orb.properties file

Description: Enables the ORB to use multiple connections to any server. In theory, setting this value promotes parallelism over the connections. In practice, performance does not benefit from setting the connection multiplicity. Do not set this parameter.

Open connections

Property names: com.ibm.CORBA.MinOpenConnections, com.ibm.CORBA.MaxOpenConnections

Valid value: An integer value for the number of connections.

Suggested value: 1024

Where to specify: WebSphere Application Server administrative console

Description: Specifies a minimum and maximum number of open connections. The ORB keeps a cache of connections that have been established with clients. These connections are purged when this value is passed. Purging connections might cause poor behavior in the data grid.

Is Growable

Property name: com.ibm.CORBA.ThreadPool.IsGrowable

Valid value: Boolean; set to `true` or `false`.

Suggested value: `false`

Where to specify: orb.properties file

Description: If set to `true`, the thread pool that the ORB uses for incoming requests can grow beyond what the pool supports. If the pool size is exceeded, new threads are created to handle the request but the threads are not pooled. Prevent thread pool growth by setting the value to `false`.

Server socket queue depth

Property name: com.ibm.CORBA.ServerSocketQueueDepth

Valid value: An integer value for the number of connections.

Suggested value: `1024`

Where to specify: orb.properties file

Description: Specifies the length of the queue for incoming connections from clients. The ORB queues incoming connections from clients. If the queue is full, then connections are refused. Refusing connections might cause poor behavior in the data grid.

Fragment size

Property name: com.ibm.CORBA.FragmentSize

Valid value: An integer number that specifies the number of bytes. The default is 1024.

Suggested value: `0`

Where to specify: orb.properties file

Description: Specifies the maximum packet size that the ORB uses when sending a request. If a request is larger than the fragment size limit, then that request is divided into request fragments that are each sent separately and reassembled on the server. Fragmenting requests is helpful on unreliable networks where packets might need to be resent. However, if the network is reliable, dividing the requests into fragments might cause unnecessary processing.

No local copies

Property name: com.ibm.CORBA.iiop.NoLocalCopies

Valid value: Boolean; set to `true` or `false`.

Suggested value: `true`

Where to specify: WebSphere Application Server administrative console, Pass by reference setting.

Description: Specifies whether the ORB passes by reference. The ORB uses pass by value invocation by default. Pass by value invocation causes extra garbage and serialization costs to the path when an interface is started locally. By setting this value to true, the ORB uses a pass by reference method that is more efficient than pass by value invocation.

No Local Interceptors

Property name: com.ibm.CORBA.NoLocalInterceptors

Valid value: Boolean; set to `true` or `false`.

Suggested value: `true`

Where to specify: orb.properties file

Description: Specifies whether the ORB starts request interceptors even when making local requests (intra-process). The interceptors that WebSphere eXtreme Scale uses are for security and route handling are not required if the request is handled within the process. Interceptors that go between processes are only required for Remote Procedure Call (RPC) operations. By setting the no local interceptors, you can avoid the extra processing that using local interceptors introduces.
Attention: If you are usingWebSphere eXtreme Scale security, set the com.ibm.CORBA.NoLocalInterceptors property value to `false`. The security infrastructure uses interceptors for authentication.

Tuning Java virtual machines

You must take into account several specific aspects of Java™ virtual machine (JVM) tuning for WebSphere® eXtreme Scale best performance. In most cases, few or no special JVM settings are required. If many objects are being stored in the data grid, adjust the heap size to an appropriate level to avoid running out of memory.

IBM eXtremeMemory

By configuring eXtremeMemory, you can store objects in native memory instead of on the Java heap. Configuring eXtremeMemory enables eXtremeIO, a new transport mechanism. By moving objects off the Java heap, you can avoid garbage collection pauses, leading to more constant performance and predicable response times. For more information, see Configuring IBM eXtremeMemory.

Tested platforms

Performance testing occurred primarily on AIX® (32 way), Linux (four way), and Windows (eight way) computers. With high-end AIX computers, you can test heavily multi-threaded scenarios to identify and fix contention points.

Garbage collection

WebSphere eXtreme Scale creates temporary objects that are associated with each transaction, such as request and response, and log sequence. Because these objects affect garbage collection efficiency, tuning garbage collection is critical.

All modern JVMs use parallel garbage collection algorithms, which means that using more cores can reduce pauses in garbage collection. A physical server with eight cores has a faster garbage collection than a physical with four cores.

When the application must manage a large amount of data for each partition, then garbage collection might be a factor. A read mostly scenario performs even with large heaps (20 GB or more) if a generational collector is used. However, after the tenure heap fills, a pause proportional to the live heap size and the number of processors on the computer occurs. This pause can be large on smaller computers with large heaps.

IBM virtual machine for Java garbage collection

For the IBM® virtual machine for Java, use the **optavgpause** collector for high update rate scenarios (100% of transactions modify entries). The **gencon** collector works much better than the **optavgpause** collector for scenarios where data is updated relatively infrequently (10% of the time or less). Experiment with both collectors to see what works best in your scenario. Run with verbose garbage collection turned on to check the percentage of the time that is being spent collecting garbage. Scenarios have occurred where 80% of the time is spent in garbage collection until tuning fixed the problem.

Use the -Xgcpolicy parameter to change the garbage collection mechanism. The value of the -Xgcpolicy parameter can be set to: -Xgcpolicy:gencon or -Xgcpolicy:optavgpause, depending on which garbage collector you want to use.

- In a WebSphere Application Server configuration, set the -Xgcpolicy parameter in the administrative console. Click Servers > Application servers > server_name > Process definition > Java Virtual Machine. Add the parameter in the Generic JVM arguments field.
- In a stand-alone configuration, pass the -jvmArgs parameter to the start server script to specify the garbage collector. The -jvmArgs parameter must be the last parameter that is passed to the script.

Other garbage collection options

Attention: If you are using an Oracle JVM, adjustments to the default garbage collection and tuning policy might be necessary.
WebSphere eXtreme Scale supports WebSphere Real Time Java. With WebSphere Real Time Java, the transaction processing response for WebSphere eXtreme Scale is more consistent and predictable. As a result, the impact of garbage collection and thread scheduling is greatly minimized. The impact is reduced to the degree that the standard deviation of response time is less than 10% of regular Java.

JVM performance

WebSphere eXtreme Scale can run on different versions of Java Platform, Standard Edition. WebSphere eXtreme Scale supports Java SE Version 5 or later . For improved developer productivity and performance, use Java SE Version 5 or later , or Java SE Version 7 to take advantage of annotations and improved garbage collection. WebSphere eXtreme Scale works on 32-bit or 64-bit Java virtual machines.

WebSphere eXtreme Scale is tested with a subset of the available virtual machines, however, the supported list is not exclusive. You can run WebSphere eXtreme Scale on any vendor JVM at Edition 5 or later. However, if a problem occurs with a vendor JVM, you must contact the JVM vendor for support. If possible, use the JVM from the WebSphere run time on any platform that WebSphere Application Server supports.

In general, use the latest available version of Java Platform, Standard Edition for the best performance.

Heap size

The recommendation is 1 to 2 GB heaps with a JVM per four cores. The optimum heap size number depends on the following factors:

- Number of live objects in the heap.
- Complexity of live objects in the heap.
- Number of available cores for the JVM.

For example, an application that stores 10 K byte arrays can run a much larger heap than an application that uses complex graphs of POJOs.

Note:
When running on Solaris, you must choose between a 32-bit or a 64-bit environment. If you do not specify either version, then the JVM runs as a 32-bit environment. If you are running WebSphere eXtreme Scale on Solaris and you encounter a heap size limit, then the -d64 option should be used to force the JVM to run in 64-bit mode which will support heap sizes greater than 3.5 GB.

Thread count

The thread count depends on a few factors. A limit exists for how many threads a single shard can manage. A shard is an instance of a partition, and can be a primary or a replica. With more shards for each JVM, you have more threads with each additional shard providing more concurrent paths to the data. Each shard is as concurrent as possible although there is a limit to the concurrency.

Object Request Broker (ORB) requirements

The IBM SDK includes an IBM ORB implementation that has been tested with WebSphere Application Server and WebSphere eXtreme Scale. To ease the support process, use an IBM-provided JVM. Other JVM implementations use a different ORB. The IBM ORB is only supplied with IBM-provided Java virtual machines. WebSphere eXtreme Scale requires a working ORB to operate. You can use WebSphere eXtreme Scale with ORBs from other vendors. However, if you have a problem with a vendor ORB, you must contact the ORB vendor for support. The IBM ORB implementation is compatible with third partyJava virtual machines and can be substituted if needed.

orb.properties tuning

In the lab, the following file was used on data grids of up to 1500 JVMs. The orb.properties file is in the lib folder of the runtime environment.

```
# IBM JDK properties for ORB
org.omg.CORBA.ORBClass=com.ibm.CORBA.iiop.ORB
org.omg.CORBA.ORBSingletonClass=com.ibm.rmi.corba.ORBSingleton

# WS Interceptors
org.omg.PortableInterceptor.ORBInitializerClass.com.ibm.ws.objectgrid.corba.ObjectGridInitializer

# WS ORB & Plugins properties
com.ibm.CORBA.ForceTunnel=never
com.ibm.CORBA.RequestTimeout=10
com.ibm.CORBA.ConnectTimeout=10

# Needed when lots of JVMs connect to the catalog at the same time
com.ibm.CORBA.ServerSocketQueueDepth=2048

# Clients and the catalog server can have sockets open to all JVMs
com.ibm.CORBA.MaxOpenConnections=1016

# Thread Pool for handling incoming requests, 200 threads here
com.ibm.CORBA.ThreadPool.IsGrowable=false
com.ibm.CORBA.ThreadPool.MaximumSize=200
com.ibm.CORBA.ThreadPool.MinimumSize=200
com.ibm.CORBA.ThreadPool.InactivityTimeout=180000

# No splitting up large requests/responses in to smaller chunks
com.ibm.CORBA.FragmentSize=0
```

Tuning the heartbeat interval setting for failover detection

You can configure the amount of time between system checks for failed servers with the heartbeat interval setting. This setting applies to catalog servers only.

About this task

Configuring failover depends on the type of environment you are using. If you are using a stand-alone environment, you can configure failover with the command line. If you are using a WebSphere® Application Server Network Deployment environment, you must configure failover in the WebSphere Application Server Network Deployment administrative console.

Procedure

- Configure failover for stand-alone environments.
  - With the -heartbeat parameter in the **startOgServer** script when you start the catalog server.

- With the heartBeatFrequencyLevel property in the server properties file for the catalog server.

Use one of the following values:

Table 1. Valid heartbeat values

Value	Action	Description
-1	Aggressive	Specifies an aggressive heartbeat level. With this value, failures are detected more quickly, but more processor and network resources are used. This level is more sensitive to missing heartbeats when the server is busy. Failovers are typically detected within 5 seconds.
0	Typical (default)	Specifies a heartbeat level at a typical rate. With this value, failover detection occurs at a reasonable rate without overusing resources. Failovers are typically detected within 30 seconds.
1	Relaxed	Specifies a relaxed heartbeat level. With this value, a decreased heartbeat frequency increases the time to detect failures, but also decreases processor and network use. Failovers are typically detected within 180 seconds.

An aggressive heartbeat interval can be useful when the processes and network are stable. If the network or processes are not optimally configured, heartbeats might be missed, which can result in a false failure detection.

- Configure failover for WebSphere Application Server environments.
You can configure WebSphere Application Server Network Deployment Version 6.1 and later to allow WebSphere eXtreme Scale to fail over very quickly. The default failover time for hard failures is approximately 200 seconds. A hard failure is a physical computer or server crash, network cable disconnection or operating system error. Failures because of process crashes or soft failures typically fail over in less than one second. Failure detection for soft failures occurs when the network sockets from the dead process are closed automatically by the operating system for the server hosting the process.

  Core group heartbeat configuration

  WebSphere eXtreme Scale running in a WebSphere Application Server process inherits the failover characteristics from the core group settings of the application server. The following sections describe how to configure the core group heartbeat settings for different versions of WebSphere Application Server Network Deployment:

  - **Update the core group settings for WebSphere Application Server Network Deployment Version 6.1 and 7.0:**
  Specify the heartbeat interval in seconds on WebSphere Application Server versions from Version 6.0 through Version 6.1.0.12 or in milliseconds starting with Version 6.1.0.13. You must also specify the number of missed heartbeats. This value indicates how many heartbeats can be missed before a peer Java™ virtual machine (JVM) is considered as failed. The hard failure detection time is approximately the product of the heartbeat interval and the number of missed heartbeats.

    These properties are specified using custom properties on the core group using the WebSphere administrative console. See Core group custom properties for configuration details. These properties must be specified for all core groups used by the application:
    - The heartbeat interval is specified using either the IBM_CS_FD_PERIOD_SEC custom property for seconds or the IBM_CS_FD_PERIOD_MILLIS custom property for milliseconds (requires Version 6.1.0.13 or later).
    - The number of missed heartbeats is specified using the IBM_CS_FD_CONSECUTIVE_MISSED custom property.

    The default value for the IBM_CS_FD_PERIOD_SEC property is 20 and for the IBM_CS_FD_CONSECUTIVE_MISSED property is 10. If the IBM_CS_FD_PERIOD_MILLIS property is specified, then it overrides any of the set IBM_CS_FD_PERIOD_SEC custom properties. The values of these properties are positive integer values.

    Use the following settings to achieve a 1500 ms failure detection time for WebSphere Application Server Network Deployment Version 6.x servers:
    - Set `IBM_CS_FD_PERIOD_MILLIS = 750` (WebSphere Application Server Network Deployment V6.1.0.13 and later)
    - Set `IBM_CS_FD_CONSECUTIVE_MISSED = 2`
  - **Update the core group settings for WebSphere Application Server Network Deployment Version 7.0**

    WebSphere Application Server Network Deployment Version 7.0 provides two core group settings that can be adjusted to increase or decrease failover detection:

    - **Heartbeat transmission period.** The default is 30000 milliseconds.
    - **Heartbeat timeout period.** The default is 180000 milliseconds.

    For more details on how change these settings, see the WebSphere Application Server Network Deployment Information center: Discovery and failure detection settings.

    Use the following settings to achieve a 1500 ms failure detection time for WebSphere Application Server Network Deployment Version 7 servers:

    - Set the heartbeat transmission period to 750 milliseconds.
    - Set the heartbeat timeout period to 1500 milliseconds.

What to do next

When these settings are modified to provide short failover times, there are some system-tuning issues to be aware of. First, Java is not a real-time environment. It is possible for threads to be delayed if the JVM is experiencing long garbage collection times. Threads might also be delayed if the machine hosting the JVM is heavily loaded (due to the JVM itself or other processes running on the machine). If threads are delayed, heartbeats might not be sent on time. In the worst case, they might be delayed by the required failover time. If threads are delayed, false failure detections occur. The system must be tuned and sized to ensure that false failure detections do not happen in production. Adequate load testing is the best way to ensure this.

Note: The current version of eXtreme Scale supports WebSphere Real Time.

Tuning garbage collection with WebSphere Real Time

Using WebSphere® eXtreme Scale with WebSphere Real Time increases consistency and predictability at a cost of performance throughput in comparison to the default garbage collection policy employed in the standard IBM® Java™ SE Runtime Environment (JRE). The cost versus benefit proposition can vary. WebSphere eXtreme Scale creates many temporary objects that are associated with each transaction. These temporary objects deal with requests, responses, log sequences, and sessions. Without WebSphere Real Time, transaction response time can go up to hundreds of milliseconds. However, using WebSphere Real Time with WebSphere eXtreme Scale can increase the efficiency of garbage collection and reduce response time to 10% of the stand-alone configuration response time.

- WebSphere Real Time in a stand-alone environment
  You can use WebSphere Real Time with WebSphere eXtreme Scale. By enabling WebSphere Real Time, you can get more predictable garbage collection along with a stable, consistent response time and throughput of transactions in a stand-alone eXtreme Scale environment.
- WebSphere Real Time in WebSphere Application Server
  You can use WebSphere® Real Time with eXtreme Scale in a WebSphere Application Server Network Deployment environment version 7.0. By enabling WebSphere Real Time, you can get more predictable garbage collection along with a stable, consistent response time and throughput of transactions.

WebSphere Real Time in a stand-alone environment

You can use WebSphere® Real Time with WebSphere eXtreme Scale. By enabling WebSphere Real Time, you can get more predictable garbage collection along with a stable, consistent response time and throughput of transactions in a stand-alone eXtreme Scale environment.

Advantages of WebSphere Real Time

WebSphere eXtreme Scale creates many temporary objects that are associated with each transaction. These temporary objects deal with requests, responses, log sequences, and sessions. Without WebSphere Real Time, transaction response time can go up to hundreds of milliseconds. However, using WebSphere Real Time with WebSphere eXtreme Scale can increase the efficiency of garbage collection and reduce response time to 10% of the stand-alone configuration response time.

Enabling WebSphere Real Time

Install WebSphere Real Time and stand-alone WebSphere eXtreme Scale onto the computers on which you plan to run eXtreme Scale. Set the JAVA_HOME environment variable to point to a standard Java™ SE Runtime Environment (JRE).

Set the JAVA_HOME environment variable to point to the installed WebSphere Real Time. Then enable WebSphere Real Time as follows.

1. Edit the stand-alone installation objectgridRoot/bin/setupCmdLine.sh | .bat file by removing the comment from the following line.
   `WXS_REAL_TIME_JAVA="-Xrealtime -Xgcpolicy:metronome -Xgc:targetUtilization=80"`
2. Save the file.

Now you have enabled WebSphere Real Time. If you want to disable WebSphere Real Time, you can add the comment back to the same line.

Best practices

WebSphere Real Time allows eXtreme Scale transactions to have a more predictable response time. Results show that the deviation of an eXtreme Scale transaction's response time improves significantly with WebSphere Real Time compared to standard Java with its default garbage collector. Enabling WebSphere Real Time with eXtreme Scale is optimal if your application's stability and response time are essential.

The best practices described in this section explain how to make WebSphere eXtreme Scale more efficient through tuning and code practices depending on your expected load.

- Set right level of processor usage for your application and garbage collector.
  WebSphere Real Time provides capacity to control the processor usage so that garbage collection impact on your application is controlled and minimized. Use the `-Xgc:targetUtilization=NN` parameter to specify `NN` percentage of the processor that is used by your application in every 20 seconds. The default for WebSphere eXtreme Scale is 80%, but you can modify the script in objectgridRoot/bin/setupCmdLine.sh file to set different number such as `70`, which provides more processor capacity to the garbage collector. Deploy enough servers to maintain processor load under 80% for your applications.

- Set a larger size of heap memory.
  WebSphere Real Time uses more memory than regular Java, so plan your WebSphere eXtreme Scale with a large heap memory and set the heap size when you start catalog servers and containers with the `-jvmArgs -XmxNNNM` parameterin the **ogStartServer** command. For example, to you might use `-jvmArgs -Xmx500M` parameter to start catalog servers, and use appropriate memory size to start containers. You can set the memory size to 60-70% of your expected data size per JVM. If you do not set this value, a OutOfMemoryError error could result. Optionally, you also can use the `-jvmArgs -Xgc:noSynchronousGCOnOOM` parameterto prevent nondeterministic behavior when the JVM runs out of memory.

- Adjust threads for garbage collection.
  WebSphere eXtreme Scale creates a lot of temporary objects associated with each transaction and Remote Procedure Call (RPC) threads. Garbage collection has performance benefits if your computer has enough processor cycles. The default number of threads is `1`. You can change the number of threads with the `-Xgcthreads n` argument. The suggested value of this argument is the number of cores that are available with consideration of the number of Java virtual machines per computer.

- Adjust the performance for short-running applications with WebSphere eXtreme Scale.
  WebSphere Real Time is tuned for long running applications. Usually you need to run WebSphere eXtreme Scale continuous transactions for two hours to get reliable performance data. You can use the `-Xquickstart` parameter to make your short-running applications perform better. This parameter tells just-in-time (JIT) compiler to use lower level of optimization.

- Minimize WebSphere eXtreme Scale client queue and WebSphere eXtreme Scale client relay.
  The main advantage of using WebSphere eXtreme Scale with WebSphere Real Time is to have highly reliable transaction response time, which usually has several times of order magnitude improvements on the deviation of transaction response time. Any queued client requests and client request relay through other software impacts the response time that is beyond the control of WebSphere Real Time and WebSphere eXtreme Scale. You should change your threads and sockets parameters to maintain steady and smooth load without any significant delay and decrease your queue depth.

- Write WebSphere eXtreme Scale applications to use WebSphere Real Time threading.
  Without modifying your application, you can get highly reliable WebSphere eXtreme Scale transaction response time with several order magnitude improvements on the deviation of response time. You can further exploit threading advantage of your transactional applications from regular Java thread to RealtimeThread which provides better control on thread priority and scheduling control.

  Your application currently includes the following code.

  ```
  public class WXSCacheAppImpl extends Thread implements WXSCacheAppIF
  ```

  You can optionally replace this code with the following.

  ```
  public class WXSCacheAppImpl extends RealtimeThread implements WXSCacheAppIF
  ```

WebSphere Real Time in WebSphere Application Server

You can use WebSphere® Real Time with eXtreme Scale in a WebSphere® Application Server Network Deployment environment version 7.0. By enabling WebSphere Real Time, you can get more predictable garbage collection along with a stable, consistent response time and throughput of transactions.

Advantages

Using WebSphere eXtreme Scale with WebSphere Real Time increases consistency and predictability at a cost of performance throughput in comparison to the default garbage collection policy employed in the standard IBM® Java™ SE Runtime Environment (JRE). The cost versus benefit proposition can vary based on several criteria. The following are some of the major criteria:

- Server capabilities - Available memory, CPU speed and size, network speed and use
- Server loads – Sustained CPU load, peak CPU load
- Java™ configuration – Heap sizes, target use, garbage-collection threads
- WebSphere eXtreme Scale copy mode configuration – byte array vs. POJO storage
- Application specifics – Thread usage, response requirements and tolerance, object size, and so on.

In addition to this metronome garbage collection policy available in WebSphere Real Time, there are optional garbage collection policies available in standard IBM Java™ SE Runtime Environment (JRE). These policies, optthruput (default), gencon (default), optavgpause and subpool are specifically designed to solve differing application requirements and environments. For more information on these policies, see Tuning Java virtual machines. Depending upon application and environment requirements, resources and restrictions, prototyping one or more of these garbage collection policies can ensure that you meet your requirements and determine an optimal policy.

Capabilities with WebSphere Application Server Network Deployment

1. The following are some supported versions.
   - WebSphere Application Server Network Deployment version 7.0.0.5 and above.
   - WebSphere Real Time V2 SR2 for Linux and above. See IBM WebSphere Real Time V2 for Linux for more information.
   - WebSphere eXtreme Scale version 7.0.0.0 and above.
   - Linux 32 and 64 bit operating systems.
2. WebSphere eXtreme Scale servers cannot be collocated with a WebSphere Application Server DMgr.
3. Real Time does not support DMgr.
4. Real Time does not support WebSphere Node Agents.

Enabling WebSphere Real Time

Install WebSphere Real Time and WebSphere eXtreme Scale onto the computers on which you plan to run eXtreme Scale. Update the WebSphere Real Time Java to SR2.

You can specify the JVM settings for each server through the WebSphere Application Server version 7.0 console as follows.

Choose Servers > Server types > WebSphere application servers > <required installed server>

On the resulting page, choose "Process definition."

On the next page, click Java Virtual Machine at the top of the column on the right. (Here you can set heap sizes, garbage collection and other flags for each server.)

Set the following flags in the "Generic JVM arguments" field:

```
-Xrealtime -Xgcpolicy:metronome  -Xnocompressedrefs -Xgc:targetUtilization=80
```

Apply and save changes.

To use Real Time in WebSphere Application Server 7.0 to with eXtreme Scale servers including the JVM flags above, you must create a JAVA_HOME environment variable.

Set JAVA_HOME as follows.

1. Expand "Environment".
2. Select "WebSphere variables".
3. Ensure that "All scopes" is checked under “Show scope".
4. Select the required server from the drop-down list. (Do not select DMgr or node agent servers.)
5. If the JAVA_HOME environment variable is not listed, select "New," and specify JAVA_HOME for the variable name. In the "Value" field, enter the fully qualified path name to Real Time.
6. Apply and then save your changes.

Best practices

For a set of best practices see the best practices section in Tuning garbage collection with WebSphere Real Time. There are some important modifications to note in this list of best practices for a stand-alone WebSphere eXtreme Scale environment when deploying into a WebSphere Application Server Network Deployment environment.

You must place any additional JVM command line parameters in the same location as the garbage collection policy parameters specified in the previous section.

An acceptable initial target for sustained processor loads is 50% with short duration peek loads hitting up to 75%. Beyond this, you must add additional capacity before you see measurable degradation in predictability and consistency. You can increase performance slightly if you can tolerate longer response times. Exceeding an 80% threshold often leads to significant degradation in consistency and predictability.

Tuning the dynamic cache provider

The WebSphere® eXtreme Scale dynamic cache provider supports the following configuration parameters for performance tuning.

About this task

- **com.ibm.websphere.xs.dynacache.ignore_value_in_change_event**: When you register a change event listener with the dynamic cache provider and generate a ChangeEvent instance, there is overhead associated with deserializing the cache entry so the value can be put inside the ChangeEvent. Setting this optional parameter on the cache instance to `true` skips the deserialization of the cache entry when generating ChangeEvents. The value returned is either null for a remove operation or a byte array containing the serialized form of the object. InvalidationEvent instances carry a similar performance penalty, which you can avoid by setting com.ibm.ws.cache.CacheConfig.ignoreValueInInvalidationEvent to `true`.
- **com.ibm.websphere.xs.dynacache.enable_compression**: By default, the eXtreme Scale dynamic cache provider compresses the cache entries in memory to increase cache density, which can save a significant amount of memory for applications like servlet caching. If you know that most of your cache data is not be compressible, consider setting this value to `false`.

Tuning the cache sizing agent for accurate memory consumption estimates

WebSphere® eXtreme Scale supports sizing the memory consumption of BackingMap instances in distributed data grids. Memory consumption sizing is not supported for local data grid instances. The value that is reported by WebSphere eXtreme Scale for a given map is very close to the value that is reported by heap dump analysis. If map object is complex, the sizings might be less accurate. The CWOBJ4543 message is displayed in the log for any cache entry object that cannot be accurately sized because it is overly complex. You can get a more accurate measurement by avoiding unnecessary map complexity.

Procedure

- Enable the sizing agent.
  If you are using a Java™ 5 or higher Java virtual machine (JVM), use the sizing agent. With the sizing agent, WebSphere eXtreme Scale can obtain additional information from the JVM to improve its estimates. The agent can be loaded by adding the following argument to the JVM command line:

  ```
  -javaagent:WXS lib directory/wxssizeagent.jar
  ```

  For an embedded topology, add the argument to the command line of the WebSphere Application Server process.

  For a distributed topology, add the argument to command line of the eXtreme Scale processes (containers) and the WebSphere Application Server process.

  When loaded correctly, the following message is written to the SystemOut.log file.

  ```
  CWOBJ4541I: Enhanced BackingMap memory sizing is enabled.
  ```

- Prefer Java data types over custom data types, where possible.
  WebSphere eXtreme Scale can accurately size the memory cost of the following types:
  - java.lang.String and arrays where String is the component class (String[])
  - All primitive wrapper types (Byte, Short, Character, Boolean, Long, Double, Float, Integer) and arrays where primitive wrappers are the component type (for example, Integer[], Character[])
  - java.math.BigDecimal and java.math.BigInteger, and arrays where these two classes are the component type (BigInteger[] and BigDecimal[])
  - Temporal types (java.util.Date, java.sql.Date, java.util.Time, java.sql.Timestamp)
  - java.util.Calendar and java.util.GregorianCalendar
- Avoid object internment, when possible.
  When an object is inserted into a map, WebSphere eXtreme Scale assumes that it holds the only reference to the object and all the objects to which the object directly refers. If you insert 1000 custom Objects into a map, and each one has a reference to the same string instance, then WebSphere eXtreme Scale sizes that string instance 1000 times, overestimating the actual size of the map on the heap. However, WebSphere eXtreme Scale correctly compensates for the following common internment scenarios:
  - References to Java 5 Enums
  - References to Classes that follow the Typesafe Enum Pattern. Classes following this pattern only have only private constructors defined, have at least one private static final field of its own type, and if they implement Serializable, the class implements the readResolve() method.
  - Java 5 Primitive wrapper internment. For example, using Integer.valueOf(1) instead of new Integer(1)

  If you must use internment, use one of the preceding techniques to get more accurate estimates.

- Use custom types thoughtfully.
  When using custom types, prefer primitive data types for fields vs Object types.

  Also, prefer the Object types listed in entry 2 over your own custom implementations.

  When using custom types, keep the Object tree to one level. When inserting a custom Object into a map, WebSphere eXtreme Scale will only calculate the cost of the inserted Object, which includes any primitive fields, and all the Objects it directly references. WebSphere eXtreme Scale will not follow references further down into the Object tree. If you insert an Object into the map, and WebSphere eXtreme Scale detects references that were not followed during the sizing process, a message coded CWOBJ4543 that includes the name of the Class that could not be fully sized results. When this error occurs, treat the size statistics on the map as trend data, rather than relying on the size statistics as an accurate total.

- Use the CopyMode.COPY_TO_BYTES copy mode if possible.
  Use the CopyMode.COPY_TO_BYTES copy mode to remove any uncertainty from sizing the value Objects being inserted into the map, even when an Object tree has too many levels to be sized normally (resulting in the CWOBJ4543 message).

- Cache memory consumption sizing
  WebSphere eXtreme Scale can accurately estimate the Java heap memory usage of a given BackingMap in bytes. Use this capability to help correctly size your Java virtual machine heap settings and eviction policies. The behavior of this feature varies with the complexity of the Objects being placed in the backing map and how the map is configured. Currently, this feature is supported only for distributed data grids. Local data grid instances do not support used bytes sizing.

Related concepts:
Cache memory consumption sizing

Cache memory consumption sizing

WebSphere® eXtreme Scale can accurately estimate the Java™ heap memory usage of a given BackingMap in bytes. Use this capability to help correctly size your Java virtual machine heap settings and eviction policies. The behavior of this feature varies with the complexity of the Objects being placed in the backing map and how the map is configured. Currently, this feature is supported only for distributed data grids. Local data grid instances do not support used bytes sizing.

Heap consumption considerations

eXtreme Scale stores all of its data inside the heap space of the JVM processes that make up the data grid. For a given map, the heap space it consumes can be broken down into the following components:

- The size all the key objects currently in the map
- The size of all the value objects currently in the map
- The size of all the EvictorData objects that are in use by the Evictor plug-ins on the map
- The overhead of the underlying data structure

The number of used bytes that is reported by the sizing statistics is the sum of these four components. These values are calculated on a per entry basis on the insert, update, and remove map operations, meaning that eXtreme Scale always has a current value for the number of bytes that a given backing map is consuming.

When data grids are partitioned, each partition contains a piece of the backing map. Because the sizing statistics are calculated at the lowest level of the eXtreme Scale code, each partition of a backing map tracks its own size. You can use the eXtreme Scale Statistics APIs to track the cumulative size of the map, as well as the size of its individual partitions.

In general, use the sizing data as a measure of the trends of data over time, not as an accurate measurement of the heap space that is being used by the map. For example, if the reported size of a map doubles from 5 MB to 10 MB, then view the memory consumption of the map as having doubled. The actual measurement of 10 MB might be inaccurate for a number of reasons. If you take the reasons into account and follow the best practices, then the accuracy of the size measurements approaches that of post-processing a Java heap dump.

The main issue with accuracy is that the Java Memory Model is not restrictive enough to allow for memory measurements that are certain to be accurate. The fundamental problem is that an object can be live on the heap due to multiple references. For example, if the same 5 KB object instance is inserted into three separate maps, then any of those three maps prevent the object from being garbage collected. In this situation, any of the following measurements would be justifiable:

- The size of each map is increased by 5 KB.
- The size of the first map the Object is placed into is increased by 5 KB.
- The other two maps are not increased in size. The size of each map is increased by a fraction of the size of the object.

This ambiguity is why these measurements should be considered trend data, unless you have removed the ambiguity through design choices, best practices, and understanding of the implementation choices that can provide more accurate statistics.

eXtreme Scale assumes that a given map holds the only long-lived reference to the key and value Objects that it contains. If the same 5 KB object is put into three maps, then the size of each map is increased by 5 KB. The increase usually is not a problem, because the feature is supported only for distributed data grids. If you insert the same Object into three different maps on a remote client, each map receives its own copy of the Object. The default transactional COPY MODE settings also usually guarantee that each map has its own copy of a given Object.

Object interning

Object interning can cause a challenge with estimating heap memory usage. When you implement object interning, your application code purposely ensures that all references to a given object value actually point to the same object instance on the heap, and therefore the same location in memory. An example of this might be the following class:

```
public class ShippingOrder implements Serializeable,Cloneable{

    public static final STATE_NEW = "new";
    public static final STATE_PROCESSING = "processing";
    public static final STATE_SHIPPED = "shipped";

    private String state;
    private int orderNumber;
       private int customerNumber;

       public Object clone(){
       ShippingOrder toReturn = new ShippingOrder();
       toReturn.state = this.state;
       toReturn.orderNumber = this.orderNumber;
       toReturn.customerNumber = this.customerNumber;
       return toReturn;
    }

    private void readResolve(){
        if (this.state.equalsIgnoreCase("new")
            this.state = STATE_NEW;
        else if (this.state.equalsIgnoreCase("processing")
            this.state = STATE_PROCESSING;
        else if (this.state.equalsIgnoreCase("shipped")
            this.state = STATE_SHIPPED:
    }
}
```

Object interning causes overestimation by the sizing statistics because eXtreme Scale assumes that the objects are using different memory locations. If a million ShippingOrder objects exist, the sizing statistics display the cost of a million Strings holding the state information. In reality, only three Strings exist that are static class members. The memory cost for the static class members never should be added to any eXtreme Scale map. However, this situation cannot be detected at runtime. There are dozens of ways that similar object interning can be implemented, which is why it is so hard to detect. It is not practical for eXtreme Scale to protect against all possible implementations. However, eXtreme Scale does protect against the most commonly used types of object interning. To optimize memory usage with Object interning, implement interning only on custom objects that fall into the following two categories to enhance the accuracy of the memory consumption statistics:

- eXtreme Scale automatically adjusts for Java 5 enums and the Typesafe Enum pattern, as described at Java 2 Platform Standard Edition 5.0 Overview: Enums.
- eXtreme Scale automatically accounts for the automatic interning of primitive wrapper types, such as Integer. Automatic interning for primitive wrapper types was introduced in Java 5 through the use of static valueOf methods.

Memory consumption statistics

Use one of the following methods to access the memory consumption statistics.

Statistics API
: Use the MapStatsModule.getUsedBytes() method, which provides statistics for a single map, including the number of entries and hit rate.

  For details, see Statistics modules.

Managed Beans (MBeans)
: Use the MapUsedBytes managed MBean statistic. You can use several different types of Java Management Extensions (JMX) MBeans to administer and monitor deployments. Each MBean refers to a specific entity, such as a map, eXtreme Scale, server, replication group, or replication group member.

  For details, see Administering with Managed Beans (MBeans).

Performance monitoring infrastructure (PMI) modules
: You can monitor the performance of your applications with the PMI modules. Specifically, use the map PMI module for containers embedded in WebSphere Application Server.

  For details, see PMI modules.

WebSphere eXtreme Scale console
: With the console, you can view the memory consumption statistics. See Monitoring with the web console.

All of these methods access the same underlying measurement of the memory consumption of a given BaseMap instance. The WebSphere eXtreme Scale runtime attempts with a best effort to calculate the number of bytes of heap memory that is consumed by the key and value objects that are stored in the map, as well as the overhead of the map itself. You can see how much heap memory each map is consuming across the whole distributed data grid.

In most cases the value reported by WebSphere eXtreme Scale for a given map is very close to the value reported by heap dump analysis. WebSphere eXtreme Scale accurately sizes its own overhead, but cannot account for every possible object that might be put into a map. Following the best practices described in Tuning the cache sizing agent for accurate memory consumption estimates can enhance the accuracy of the size in bytes measurements provided by WebSphere eXtreme Scale.

Tuning the cache sizing agent for accurate memory consumption estimates

Tuning and performance for application development

To improve performance for your in-memory data grid or database processing space, you can investigate several considerations such using the best practices for product features such as locking, serialization, and query performance.

- Tuning the copy mode
  WebSphere® eXtreme Scale makes a copy of the value based on the available CopyMode settings. Determine which setting works best for your deployment requirements.
- Tuning evictors
  If you use plug-in evictors, they are not active until you create them and associate them with a backing map. The following best practices increase performance for least frequently used (LFU) and least recently used (LRU) evictors.
- Tuning locking performance
  Locking strategies and transaction isolation settings affect the performance of your applications.
- Tuning serialization performance
  WebSphere eXtreme Scale uses multiple Java™ processes to hold data. These processes serialize the data: That is, they convert the data (which is in the form of Java object instances) to bytes and back to objects again as needed to move the data between client and server processes. Marshalling the data is the most expensive operation and must be addressed by the application developer when designing the schema, configuring the data grid and interacting with the data-access APIs.
- Tuning query performance
  To tune the performance of your queries, use the following techniques and tips.
- Tuning EntityManager interface performance
  The EntityManager interface separates applications from the state held in its server grid data store.

Tuning the copy mode

WebSphere® eXtreme Scale makes a copy of the value based on the available CopyMode settings. Determine which setting works best for your deployment requirements.

You can use the BackingMap API setCopyMode(CopyMode, valueInterfaceClass) method to set the copy mode to one of the following final static fields that are defined in the com.ibm.websphere.objectgrid.CopyMode class.

When an application uses the ObjectMap interface to obtain a reference to a map entry, use that reference only within the data grid transaction that obtained the reference. Using the reference in a different transaction can lead to errors. For example, if you use the pessimistic locking strategy for the BackingMap, a get or getForUpdate method call acquires an S (shared) or U (update) lock, depending on the transaction. The get method returns the reference to the value and the lock that is obtained is released when the transaction completes. The transaction must call the get or getForUpdate method to lock the map entry in a different transaction. Each transaction must obtain its own reference to the value by calling the get or getForUpdate method instead of reusing the same value reference in multiple transactions.

CopyMode for entity maps

When using a map associated with an EntityManager API entity, the map always returns the entity Tuple objects directly without making a copy unless you are using COPY_TO_BYTES copy mode. It is important that the CopyMode is updated or the Tuple is copied appropriately when making changes.

COPY_ON_READ_AND_COMMIT

The COPY_ON_READ_AND_COMMIT mode is the default mode. The valueInterfaceClass argument is ignored when this mode is used. This mode ensures that an application does not contain a reference to the value object that is in the BackingMap. Instead, the application is always working with a copy of the value that is in the BackingMap. The COPY_ON_READ_AND_COMMIT mode ensures that the application can never inadvertently corrupt the data that is cached in the BackingMap. When an application transaction calls an ObjectMap.get method for a given key, and it is the first access of the ObjectMap entry for that key, a copy of the value is returned. When the transaction is committed, any changes that are committed by the application are copied to the BackingMap to ensure that the application does not have a reference to the committed value in the BackingMap.

COPY_ON_READ

The COPY_ON_READ mode improves performance over the COPY_ON_READ_AND_COMMIT mode by eliminating the copy that occurs when a transaction is committed. The valueInterfaceClass argument is ignored when this mode is used. To preserve the integrity of the BackingMap data, the application ensures that every reference that it has for an entry is destroyed after the transaction is committed. With this mode, the ObjectMap.get method returns a copy of the value instead of a reference to the value to ensure that changes that are made by the application to the value does not affect the BackingMap value until the transaction is committed. However, when the transaction does commit, a copy of changes is not made. Instead, the reference to the copy that was returned by the ObjectMap.get method is stored in the BackingMap. The application destroys all map entry references after the transaction is committed. If application does not destroy the map entry references, the application might cause the data cached in BackingMap to become corrupted. If an application is using this mode and is having problems, switch to COPY_ON_READ_AND_COMMIT mode to see if the problem still exists. If the problem goes away, then the application is failing to destroy all of its references after the transaction has committed.

COPY_ON_WRITE

The COPY_ON_WRITE mode improves performance over the COPY_ON_READ_AND_COMMIT mode by eliminating the copy that occurs when the ObjectMap.get method is called for the first time by a transaction for a given key. The ObjectMap.get method returns a proxy to the value instead of a direct reference to the value object. The proxy ensures that a copy of the value is not made unless the application calls a set method on the value interface that is specified by the valueInterfaceClass argument. The proxy provides a copy on write implementation. When a transaction commits, the BackingMap examines the proxy to determine if any copy was made as a result of a set method being called. If a copy was made, then the reference to that copy is stored in the BackingMap. The main advantage of using this mode is that a value is never copied on a read operation or during a commit operation, when the transaction never calls a set method to change the value.

The COPY_ON_READ_AND_COMMIT and COPY_ON_READ modes both make a deep copy when a value is retrieved from the ObjectMap. If an application only updates some of the values that are retrieved in a transaction then this mode is not optimal. The COPY_ON_WRITE mode supports this behavior efficiently but requires that the application uses a simple pattern. The value objects are required to support an interface. The application must use the methods on this interface when it is interacting with the value in a session. If this is the case, then proxies are created for the values that are returned to the application. The proxy has a reference to the real value. If the application performs read operations only, the read operations always run against the real copy. If the application modifies an attribute on the object, the proxy makes a copy of the real object and then modifies the copy. The proxy then uses the copy from that point on. Using the copy allows the copy operation to be avoided completely for objects that are only read by the application. All modify operations must start with the set prefix. Enterprise JavaBeans normally are coded to use this style of method naming for methods that modify the objects attributes. This convention must be followed. Any objects that are modified are copied at the time that they are modified by the application. This read and write scenario is the most efficient scenario supported by eXtreme Scale. To configure a map to use COPY_ON_WRITE mode, use the following example. In this example, the application stores Person objects that are keyed by using the name in the Map. The person object is represented in the following code snippet.

```
class Person {
    String name;
    int age;
    public Person() {
    }
    public void setName(String n)        {
        name = n;
    }
    public String getName() {
        return name;
    }
    public void setAge(int a) {
        age = a;
    }
    public int getAge() {
        return age;
    }
}
```

The application uses the IPerson interface only when it interacts with values that are retrieved from a ObjectMap. Modify the object to use an interface as in the following example.

```
interface IPerson
{
    void setName(String n);
    String getName();
    void setAge(int a);
    int getAge();
}
// Modify Person to implement IPerson interface
class Person implements IPerson {
```

```
    ...
}
```

The application then needs to configure the BackingMap to use COPY_ON_WRITE mode, like in the following example:

```
ObjectGrid dg = ...;
BackingMap bm = dg.defineMap("PERSON");
// use COPY_ON_WRITE for this Map with
// IPerson as the valueProxyInfo Class
bm.setCopyMode(CopyMode.COPY_ON_WRITE,IPerson.class);
// The application should then use the following
// pattern when using the PERSON Map.
Session sess = ...;
ObjectMap person = sess.getMap("PERSON");
...
sess.begin();
// the application casts the returned value to IPerson and not Person
IPerson p = (IPerson)person.get("Billy");
p.setAge(p.getAge()+1);
...
// make a new Person and add to Map
Person p1 = new Person();
p1.setName("Bobby");
p1.setAge(12);
person.insert(p1.getName(), p1);
sess.commit();
// the following snippet WON'T WORK. Will result in ClassCastException
sess.begin();
// the mistake here is that Person is used rather than
// IPerson
Person a = (Person)person.get("Bobby");
sess.commit();
```

The first section of the application retrieves a value that was named `Billy` in the map. The application casts the returned value to the IPerson object, not the Person object because the proxy that is returned implements two interfaces:

- The interface specified in the BackingMap.setCopyMode method call
- The com.ibm.websphere.objectgrid.ValueProxyInfo interface

You can cast the proxy to two types. The last part of the preceding code snippet demonstrates what is not allowed in COPY_ON_WRITE mode. The application retrieves the Bobby record and tries to cast the record to a Person object. This action fails with a class cast exception because the proxy that is returned is not a Person object. The returned proxy implements the IPerson object and ValueProxyInfo.

ValueProxyInfo interface and partial update support: This interface allows an application to retrieve either the committed read-only value referenced by the proxy or the set of attributes that have been modified during this transaction.

```
public interface ValueProxyInfo {
    List /**/ ibmGetDirtyAttributes();
    Object ibmGetRealValue();
}
```

The ibmGetRealValue method returns a read-only copy of the object. The application must not modify this value. The ibmGetDirtyAttributes method returns a list of strings that represent the attributes that were modified by the application during this transaction. The main use case for the ibmGetDirtyAttributes method is in a Java™ database connectivity (JDBC) or CMP-based loader. Only the attributes that are named in the list need be updated on either the SQL statement or object mapped to the table. This practice leads to more efficient SQL statements that are generated by the Loader. When a copy on write transaction is committed and if a loader is plugged in, the loader can cast the values of the modified objects to the ValueProxyInfo interface to obtain this information.

Handling the equals method when using COPY_ON_WRITE or proxies: For example, the following code constructs a Person object and then inserts it to an ObjectMap. Next, it retrieves the same object using the ObjectMap.get method. The value is cast to the interface. If the value is cast to the Person interface, a ClassCastException exception results because the returned value is a proxy that implements the IPerson interface and is not a Person object. The equality check fails when using the == operation because they are not the same object.

```
session.begin();
// new the Person object
Person p = new Person(...);
personMap.insert(p.getName, p);
// retrieve it again, remember to use the interface for the cast
IPerson p2 = personMap.get(p.getName());
if(p2 == p) {
    // they are the same
} else {
    // they are not
}
```

Another consideration is when you must override the equals method. The equals method must verify that the argument is an object that implements the IPerson interface and cast the argument to be an IPerson object. Because the argument might be a proxy that implements the IPerson interface, you must use the getAge and getName methods when comparing instance variables for equality. See the following example:

```
{
    if ( obj == null ) return false;
    if ( obj instanceof IPerson ) {
        IPerson x = (IPerson) obj;
        return ( age.equals( x.getAge() ) && name.equals( x.getName() ) )
    }
    return false;
}
```

ObjectQuery and HashIndex configuration requirements: When you are using COPY_ON_WRITE with ObjectQuery or a HashIndex plug-ins, you must configure the ObjectQuery schema and HashIndex plug-in to access the objects using property methods, which is the default. If you configured field access, the query engine and index attempts to access the fields in the proxy object, which always returns null or 0 because the object instance is a proxy.

NO_COPY

The NO_COPY mode allows an application to obtain performance improvements, but requires that application to never modify a value object that is obtained using an ObjectMap.get method. The valueInterfaceClass argument is ignored when this mode is used. If this mode is used, no copy of the value is ever made. If the application modifies any value object instances that are retrieved from or added to the ObjectMap, then the data in the BackingMap is corrupted. The NO_COPY mode is primarily useful for read-only maps where data is never modified by the application. If the application is using this mode and it is having problems, then switch to the COPY_ON_READ_AND_COMMIT mode to see if the problem still exists. If the problem goes away, then the application is modifying the value returned by ObjectMap.get method, either during transaction or after transaction has committed. All maps associated with EntityManager API entities automatically use this mode regardless of what is specified in the eXtreme Scale configuration.

All maps associated with EntityManager API entities automatically use this mode regardless of what is specified in the eXtreme Scale configuration.

COPY_TO_BYTES

You can store objects in a serialized format instead of POJO format. By using the COPY_TO_BYTES setting, you can reduce the memory footprint that a large graph of objects can consume. For more information, see Improving performance with byte array maps.

COPY_TO_BYTES_RAW

With COPY_TO_BYTES_RAW, you can directly access the serialized form of your data. This copy mode offers an efficient way for you to interact with serialized bytes, which allows you to bypass the deserialization process to access objects in memory.

In the ObjectGrid descriptor XML file, you can set the copy mode to COPY_TO_BYTES, and programmatically set the copy mode to COPY_TO_BYTES_RAW in the instances where you want to access the raw, serialized data. Set the copy mode to COPY_TO_BYTES _RAW in the ObjectGrid descriptor XML file only when your application uses the raw data as a part of a main application process.

Incorrect use of CopyMode

Errors occur when an application attempts to improve performance by using the COPY_ON_READ, COPY_ON_WRITE, or NO_COPY copy mode, as described above. The intermittent errors do not occur when you change the copy mode to the COPY_ON_READ_AND_COMMIT mode.

Problem

The problem might be due to corrupted data in the ObjectGrid map, which is a result of the application violating the programming contract of the copy mode that is being used. Data corruption can cause unpredictable errors to occur intermittently or in an unexplained or unexpected fashion.

Solution

The application must comply with the programming contract that is stated for the copy mode being used. For the COPY_ON_READ and COPY_ON_WRITE copy modes, the application uses a reference to a value object outside of the transaction scope from which the value reference was obtained. To use these modes, the application must delete the reference to the value object after the transaction completes, and obtain a new reference to the value object in each transaction that accesses the value object. For the NO_COPY copy mode, the application must never change the value object. In this case, either write the application so that it does not change the value object, or set the application to use a different copy mode.

- Improving performance with byte array maps
  You can store values in your maps in a byte array instead of POJO form, which reduces the memory footprint that a large graph of objects can consume.
- Tuning copy operations with the ObjectTransformer interface
  The ObjectTransformer interface uses callbacks to the application to provide custom implementations of common and expensive operations such as object serialization and deep copies on objects.

Improving performance with byte array maps

You can store values in your maps in a byte array instead of POJO form, which reduces the memory footprint that a large graph of objects can consume.

Advantages

The amount of memory that is consumed increases with the number of objects in a graph of objects. By reducing a complicated graph of objects to a byte array, only one object is maintained in the heap instead of several objects. With this reduction of the number of objects in the heap, the Java™ run time has fewer objects to search for during garbage collection.

The default copy mechanism used by WebSphere® eXtreme Scale is serialization, which is expensive. For instance, if using the default copy mode of `COPY_ON_READ_AND_COMMIT`, a copy is made both at read time and at get time. Instead of making a copy at read time, with byte arrays, the value is inflated from bytes, and instead of making a copy at commit time, the value is serialized to bytes. Using byte arrays results in equivalent data consistency to the default setting with a reduction of memory used.

When using byte arrays, note that having an optimized serialization mechanism is critical to seeing a reduction of memory consumption. For more information, see Tuning serialization performance.

Configuring byte array maps

You can enable byte array maps with the ObjectGrid XML file by modifying the CopyMode attribute that is used by a map to the setting COPY_TO_BYTES, shown in the following example:

```
<backingMap name="byteMap" copyMode="COPY_TO_BYTES" />
```

Considerations

You must consider whether or not to use byte array maps in a given scenario. Although you can reduce your memory use, processor use can increase when you use byte arrays.

The following list outlines several factors that should be considered before choosing to use the byte array map function.

Object type

Comparatively, memory reduction may not be possible when using byte array maps for some object types. Consequently, several types of objects exist for which you should not use byte array maps. If you are using any of the Java primitive wrappers as values, or a POJO that does not contain references to other objects (only storing primitive fields), the number of Java Objects is already as low as possible–there is only one. Since the amount of memory used by the object is already optimized, using a byte array map for these types of objects is not recommended. Byte array maps are more suitable to object types that contain other objects or collections of objects where the total number of POJO objects is greater than one.

For example, if you have a Customer object that had a business Address and a home Address, as well as a collection of Orders, the number of objects in the heap and the number of bytes used by those objects can be reduced by using byte array maps.

Local access

When using other copy modes, applications can be optimized when copies are made if objects are Cloneable with the default ObjectTransformer or when a custom ObjectTransformer is provided with an optimized copyValue method. Compared to the other copy modes, copying on reads, writes, or commit operations will have additional cost when accessing objects locally. For example, if you have a near cache in a distributed topology or are directly accessing a local or server ObjectGrid instance, the access and commit time will increase when using byte array maps due to the cost of serialization. You will see a similar cost in a distributed topology if you use data grid agents or you access the server primary when using the ObjectGridEventGroup.ShardEvents plug-in.

Plug-in interactions

With byte array maps, objects are not inflated when communicating from a client to a server unless the server needs the POJO form. Plug-ins that interact with the map value will experience a reduction in performance due to the requirement to inflate the value.

Any plug-in that uses LogElement.getCacheEntry or LogElement.getCurrentValue will see this additional cost. If you want to get the key, you can use LogElement.getKey, which avoids the additional overhead associated with the LogElement.getCacheEntry().getKey method. The following sections discuss plug-ins in light of the usage of byte arrays.

Indexes and queries

To avoid the overhead of serialization, use byte arrays instead of Java objects. Byte arrays are much cheaper to store in memory since the JDK has less objects to search for during garbage collection, and they can be inflated only when needed. Previously, you only used byte arrays if you did not need to access the objects using queries or indexes, since the data is stored as bytes and could only be accessed through its key. However, beginning in V7.1.1, indexes and queries are more doable because serializer plug-ins lift copy-to-bytes restrictions that previously existed.

Optimistic locking

When using the optimistic locking strategy, you will have the additional cost during updates and invalidate operations. This comes from having to inflate the value on the server to get the version value to do optimistic collision checking. If you are just using optimistic locking to guarantee fetch operations and do not need optimistic collision checking, you can use the com.ibm.websphere.objectgrid.plugins.builtins.NoVersioningOptimisticCallback to disable version checking.

Loader

With a Loader, you will also have the cost in the eXtreme Scale run time from inflating and reserializing the value when it is used by the Loader. You can still use byte array maps with Loaders, but consider the cost of making changes to the value in such a scenario. For example, you can use the byte array feature in the context of a read mostly cache. In this case, the benefit of having less objects in the heap and less memory used will outweigh the cost incurred from using byte arrays on insert and update operations.

ObjectGridEventListener

When using the transactionEnd method in the ObjectGridEventListener plug-in, you will have an additional cost on the server side for remote requests when accessing a LogElement's CacheEntry or current value. If the implementation of the method does not access these fields, then you will not have the additional cost.

Tuning copy operations with the ObjectTransformer interface

The ObjectTransformer interface uses callbacks to the application to provide custom implementations of common and expensive operations such as object serialization and deep copies on objects.

The ObjectTransformer interface has been replaced by the DataSerializer plug-ins, which you can use to efficiently store arbitrary data in WebSphere® eXtreme Scale so that existing product APIs can efficiently interact with your data.

Overview

Copies of values are always made except when the NO_COPY mode is used. The default copying mechanism that is employed in eXtreme Scale is serialization, which is known as an expensive operation. The ObjectTransformer interface is used in this situation. The ObjectTransformer interface uses callbacks to the application to provide a custom implementation of common and expensive operations, such as object serialization and deep copies on objects.

An application can provide an implementation of the ObjectTransformer interface to a map, and eXtreme Scale then delegates to the methods on this object and relies on the application to provide an optimized version of each method in the interface. The ObjectTransformer interface follows:

```
public interface ObjectTransformer {
    void serializeKey(Object key, ObjectOutputStream stream) throws IOException;
    void serializeValue(Object value, ObjectOutputStream stream) throws IOException;
    Object inflateKey(ObjectInputStream stream) throws IOException, ClassNotFoundException;
    Object inflateValue(ObjectInputStream stream) throws IOException, ClassNotFoundException;
    Object copyValue(Object value);
    Object copyKey(Object key);
}
```

You can associate an ObjectTransformer interface with a BackingMap by using the following example code:

```
ObjectGrid g = ...;
BackingMap bm = g.defineMap("PERSON");
MyObjectTransformer ot = new MyObjectTransformer();
bm.setObjectTransformer(ot);
```

Tune deep copy operations

After an application receives an object from an ObjectMap, eXtreme Scale performs a deep copy on the object value to ensure that the copy in the BaseMap map maintains data integrity. The application can then modify the object value safely. When the transaction commits, the copy of the object value in the BaseMap map is updated to the new modified value and the application stops using the value from that point on. You could have copied the object again at the commit phase to make a private copy. However, in this case the performance cost of this action was traded off against requiring the application programmer not to use the value after the transaction commits. The default ObjectTransformer attempts to use either a clone or a serialize and inflate pair to generate a copy. The serialize and inflate pair is the worst case performance scenario. If profiling reveals that serialize and inflate is a problem for your application, write an appropriate clone method to create a deep copy. If you cannot alter the class, then create a custom ObjectTransformer plug-in and implement more efficient copyValue and copyKey methods.

ObjectTransformer plug-in
Serialization using the DataSerializer plug-ins

Tuning evictors

If you use plug-in evictors, they are not active until you create them and associate them with a backing map. The following best practices increase performance for least frequently used (LFU) and least recently used (LRU) evictors.

Least frequently used (LFU) evictor

The concept of a LFU evictor is to remove entries from the map that are used infrequently. The entries of the map are spread over a set amount of binary heaps. As the usage of a particular cache entry grows, it becomes ordered higher in the heap. When the evictor attempts a set of evictions it removes only the cache entries that are located lower than a specific point on the binary heap. As a result, the least frequently used entries are evicted.

Least recently used (LRU) evictor

The LRU Evictor follows the same concepts of the LFU Evictor with a few differences. The main difference is that the LRU uses a first in, first out queue (FIFO) instead of a set of binary heaps. Every time a cache entry is accessed, it moves to the head of the queue. Consequently, the front of the queue contains the most recently used map entries and the end becomes the least recently used map entries. For example, the A cache entry is used 50 times, and the B cache entry is used only once right after the A cache entry. In this situation, the B cache entry is at the front of the queue because it was used most recently, and the A cache entry is at the end of the queue. The LRU evictor evicts the cache entries that are at the tail of the queue, which are the least recently used map entries.

LFU and LRU properties and best practices to improve performance

Number of heaps

When using the LFU evictor, all of the cache entries for a particular map are ordered over the number of heaps that you specify, improving performance drastically and preventing all of the evictions from synchronizing on one binary heap that contains all of the ordering for the map. More heaps also speeds up the time that is required for reordering the heaps because each heap has fewer entries. Set the number of heaps to 10% of the number of entries in your BaseMap.

Number of queues

When using the LRU evictor, all of the cache entries for a particular map are ordered over the number of LRU queues that you specify, improving performance drastically and preventing all of the evictions from synchronizing on one queue that contains all of the ordering for the map. Set the number of queues to 10% of the number of entries in your BaseMap.

MaxSize property

When an LFU or LRU evictor begins evicting entries, it uses the MaxSize evictor property to determine how many binary heaps or LRU queue elements to evict. For example, assume that you set the number of heaps or queues to have about 10 map entries in each map queue. If your MaxSize property is set to 7, the evictor evicts 3 entries from each heap or queue object to bring the size of each heap or queue back down to 7. The evictor only evicts map entries from a heap or queue when that heap or queue has more than the MaxSize property value of elements in it. Set the MaxSize to 70% of your heap or queue size. For this example, the value is set to 7. You can get an approximate size of each heap or queue by dividing the number of BaseMap entries by the number of heaps or queues that are used.

SleepTime property

An evictor does not constantly remove entries from your map. Instead it is idle for a set amount of time, only checking the map every n number of seconds, where n refers to the SleepTime property. This property also positively affects performance: running an eviction sweep too often lowers performance because of the resources that are needed for processing them. However, not using the evictor often can result in a map that has entries that are not needed. A map full of entries that are not needed can negatively affect both the memory requirements and processing resources that are required for your map. Setting the eviction sweep interval to fifteen seconds is a good practice for most maps. If the map is written to frequently and is used at a high transaction rate, consider setting the value to a lower time. If the map is accessed infrequently, you can set the time to a higher value.

Example

The following example defines a map, creates a new LFU evictor, sets the evictor properties, and sets the map to use the evictor:

```
//Use ObjectGridManager to create/get the ObjectGrid. Refer to
// the ObjectGridManger section
ObjectGrid objGrid = ObjectGridManager.create.....
BackingMap bMap = objGrid.defineMap("SomeMap");

//Set properties assuming 50,000 map entries
LFUEvictor someEvictor = new LFUEvictor();
someEvictor.setNumberOfHeaps(5000);
someEvictor.setMaxSize(7);
someEvictor.setSleepTime(15);
bMap.setEvictor(someEvictor);
```

Using the LRU evictor is very similar to using an LFU evictor. An example follows:

```
ObjectGrid objGrid = new ObjectGrid;
BackingMap bMap = objGrid.defineMap("SomeMap");

//Set properties assuming 50,000 map entries
LRUEvictor someEvictor = new LRUEvictor();
someEvictor.setNumberOfLRUQueues(5000);
someEvictor.setMaxSize(7);
someEvictor.setSleepTime(15);
bMap.setEvictor(someEvictor);
```

Notice that only two lines are different from the LFUEvictor example.

Tuning locking performance

Locking strategies and transaction isolation settings affect the performance of your applications.

Pessimistic locking strategy

Use the pessimistic locking strategy for read and write map operations where keys often collide. The pessimistic locking strategy has the greatest impact on performance.

Read committed and read uncommitted transaction isolation

When you are using pessimistic locking strategy, set the transaction isolation level with the Session.setTransactionIsolation method. For read committed or read uncommitted isolation, use the Session.TRANSACTION_READ_COMMITTED or Session.TRANSACTION_READ_UNCOMMITTED arguments depending on the isolation. To reset the transaction isolation level to the default pessimistic locking behavior, use the Session.setTransactionIsolation method with the Session.REPEATABLE_READ argument.

Read committed isolation reduces the duration of shared locks, which can improve concurrency and reduce the chance for deadlocks. This isolation level should be used when a transaction does not need assurances that read values remain unchanged for the duration of the transaction.

Use an uncommitted read when the transaction does not need to see the committed data.

Optimistic locking strategy

Optimistic locking is the default configuration. This strategy improves both performance and scalability compared to the pessimistic strategy. Use this strategy when your applications can tolerate some optimistic update failures, while still performing better than the pessimistic strategy. This strategy is excellent for read operations and infrequent update applications.

OptimisticCallback plug-in

The optimistic locking strategy makes a copy of the cache entries and compares them as needed. This operation can be expensive because copying the entry might involve cloning or serialization. To implement the fastest possible performance, implement the custom plug-in for non-entity maps.

Use version fields for entities

When you are using optimistic locking with entities, use the @Version annotation or the equivalent attribute in the Entity metadata descriptor file. The version annotation gives the ObjectGrid a very efficient way of tracking the version of an object. If the entity does not have a version field and optimistic locking is used for the entity, then the entire entity must be copied and compared.

None locking strategy

Use the none locking strategy for applications that are read only. The none locking strategy does not obtain any locks or use a lock manager. Therefore, this strategy offers the most concurrency, performance and scalability.

Tuning serialization performance

WebSphere® eXtreme Scale uses multiple Java™ processes to hold data. These processes serialize the data: That is, they convert the data (which is in the form of Java object instances) to bytes and back to objects again as needed to move the data between client and server processes. Marshalling the data is the most expensive operation and must be addressed by the application developer when designing the schema, configuring the data grid and interacting with the data-access APIs.

The default Java serialization and copy routines are relatively slow and can consume 60 to 70 percent of the processor in a typical setup. The following sections are choices for improving the performance of the serialization.

The ObjectTransformer interface has been replaced by the DataSerializer plug-ins, which you can use to efficiently store arbitrary data in WebSphere eXtreme Scale so that existing product APIs can efficiently interact with your data.

Write an ObjectTransformer for each BackingMap

An ObjectTransformer can be associated with a BackingMap. Your application can have a class that implements the ObjectTransformer interface and provides implementations for the following operations:

- Copying values
- Serializing and inflating keys to and from streams
- Serializing and inflating values to and from streams

The application does not need to copy keys because keys are considered immutable.

Note: The ObjectTransformer is only invoked when the ObjectGrid knows about the data that is being transformed. For example, when DataGrid API agents are used, the agents themselves as well as the agent instance data or data returned from the agent must be optimized using custom serialization techniques. The ObjectTransformer is not invoked for DataGrid API agents.

Using entities

When using the EntityManager API with entities, the ObjectGrid does not store the entity objects directly into the BackingMaps. The EntityManager API converts the entity object to Tuple objects. Entity maps are automatically associated with a highly optimized ObjectTransformer. Whenever the ObjectMap API or

EntityManager API is used to interact with entity maps, the entity ObjectTransformer is invoked.

Custom serialization

Some cases exist where objects must be modified to use custom serialization, such as implementing the java.io.Externalizable interface or by implementing the writeObject and readObject methods for classes implementing the java.io.Serializable interface. Custom serialization techniques should be employed when the objects are serialized using mechanisms other than the ObjectGrid API or EntityManager API methods.

For example, when objects or entities are stored as instance data in a DataGrid API agent or the agent returns objects or entities, those objects are not transformed using an ObjectTransformer. The agent, will however, automatically use the ObjectTransformer when using `EntityMixin` interface. See DataGrid agents and entity based Maps for further details.

Byte arrays

When using the ObjectMap or DataGrid APIs, the key and value objects are serialized whenever the client interacts with the data grid and when the objects are replicated. To avoid the overhead of serialization, use byte arrays instead of Java objects. Byte arrays are much cheaper to store in memory since the JDK has less objects to search for during garbage collection and they can be inflated only when needed. Previously, you only used byte arrays if you did not need to access the objects using queries or indexes, since the data is stored as bytes and could only be accessed through its key. However, beginning in V7.1.1, indexes and queries are more doable because serializer plug-ins lift copy-to-bytes restrictions that previously existed.

WebSphere eXtreme Scale can automatically store data as byte arrays using the CopyMode.COPY_TO_BYTES map configuration option, or it can be handled manually by the client. This option will store the data efficiently in memory and can also automatically inflate the objects within the byte array for use by queries and indexes on demand.

A MapSerializerPlugin plug-in can be associated with a BackingMap plug-in when you use the COPY_TO_BYTES or COPY_TO_BYTES_RAW copy modes. This association allows data to be stored in serialized form in memory, rather than the native Java object form. Storing serialized data conserves memory and improves replication and performance on the client and server. You can use a DataSerializer plug-in to develop high-performance serialization streams that can be compressed, encrypted, evolved, and queried.

- Tuning serialization
  The DataSerializer plug-ins expose metadata that tells WebSphere eXtreme Scale which attributes it can and cannot directly use during serialization, the path to the data that will be serialized, and the type of data that is stored in memory. You can optimize object serialization and inflation performance so that you can efficiently interact with the byte array.

Tuning serialization

The DataSerializer plug-ins expose metadata that tells WebSphere® eXtreme Scale which attributes it can and cannot directly use during serialization, the path to the data that will be serialized, and the type of data that is stored in memory. You can optimize object serialization and inflation performance so that you can efficiently interact with the byte array.

Overview

The ObjectTransformer interface has been replaced by the DataSerializer plug-ins, which you can use to efficiently store arbitrary data in WebSphere eXtreme Scale so that existing product APIs can efficiently interact with your data.

Copies of values are always made except when the NO_COPY mode is used. The default copying mechanism that is employed in eXtreme Scale is serialization, which is known as an expensive operation. The ObjectTransformer interface is used in this situation. The ObjectTransformer interface uses callbacks to the application to provide a custom implementation of common and expensive operations, such as object serialization and deep copies on objects. However, for improved performance in most cases, you can use the DataSerializer plug-ins to serialize objects. You must use either the COPY_TO_BYTES or COPY_TO_BYTES_RAW copy modes to use the DataSerializer plug-ins. For more information, see Serialization using the DataSerializer plug-ins.

An application can provide an implementation of the ObjectTransformer interface to a map, and eXtreme Scale then delegates to the methods on this object and relies on the application to provide an optimized version of each method in the interface. The ObjectTransformer interface follows:

```
public interface ObjectTransformer {
    void serializeKey(Object key, ObjectOutputStream stream) throws IOException;
    void serializeValue(Object value, ObjectOutputStream stream) throws IOException;
    Object inflateKey(ObjectInputStream stream) throws IOException, ClassNotFoundException;
    Object inflateValue(ObjectInputStream stream) throws IOException, ClassNotFoundException;
    Object copyValue(Object value);
    Object copyKey(Object key);
}
```

You can associate an ObjectTransformer interface with a BackingMap by using the following example code:

```
ObjectGrid g = ...;
BackingMap bm = g.defineMap("PERSON");
MyObjectTransformer ot = new MyObjectTransformer();
bm.setObjectTransformer(ot);
```

Tune object serialization and inflation

Object serialization is typically the most important performance consideration with eXtreme Scale, which uses the default serializable mechanism if an ObjectTransformer plug-in is not supplied by the application. An application can provide implementations of either the Serializable readObject and writeObject, or it can have the objects implement the Externalizable interface, which is approximately ten times faster. If the objects in the map cannot be modified, then an application can associate an ObjectTransformer interface with the ObjectMap. The serialize and inflate methods are provided to allow the application to provide custom code to optimize these operations, given their large performance impact on the system. The serialize method serializes the object to the provided stream. The inflate method provides the input stream and expects the application to create the object, inflate it using data in the stream and return the object. Implementations of the serialize and inflate methods must mirror each other.

The DataSerializer plug-ins replace the ObjectTransformer plug-ins, which are deprecated. To serialize your data in the most efficient way, use the DataSerializer plug-ins to improve performance in most cases. For example, if you intend to use functions, such as query and indexing, then you can immediately take advantage of the performance improvement that the DataSerializer plug-ins yield without making configuration or programmatic changes to your application code.

Serialization using the DataSerializer plug-ins
Tuning copy operations with the ObjectTransformer interface

Tuning query performance

To tune the performance of your queries, use the following techniques and tips.

Using parameters

When a query runs, the query string must be parsed and a plan developed to run the query, both of which can be costly.WebSphere® eXtreme Scale caches query plans by the query string. Since the cache is a finite size, it is important to reuse query strings whenever possible. Using named or positional parameters also helps performance by fostering query plan reuse.

```
Positional Parameter Example Query q = em.createQuery("select c from Customer c where c.surname=?1"); q.setParameter(1,
"Claus");
```

Using indexes

Proper indexing on a map might have a significant impact on query performance, even though indexing has some overhead on overall map performance. Without indexing on object attributes involved in queries, the query engine performs a table scan for each attribute. The table scan is the most expensive operation during a query run. Indexing on object attributes that are involved in queries allow the query engine to avoid an unnecessary table scan, improving the overall query performance. If the application is designed to use query intensively on a read-most map, configure indexes for object attributes that are involved in the query. If the map is mostly updated, then you must balance between query performance improvement and indexing overhead on the map.

When plain old Java™ objects (POJO) are stored in a map, proper indexing can avoid a Java reflection. In the following example, query replaces the WHERE clause with range index search, if the budget field has an index built over it. Otherwise, query scans the entire map and evaluates the WHERE clause by first getting the budget using Java reflection and then comparing the budget with the value 50000:

```
SELECT d FROM DeptBean d WHERE d.budget=50000
```

See Query plan for details on how to best tune individual queries and how different syntax, object models and indexes can affect query performance.

Using pagination

In client-server environments, the query engine transports the entire result map to the client. The data that is returned should be divided into reasonable chunks. The EntityManager Query and ObjectMap ObjectQuery interfaces both support the setFirstResult and setMaxResults methods that allow the query to return a subset of the results.

Return primitive values instead of entities

With the EntityManager Query API, entities are returned as query parameters. The query engine currently returns the keys for these entities to the client. When the client iterates over these entities using the Iterator from the getResultIterator method, each entity is automatically inflated and managed as if it were created with the find method on the EntityManager interface. The entire entity graph is built from the entity ObjectMap on the client. The entity value attributes and any related entities are eagerly resolved.

To avoid building the costly graph, modify the query to return the individual attributes with path navigation.

For example:

```
// Returns an entity
SELECT p FROM Person p
// Returns attributes SELECT p.name, p.address.street, p.address.city, p.gender FROM Person p
```

- Query plan
  All eXtreme Scale queries have a query plan. The plan describes how the query engine interacts with ObjectMaps and indexes. Display the query plan to determine if the query string or indexes are being used appropriately. The query plan can also be used to explore the differences that subtle changes in a query string make in the way eXtreme Scale runs a query.
- Query optimization using indexes
  Defining and using indexes properly can significantly improve query performance.

Query plan

All eXtreme Scale queries have a query plan. The plan describes how the query engine interacts with ObjectMaps and indexes. Display the query plan to determine if the query string or indexes are being used appropriately. The query plan can also be used to explore the differences that subtle changes in a query string make in the way eXtreme Scale runs a query.

The query plan can be viewed one of two ways:

- EntityManager Query or ObjectQuery getPlan API methods
- ObjectGrid diagnostic trace

getPlan method

The getPlan method on the ObjectQuery and Query interfaces return a String that describes the query plan. This string can be displayed to standard output or a log to display a query plan.
Note: In a distributed environment, the getPlan method does not run against the server and does not reflect any defined indexes. To view the plan, use an agent to view the plan on the server.

Query plan trace

The query plan can be displayed using ObjectGrid trace. To enable query plan trace, use the following trace specification:

```
QueryEnginePlan=debug=enabled
```

See Collecting trace for details on how to enable trace and locate the trace log files.

Query plan examples

Query plan uses the word for to indicate that the query is iterating through an ObjectMap collection or through a derived collection such as: q2.getEmps(), q2.dept, or a temporary collection returned by an inner loop. If the collection is from an ObjectMap, the query plan shows whether a sequential scan (denoted by `INDEX SCAN`), unique or non-unique index is used. Query plan uses a filter string to list the condition expressions applied to a collection.

A Cartesian product is not commonly used in object query. The following query scans the entire EmpBean map in the outer loop and scans the entire DeptBean map in the inner loop:

```
SELECT e, d FROM EmpBean e, DeptBean d

Plan trace:

for q2 in EmpBean ObjectMap using INDEX SCAN
     for q3 in DeptBean ObjectMap using INDEX SCAN
   returning new Tuple( q2,  q3  )
```

The following query retrieves all employee names from a particular department by sequentially scanning the EmpBean map to get an employee object. From the employee object, the query navigates to its department object and applies the d.no=1 filter. In this example, each employee has only one department object reference, so the inner loop runs one time:

```
SELECT e.name FROM EmpBean e JOIN e.dept d WHERE d.no=1

Plan trace:

for q2 in EmpBean ObjectMap using INDEX SCAN
     for q3 in  q2.dept
      filter ( q3.getNo() = 1 )
   returning new Tuple( q2.name  )
```

The following query is equivalent to the previous query. However, the following query performs better because it first narrows the result down to one department object by using the unique index that is defined over the DeptBean primary key field number. From the department object, the query navigates to its employee objects to get their names:

```
SELECT e.name FROM DeptBean d JOIN d.emps e WHERE d.no=1
```

```
Plan trace:

for q2 in DeptBean ObjectMap using UNIQUE INDEX key=(1)
     for q3 in  q2.getEmps()
   returning new Tuple( q3.name  )
```

The following query finds all the employees that work for development or sales. The query scans the entire EmpBean map and performs additional filtering by evaluating the expressions: d.name = 'Sales' or d.name='Dev'

```
SELECT e FROM EmpBean e, in (e.dept) d WHERE d.name = 'Sales'
        or d.name='Dev'

Plan trace:

for q2 in EmpBean ObjectMap using INDEX SCAN
     for q3 in  q2.dept
      filter (( q3.getName() = Sales ) OR ( q3.getName() = Dev ) )
   returning new Tuple( q2  )
```

The following query is equivalent to the previous query, but this query runs a different query plan and uses the range index built over the field name. In general, this query performs better because the index over the name field is used for narrowing down the department objects, which run quickly if only a few departments are development or sales.

```
SELECT e FROM DeptBean d, in(d.emps) e WHERE d.name='Dev' or d.name='Sales'

Plan trace:

IteratorUnionIndex of

     for q2 in DeptBean ObjectMap using INDEX on name = (Dev)
       for q3 in  q2.getEmps()

     for q2 in DeptBean ObjectMap using INDEX on name = (Sales)
       for q3 in  q2.getEmps()
```

The following query finds departments that do not have any employees:

```
SELECT d FROM DeptBean d WHERE NOT EXISTS(select e from d.emps e)

Plan trace:

for q2 in DeptBean ObjectMap using INDEX SCAN
    filter ( NOT  EXISTS (    correlated collection defined as

       for q3 in  q2.getEmps()
       returning new Tuple( q3      )

   returning new Tuple( q2  )
```

The following query is equivalent to the previous query but uses the SIZE scalar function. This query has similar performance but is easier to write.

```
SELECT d FROM DeptBean d WHERE SIZE(d.emps)=0
for q2 in DeptBean ObjectMap using INDEX SCAN
    filter (SIZE( q2.getEmps()) = 0 )
   returning new Tuple( q2  )
```

The following example is another way of writing the same query as the previous query with similar performance, but this query is easier to write as well:

```
SELECT d FROM DeptBean d WHERE d.emps is EMPTY

Plan trace:

for q2 in DeptBean ObjectMap using INDEX SCAN
    filter ( q2.getEmps() IS EMPTY  )
   returning new Tuple( q2  )
```

The following query finds any employees with a home address matching at least one of the addresses of the employee whose name equals the value of the parameter. The inner loop has no dependency on the outer loop. The query runs the inner loop one time.

```
SELECT e FROM EmpBean e WHERE e.home =  any (SELECT e1.home FROM EmpBean e1
        WHERE e1.name=?1)
for q2 in EmpBean ObjectMap using INDEX SCAN
    filter ( q2.home =ANY     temp collection defined as

       for q3 in EmpBean ObjectMap using INDEX on name = ( ?1)
       returning new Tuple( q3.home      )
 )
   returning new Tuple( q2  )
```

The following query is equivalent to the previous query, but has a correlated subquery; also, the inner loop runs repeatedly.

```
SELECT e FROM EmpBean e WHERE EXISTS(SELECT e1 FROM EmpBean e1 WHERE
        e.home=e1.home and e1.name=?1)

Plan trace:

for q2 in EmpBean ObjectMap using INDEX SCAN
    filter ( EXISTS (    correlated collection defined as
```

```
      for q3 in EmpBean ObjectMap using INDEX on name = (?1)
       filter ( q2.home =  q3.home )
      returning new Tuple( q3      )

   returning new Tuple( q2  )
```

Query optimization using indexes

Defining and using indexes properly can significantly improve query performance.

WebSphere® eXtreme Scale queries can use built-in HashIndex plug-ins to improve performance of queries. Indexes can be defined on entity or object attributes. The query engine will automatically use the defined indexes if its WHERE clause uses one of the following strings:

- A comparison expression with the following operators: =, <, >, <= or >= (any comparison expressions except not equals <>)
- A BETWEEN expression
- Operands of the expressions are constants or simple terms

Requirements

Indexes have the following requirements when used by Query:

- All indexes must use the built-in HashIndex plug-in.
- All indexes must be statically defined. Dynamic indexes are not supported.
- The @Index annotation may be used to automatically create static HashIndex plug-ins.
- All single-attribute indexes must have the RangeIndex property set to true.
- All composite indexes must have the RangeIndex property set to false.
- All association (relationship) indexes must have the RangeIndex property set to false.

For information about configuring the HashIndex, refer to Plug-ins for indexing data.

For information regarding indexing, see Indexing.

For a more efficient way to search for cached objects, see Using a composite index

Using hints to choose an index

An index can be manually selected using the setHint method on the Query and ObjectQuery interfaces with the HINT_USEINDEX constant. This can be helpful when optimizing a query to use the best performing index.

Query examples that use attribute indexes

The following examples use simple terms: e.empid, e.name, e.salary, d.name, d.budget and e.isManager. The examples assume that indexes are defined over the name, salary and budget fields of an entity or value object. The empid field is a primary key and isManager has no index defined.

The following query uses both indexes over the fields of name and salary. It returns all employees with names that equal the value of the first parameter or a salary equal to the value of the second parameter:

```
SELECT e FROM EmpBean e where e.name=?1 or e.salary=?2
```

The following query uses both indexes over the fields of name and budget. The query returns all departments named 'DEV' with a budget that is greater than 2000.

```
SELECT d FROM DeptBean dwhere d.name='DEV' and d.budget>2000
```

The following query returns all employees with a salary greater than 3000 and with an isManager flag value that equals the value of the parameter. The query uses the index that is defined over the salary field and performs additional filtering by evaluating the comparison expression: `e.isManager=?1`.

```
SELECT e FROM EmpBean e where e.salary>3000 and e.isManager=?1
```

The following query finds all employees who earn more than the first parameter, or any employee that is a manager. Although the salary field has an index defined, query scans the built-in index that is built over the primary keys of the EmpBean field and evaluates the expression: `e.salary>?1` or `e.isManager=TRUE`.

```
SELECT e FROM EmpBean e WHERE e.salary>?1 or e.isManager=TRUE
```

The following query returns employees with a name that contains the letter a. Although the name field has an index defined, query does not use the index because the name field is used in the LIKE expression.

```
SELECT e FROM EmpBean e WHERE e.name LIKE '%a%'
```

The following query finds all employees with a name that is not "Smith". Although the name field has an index defined, query does not use the index because the query uses the not equals (<>) comparison operator.

```
SELECT e FROM EmpBean e where e.name<>'Smith'
```

The following query finds all departments with a budget less than the value of the parameter, and with an employee salary greater than 3000. The query uses an index for the salary, but it does not use an index for the budget because dept.budget is not a simple term. The dept objects are derived from collection e. You do not need to use the budget index to look for dept objects.

```
SELECT dept from EmpBean e, in (e.dept) dept where e.salary>3000 and dept.budget<?
```

The following query finds all employees with a salary greater than the salary of the employees that have the empid of 1, 2, and 3. The index salary is not used because the comparison involves a subquery. The empid is a primary key, however, and is used for a unique index search because all the primary keys have a built-in index defined.

```
SELECT e FROM EmpBean e WHERE e.salary > ALL (SELECT e1.salary FROM EmpBean e1 WHERE e1.empid=1 or e1.empid =2 or
e1.empid=99)
```

To check if the index is being used by the query, you can view the Query plan. Here is an example query plan for the previous query:

```
for q2 in EmpBean ObjectMap using INDEX SCAN
    filter ( q2.salary >ALL     temp collection defined as
       IteratorUnionIndex of

         for q3 in EmpBean ObjectMap using UNIQUE INDEX key=(1)
        )

         for q3 in EmpBean ObjectMap using UNIQUE INDEX key=(2)
        )

         for q3 in EmpBean ObjectMap using UNIQUE INDEX key=(99)
        )
       returning new Tuple( q3.salary )
   returning new Tuple( q2  )

for q2 in EmpBean ObjectMap using RANGE INDEX on salary with range(3000,)
     for q3 in  q2.dept
      filter ( q3.budget <  ?1 )
   returning new Tuple( q3  )
```

Indexing attributes

Indexes can be defined over any single attribute type with the constraints previously defined.

Defining entity indexes using @Index

To define an index on an entity, simply define an annotation:

```
Entities using annotations

        @Entity
        public class Employee {
        @Id int empid;
        @Index String name
        @Index double salary
        @ManyToOne Department dept;
}
@Entity
        public class Department {
        @Id int deptid;
        @Index String name;
        @Index double budget;
        boolean isManager;
        @OneToMany Collection<Employee> employees;
        }
```

With XML

Indexes can also be defined using XML:

```
        Entities without annotations

        public class Employee {
        int empid;
        String name
        double salary
        Department dept;
        }

        public class Department {
        int deptid;
        String name;
        double budget;
        boolean isManager;
        Collection employees;
        }

ObjectGrid XML with attribute indexes

<?xml version="1.0" encoding="UTF-8"?>
        <objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"

Entity XML

<?xml version="1.0" encoding="UTF-8"?>
        <entity-mappings xmlns="http://ibm.com/ws/projector/config/emd"
        xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/projector/config/emd ./emd.xsd">

        <description>Department entities</description>
        <entity class-name="acme.Employee" name="Employee" access="FIELD">
        <attributes>
        <id name="empid" />
        <basic name="name" />
        <basic name="salary" />
        <many-to-one name="department"
        target-entity="acme.Department"
        fetch="EAGER">
        <cascade><cascade-persist/></cascade>
        </many-to-one>
        </attributes>
        </entity>
        <entity class-name="acme.Department" name="Department" access="FIELD">
        <attributes>
        <id name="deptid" />
        <basic name="name" />
        <basic name="budget" />
        <basic name="isManager" />
        <one-to-many name="employees"
        target-entity="acme.Employee"
        fetch="LAZY" mapped-by="parentNode">
        <cascade><cascade-persist/></cascade>
        </one-to-many>
        </attributes>
        </entity>
        </entity-mappings>
```

Defining indexes for non-entities using XML

Indexes for non-entity types are defined in XML. There is no difference when creating the MapIndexPlugin for entity maps and non-entity maps.

```
Java bean
public class Employee {
        int empid;
        String name
        double salary
        Department dept;

        public class Department {
        int deptid;
```

```
        String name;
        double budget;
        boolean isManager;
        Collection employees;
        }
```

```
ObjectGrid XML with attribute indexes
```

```
<?xml version="1.0" encoding="UTF-8"?>
        <objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">
        <objectGrids>
        <objectGrid name="DepartmentGrid">
        <backingMap name="Employee" pluginCollectionRef="Emp"/>
        <backingMap name="Department" pluginCollectionRef="Dept"/>
        <querySchema>
        <mapSchemas>
        <mapSchema mapName="Employee" valueClass="acme.Employee"
        primaryKeyField="empid" />
        <mapSchema mapName="Department" valueClass="acme.Department"
        primaryKeyField="deptid" />
        </mapSchemas>
        <relationships>
        <relationship source="acme.Employee"
        target="acme.Department"
        relationField="dept" invRelationField="employees" />
        </relationships>
        </querySchema>
        </objectGrid>
        </objectGrids>
        <backingMapPluginCollections>
        <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_Emp">

        </bean>
        </backingMapPluginCollection>
        </backingMapPluginCollections>
        </objectGridConfig>
```

Indexing relationships

WebSphere eXtreme Scale stores the foreign keys for related entities within the parent object. For entities, the keys are stored in the underlying tuple. For non-entity objects, the keys are explicitly stored in the parent object.

Adding an index on a relationship attribute can speed up queries that use cyclical references or use the IS NULL, IS EMPTY, SIZE and MEMBER OF query filters. Both single- and multi-valued associations may have the @Index annotation or a HashIndex plug-in configuration in an ObjectGrid descriptor XML file.

Defining entity relationship indexes using @Index

The following example defines entities with @Index annotations:

```
Entity with annotation
```

```
@Entity
public class Node {
```

```
    @ManyToOne @Index
    Node parentNode;

    @OneToMany @Index
    List<Node> childrenNodes = new ArrayList();

    @OneToMany @Index
    List<BusinessUnitType> businessUnitTypes = new ArrayList();
}
```

Defining entity relationship indexes using XML

The following example defines the same entities and indexes using XML with HashIndex plug-ins:

```
        Entity without annotations

        public class Node {
        int nodeId;
        Node parentNode;
        List<Node> childrenNodes = new ArrayList();
        List<BusinessUnitType> businessUnitTypes = new ArrayList();
        }

ObjectGrid XML

<?xml version="1.0" encoding="UTF-8"?>
        <objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">
        <objectGrids>
        <objectGrid name="ObjectGrid_Entity" entityMetadataXMLFile="entity.xml>
        <backingMap name="Node" pluginCollectionRef="Node"/>
        <backingMap name="BusinessUnitType" pluginCollectionRef="BusinessUnitType"/>
        </objectGrid>
        </objectGrids>
        <backingMapPluginCollections>
        <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_Node">
        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
        <property name="Name" type="java.lang.String" value="parentNode"/>
        <property name="AttributeName" type="java.lang.String" value="parentNode"/>
<property name="RangeIndex" type="boolean" value="false"
        description="Ranges are not supported for association indexes." />      </bean>
        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
        <property name="Name" type="java.lang.String" value="businessUnitType"/>
        <property name="AttributeName" type="java.lang.String" value="businessUnitTypes"/>

<property name="RangeIndex" type="boolean" value="false"
        description="Ranges are not supported for association indexes." />
        </bean>
        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
        <property name="Name" type="java.lang.String" value="childrenNodes"/>
        <property name="AttributeName" type="java.lang.String" value="childrenNodes"/>
<property name="RangeIndex" type="boolean" value="false"
        description="Ranges are not supported for association indexes." />
        </bean>
        </backingMapPluginCollection>
        </backingMapPluginCollections>
        </objectGridConfig>

 Entity XML

        <?xml version="1.0" encoding="UTF-8"?>
        <entity-mappings xmlns="http://ibm.com/ws/projector/config/emd"
        xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/projector/config/emd ./emd.xsd">

        <description>My entities</description>
        <entity class-name="acme.Node" name="Account" access="FIELD">
        <attributes>
        <id name="nodeId" />
        <one-to-many name="childrenNodes"
        target-entity="acme.Node"
        fetch="EAGER" mapped-by="parentNode">
        <cascade><cascade-all/></cascade>
        </one-to-many>
        <many-to-one name="parentNodes"
        target-entity="acme.Node"
        fetch="LAZY" mapped-by="childrenNodes">
        <cascade><cascade-none/></cascade>
        </one-to-many>
        <many-to-one name="businessUnitTypes"
        target-entity="acme.BusinessUnitType"
        fetch="EAGER">
        <cascade><cascade-persist/></cascade>
```

```
        </many-to-one>
</attributes>
        </entity>
        <entity class-name="acme.BusinessUnitType" name="BusinessUnitType" access="FIELD">
        <attributes>
        <id name="buId" />
        <basic name="TypeDescription" />
        </attributes>
        </entity>
        </entity-mappings>
```

Using the previously defined indexes, the following entity query examples are optimized:

```
SELECT n FROM Node n WHERE n.parentNode is null
SELECT n FROM Node n WHERE n.businessUnitTypes is EMPTY
        SELECT n FROM Node n WHERE size(n.businessUnitTypes)>=10
        SELECT n FROM BusinessUnitType b, Node n WHERE b member of n.businessUnitTypes and b.name='TELECOM'
```

Defining non-entity relationship indexes

The following example defines a HashIndex plug-in for non-entity maps in an ObjectGrid descriptor XML file:

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
  xmlns="http://ibm.com/ws/objectgrid/config">
  <objectGrids>
    <objectGrid name="ObjectGrid_POJO">
      <backingMap name="Node" pluginCollectionRef="Node"/>
      <backingMap name="BusinessUnitType" pluginCollectionRef="BusinessUnitType"/>
      <querySchema>
        <mapSchemas>
          <mapSchema mapName="Node"
                                        valueClass="com.ibm.websphere.objectgrid.samples.entity.Node"
            primaryKeyField="id" />
          <mapSchema mapName="BusinessUnitType"
            valueClass="com.ibm.websphere.objectgrid.samples.entity.BusinessUnitType"
            primaryKeyField="id" />
        </mapSchemas>
        <relationships>
          <relationship source="com.ibm.websphere.objectgrid.samples.entity.Node"
            target="com.ibm.websphere.objectgrid.samples.entity.Node"
            relationField="parentNodeId" invRelationField="childrenNodeIds" />
          <relationship source="com.ibm.websphere.objectgrid.samples.entity.Node"
            target="com.ibm.websphere.objectgrid.samples.entity.BusinessUnitType"
            relationField="businessUnitTypeKeys" invRelationField="" />
        </relationships>
      </querySchema>
    </objectGrid>
  </objectGrids>
  <backingMapPluginCollections>
    <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_Node">
      <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
        <property name="Name" type="java.lang.String" value="parentNode"/>
<property name="Name" type="java.lang.String" value="parentNodeId"/>
<property name="AttributeName" type="java.lang.String" value="parentNodeId"/>
<property name="RangeIndex" type="boolean" value="false"
        description="Ranges are not supported for association indexes." />
      </bean>
      <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
        <property name="Name" type="java.lang.String" value="businessUnitType"/>
        <property name="AttributeName" type="java.lang.String" value="businessUnitTypeKeys"/>

<property name="RangeIndex" type="boolean" value="false"
        description="Ranges are not supported for association indexes." />
   </bean>
      <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsqryoptmiz_MapIndexPlugin"
className="com.ibm.websphere.objectgrid.plugins.index.HashIndex">
<property name="Name" type="java.lang.String" value="childrenNodeIds"/>
        <property name="AttributeName" type="java.lang.String" value="childrenNodeIds"/>
  <property name="RangeIndex" type="boolean" value="false"
                                        description="Ranges are not supported for association indexes." />
</bean>
    </backingMapPluginCollection>
  </backingMapPluginCollections>
</objectGridConfig>
```

Given the above index configurations, the following object query examples are optimized:

```
SELECT n FROM Node n WHERE n.parentNodeId is null
SELECT n FROM Node n WHERE n.businessUnitTypeKeys is EMPTY
SELECT n FROM Node n WHERE size(n.businessUnitTypeKeys)>=10
SELECT n FROM BusinessUnitType b, Node n WHERE
        b member of n.businessUnitTypeKeys and b.name='TELECOM'
```

Tuning EntityManager interface performance

The EntityManager interface separates applications from the state held in its server grid data store.

The cost of using the EntityManager interface is not high and depends on the type of work being performed. Always use the EntityManager interface and optimize the crucial business logic after the application is complete. You can rework any code that uses EntityManager interfaces to use maps and tuples. Generally, this code rework might be necessary for 10 percent of the code.

If you use relationships between objects, then the performance impact is lower because an application that is using maps needs to manage those relationships similarly to the EntityManager interface.

Applications that use the EntityManager interface do not need to provide an ObjectTransformer implementation. The applications are optimized automatically.

Reworking EntityManager code for maps

A sample entity follows:

```
@Entity
public class Person
{
        @Id
        String ssn;
        String firstName;
        @Index
        String middleName;
        String surname;
}
```

Some code to find the entity and update the entity follows:

```
Person p = null;
s.begin();
p = (Person)em.find(Person.class, "1234567890");
p.middleName = String.valueOf(inner);
s.commit();
```

The same code using Maps and Tuples follows:

```
Tuple key = null;
key = map.getEntityMetadata().getKeyMetadata().createTuple();
key.setAttribute(0, "1234567890");

// The Copy Mode is always NO_COPY for entity maps if not using COPY_TO_BYTES.
// Either we need to copy the tuple or we can ask the ObjectGrid to do it for us:
map.setCopyMode(CopyMode.COPY_ON_READ);
s.begin();
Tuple value = (Tuple)map.get(key);
value.setAttribute(1, String.valueOf(inner));
map.update(key, value);
value = null;
s.commit();
```

Both of these code snippets have the same result, and an application can use either or both snippets.
The second code snippet shows how to use maps directly and how to work with the tuples (the key and value pairs). The value tuple has three attributes: firstName, middlename, and surname, indexed at 0, 1, and 2. The key tuple has a single attribute the ID number is indexed at zero. You can see how Tuples are created by using the EntityMetadata#getKeyMetaData or EntityMetadata#getValueMetaData methods. You must use these methods to create Tuples for an Entity. You cannot implement the Tuple interface and pass an instance of your Tuple implementation.

- Entity performance instrumentation agent
  You can improve the performance of field-access entities by enabling the WebSphere® eXtreme Scale instrumentation agent when using Java™ Development Kit (JDK) Version 5 or later.

Entity performance instrumentation agent

You can improve the performance of field-access entities by enabling the WebSphere® eXtreme Scale instrumentation agent when using Java™ Development Kit (JDK) Version 5 or later.

Enabling eXtreme Scale agent on JDK Version 5 or later

The ObjectGrid agent can be enabled with a Java command line option with the following syntax:

```
-javaagent:jarpath[=options]
```

The *jarpath* value is the path to an eXtreme Scale runtime Java archive (JAR) file that contains eXtreme Scale agent class and supporting classes such as the objectgrid.jar, wsobjectgrid.jar, ogclient.jar, wsogclient.jar, and ogagent.jar files. Typically, in a stand-alone Java program or in a Java Platform, Enterprise Edition environment that is not running WebSphere Application Server, use the objectgrid.jar or ogclient.jar file. In a WebSphere Application Server or a multi-classloaders environment, you must use the ogagent.jar file in the Java command line agent option. Provide the ogagent.config file in the class path or use agent options to specify additional information.

eXtreme Scale agent options

config
: Overrides the configuration file name.

include
: Specifies or overrides transformation domain definition that is the first part of the configuration file.

exclude
: Specifies or overrides the @Exclude definition.

fieldAccessEntity
: Specifies or overrides the @FieldAccessEntity definition.

trace
: Specifies a trace level. Levels can be ALL, CONFIG, FINE, FINER, FINEST, SEVERE, WARNING, INFO, and OFF.

trace.file
: Specifies the location of the trace file.

The semicolon (`;`) is used as a delimiter to separate each option. The comma (`,`) is used as a delimiter to separate each element within an option. The following example demonstrates the eXtreme Scale agent option for a Java program:

```
-javaagent:objectgridRoot/lib/objectgrid.jar=config=myConfigFile;
include=includedPackage;exclude=excludedPackage;
fieldAccessEntity=package1,package2
```

ogagent.config file

The ogagent.config file is the designated eXtreme Scale agent configuration file name. If the file name is in the class path, the eXtreme Scale agent finds and parses the file. You can override the designated file name through the config option of eXtreme Scale agent. The following example shows how to specify the configuration file:

```
-javaagent:objectgridRoot/lib/objectgrid.jar=config=myOverrideConfigFile
```

An eXtreme Scale agent configuration file has the following parts:

- **Transformation domain:** The transformation domain part is first in the configuration file. The transformation domain is a list of packages and classes that are included in the class transformation process. This transformation domain must include all classes that are field-access entity classes, and other classes that refer to these field-access entity classes. Field-access entity classes and those classes that refer to these field-access entity classes construct the transformation domain. If you plan to specify field-access entity classes in the @FieldAccessEntity part, then you do not need to include field-access entity classes here. The transformation domain must be complete. Otherwise, you might see a FieldAccessEntityNotInstrumentedException exception.
- **@Exclude:** The @Exclude token indicates that packages and classes listed after this token are excluded from the transformation domain.
- **@FieldAccessEntity:** The @FieldAccessEntity token indicates that packages and classes listed after this token are field-access Entity packages and classes. If no line exists after the @FieldAccessEntity token, then its equivalent is "No @FieldAccessEntity specified". The eXtreme Scale agent determines that there are no field-access Entity packages and classes defined. If there are lines after the @FieldAccessEntity token, then they represent the user-specified field-access Entity packages and classes. For example, "field-access entity domain". The field-access entity domain is a sub-domain of the transformation domain. Packages and classes that are listed in the field-access entity domain are a part of the transformation domain, even when they are not listed in the transformation domain. The @Exclude token, which lists packages and classes that are excluded from transformation, has no impact on the field-access Entity domain. When @FieldAccessEntity token is specified, all field-access entities must be in this field-access Entity domain. Otherwise, a FieldAccessEntityNotInstrumentedException exception might occur.

Example agent configuration file (ogagent.config)

```
################################
# The # indicates comment line
################################
# This is an ObjectGrid agent config file (the designated file name is ogagent.config) that can be found and parsed by
the ObjectGrid agent
# if it is in classpath.
# If the file name is "ogagent.config" and in classpath, Java program runs with -javaagent:objectgridRoot/ogagent.jar
will have
```

```
# ObjectGrid agent enabled.
# If the file name is not "ogagent.config" but in classpath, you can specify the file name in config option of
ObjectGrid agent
#     -javaagent:objectgridRoot/lib/objectgrid.jar=config=myOverrideConfigFile
# See comments below for more info regarding instrumentation setting override.

# The first part of the configuration is the list of packages and classes that should be included in transformation
domain.
# The includes (packages/classes, construct the instrumentation doamin) should be in the beginning of the file.
com.testpackage
com.testClass

# Transformation domain: The above lines are packages/classes that construct the transformation domain.
# The system will process classes with name starting with above packages/classes for transformation.
#
# @Exclude token : Exclude from transformation domain.
# The @Exclude token indicates packages/classes after that line should be excluded from transformation domain.
# It is used when user want to exclude some packages/classes from above specified included packages
#
# @FieldAccessEntity token: Field-access Entity domain.
# The @FieldAccessEntity token indicates packages/classes after that line are field-access Entity packages/classes.
# If there is no lilne after the @FieldAccessEntity token, it is equivalent to "No @FieldAccessEntity specified".
# The runtime will consider the user does not specify any field-access Entity packages/classes.
# The "field-acces Entity domain" is a sub-domain of transformation domain.
#
# Packages/classes listed in the "field-access Entity domain" will always be part of transformation domain,
# even they are not listed in transformation domain.
# The @Exclude, which lists packages/classes excluded from transformation, has no impact on the "field-acces Entity
domain".
# Note: When @FieldAccessEntity is specified, all field-access entities must be in this field-acces Entity domain,
#       otherwise, FieldAccessEntityNotInstrumentedException may occur.
#
# The default ObjectGrid agent config file name is ogagent.config
# The runtime will look for this file as a resource in classpath and process it.
# Users can override this designated ObjectGrid agent config file name via config option of agent.
#
# e.g.
#       javaagent:objectgridRoot/lib/objectgrid.jar=config=myOverrideConfigFile
#
# The instrumentation definition, including transformation domain, @Exclude, and  @FieldAccessEntity can be overriden
individually
# by corresponding designated agent options.
# Designated agent options include:
#    include              -> used to override instrumentation domain definition that is the first part of the config
file
#    exclude              -> used to override @Exclude definition
#    fieldAccessEntity    -> used to override @FieldAccessEntity definition
#
# Each agent option should be separated by ";"
# Within the agent option, the package or class should be seperated by ","
#
# The following is an example that does not override the config file name:
#    -
javaagent:objectgridRoot/lib/objectgrid.jar=include=includedPackage;exclude=excludedPackage;fieldAccessEntity=package1,p
ackage2
#
################################

@Exclude
com.excludedPackage
com.excludedClass

@FieldAccessEntity
```

Performance consideration

Security

WebSphere® eXtreme Scale can secure data access, including allowing for integration with external security providers. Aspects of security include authentication, authorization, transport security, data grid security, local security, and JMX (MBean) security.

- Data grid authentication
  You can use the secure token manager plug-in to enable server-to-server authentication, which requires you to implement the SecureTokenManager interface.
- Data grid security
  Data grid security ensures that a joining server has the right credentials, so a malicious server cannot join the data grid. Data grid security uses a shared secret string mechanism.
- Authenticating and authorizing clients
  You can enable security and credential authentication to authenticate clients. In addition, you can authorize administrative clients to access the data grid.
- Configuring secure transport types
  Transport layer security (TLS) provides secure communication between the client and server. The communication mechanism that is used depends on the value of the transportType parameter that is specified in the client and server configuration files.
- Java Management Extensions (JMX) security
  You can secure managed beans (MBean) invocations in a distributed environment.
- Security integration with external providers
  To protect your data, the product can integrate with several security providers.
- Securing the REST data service
  Secure multiple aspects of the REST data service. Access to the eXtreme Scale REST data service can be secured through authentication and authorization. Access can also be controlled by service-scoped configuration rules, known as access rules. Transport security is the third consideration.
- Security integration with WebSphere Application Server
  When WebSphere eXtreme Scale is deployed in a WebSphere Application Server environment, you can simplify the authentication flow and transport layer security configuration from WebSphere Application Server.
- Enabling data grid authorization
  WebSphere eXtreme Scale provides several security endpoints to integrate custom mechanisms. In the local programming model, the main security function is authorization, and has no authentication support. You must authenticate independently from the already existing WebSphere Application Server authentication. However, you can use the provided plug-ins to obtain and validate Subject objects.
- Starting and stopping secure servers
  Security is enabled by specifying security-specific configurations when you start and stop servers.
- Configuring security profiles for the xscmd utility
  By creating a security profile, you can use saved security parameters to use the **xscmd** utility with secure environments.
- Securing J2C client connections
  Use the Java™ 2 Connector (J2C) architecture to secure connections between WebSphere eXtreme Scale clients and your applications.
- Programming for security
  Use programming interfaces to handle various aspects of security in a WebSphere eXtreme Scale environment.

Data grid authentication

You can use the secure token manager plug-in to enable server-to-server authentication, which requires you to implement the SecureTokenManager interface.

The generateToken(Object) method takes an object protect, and then generates a token that cannot be understood by others. The verifyTokens(byte[]) method does the reverse process: it converts the token back to the original object.
A simple SecureTokenManager implementation uses a simple encoding algorithm, such as a XOR algorithm, to encode the object in serialized form and then use corresponding decoding algorithm to decode the token. This implementation is not secure and is easy to break.
WebSphere® eXtreme Scale default implementation
WebSphere eXtreme Scale provides an immediately available implementation for this interface. This default implementation uses a key pair to sign and verify the signature, and uses a secret key to encrypt the content. Every server has a JCEKS type keystore to store the key pair, a private key and public key, and a secret key. The keystore has to be the JCEKS type to store secret keys. These keys are used to encrypt and sign or verify the secret string on the sending end. Also, the token is associated with an expiration time. On the receiving end, the data is verified, decrypted, and compared to the receiver secret string. Secure Sockets Layer (SSL) communication protocols are not required between a pair of servers for authentication because the private keys and public keys serve the same purpose. However, if server communication is not encrypted, the data can be stolen by looking at the communication. Because the token expires soon, the replay attack threat is minimized. This possibility is significantly decreased if all servers are deployed behind a firewall.
The disadvantage of this approach is that the WebSphere eXtreme Scale administrators have to generate keys and transport them to all servers, which can cause security breach during transportation.

Data grid security

Data grid security ensures that a joining server has the right credentials, so a malicious server cannot join the data grid. Data grid security uses a shared secret string mechanism.

All WebSphere® eXtreme Scale servers, including catalog servers, agree on a shared secret string. When a server joins the data grid, it is challenged to present the secret string. If the secret string of the joining server matches the string in the president server or catalog server, the joining server is accepted. If the string does not match, the join request is rejected.

Sending a clear text secret is not secure. The WebSphere eXtreme Scale security infrastructure provides a secure token manager plug-in to allow the server to secure this secret before sending. You must decide how to implement the secure operation. WebSphere eXtreme Scale provides an out-of-the-box implementation, in which the secure operation is implemented to encrypt and sign the secret.

The secret string is set in the server.properties file. See Server properties file for more information about the authenticationSecret property.

SecureTokenManager plug-in

A secure token manager plug-in is represented by the com.ibm.websphere.objectgrid.security.plugins.SecureTokenManager interface.

For more information about the SecureTokenManager plug-in, see SecureTokenManager API documentation.

The generateToken(Object) method takes an object, and then generates a token that cannot be understood by others. The verifyTokens(byte[]) method does the reverse process: the method converts the token back to the original object.

A simple SecureTokenManager implementation uses a simple encoding algorithm, such as an exclusive or (XOR) algorithm, to encode the object in serialized form and then use the corresponding decoding algorithm to decode the token. This implementation is not secure.

WebSphere eXtreme Scale provides an immediately available implementation for this interface.

The default implementation uses a key pair to sign and verify the signature, and uses a secret key to encrypt the content. Every server has a JCEKS type keystore to store the key pair, a private key and public key, and a secret key. The keystore has to be the JCEKS type to store secret keys.

These keys are used to encrypt and sign or verify the secret string on the sending end. Also, the token is associated with an expiration time. On the receiving end, the data is verified, decrypted, and compared to the receiver secret string. Secure Sockets Layer (SSL) communication protocols are not required between a pair of servers for authentication because the private keys and public keys serve the same purpose. However, if server communication is not encrypted, the data can be stolen by looking at the communication. Because the token expires soon, the replay attack threat is minimized. This possibility is significantly decreased if all servers are deployed behind a firewall.

The disadvantage of this approach is that the WebSphere eXtreme Scale administrators have to generate keys and transport them to all servers, which can cause security breach during transportation.

Sample scripts to create default secure token manager properties

As noted in the previous section, you can create a keystore that contains a key pair to sign and verify the signature and a secret key to encrypt the content.

For example, you can use the JDK 6 keytool command to create the keys as follows:

```
keytool -genkeypair -alias keypair1 -keystore key1.jck -storetype JCEKS -keyalg
rsa -dname "CN=sample.ibm.com, OU=WebSphere eXtreme Scale" -storepass key111 -keypass
keypair1 -validity 10000
```

```
keytool -genseckey -alias seckey1 -keystore key1.jck -storetype JCEKS -keyalg
DES  -storepass key111 -keypass seckey1 -validity 1000
```

These two commands create a key pair "keypair1" and a secret key "seckey1". You can then configure the following in the server property file:

```
secureTokenKeyStore=key1.jck
secureTokenKeyStorePassword=key111
secureTokenKeyStoreType=JCEKS
secureTokenKeyPairAlias=keypair1
secureTokenKeyPairPassword=keypair1
secureTokenSecretKeyAlias=seckey1
secureTokenSecretKeyPassword=seckey1
secureTokenCipherAlgorithm=DES
secureTokenSignAlgorithm=RSA
```

Configuration

See Server properties for more information about the properties that you use to configure the secure token manager.

Class ClientSecurityConfigurationFactory

Transport layer security and secure sockets layer

WebSphere® eXtreme Scale supports both TCP/IP and Transport Layer Security/Secure Sockets Layer (TLS/SSL) for secure communication between clients and servers.

TLS and SSL encryption for clients and servers

TLS/SSL is sometimes enabled in one direction. For example, the server public certificate is imported in the client truststore, but the client public certificate is not imported into the server truststore. However, WebSphere eXtreme Scale extensively uses data grid agents. A characteristic of a data grid agent, when ORB transport is used, is that when the server sends responses back to the client, it creates a new connection. The eXtreme Scale server then acts as a client. Therefore, you must import the client public certificate into the server truststore.

Transport layer security for the Oracle JDK

Use the Oracle JRE for SSL with the following limitations.

- When you use the ORB transport, the eXtreme Scale client can run SSL or TLS using the Oracle JRE. When you use the Oracle JRE, specify the Sun JSSE provider (instead of the IBMJSSE2 provider) in the contextProvider property of the eXtreme Scale client properties file (for clients) or the eXtreme Scale server properties file (for servers).

Configuring secure transport types

Transport layer security (TLS) provides secure communication between the client and server. The communication mechanism that is used depends on the value of the transportType parameter that is specified in the client and server configuration files.

About this task

When Secure Sockets Layer (SSL) is used, the SSL configuration parameters must be provided on both the client and server side. In a Java™ SE environment, the SSL configuration is configured in the client or server property files. If the client or server is in WebSphere® Application Server, then you can use the existing WebSphere Application Server CSIV2 transport settings for your container servers and clients. See Security integration with WebSphere Application Server for more information.

Table 1. Transport protocol to use under client transport and server transport settings.
If the transportType settings are different between the client and server, the resulting protocol can vary or result in an error.

Client transportType property	Server transportType property	Resulting protocol
TCP/IP	TCP/IP	TCP/IP
TCP/IP	SSL-supported	TCP/IP
TCP/IP	SSL-required	Error
SSL-supported	TCP/IP	TCP/IP
SSL-supported	SSL-supported	SSL (if SSL fails, then TCP/IP)
SSL-supported	SSL-required	SSL
SSL-required	TCP/IP	Error
SSL-required	SSL-supported	SSL
SSL-required	SSL-required	SSL

Procedure

1. To set the transportType property in the client security configuration, see Client properties file.
2. To set the transportType property in the container and catalog server security configuration, see Server properties file.

- Transport layer security and secure sockets layer
  WebSphere eXtreme Scale supports both TCP/IP and Transport Layer Security/Secure Sockets Layer (TLS/SSL) for secure communication between clients and servers.
- Configuring Secure Sockets Layer (SSL) parameters for clients or servers
  How you configure SSL parameters varies between clients and servers.

Configuring Secure Sockets Layer (SSL) parameters for clients or servers

How you configure SSL parameters varies between clients and servers.

About this task

TLS/SSL is sometimes enabled in one direction. For example, the server public certificate is imported in the client truststore, but the client public certificate is not imported to the server truststore. However, WebSphere® eXtreme Scale extensively uses data grid agents. A characteristic of a data grid agent is when the server sends responds back to the client, it creates a connection. The eXtreme Scale server then acts as a client. Therefore, you must import the client public certificate into the server truststore.

Procedure

- Configure client SSL parameters.
  Use one of the following options to configure SSL parameters on the client:
  - Create a com.ibm.websphere.objectgrid.security.config.SSLConfiguration object by using the com.ibm.websphere.objectgrid.security.config.ClientSecurityConfigurationFactory factory class.
  - Configure the parameters in the client.properties file. You can then either set the property file as a JVM client property or you can use the WebSphere eXtreme Scale APIs. Pass the properties file into the ClientSecurityConfigurationFactory.getClientSecurityConfiguration(String) method for the client and use the returned object as a parameter to the ObjectGridManager.connect(String, ClientSecurityConfiguration, URL) method.
- Configure server SSL parameters.
  SSL parameters are configured for servers using the server.properties file. To start a container or catalog server with a specific property file, use the -serverProps parameter on the **startOgServer** script. For more information about the SSL parameters you can set for eXtreme Scale servers, see Security server properties.

Java Management Extensions (JMX) security

You can secure managed beans (MBean) invocations in a distributed environment.

For more information about the MBeans that are available, see Administering with Managed Beans (MBeans).

In the distributed deployment topology, MBeans are directly hosted in the catalog servers and container servers. In general, JMX security in a distributed topology follows the JMX security specification as specified in the Java Management Extensions (JMX) Specification. It consists of the following three parts:

1. Authentication: The remote client needs to be authenticated in the connector server.
2. Access control: MBean access control limits who can access the MBean information and who can perform the MBean operations.
3. Secure transport: The transport between the JMX client and server can be secured with TLS/SSL.

Authentication

JMX provides methods for the connector servers to authenticate the remote clients. For the RMI connector, authentication is completed by supplying an object that implements the JMXAuthenticator interface when the connector server is created. So eXtreme Scale implements this JMXAuthenticator interface to use the ObjectGrid Authenticator plug-in to authenticate the remote clients. See Java SE security tutorial - Step 2 for details on how eXtreme Scale authenticates a client.

The JMX client follows the JMX APIs to provide credentials to connect to the connector server. The JMX framework passes the credential to the connector server, and then calls the JMXAuthenticator implementation for authentication. As described previously, the JMXAuthenticator implementation then delegates the authentication to the ObjectGrid Authenticator implementation.

Review the following example that describes how to connect to a connector server with a credential:

```
javax.management.remote.JMXServiceURL jmxUrl = new JMXServiceURL(
        "service:jmx:rmi:///jndi/rmi://localhost:1099/objectgrid/MBeanServer");

    environment.put(JMXConnector.CREDENTIALS, new UserPasswordCredential("admin", "xxxxxx"));

    // Create the JMXCconnectorServer
    JMXConnector cntor = JMXConnectorFactory.newJMXConnector(jmxUrl, null);

    // Connect and invoke an operation on the remote MBeanServer
    cntor.connect(environment);
```

In the preceding example, a UserPasswordCredential object is provided with the user ID set to `admin` and the password set to `xxxxx`. This UserPasswordCredential object is set in the environment map, which is used in the JMXConnector.connect(Map) method. This UserPasswordCredential object is then passed to the server by the JMX framework, and finally passed to the ObjectGrid authentication framework for authentication.

The client programming model strictly follows the JMX specification.

Access control

A JMX MBean server might have access to sensitive information and might be able to perform sensitive operations. JMX provides necessary access control that identifies which clients can access that information and who can perform those operations. The access control is built on the standard Java security model by defining permissions that control access to the MBean server and its operations.

For JMX operation access control or authorization, eXtreme Scale relies on the JAAS support provided by the JMX implementation. At any point in the execution of a program, there is a current set of permissions that a thread of execution holds. When such a thread calls a JMX specification operation, these permissions

are known as the held permissions. When a JMX operation is performed, a security check is done to check whether the needed permission is implied by the held permission.

The MBean policy definition follows the Java policy format. For example, the following policy grants all signers and all code bases with the right to retrieve the server JMX address for the PlacementServiceMBean. However, the signers and code bases are restricted to the com.ibm.websphere.objectgrid domain.

```
grant {
    permission javax.management.MBeanPermission
        "com.ibm.websphere.objectgrid.management.PlacementServiceMBean#retrieveServerJMXAddress
                                        [com.ibm.websphere.objectgrid:*,type=PlacementService]",
        "invoke";
}
```

You can use the following policy example to complete authorization based on remote client identity. The policy grants the same MBean permission as shown in the preceding example, except only to users with X500Principal name as: `CN=Administrator,OU=software,O=IBM,L=Rochester,ST=MN,C=US`.

```
grant principal javax.security.auth.x500.X500Principal "CN=Administrator,OU=software,O=IBM,
                                L=Rochester,ST=MN,C=US" {permission javax.management.MBeanPermission
        "com.ibm.websphere.objectgrid.management.PlacementServiceMBean#retrieveServerJMXAddress
                                [com.ibm.websphere.objectgrid:*,type=PlacementService]",
        "invoke";
}
```

Java policies are checked only if the security manager is turned on. Start catalog servers and container servers with the -Djava.security.manager JVM argument to enforce the MBean operation access control.

Secure transport

The transport between the JMX client and server can be secured with TLS/SSL. If the transportType of catalog server or container server is set to SSL_Required or SSL_Supported, then you must use SSL to connect to the JMX server.

To use SSL, you need to configure the truststore, truststore type, and truststore password on the MBean client with -D system properties:

1. `-Djavax.net.ssl.trustStore=TRUST_STORE_LOCATION`
2. `-Djavax.net.ssl.trustStorePassword=TRUST_STORE_PASSWORD`
3. `-Djavax.net.ssl.trustStoreType=TRUST_STORE_TYPE`

If you use com.ibm.websphere.ssl.protocol.SSLSocketFactory as your SSL socket factory in your *java_home*/jre/lib/security/java.security file, then use the following properties:

1. `-Dcom.ibm.ssl.trustStore=TRUST_STORE_LOCATION`
2. `-Dcom.ibm.ssl.trustStorePassword=TRUST_STORE_PASSWORD`
3. `-Dcom.ibm.ssl.trustStoreType=TRUST_STORE_TYPE`

To obtain this information when Transport Layer Security/Secure Sockets Layer (TLS/SSL) is enabled in stand-alone configurations, you must start the catalog and container servers with the JMX service port set. Use one of the following methods to set the JMX service port:

- Use the -JMXServicePort option on the **startOgServer** script.
- If you are using an embedded server, call the setJMXServicePort method in the ServerProperties interface to set the JMX service port.

The default value for the JMX service port on catalog servers is `1099`. You must use a different port number for each JVM in your configuration. If you want to use JMX/RMI, explicitly specify the-JMXServicePort option and port number, even if you want to use the default port value.
Setting the JMX service port is required when you want to display container server information from the catalog server. For example, the port is required when you are using the xscmd -c showMapSizes command.

Set the JMX connector port to avoid ephemeral port creation. Use one of the following methods to set the JMX connector port.

- Use the -JMXConnectorPort option on the **startOgServer** script.
- If you are using an embedded server, call the setJMVConnectorPort method in the ServerProperties interface.

Security integration with external providers

To protect your data, the product can integrate with several security providers.

WebSphere® eXtreme Scale can integrate with an external security implementation. This external implementation must provide authentication and authorization services for WebSphere eXtreme Scale. WebSphere eXtreme Scale has plug-in points to integrate with a security implementation.WebSphere eXtreme Scale has been successfully integrated with the following components:

- Lightweight Directory Access Protocol (LDAP)
- Kerberos
- ObjectGrid security
- Tivoli® Access Manager
- Java™ Authentication and Authorization Service (JAAS)

eXtreme Scale uses the security provider for the following tasks:

- Authenticating clients to servers.
- Authorizing clients to access certain eXtreme Scale artifacts or to specify what can be done with eXtreme Scale artifacts.

eXtreme Scale has the following types of authorizations:

Map authorization
: Clients or groups can be authorized to perform insert, read, update, evict or delete operations on maps.

ObjectGrid authorization
: Clients or groups can be authorized to perform object or entity queries on objectGrids.

DataGrid agent authorization
: Clients or groups can be authorized to allow DataGrid agents to be deployed to an ObjectGrid.

Server-side map authorization
: Clients or groups can be authorized to replicate a server map to client side or create a dynamic index to the server map.

Administration authorization
: Clients or groups can be authorized to perform administration tasks.

Note: If you had security already enabled for your back end , remember that these security settings are no longer sufficient to protect your data. Security settings from your database or other datastore does not in any way transfer to your cache. You must separately protect the data that is now cached using the eXtreme Scale security mechanism, including authentication, authorization, and transport level security.
Important: Use a Development Kit or Runtime Environment at Version 1.6 and later to support SSL Transport security with WebSphere eXtreme Scale Version 7.1.1 and later.

Securing the REST data service

Secure multiple aspects of the REST data service. Access to the eXtreme Scale REST data service can be secured through authentication and authorization. Access can also be controlled by service-scoped configuration rules, known as access rules. Transport security is the third consideration.

About this task

Access to the eXtreme Scale REST data service can be secured through authentication and authorization. Authentication and authorization is accomplished by integrating with eXtreme Scale security.

Access can also be controlled by service-scoped configuration rules, known as access rules Two types of access rules exist, service operation rights which control the CRUD operations that are allowed by the service and entity access rights which control the CRUD operations that are allowed for a particular entity type.

Transport security is provided by the hosting container configuration for connections between the web client and the REST service. And transport security is provided by eXtreme Scale client configuration (for REST service to eXtreme Scale data grid connections).

Procedure

- Control authentication and authorization.
  Access to the eXtreme Scale REST data service can be secured through authentication and authorization. Authentication and authorization are accomplished by integrating with eXtreme Scale security.

  The eXtreme Scale REST data service uses eXtreme Scale security, for authentication and authorization, to control which users can access the service and the operations a user is allowed to perform through the service. The eXtreme Scale REST data service uses either a configured global credential, with user and password, or a credential derived from an HTTP BASIC challenge that is sent with each transaction to the eXtreme Scale data grid where authentication and authorization is performed.

  1. Configure eXtreme Scale client authentication and authorization on the grid See Security integration with external providers for details about how to configure eXtreme Scale client authentication and authorization.
  2. Configure the eXtreme Scale client, which is used by the REST service, for security.
     The eXtreme Scale REST data service invokes the eXtreme Scale client library when communicating with the eXtreme Scale grid. Therefore, the eXtreme Scale client must be configured for eXtreme Scale security.

     eXtreme Scale client authentication is enabled via properties in objectgrid client properties file. At a minimum, the following attributes must be enabled when using client security with the REST service:

     ```
     securityEnabled=true
     credentialAuthentication=Supported [-or-] Required
     credentialGeneratorProps=user:pass [-or-] {xor encoded user:pass}
     ```

     Remember: The user and password specified in the credentialGeneratorProps property must map to an ID in the authentication registry and have sufficient ObjectGrid policy rights to connect to and create ObjectGrids.
     A sample objectgrid client policy file is located in *restservice_home*/security/security.ogclient.properties. See also Client properties file.

  3. Configure the eXtreme Scale REST data service for security.
     The eXtreme Scale REST data service configuration properties file needs to contain the following entries to integrate with eXtreme Scale security:

     ```
     ogClientPropertyFile=file_name
     ```

     The ogClientPropertyFile is the location of the propery file that contains ObjectGrid client properties mentioned in the preceding step. The REST service uses this file to initialize the eXtreme Scale client to talk to the grid when security is enabled.

     ```
     loginType=basic [-or-] none
     ```

     The loginType property configures the REST service for the login type. If a value of `none` is specified, the “global” user id and password defined by the credentialGeneratorProps will be sent to the grid for each transaction. If a value of `basic` is specified, the REST service will present an HTTP

BASIC challenge to the client asking for credentials that it will send in each transaction when communicating with the grid.

For more information about the ogClientPropertyFile and loginType properties, refer to REST data service properties file.

- Apply access rules.
  Access can also be controlled by service scoped configuration rules, known as access rules Two types of access rules exist, service operation rights which control the CRUD operations that are allowed by the service and entity access rights which control the CRUD operations that are allowed for a particular entity type.

  The eXtreme Scale REST data service optionally allows access rules that can be configured to restrict access to the service and entities in the service. These access rules are specified in the REST service access rights property file. The name of this file is specified in the REST data service properties file by the wxsRestAccessRightsFile property. For more information about this property, see REST data service properties file. This file is a typical Java™ property file with key and value pairs. Two types of access rules exist, service operation rights which control the CRUD operations that are allowed by the service and entity access rights which control the CRUD operations that are allowed for a particular entity type.

  1. Configure service operation rights.
     Service Operations rights specify access rights that apply to all the ObjectGrids exposed via the REST service or to all entities of an individual ObjectGrid as specified.

     Use the following syntax.

     ```
     serviceOperationRights=service_operation_right
     serviceOperationRights.grid_name -OR- *=service_operation_right
     ```

     where
     - serviceOperationRights can be one of the following [NONE, READSINGLE, READMULTIPLE, ALLREAD, ALL]
     - serviceOperationRights.*grid_name -OR- ** implies that the access right applies to all the ObjectGrids, else name of a specific ObjectGrid can be provided.

     For example:

     ```
     serviceOperationsRights=ALL
     serviceOperationsRights.*=NONE
     serviceOperationsRights.EMPLOYEEGRID=READSINGLE
     ```

     The first example specifies that all service operations are allowed for all the ObjectGrids exposed by this REST Service. The second example is similar to the first example as it also applies to all the ObjectGrids exposed by the REST service, however it specifies the access right as NONE, which means none of the service operations are allowed on the ObjectGrids. The last example specifies how to control the service operations for a specific grid, here only Reads which results in a single record are allowed for all entities of the EMPLOYEEGRID.

     The default assumed by the REST service is `serviceOperationsRights=ALL` which means that all operations are allowed for all the ObjectGrids exposed by this service. This is different from the Microsoft implementation, for which the default is `NONE`, so no operations are allowed on the REST Service.

     Important: The service operations rights are evaluated in the order they are specified in this file, so the last specified right will override the rights preceding it.
  2. Configure entity access rights.
     Entity set rights specify access rights that apply to specific ObjectGrid entities exposed via the REST service. These rights provide a way to impose tighter and more finer-grained access control on individual ObjectGrid entities than compared to Service Operation rights.

     Use the following syntax.

     ```
     entitySetRights.grid_name.entity_name=entity_set_right
     ```

     where
     - *entity_set_right* can be one of the following rights.

       Table 1. Entity access rights. Supported values.

Access right	Description
NONE	Denies all rights to access data
READSINGLE	Allows to read single data items
READMULTIPLE	Allows reading sets of data
ALLREAD	Allows reading single or multiple sets of data
WRITEAPPEND	Allows creating new data items in data sets
WRITEREPLACE	Allows replacing data
WRITEDELETE	Allows deleting data items from data sets
WRITEMERGE	Allows merging data
ALLWRITE	Allows to write (i.e. create, replace, merge or delete) data
ALL	Allows creating, reading, updating, and deleting data

     - *entity_name* is the name of a specific ObjectGrid within the REST service.
     - *grid_name* is the name of a specific entity within the specified ObjectGrid.

     Note: If both service operation rights and entity set rights are specified for a respective ObjectGrid and its entities, then the more restrictive of those rights will be enforced, as illustrated in the following examples. Note also that the entity set rights are evaluated in the order they are specified in the file. The last specified right will override the rights preceding it.

Example 1: If serviceOperationsRights.NorthwindGrid=READSINGLE and entitySetRights.NorthwindGrid.Customer=ALL are specified. READSINGLE will be enforced for the Customer entity.

Example 2: If serviceOperationsRights.NorthwindGrid=ALLREAD is specified and entitySetRights.NorthwindGrid.Customer=ALLWRITE is specified then only Reads will be allowed for all entities of NorthwindGrid. However for Customer its entity set rights will prevent any Reads (since it specified ALLWRITE) and hence effectively the Customer entity will have access right as NONE.

- Secure transports.
  Transport security is provided by the hosting container configuration for connections between the web client and REST service. Transport security is provided by the eXtreme Scale client configuration for connections between the REST service and the eXtreme Scale grid.

  1. Secure the connection from the client and REST service. Transport security for this connection is provided by the hosting container environment, not in eXtreme Scale.
  2. Secure the connection from the REST service and the eXtreme Scale grid. Transport security for this connection is configured in eXtreme Scale. See Transport layer security and secure sockets layer.

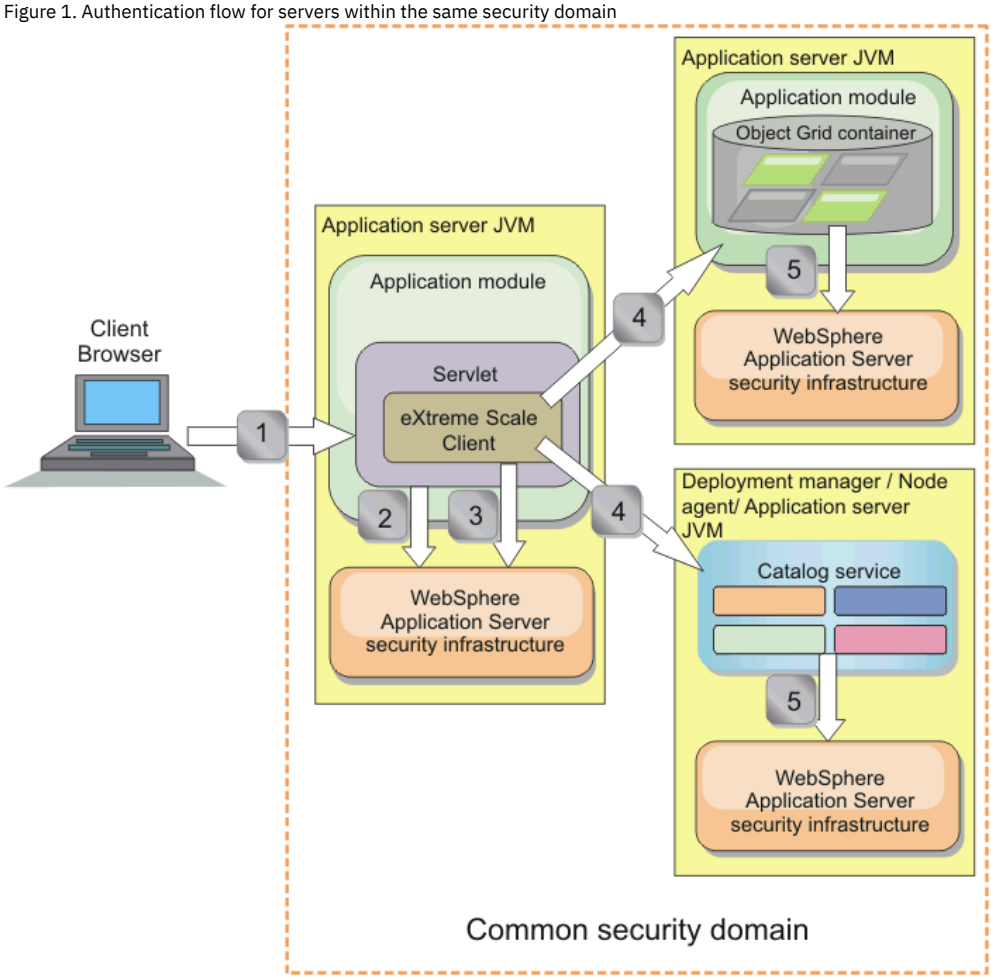
Security integration with WebSphere Application Server

When WebSphere® eXtreme Scale is deployed in a WebSphere Application Server environment, you can simplify the authentication flow and transport layer security configuration from WebSphere Application Server.

Simplified authentication flow

When eXtreme Scale clients and servers are running in WebSphere Application Server and in the same security domain, you can use the WebSphere Application Server security infrastructure to propagate the client authentication credentials to the eXtreme Scale server. For example, if a servlet acts as an eXtreme Scale client to connect to an eXtreme Scale server in the same security domain, and the servlet is already authenticated, it is possible to propagate the authentication token from the client (servlet) to the server, and then use the WebSphere Application Server security infrastructure to convert the authentication token back to the client credentials.

Figure 1. Authentication flow for servers within the same security domain



In the previous diagram, the application servers are in the same security domain. One application server hosts the web application, which is also an eXtreme Scale client. The other application server hosts the container server. The deployment manager or node agent Java virtual machine (JVM) hosts the catalog service.
Note: Use this type of configuration in development environments. However, for production environments run the catalog servers in separate processes, and if possible, run catalog servers on a different system from where the container servers are running.
The arrows in the diagram indicate how the authentication process flows:

1. An enterprise application user uses a Web browser to log in to the first application server with a user name and password.
2. The first application server sends the client user name and password to the WebSphere Application Server security infrastructure to authenticate with the user registry. For example, this user registry might be an LDAP server. As a result, the security information is stored in the application server thread.
3. The JavaServer Pages (JSP) file acts as an eXtreme Scale client to retrieve the security information from the server thread. The JSP file calls the WebSphere Application Server security infrastructure to get the security tokens that represent the enterprise application user.
4. The eXtreme Scale client, or JSP file, sends the security tokens with the request to the container server and catalog service that is hosted in the other JVMs. The catalog server and container server use the WebSphere Application Server security tokens as an eXtreme Scale client credential.
5. The catalog and container servers send the security tokens to the WebSphere Application Server security infrastructure to convert the security tokens into user security information. This user security information is represented by a Subject object, which contains the principals, public credentials, and private credentials. This conversion can occur because the application servers that are hosting the eXtreme Scale client, catalog server, and container server are sharing the same WebSphere Application Server Lightweight Third-Party Authentication (LTPA) tokens.

Authentication integration

Distributed security integration with WebSphere Application Server:

For the distributed model, use the following classes:

- com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator
- com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenAuthenticator
- com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredential

For examples on how to use these classes, see Tutorial: Integrate WebSphere eXtreme Scale security with WebSphere Application Server.

On the server side, use the WSTokenAuthentication authenticator to authenticate the WSTokenCredential object.

Local security integration with WebSphere Application Server:

For the local ObjectGrid model, use the following classes:

- com.ibm.websphere.objectgrid.security.plugins.builtins.WSSubjectSourceImpl
- com.ibm.websphere.objectgrid.security.plugins.builtins.WSSubjectValidationImpl

For more information about these classes, see Local security programming. You can configure the WSSubjectSourceImpl class as the SubjectSource plug-in, and the WSSubjectValidationImpl class as the SubjectValidation plug-in.

Transport layer security support in WebSphere Application Server

When an eXtreme Scale client, container server, or catalog server is running in a WebSphere Application Server process, eXtreme Scale transport security is managed by the WebSphere Application Server CSIV2 transport settings. For the eXtreme Scale client or container server, you should not use eXtreme Scale client or server properties to configure the SSL settings. All the SSL settings should be specified in the WebSphere Application Server configuration.

However, the catalog server is a little different. The catalog server has its own proprietary transport paths which cannot be managed by the WebSphere Application Server CSIV2 transport settings. Therefore, the SSL properties still need to be configured in the server properties file for the catalog server. See Tutorial: Integrate WebSphere eXtreme Scale security with WebSphere Application Server for more information.

- Configuring client security on a catalog service domain
  By configuring client security on a catalog service domain, you can define default client authentication configuration properties. These properties are used when a client properties file is not located in the Java virtual machine (JVM) that is hosting the client or when the client does not programmatically specify security properties. If a client properties file exists, the properties that you specify in the console override the values in the file. You can override these properties by specifying a splicer.properties file with the com.ibm.websphere.xs.sessionFilterProps custom property or by splicing the application EAR file.

Configuring client security on a catalog service domain

By configuring client security on a catalog service domain, you can define default client authentication configuration properties. These properties are used when a client properties file is not located in the Java virtual machine (JVM) that is hosting the client or when the client does not programmatically specify security properties. If a client properties file exists, the properties that you specify in the console override the values in the file. You can override these properties by specifying a splicer.properties file with the com.ibm.websphere.xs.sessionFilterProps custom property or by splicing the application EAR file.

Before you begin

- You must know the CredentialGenerator implementation that you are using to authenticate clients with the remote data grid. You can use one of the implementations that are provided by WebSphere® eXtreme Scale: UserPasswordCredentialGenerator or WSTokenCredentialGenerator.
  You can also use a custom implementation of the CredentialGenerator interface. The custom implementation must be in the class path of the runtime client and the server. If you are configuring an HTTP session scenario with WebSphere Application Server, you must put the implementation in the class path of the deployment manager and the class path of the application server in which the client is running.
- You must have a catalog service domain defined. See Creating catalog service domains in WebSphere Application Server for more information.

About this task

You must configure client security on the catalog service domain when you have enabled credential authentication on the server side, by configuring one of the following scenarios:

- The server-side security policy has the credentialAuthentication property set to `Required`.
- The server-side security policy has the credentialAuthentication property set to `Supported` AND an authorizationMechanism has been specified in the ObjectGrid XML file.

In these scenarios, a credential must be passed from the client. The credential that is passed from the client is retrieved from the getCredential method on a class that implements the CredentialGenerator interface. In an HTTP session configuration scenario, the run time must know the CredentialGenerator implementation to use to generate a credential that is passed to a remote data grid. If you do not specify the CredentialGenerator implementation class to use, the remote data grid would reject requests from the client because the client cannot be authenticated.

Procedure

Define client security properties. In the WebSphere Application Server administrative console, click System administration > WebSphere eXtreme Scale > Catalog service domains > *catalog_service_domain_name* > Client security properties. Specify client security properties on the page and save your changes. See Client security properties for a list of the properties you can set.

Results

The client security properties that you configured on the catalog service domain are used as default values. The values you specify override any properties that are defined in the client.properties files.

What to do next

Configure your applications to use WebSphere eXtreme Scale for session management. See Configuring WebSphere Application Server HTTP session persistence to a data grid for more information.

Enabling data grid authorization

WebSphere® eXtreme Scale provides several security endpoints to integrate custom mechanisms. In the local programming model, the main security function is authorization, and has no authentication support. You must authenticate independently from the already existing WebSphere Application Server authentication. However, you can use the provided plug-ins to obtain and validate Subject objects.

About this task

You can enable local security with the ObjectGrid XML descriptor file or programmatically.

Procedure

- Enable local security with the ObjectGrid XML descriptor XML file.
  The secure-objectgrid-definition.xml file that is used in the ObjectGridSample enterprise application sample is shown in the following example. Set the securityEnabled attribute to `true` to enable security.

```
<objectGrids>
    <objectGrid name="secureClusterObjectGrid" securityEnabled="true"
        authorizationMechanism="AUTHORIZATION_MECHANISM_JAAS">
    ...
</objectGrids>
```

- Enable local security programmatically.
  To create an ObjectGrid using the ObjectGrid.setSecurityEnabled method, call the following method on the ObjectGrid interface:

```
/**
 * Enable the ObjectGrid security
 */
void setSecurityEnabled();
```

What to do next

Start the container and catalog servers with security enabled.
Related reference:
Deployment policy descriptor XML file

Starting and stopping secure servers

Security is enabled by specifying security-specific configurations when you start and stop servers.

- Starting secure servers in a stand-alone environment
  To start secure stand-alone servers, you pass the proper configuration files by specifying parameters on the **startOgServer** or command.
- Starting secure servers in WebSphere Application Server
  To start secure servers in WebSphere® Application Server, you must specify the security configuration files in the generic Java™ virtual machine (JVM)

arguments.
- Stopping secure servers
  Stopping secure catalog servers or container servers requires one security configuration file.

Related tasks:
Configuring WebSphere Application Server applications to automatically start container servers

Starting secure servers in a stand-alone environment

To start secure stand-alone servers, you pass the proper configuration files by specifying parameters on the **startOgServer** or command.

Procedure

- Start secure container servers.
  Starting a secure container server requires the following security configuration file:
  - **Server property file:** The server property file configures the security properties specific to the server. Refer to the Server properties file for more details.

  Specify the location of this configuration file by providing the following argument to the **startOgServer** script:

  -serverProps
  Specifies the location of the server property file, which contains the server-specific security properties. The file name specified for this property is in plain file path format, such as ../security/server.properties.

  Enter the following lines when you run the **startOgServer** command command: UNIX Linux

```
startOgServer.sh <arguments> -jvmargs -Djava.security.auth.login.config=jaas.config
-Djava.security.manager -Djava.security.policy="auth.policy" -Dobjectgrid.home=$OBJECTGRID_HOME
```

  Windows

```
startOgServer.bat <arguments> -jvmargs -Djava.security.auth.login.config=jaas.config
-Djava.security.manager -Djava.security.policy="auth.policy" -Dobjectgrid.home=%OBJECTGRID_HOME%
```

- Start secure catalog servers.
  To start a secure catalog service, you must have the following configuration files:
  - **Security descriptor XML file:** The security descriptor XML file describes the security properties common to all servers, including catalog servers and container servers. One property example is the authenticator configuration which represents the user registry and authentication mechanism.
  - **Server property file:** The server property file configures the security properties that are specific to the server.

  Specify the location of these configuration files by providing the following arguments to the **startOgServer** script:

  -clusterSecurityFile and -clusterSecurityUrl
  These arguments specify the location of the Security descriptor XML file. Use the -clusterSecurityFile parameter to specify a local file, or the -clusterSecurityUrl parameter to specify the URL of the objectGridSecurity.xml file.
  -serverProps
  Specifies the location of the server property file, which contains the server-specific security properties. The file name specified for this property is in plain file path format, such as c:/tmp/og/catalogserver.props.

Starting secure servers in WebSphere Application Server

To start secure servers in WebSphere® Application Server, you must specify the security configuration files in the generic Java™ virtual machine (JVM) arguments.

Procedure

- Associate WebSphere eXtreme Scale catalog servers with WebSphere application servers using the administrative console. In the administrative console, click System Administration > WebSphere eXtreme Scale > Catalog Service Domains.
- Associate WebSphere eXtreme Scale container servers with particular WebSphere application servers by deploying an enterprise archive (EAR) file that contains the required XML descriptors for the data grid. For more information about this procedure, see Tutorial: Integrate WebSphere eXtreme Scale security with WebSphere Application Server.
- Specify Java virtual machine (JVM) arguments that point to configuration files to make the catalog and container servers secure. In addition, specify `securityEnabled="true"` in the objectgrid xml file for each data grid. After you specify the JVM arguments and enable security in your data grids, you can start the servers or clusters that act as eXtreme Scale catalog servers or container servers.
- Start catalog and containers servers with the WebSphere Application Server administrative console, or use the WebSphere Application Server command line.

What to do next

Stopping secure servers

Stopping secure servers

Stopping secure catalog servers or container servers requires one security configuration file.

Procedure

- Stop a secure catalog server or container server in stand-alone deployments. In stand-alone environments, stop WebSphere® eXtreme Scale catalog and container servers using the teardown function of the **xscmd** command, or using the **stopXsServer** or **stopOgServer** commands.
- Use the WebSphere Application Server administrative console to stop eXtreme Scale server that run with WebSphere Application Server.

Configuring WebSphere eXtreme Scale to use FIPS 140-2

Federal Information Processing Standard (FIPS) 140-2 specifies required levels of encryption for Transport Layer Security/Secure Sockets Layer (TLS/SSL). This standard ensures high protection of data as it is sent over the wire.

Before you begin

- You must be using an IBM® Runtime Environment. For more information, see Java SE considerations.
- Configure transport layer security and secure sockets layer in both directions. Your catalog server truststore file must contain the self-signed certificates for the container servers. The container servers must contain the self-signed certificates for the catalog server. For more information, see Transport layer security and secure sockets layer.

About this task

You can use the following steps to configure the catalog servers and container servers in your WebSphere eXtreme Scale stand-alone installation to use FIPS.

Procedure

1. Edit the java.security file. The location of the java.security depends on your Java virtual machine (JVM) configuration:
   - If you are using the default JVM that ships with the product, the file is in the *wxs_install_root*/java/jre/lib/security directory.
   - If you are using a different JVM, edit the file in the *java_home*/jre/lib/security directory.
   - If you installed WebSphere eXtreme Scale on an HP-UX or Solaris operating system, WebSphere eXtreme Scale requires the IBM hybrid JDK. A hybrid platform is a platform where you get 32-bit and 64-bit instance support in the same installation. You must update the java.security file in the jre/lib/security directory to include the IBMJCEFIPS provider first, such as:
     `security.provider.1=com.ibm.crypto.fips.provider.IBMJCEFIPS`.

   The file must contain the following text:

   ```
   security.provider.1=com.ibm.crypto.fips.provider.IBMJCEFIPS
   security.provider.2=com.ibm.jsse2.IBMJSSEProvider2
   security.provider.3=com.ibm.crypto.provider.IBMJCE
   security.provider.4=com.ibm.security.jgss.IBMJGSSProvider
   security.provider.5=com.ibm.security.cert.IBMCertPath
   security.provider.6=com.ibm.security.sasl.IBMSASL
   security.provider.7=com.ibm.xml.crypto.IBMXMLCryptoProvider
   security.provider.8=com.ibm.xml.enc.IBMXMLEncProvider
   security.provider.9=org.apache.harmony.security.provider.PolicyProvider
   security.provider.10=com.ibm.security.jgss.mech.spnego.IBMSPNEGO
   ```

   Important: If you are running Solaris or HP-UX you need to include the following line:

   ```
   security.provider.11=sun.security.provider.Sun
   ```

2. Edit the Secure Sockets Layer (SSL) configuration in the server properties files for the catalog server and container servers to use the TLSv1 protocol. You must also configure any clients that access the catalog and container servers to use the TLSv1 protocol.
   These files must contain the following properties and values:

   ```
   contextProvider=IBMJSSE2
   transportType=SSL-Required
   protocol=TLSv1
   fips=true
   ```

   For more information about SSL properties, see Server properties file and Client properties file.
3. Create a keystore with a FIPS 140-2 compatible certificate, for use by the catalog and container servers. The certificate should not use an MD5 signature algorithm. FIPS does not dictate RSA or key length.
4. Restart your catalog and container servers.
   When you start the catalog servers, you must specify Java virtual machine (JVM) arguments. The arguments that you use depend on which version of Java SE you are using. If the FIPS property is set and -Dcom.ibm.jsse2.usefipsprovider=true argument is set when you start the server, the JVM setting overrides the FIPS option that is configured in the security server properties.
   - For Java 6 SR 10 and later, or Java 7, specify the -Dcom.ibm.jsse2.usefipsprovider=true argument when you start the server.

   Restriction: When WebSphere eXtreme Scale is configured to run with the ORB transport, you cannot configure SSL to use both FIPS encryption and SP800-131a data protection. Running with both security standards is only allowed when eXtreme Scale is configured to run with the eXtremeIO (XIO) transport.

For more information, see Starting and stopping secure servers.

Configuring security profiles for the xscmd utility

By creating a security profile, you can use saved security parameters to use the **xscmd** utility with secure environments.

Before you begin

For more information about setting up the **xscmd** utility, see Administering with the xscmd utility.

About this task

You can use the -ssp *profile_name* or --saveSecProfile *profile_name* parameter with the rest of your **xscmd** command to save a security profile. The profile can contain settings for user names and passwords, credential generators, keystores, truststores, and transport types.

The ProfileManagement command group in the **xscmd** utility contains commands for managing your security profiles.

Procedure

- Save a security profile.
  To save a security profile, use the -ssp *profile_name* or --saveSecProfile *profile_name* parameter with the rest of your command. Adding this parameter to your command saves the following parameters:

  ```
  -al,--alias <alias>
  -arc,--authRetryCount <integer>
  -ca,--credAuth <support>
  -cgc,--credGenClass <className>
  -cgp,--credGenProps <property>
  -cxpv,--contextProvider <provider>
  -ks,--keyStore <filePath>
  -ksp,--keyStorePassword <password>
  -kst,--keyStoreType <type>
  -prot,--protocol <protocol>
  -pwd,--password <password>
  -ts,--trustStore <filePath>
  -tsp,--trustStorePassword <password>
  -tst,--trustStoreType <type>
  -tt,--transportType <type>
  -user,--username <username>
  ```

  Security profiles are saved in the *user_home*\.xscmd\profiles\security\<*profile_name*>.properties file.
  Important: Do not include the .properties file name extension on the *profile_name* parameter. This extension is automatically added to the file name.
- Use a saved security profile.
  To use a saved security profile, add the **-sp** *profile_name* or **--securityProfile** *profile_name* parameter to the command you are running.

  Command example: `xscmd -c listHosts -cep myhost.mycompany.com -sp myprofile`
- List the commands in the ProfileManagement command group.
  Run the following command: **xscmd -lc ProfileManagement**.
- List the existing security profiles.
  Run the following command: **xscmd -c listProfiles -v**.
- Display the settings that are saved in a security profile.
  Run the following command: **xscmd -c showProfile -pn** *profile_name*.
- Remove an existing security profile.
  Run the following command: **xscmd -c RemoveProfile -pn** *profile_name*.

Securing J2C client connections

8.5+ Use the Java™ 2 Connector (J2C) architecture to secure connections between WebSphere® eXtreme Scale clients and your applications.

About this task

Applications reference the connection factory, which establishes the connection to the remote data grid. Each connection factory hosts a single eXtreme Scale client connection that is reused for all application components.
Important: Since the eXtreme Scale client connection might include a near cache, it is important that applications do not share a connection. A connection factory must exist for a single application instance to avoid problems sharing objects between applications.
You can set the credential generator with the API or in the client properties file. In the client properties file, the securityEnabled and credentialGenerator properties are used.
Attention: In the following example, some lines of code are continued on the next line for publication purposes.

```
securityEnabled=true
credentialGeneratorClass=com.ibm.websphere.objectgrid.security.plugins.builtins.
     UserPasswordCredentialGenerator
credentialGeneratorProps=operator XXXXXX
```

The credential generator and credential in the client properties file are used for the eXtreme Scale connect operation and the default J2C credentials. Therefore, the credentials that are specified with the API are used at J2C connect time for the J2C connection. However, if no credentials are specified at J2C connect time, then the credential generator in the client properties file is used.

Procedure

1. Set up secure access where the J2C connection represents the eXtreme Scale client. Use the ClientPropertiesResource connection factory property or the ClientPropertiesURL connection factory property to configure client authentication.
   If you are using WebSphere eXtreme Scale with WebSphere Application Server, then specify the client properties on the catalog service domain configuration. When the connection factory references the domain, it automatically uses this configuration.

2. Configure the client security properties to use the connection factory that references the appropriate credential generator object for eXtreme Scale. These properties are also compatible with eXtreme Scale server security. For example, use the WSTokenCredentialGenerator credential generator for WebSphere credentials when eXtreme Scale is installed with WebSphere Application Server. Alternatively, use the UserPasswordCredentialGenerator credential generator when you run the eXtreme Scale in a stand-alone environment. In the following example, credentials are passed programmatically using the API call instead of using the configuration in the client properties:

   ```
   XSConnectionSpec spec = new XSConnectionSpec();
   spec.setCredentialGenerator(new UserPasswordCredentialGenerator("operator", "xxxxxx"));
   Connection conn = connectionFactory.getConnection(spec);
   ```

3. (Optional) Disable the near cache, if required.
   All J2C connections from a single connection factory share a single near cache. Grid entry permissions and map permissions are validated on the server, but not on the near cache. When an application uses multiple credentials to create J2C connections, and the configuration uses specific permissions for grid entries and maps for those credentials, then disable the near cache. Disable the near cache using the connection factory property, ObjectGridResource or ObjectGridURL. For more information about disabling the near cache, see Configuring the near cache.

4. (Optional) Set security policy settings, if required.
   If the J2EE application contains the embedded eXtreme Scale resource adapter archive (RAR) file configuration, you might be required to set additional security policy settings in the security policy file for the application. For example, these policies are required:

   ```
   permission com.ibm.websphere.security.WebSphereRuntimePermission "accessRuntimeClasses";
   permission java.lang.RuntimePermission "accessDeclaredMembers";
   permission javax.management.MBeanTrustPermission "register";
   permission java.lang.RuntimePermission "getClassLoader";
   ```

   Additionally, any property or resource files used by connection factories require file or other permissions, such as `permission java.io.FilePermission "filePath";`. For WebSphere Application Server, the policy file is META-INF/was.policy, and it is located in the J2EE EAR file.

Results

The client security properties that you configured on the catalog service domain are used as default values. The values that you specify override any properties that are defined in the client.properties files.

What to do next

Use eXtreme Scale data access APIs to develop client components that you want to use transactions.
Previous topic: 8.5+ Configuring applications to connect with eXtreme Scale
Next topic: 8.5+ Developing eXtreme Scale client components to use transactions

Programming for security

Use programming interfaces to handle various aspects of security in a WebSphere® eXtreme Scale environment.

- Security API
  WebSphere eXtreme Scale adopts an open security architecture. It provides a basic security framework for authentication, authorization, and transport security, and requires users to implement plug-ins to complete the security infrastructure.
- Client authentication programming
  For authentication, WebSphere eXtreme Scale provides a runtime to send the credential from the client to the server side, and then calls the authenticator plug-in to authenticate the users.

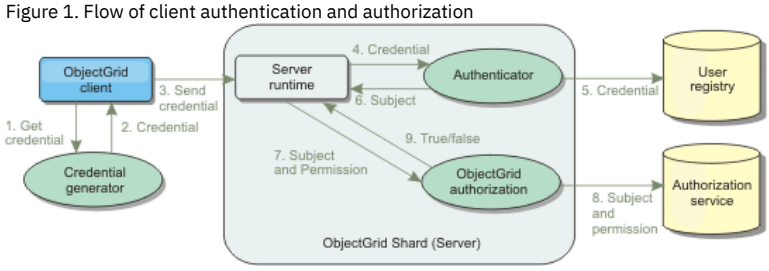
- Client authorization programming
  WebSphere eXtreme Scale supports Java™ Authentication and Authorization Service (JAAS) authorization that is ready to use and also supports custom authorization using the ObjectGridAuthorization interface.
- Data grid authentication
  You can use the secure token manager plug-in to enable server-to-server authentication, which requires you to implement the SecureTokenManager interface.
- Local security programming
  WebSphere eXtreme Scale provides several security endpoints to allow you to integrate custom mechanisms. In the local programming model, the main security function is authorization, and has no authentication support . You must authenticate outside of WebSphere Application Server. However, there are provided plug-ins to obtain and validate Subject objects.

Security API

WebSphere® eXtreme Scale adopts an open security architecture. It provides a basic security framework for authentication, authorization, and transport security, and requires users to implement plug-ins to complete the security infrastructure.

The following image shows the basic flow of client authentication and authorization for an eXtreme Scale server.

Figure 1. Flow of client authentication and authorization



The authentication flow and authorization flow are as follows.

Authentication flow

1. The authentication flow starts with an eXtreme Scale client getting a credential. This is done by the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator plug-in.
2. A CredentialGenerator object knows how to generate a valid client credential, for example, a user ID and password pair, Kerberos ticket, and so on. This generated credential is sent back to the client.
3. After the client retrieves the Credential object using the CredentialGenerator object, this Credential object is sent along with the eXtreme Scale request to the eXtreme Scale server.
4. The eXtreme Scale server authenticates the Credential object before processing the eXtreme Scale request. Then the server uses the Authenticator plug-in to authenticate the Credential object.
5. The Authenticator plug-in represents an interface to the user registry, for example, a Lightweight Directory Access Protocol (LDAP) server or an operating system user registry. The Authenticator consults the user registry and makes authentication decisions.
6. If the authentication is successful, a Subject object is returned to represent this client.
   Authorization flow

   WebSphere eXtreme Scale adopts a permission-based authorization mechanism, and has different permission categories represented by different permission classes. For example, a com.ibm.websphere.objectgrid.security.MapPermission object represents permissions to read, write, insert, invalidate, and remove the data entries in an ObjectMap. Because WebSphere eXtreme Scale supports Java™ Authentication and Authorization Service (JAAS) authorization out-of-box, you can use JAAS to handle authorization by providing authorization policies.

   Also, eXtreme Scale supports custom authorizations. Custom authorizations are plugged in by the plug-in com.ibm.websphere.objectgrid.security.plugins.ObjectGridAuthorization. The flow of the customer authorization is as follows.

7. The server runtime sends the Subject object and the required permission to the authorization plug-in.
8. The authorization plug-in consults the Authorization service and makes an authorization decision. If permission is granted for this Subject object, a value of `true` is returned, otherwise `false`is returned.
9. This authorization decision, true or false, is returned to the server runtime.

Security implementation

The topics in this section discuss how to program a secure WebSphere eXtreme Scale deployment and how to program the plug-in implementations. The section is organized based on the various security features. In each subtopic, you will learn about relevant plug-ins and how to implement the plug-ins. In the authentication section, you will see how to connect to a secure WebSphere eXtreme Scale deployment environment.

Client Authentication: The client authentication topic describes how a WebSphere eXtreme Scale client gets a credential and how a server authenticates the client. It will also discuss how a WebSphere eXtreme Scale client connects to a secure WebSphere eXtreme Scale server.

Authorization: The authorization topic explains how to use the ObjectGridAuthorization to do customer authorization besides JAAS authorization.

Grid Authentication: The data grid authentication topic discusses how you can use SecureTokenManager to securely transport server secrets.

Java Management Extensions (JMX) programming: When the WebSphere eXtreme Scale server is secured, the JMX client might need to send a JMX credential to the server.

Client authentication programming

For authentication, WebSphere® eXtreme Scale provides a runtime to send the credential from the client to the server side, and then calls the authenticator plug-in to authenticate the users.

WebSphere eXtreme Scale requires you to implement the following plug-ins to complete the authentication.

- Credential: A Credential represents a client credential, such as a user ID and password pair.
- CredentialGenerator: A CredentialGenerator represents a credential factory to generate the credential.
- Authenticator: An Authenticator authenticates the client credential and retrieves client information.

Credential and CredentialGenerator plug-ins

When an eXtreme Scale client connects to a server that requires authentication, the client is required to provide a client credential. A client credential is represented by a com.ibm.websphere.objectgrid.security.plugins.Credential interface. A client credential can be a user name and password pair, a Kerberos ticket, a client certificate, or data in any format that the client and server agree upon. This interface explicitly defines the equals(Object) and hashCode methods. These two methods are important because the authenticated Subject objects are cached by using the Credential object as the key on the server side. WebSphere eXtreme Scale also provides a plug-in to generate a credential. This plug-in is represented by the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface and is useful when the credential can expire. In this case, the getCredential method is called to renew a credential.

The Credential interface explicitly defines the equals(Object) and hashCode methods. These two methods are important because the authenticated Subject objects are cached by using the Credential object as the key on the server side.

You may also use the provided plug-in to generate a credential. This plug-in is represented by the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface, and is useful when the credential can expire. In this case, the getCredential method is called to renew a credential. See CredentialGenerator interface for more details.

There are three provided default implementations for the Credential interfaces:

- The com.ibm.websphere.objectgrid.security.plugins.builtins.UserPasswordCredential implementation, which contains a user ID and password pair.
- The com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredential implementation, which contains WebSphere Application Server-specific authentication and authorization tokens. These tokens can be used to propagate the security attributes across the application servers in the same security domain.

WebSphere eXtreme Scale also provides a plug-in to generate a credential. This plug-in is represented by the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface.WebSphere eXtreme Scale provides two default built-in implementations:

- The com.ibm.websphere.objectgrid.security.plugins.builtins.UserPasswordCredentialGenerator constructor takes a user ID and a password. When the getCredential method is called, it returns a UserPasswordCredential object that contains the user ID and password.
- The com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator represents a credential (security token) generator when running in WebSphere Application Server. When the getCredential method is called, the Subject that is associated with the current thread is retrieved. Then the security information in this Subject object is converted into a WSTokenCredential object. You can specify whether to retrieve a runAs subject or a caller subject from the thread by using the constant WSTokenCredentialGenerator.RUN_AS_SUBJECT or WSTokenCredentialGenerator.CALLER_SUBJECT.

UserPasswordCredential and UserPasswordCredentialGenerator

For testing purposes, WebSphere eXtreme Scale provides the following plug-in implementations:

1. `com.ibm.websphere.objectgrid.security.plugins.builtins.UserPasswordCredential`
2. `com.ibm.websphere.objectgrid.security.plugins.builtins.UserPasswordCredentialGenerator`

The user password credential stores a user ID and password. The user password credential generator then contains this user ID and password.

The following example code shows how to implement these two plug-ins.

```
UserPasswordCredential.java
// This sample program is provided AS IS and may be used, executed, copied and modified

}
```

The UserPasswordCredential class contains two attributes: user name and password. The UserPasswordCredentialGenerator serves as a factory that contains the UserPasswordCredential objects.

WSTokenCredential and WSTokenCredentialGenerator

When the WebSphere eXtreme Scale clients and servers are all deployed in WebSphere Application Server, the client application can use these two built-in implementations when the following conditions are satisfied:

1. WebSphere Application Server global security is turned on.
2. All WebSphere eXtreme Scale clients and servers are running in WebSphere Application Server Java™ virtual machines.
3. The application servers are in the same security domain.
4. The client is already authenticated in WebSphere Application Server.

In this situation, the client can use the com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator class to generate a credential. The server uses the WSAuthenticator implementation class to authenticate the credential.

This scenario takes advantage of the fact that the eXtreme Scale client has already been authenticated. Because the application servers that have the servers are in the same security domain as the application servers that house the clients, the security tokens can be propagated from the client to the server so that the same user registry does not need to be authenticated again.

Note: Do not assume that a CredentialGenerator always generates the same credential. For an expirable and refreshable credential, the CredentialGenerator should be able to generate the latest valid credential to make sure the authentication succeeds. One example is using the Kerberos ticket as a Credential object. When the Kerberos ticket refreshes, the CredentialGenerator should retrieve the refreshed ticket when CredentialGenerator.getCredential is called.

Authenticator plug-in

After the eXtreme Scale client retrieves the Credential object using the CredentialGenerator object, this client Credential object is sent along with the client request to the eXtreme Scale server. The server authenticates the Credential object before processing the request. If the Credential object is authenticated successfully, a Subject object is returned to represent this client.

This Subject object is then cached, and it expires after its lifetime reaches the session timeout value. The login session timeout value can be set by using the loginSessionExpirationTime property in the cluster XML file. For example, setting `loginSessionExpirationTime="300"` makes the Subject object expire in 300 seconds.

This Subject object is then used for authorizing the request, which is shown later. An eXtreme Scale server uses the Authenticator plug-in to authenticate the Credential object. See Authenticator for more details.

The Authenticator plug-in is where the eXtreme Scale runtime authenticates the Credential object from the client user registry, for example, a Lightweight Directory Access Protocol (LDAP) server.

WebSphere eXtreme Scale does not provide an immediately available user registry configuration. The configuration and management of user registry is left outside of WebSphere eXtreme Scale for simplicity and flexibility. This plug-in implements connecting and authenticating to the user registry. For example, an Authenticator implementation extracts the user ID and password from the credential, uses them to connect and validate to an LDAP server, and creates a Subject object as a result of the authentication. The implementation might use JAAS login modules. A Subject object is returned as a result of authentication.

Notice that this method creates two exceptions: InvalidCredentialException and ExpiredCredentialException. The InvalidCredentialException exception indicates that the credential is not valid. The ExpiredCredentialException exception indicates that the credential expired. If one of these two exceptions result from the authenticate method, the exceptions are sent back to the client. However, the client runtime handles these two exceptions differently:

- If the error is an InvalidCredentialException exception, the client run time displays this exception. Your application must handle the exception. You can correct the CredentialGenerator, for example, and then try the operation again.
- If the error is an ExpiredCredentialException exception, and the retry count is not 0, the client run time calls the CredentialGenerator.getCredential method again, and sends the new Credential object to the server. If the new credential authentication succeeds, the server processes the request. If the new credential authentication fails, the exception is sent back to the client. If the number of authentication retry attempts reaches the supported value and the client still gets an ExpiredCredentialException exception, the ExpiredCredentialException exception results. Your application must handle the error.

The Authenticator interface provides great flexibility. You can implement the Authenticator interface in your own specific way. For example, you can implement this interface to support two different user registries.

WebSphere eXtreme Scale provides sample authenticator plug-in implementations. Except for the WebSphere Application Server authenticator plug-in, the other implementations are only samples for testing purposes.

KeyStoreLoginAuthenticator

This example uses an eXtreme Scale built-in implementation: KeyStoreLoginAuthenticator, which is for testing and sample purposes (a keystore is a simple user registry and should not be used for a production environment). Again, the class is displayed to further demonstrate how to implement an authenticator.

Attention: In the following example, some lines of code are continued on the next line for publication purposes.

                // The first certificate is not an X509Certificate
                // We just add the certificate to the public credential set
                // and the private key to the private credential set.
                publicCreds.add(certs[0]);
                privateCreds.add(privateKey);
            }
        }
    }
}
```

Using the LDAP authenticator plug-in

You are provided with the com.ibm.websphere.objectgrid.security.plugins.builtins.LDAPAuthenticator default implementation to handle the user name and password authentication to an LDAP server. This implementation uses the LDAPLogin login module to log the user into a Lightweight Directory Access Protocol (LDAP) server.The following snippet demonstrates how the authenticate method is implemented:

Attention: In the following example, some lines of code are continued on the next line for publication purposes.

```
/**
* @see com.ibm.ws.objectgrid.security.plugins.Authenticator#
* authenticate(LDAPLogin)
*/
public Subject authenticate(Credential credential) throws
InvalidCredentialException, ExpiredCredentialException {

    UserPasswordCredential cred = (UserPasswordCredential) credential;
    LoginContext lc = null;
    try {
        lc = new LoginContext("LDAPLogin",
            new UserPasswordCallbackHandlerImpl(cred.getUserName(),
            cred.getPassword().toCharArray()));

        lc.login();

        Subject subject = lc.getSubject();

        return subject;
    }
    catch (LoginException le) {
        throw new InvalidCredentialException(le);
    }
```

```
    catch (IllegalArgumentException ile) {
        throw new InvalidCredentialException(ile);
    }
}
```

Also, eXtreme Scale ships a login module com.ibm.websphere.objectgrid.security.plugins.builtins.LDAPLoginModule for this purpose. You must provide the following two options in the JAAS login configuration file.

- providerURL: The LDAP server provider URL
- factoryClass: The LDAP context factory implementation class

The LDAPLoginModule module calls the com.ibm.websphere.objectgrid.security.plugins.builtins.LDAPAuthentcationHelper.authenticate method. The following code snippet shows how you can implement the authenticate method of the LDAPAuthenticationHelper.

```
/**
* Authenticate the user to the LDAP directory.
* @param user the user ID, e.g., uid=xxxxxx,c=us,ou=bluepages,o=ibm.com
* @param pwd the password
*
* @throws NamingException
*/
public String[] authenticate(String user, String pwd)
throws NamingException {
    Hashtable env = new Hashtable();
    env.put(Context.INITIAL_CONTEXT_FACTORY, factoryClass);
    env.put(Context.PROVIDER_URL, providerURL);
    env.put(Context.SECURITY_PRINCIPAL, user);
    env.put(Context.SECURITY_CREDENTIALS, pwd);
    env.put(Context.SECURITY_AUTHENTICATION, "simple");

    InitialContext initialContext = new InitialContext(env);

    // Look up for the user
    DirContext dirCtx = (DirContext) initialContext.lookup(user);

    String uid = null;
    int iComma = user.indexOf(",");
    int iEqual = user.indexOf("=");
    if (iComma > 0 && iComma > 0) {
        uid = user.substring(iEqual + 1, iComma);
    }
    else {
        uid = user;
    }

    Attributes attributes = dirCtx.getAttributes("");

    // Check the UID
    String thisUID = (String) (attributes.get(UID).get());

    String thisDept = (String) (attributes.get(HR_DEPT).get());

    if (thisUID.equals(uid)) {
        return new String[] { thisUID, thisDept };
    }
    else {
        return null;
    }
}
```

If authentication succeeds, the ID and password are considered valid. Then the login module gets the ID information and department information from this authenticate method. The login module creates two principals: SimpleUserPrincipal and SimpleDeptPrincipal. You can use the authenticated subject for group authorization (in this case, the department is a group) and individual authorization.

The following example shows a login module configuration that is used to log in to the LDAP server:

```
LDAPLogin { com.ibm.websphere.objectgrid.security.plugins.builtins.LDAPLoginModule required
    providerURL="ldap://directory.acme.com:389/"
    factoryClass="com.sun.jndi.ldap.LdapCtxFactory";
};
```

In the previous configuration, the LDAP server points to the ldap://directory.acme.com:389/server. Change this setting to your LDAP server. This login module uses the provided ID and password to connect to the LDAP server. This implementation is for testing purposes only.

Using the WebSphere Application Server authenticator plug-in

Also, eXtreme Scale provides the com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenAuthenticator built-in implementation to use the WebSphere Application Server security infrastructure. This built-in implementation can be used when the following conditions are true.

1. WebSphere Application Server global security is turned on.
2. All eXtreme Scale clients and servers are launched in WebSphere Application Server JVMs.
3. These application servers are in the same security domain.
4. The eXtreme Scale client is already authenticated in WebSphere Application Server.

The client can use the com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator class to generate a credential. The server uses this Authenticator implementation class to authenticate the credential. If the token is authenticated successfully, a Subject object returns.

This scenario takes advantage of the fact that the client has already been authenticated. Because the application servers that have the servers are in the same security domain as the application servers that house the clients, the security tokens can be propagated from the client to the server so that the same user registry does not need to be authenticated again.

Using the Tivoli® Access Manager authenticator plug-in

Tivoli Access Manager is used widely as a security server. You can also implement Authenticator using the Tivoli Access Manager's provided login modules.

To authenticate a user for Tivoli Access Manager, apply the the com.tivoli.mts.PDLoginModule login module, which requires that the calling application provide the following information:

1. A principal name, specified as either a short name or an X.500 name (DN)
2. A password

The login module authenticates the principal and returns the Tivoli Access Manager credential. The login module expects the calling application to provide the following information:

1. The user name, through a javax.security.auth.callback.NameCallback object.
2. The password, through a javax.security.auth.callback.PasswordCallback object.

When the Tivoli Access Manager credential is successfully retrieved, the JAAS LoginModule creates a Subject and a PDPrincipal. No built-in for Tivoli Access Manager authentication is provided, because it is just with the PDLoginModule module. See the IBM® Tivoli Access Manager Authorization Java Classes Developer Reference for more details.

Connecting to WebSphere eXtreme Scale securely

To connect an eXtreme Scale client to a server securely, you can use any connect method in the ObjectGridManager interface which takes a ClientSecurityConfiguration object. The following is a brief example.

```
public ClientClusterContext connect(String catalogServerEndpoints,
                 ClientSecurityConfiguration securityProps,
     URL overRideObjectGridXml) throws ConnectException;
```

This method takes a parameter of the ClientSecurityConfiguration type, which is an interface representing a client security configuration. You can use com.ibm.websphere.objectgrid.security.config.ClientSecurityConfigurationFactory public API to create an instance with default values, or you can create an instance by passing the WebSphere eXtreme Scale client property file. This file contains the following properties that are related to authentication. The value marked with a plus sign (+) is the default.

- `securityEnabled (true, false+)`: This property indicates if security is enabled. When a client connects to a server, the securityEnabled value on the client and server side must be both `true` or both `false`. For example, if the connected server security is enabled, the client has to set this property to true to connect to the server.
- authenticationRetryCount (an integer value, 0+): This property determines how many retries are attempted for login when a credential is expired. If the value is 0, no retries are attempted. The authentication retry only applies to the case when the credential is expired. If the credential is not valid, there is no retry. Your application is responsible for trying the operation again.

After you create a com.ibm.websphere.objectgrid.security.config.ClientSecurityConfiguration object, set the credentialGenerator object on the client using the following method:

```
/**
* Set the {@link CredentialGenerator} object for this client.
* @param generator the CredentialGenerator object associated with this client
*/
void setCredentialGenerator(CredentialGenerator generator);
```

You can set the CredentialGenerator object in the WebSphere eXtreme Scale client property file too, as follows.

- credentialGeneratorClass: The class implementation name for the CredentialGenerator object. It must have a default constructor.
- credentialGeneratorProps: The properties for the CredentialGenerator class. If the value is not null, it is set to the constructed CredentialGenerator object using the setProperties(String) method.

Here is a sample to instantiate a ClientSecurityConfiguration and then use it to connect to the server.

```
/**
* Get a secure ClientClusterContext
* @return a secure ClientClusterContext object
*/
protected ClientClusterContext connect() throws ConnectException {
ClientSecurityConfiguration csConfig = ClientSecurityConfigurationFactory
.getClientSecurityConfiguration("/properties/security.ogclient.props");

UserPasswordCredentialGenerator gen= new
UserPasswordCredentialGenerator("manager", "manager1");

csConfig.setCredentialGenerator(gen);

return objectGridManager.connect(csConfig, null);
}
```

When the connect is called, the WebSphere eXtreme Scale client calls the CredentialGenerator.getCredential method to get the client credential. This credential is sent along with the connect request to the server for authentication.

Using a different CredentialGenerator instance per session

In some cases, a WebSphere eXtreme Scale client represents just one client identity, but in others, it might represent multiple identities. Here is one scenario for the latter case: An WebSphere eXtreme Scale client is created and shared in a Web server. All servlets in this Web server use this one WebSphere eXtreme Scale client. Because every servlet represents a different Web client, use different credentials when sending requests to WebSphere eXtreme Scale servers.

WebSphere eXtreme Scale provides for changing the credential on the session level. Every session can uses a different CredentialGenerator object. Therefore, the previous scenarios can be implemented by letting the servlet get a session with a different CredentialGenerator object. The following example illustrates the ObjectGrid.getSession(CredentialGenerator) method in the ObjectGridManager interface.

Attention: In the following example, some lines of code are continued on the next line for publication purposes.

```
/**
     * Get a session using a <code>CredentialGenerator</code>.
     * <p>
     * This method can only be called by the ObjectGrid client in an ObjectGrid
     * client server environment. If ObjectGrid is used in a local model, that is,
     * within the same JVM with no client or server existing, <code>getSession(Subject)</code>
     * or the <code>SubjectSource</code> plugin should be used to secure the ObjectGrid.
     *
     * <p>If the <code>initialize()</code> method has not been invoked prior to
     * the first <code>getSession</code> invocation, an implicit initialization
     * will occur.  This ensures that all of the configuration is complete
     * before any runtime usage is required.</p>
     *
     * @param credGen A <code>CredentialGenerator</code> for generating a credential
     *                for the session returned.
     *
     * @return An instance of <code>Session</code>
     *
     * @throws ObjectGridException if an error occurs during processing
     * @throws TransactionCallbackException if the <code>TransactionCallback</code>
     *         throws an exception
     * @throws IllegalStateException if this method is called after the
     *         <code>destroy()</code> method is called.
     *
     * @see #destroy()
     * @see #initialize()
     * @see CredentialGenerator
     * @see Session
     * @since WAS XD 6.0.1
 */
Session getSession(CredentialGenerator credGen) throws
ObjectGridException, TransactionCallbackException;
```

The following is an example:

```
ObjectGridManager ogManager = ObjectGridManagerFactory.getObjectGridManager();

CredentialGenerator credGenManager = new UserPasswordCredentialGenerator("manager", "xxxxxx");
CredentialGenerator credGenEmployee = new UserPasswordCredentialGenerator("employee", "xxxxxx");

ObjectGrid og = ogManager.getObjectGrid(ctx, "accounting");

// Get a session with CredentialGenerator;
Session session = og.getSession(credGenManager );

// Get the employee map
ObjectMap om = session.getMap("employee");

// start a transaction.
session.begin();

Object rec1 = map.get("xxxxxx");

session.commit();

// Get another session with a different CredentialGenerator;
session = og.getSession(credGenEmployee );

// Get the employee map
om = session.getMap("employee");

// start a transaction.
session.begin();

Object rec2 = map.get("xxxxx");

session.commit();
```

If you use the ObjectGird.getSession method to get a Session object, the session uses the CredentialGenerator object set on the ClientConfigurationSecurity object. The ObjectGrid.getSession(CredentialGenerator) method overrides the CredentialGenerator set in the ClientSecurityConfiguration object.

If you can reuse the Session object, a performance gain results. However, calling the ObjectGrid.getSession(CredentialGenerator) method is not very expensive. The major overhead is the increased object garbage collection time. Make sure that you release the references after you are done with the Session objects. Generally, if your Session object can share the identity, try to reuse the Session object. If not, use the ObjectGrid.getSession(CredentialGenerator) method.

Credential API

Client authorization programming

WebSphere® eXtreme Scale supports Java™ Authentication and Authorization Service (JAAS) authorization that is ready to use and also supports custom authorization using the ObjectGridAuthorization interface.

The ObjectGridAuthorization plug-in is used to authorize ObjectGrid, ObjectMap, and JavaMap accesses to the Principals represented by a Subject object in a custom way. A typical implementation of this plug-in is to retrieve the Principals from the Subject object, and then check whether the specified permissions are granted to the Principals.

A permission passed to the checkPermission(Subject, Permission) method can be one of the following permissions:

- MapPermission
- ObjectGridPermission
- ServerMapPermission
- AgentPermission

Refer to ObjectGridAuthorization API documentation for more details.

MapPermission

The com.ibm.websphere.objectgrid.security.MapPermission public class represents permissions to the ObjectGrid resources, specifically the methods of ObjectMap or JavaMap interfaces. WebSphere eXtreme Scale defines the following permission strings to access the methods of ObjectMap and JavaMap:

- **read:** Permission to read the data from the map. The integer constant is defined as `MapPermission.READ`.
- **write:** Permission to update the data in the map. The integer constant is defined as `MapPermission.WRITE`.
- **insert:** Permission to insert the data into the map. The integer constant is defined as `MapPermission.INSERT`.
- **remove:** Permission to remove the data from the map. The integer constant is defined as `MapPermission.REMOVE`.
- **invalidate:** Permission to invalidate the data from the map. The integer constant is defined as `MapPermission.INVALIDATE`.
- **all:** All above permissions: read, write, insert, remote, and invalidate. The integer constant is defined as `MapPermission.ALL`.

Refer to MapPermission API documentation for more details.

You can construct a MapPermission object by passing the fully qualified ObjectGrid map name (in format [ObjectGrid_name].[ObjectMap_name]) and the permission string or integer value. A permission string can be a comma-delimited string of the previous permission strings such as read, insert, or it can be all. A permission integer value can be any previously mentioned permission integer constants or a mathematical value of several integer permission constants, such as MapPermission.READ|MapPermission.WRITE.

The authorization occurs when an ObjectMap or JavaMap method is called. The run time checks different permissions for different methods. If the required permissions are not granted to the client, an AccessControlException results.

Table 1. List of methods and the required MapPermission

Permission	ObjectMap/JavaMap
read	Boolean containsKey(Object)
	Boolean equals(Object)
	Object get(Object)
	Object get(Object, Serializable)
	List getAll(List)
	List getAll(List keyList, Serializable)
	List getAllForUpdate(List)
	List getAllForUpdate(List, Serializable)
	Object getForUpdate(Object)
	Object getForUpdate(Object, Serializable)
	public Object getNextKey(long)
write	Object put(Object key, Object value)
	void put(Object, Object, Serializable)
	void putAll(Map)
	void putAll(Map, Serializable)
	void update(Object, Object)
	void update(Object, Object, Serializable)
insert	public void insert (Object, Object)
	void insert(Object, Object, Serializable)
remove	Object remove (Object)
	void removeAll(Collection)

Permission	ObjectMap/JavaMap
	void clear()
invalidate	public void invalidate (Object, Boolean)
	void invalidateAll(Collection, Boolean)
	void invalidateUsingKeyword(Serializable)
	int setTimeToLive(int)

Authorization is based solely on which method is used, rather than what the method really does. For example, a put method can insert or update a record based on whether the record exists. However, the insert or update cases are not distinguished.

An operation type can be achieved by combinations of other types. For example, an update can be achieved by a remove and then an insert. Consider these combinations when designing your authorization policies.

ObjectGridPermission

A com.ibm.websphere.objectgrid.security.ObjectGridPermission represents permissions to the ObjectGrid:

- Query: permission to create an object query or entity query. The integer constant is defined as ObjectGridPermission.QUERY.
- Dynamic map: permission to create a dynamic map based on the map template. The integer constant is defined as ObjectGridPermission.DYNAMIC_MAP.

Refer to ObjectGridPermission API documentation for more details.
The following table summarizes the methods and the required ObjectGridPermission:

Table 2. List of methods and the required ObjectGridPermission

Permission action	Methods
`query`	com.ibm.websphere.objectgrid.Session.createObjectQuery(String)
`query`	com.ibm.websphere.objectgrid.em.EntityManager.createQuery(String)
`dynamicmap`	com.ibm.websphere.objectgrid.Session.getMap(String)

ServerMapPermission

An ServerMapPermission represents permissions to an ObjectMap hosted in a server. The name of the permission is the full name of the ObjectGrid map name. It has the following actions:

- **replicate**: permission to replicate a server map to near cache
- **dynamicIndex**: permission for a client to create or remove a dynamic index on a server

Refer to ServerMapPermission API documentation for more details. The detailed methods, which require different ServerMapPermission, are listed in the following table:

Table 3. Permissions to a server-hosted ObjectMap

Permission action	Methods
`replicate`	com.ibm.websphere.objectgrid.ClientReplicableMap.enableClientReplication(Mode, int[], ReplicationMapListener)
`dynamicIndex`	com.ibm.websphere.objectgrid.BackingMap.createDynamicIndex(String, Boolean, String, DynamicIndexCallback)
`dynamicIndex`	com.ibm.websphere.objectgrid.BackingMap.removeDynamicIndex(String)

AgentPermission

An AgentPermission represents permissions to the datagrid agents. The name of the permission is the full name of the ObjectGrid map, and the action is a comma-delimited string of agent implementation class names or package names.

Refer to AgentPermission API documentation for more information.

The following methods in the class com.ibm.websphere.objectgrid.datagrid.AgentManager require AgentPermission.

`com.ibm.websphere.objectgrid.datagrid.AgentManager#callMapAgent(MapGridAgent, Collection)`

`com.ibm.websphere.objectgrid.datagrid.AgentManager#callMapAgent(MapGridAgent)`

`com.ibm.websphere.objectgrid.datagrid.AgentManager#callReduceAgent(ReduceGridAgent, Collection)`

`com.ibm.websphere.objectgrid.datagrid.AgentManager#callReduceAgent(ReduceGridAgent, Collection)`

Authorization mechanisms

WebSphere eXtreme Scale supports two kinds of authorization mechanisms: Java Authentication and Authorization Service (JAAS) authorization and custom authorization. These mechanisms apply to all authorizations. JAAS authorization augments the Java security policies with user-centric access controls. Permissions can be granted based not just on what code is running, but also on who is running it. JAAS authorization is part of the SDK Version 5 and later.

Additionally, WebSphere eXtreme Scale also supports custom authorization with the following plug-in:

- ObjectGridAuthorization: custom way to authorize access to all artifacts.

You can implement your own authorization mechanism if you do not want to use JAAS authorization. By using a custom authorization mechanism, you can use the policy database, policy server, or Tivoli® Access Manager to manage the authorizations.

You can configure the authorization mechanism in two ways:

- XML configuration
  You can use the ObjectGrid XML file to define an ObjectGrid and set the authorization mechanism to either AUTHORIZATION_MECHANISM_JAAS or AUTHORIZATION_MECHANISM_CUSTOM. Here is the secure-objectgrid-definition.xml file that is used in the enterprise application ObjectGridSample:

  ```
  <objectGrids>
          <objectGrid name="secureClusterObjectGrid" securityEnabled="true"
                  authorizationMechanism="AUTHORIZATION_MECHANISM_JAAS">
                  <bean
  id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsprgauthor_TransactionCallback
  "
  classname="com.ibm.websphere.samples.objectgrid.HeapTransactionCallback" />
  ...
  </objectGrids>
  ```

- Programmatic configuration
  If you want to create an ObjectGrid using method ObjectGrid.setAuthorizationMechanism(int), you can call the following method to set the authorization mechanism. Calling this method applies only to the local WebSphere eXtreme Scale programming model when you directly instantiate the ObjectGrid instance:

  ```
  /**
   * Set the authorization Mechanism. The default is
   * com.ibm.websphere.objectgrid.security.SecurityConstants.
   * AUTHORIZATION_MECHANISM_JAAS.
   * @param authMechanism the map authorization mechanism
  */
  void setAuthorizationMechanism(int authMechanism);
  ```

JAAS authorization

A javax.security.auth.Subject object represents an authenticated user. A Subject consists of a set of principals, and each Principal represents an identity for that user. For example, a Subject can have a name principal, for example, Joe Smith, and a group principal, for example, manager.

Using the JAAS authorization policy, permissions can be granted to specific Principals. WebSphere eXtreme Scale associates the Subject with the current access control context. For each call to the ObjectMap or Javamap method, the Java runtime automatically determines if the policy grants the required permission only to a specific Principal and if so, the operation is allowed only if the Subject associated with the access control context contains the designated Principal.

You must be familiar with the policy syntax of the policy file. For detailed description of JAAS authorization, refer to the JAAS Reference Guide.

WebSphere eXtreme Scale has a special code base that is used for checking the JAAS authorization to the ObjectMap and JavaMap method calls. This special code base is `http://www.ibm.com/com/ibm/ws/objectgrid/security/PrivilegedAction`. Use this code base when granting ObjectMap or JavaMap permissions to principals. This special code was created because the Java archive (JAR) file for eXtreme Scale is granted with all permissions.

The template of the policy to grant the MapPermission permission is:

```
grant codeBase "http://www.ibm.com/com/ibm/ws/objectgrid/security/PrivilegedAction"
   <Principal field(s)>{
    permission com.ibm.websphere.objectgrid.security.MapPermission
               "[ObjectGrid_name].[ObjectMap_name]", "action";
    ....
    permission com.ibm.websphere.objectgrid.security.MapPermission
               "[ObjectGrid_name].[ObjectMap_name]", "action";
  };
```

A Principal field looks like the following example:

```
principal Principal_class "principal_name"
```

In this policy, only insert and read permissions are granted to these four maps to a certain principal. The other policy file, fullAccessAuth.policy, grants all permissions to these maps to a principal. Before running the application, change the principal_name and principal class to appropriate values. The value of the principal_name depends on the user registry. For example, if local OS is used as user registry, the machine name is MACH1, the user ID is user1, and the principal_name is `MACH1/user1`.

The JAAS authorization policy can be put directly into the Java policy file, or it can be put in a separate JAAS authorization file and then set in either of two ways:

- Use the following JVM argument:

  ```
  -Djava.security.policy=file:[JAAS_AUTH_POLICY_FILE]
  ```

- Use the following property in the java.security file:

  ```
  -Dauth.policy.url.x=file:[JAAS_AUTH_POLICY_FILE]
  ```

Custom ObjectGrid authorization

ObjectGridAuthorization plug-in is used to authorize ObjectGrid, ObjectMap, and JavaMap accesses to the Principals represented by a Subject object in a custom way. A typical implementation of this plug-in is to retrieve the Principals from the Subject object, and then check whether or not the specified permissions are granted to the Principals.

A permission passed to the checkPermission(Subject, Permission) method could be one of the following:

- MapPermission
- ObjectGridPermission
- AgentPermission
- ServerMapPermission

Refer to ObjectGridAuthorization API documentation for more details.

The ObjectGridAuthorization plug-in can be configured in the following ways:

- XML configuration
  You can use the ObjectGrid XML file to define an ObjectAuthorization plug-in. Here is an example:

```
<objectGrids>
        <objectGrid name="secureClusterObjectGrid" securityEnabled="true"
                authorizationMechanism="AUTHORIZATION_MECHANISM_CUSTOM">
...
                <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxsprgauthor_ObjectGridAuthoriza
tion"
className="com.acme.ObjectGridAuthorizationImpl" />
</objectGrids>
```

- Programmatic configuration
  If you want to create an ObjectGrid using the API method ObjectGrid.setObjectGridAuthorization(ObjectGridAuthorization), you can call the following method to set the authorization plug-in. This method only applies to the local eXtreme Scale programming model when you directly instantiate the ObjectGrid instance.

  Attention: In the following example, some lines of code are continued on the next line for publication purposes.

```
/**
     * Sets the <code>ObjectGridAuthorization</code> for this ObjectGrid instance.
     * <p>
     * Passing <code>null</code> to this method removes a previously set
     * <code>ObjectGridAuthorization</code> object from an earlier invocation of this method
     * and indicates that this <code>ObjectGrid</code> is not associated with a
     * <code>ObjectGridAuthorization</code> object.
     * <p>
     * This method should only be used when ObjectGrid security is enabled. If
     * the ObjectGrid security is disabled, the provided <code>ObjectGridAuthorization</code> object
     * will not be used.
     * <p>
     * A <code>ObjectGridAuthorization</code> plug-in can be used to authorize
     * access to the ObjectGrid and maps. Please refer to <code>ObjectGridAuthorization</code> for more details.
     *
     * <p>
     * As of XD 6.1, the <code>setMapAuthorization</code> is deprecated and
     * <code>setObjectGridAuthorization</code> is recommended for use. However,
     * if both <code>MapAuthorization</code> plug-in and <code>ObjectGridAuthorization</code> plug-in
     * are used, ObjectGrid will use the provided <code>MapAuthorization</code> to authorize map accesses,
     * even though it is deprecated.
     * <p>
     * Note, to avoid an <code>IllegalStateException</code>, this method must be
     * called prior to the <code>initialize()</code> method.  Also, keep in mind
     * that the <code>getSession</code> methods implicitly call the
     * <code>initialize()</code> method if it has yet to be called by the
     * application.
     *
     * @param ogAuthorization the <code>ObjectGridAuthorization</code> plug-in
     *
     * @throws IllegalStateException if this method is called after the
     *         <code>initialize()</code> method is called.
     *
     * @see #initialize()
     * @see ObjectGridAuthorization
     * @since WAS XD 6.1
     */
    void setObjectGridAuthorization(ObjectGridAuthorization ogAuthorization);
```

Implementing ObjectGridAuthorization

The Boolean checkPermission(Subject subject, Permission permission) method of the ObjectGridAuthorization interface is called by theWebSphere eXtreme Scale run time to check whether the passed-in subject object has the passed-in permission. The implementation of the ObjectGridAuthorization interface returns true if the object has the permission, and false if not.

A typical implementation of this plug-in is to retrieve the principals from the Subject object and check whether the specified permissions are granted to the principals by consulting specific policies. These policies are defined by users. For example, the policies can be defined in a database, a plain file, or a Tivoli Access Manager policy server.

For example, we can use Tivoli Access Manager policy server to manage the authorization policy and use its API to authorize the access. For how to use Tivoli Access Manager Authorization APIs, refer to the IBM® Tivoli Access Manager Authorization Java Classes Developer Reference for more details.

This sample implementation has the following assumptions:

- Check authorization for MapPermission only. For other permissions, always return `true`.
- The Subject object contains a com.tivoli.mts.PDPrincipal principal.

- The Tivoli Access Manager policy server has defined the following permissions for the ObjectMap or JavaMap name object. The object that is defined in the policy server must have the same name as the ObjectMap or JavaMap name in the format of [ObjectGrid_name].[ObjectMap_name]. The permission is the first character of the permission strings that are defined in the MapPermission permission. For example, the permission "r" that is defined in the policy server represents the read permission to the ObjectMap map.

The following code snippet demonstrates how to implement the checkPermission method:

```
/**
* @see com.ibm.websphere.objectgrid.security.plugins.
*               MapAuthorization#checkPermission
* (javax.security.auth.Subject, com.ibm.websphere.objectgrid.security.
*               MapPermission)
*/
public boolean checkPermission(final Subject subject,
        Permission p) {

  // For non-MapPermission, we always authorize.
  if (!(p instanceof MapPermission)){
    return true;
  }

  MapPermission permission = (MapPermission) p;

  String[] str = permission.getParsedNames();

  StringBuffer pdPermissionStr = new StringBuffer(5);
  for (int i=0; i<str.length; i++) {
    pdPermissionStr.append(str[i].substring(0,1));
  }

  PDPermission pdPerm = new PDPermission(permission.getName(),
               pdPermissionStr.toString());

  Set principals = subject.getPrincipals();

  Iterator iter= principals.iterator();
  while(iter.hasNext()) {
    try {
      PDPrincipal principal = (PDPrincipal) iter.next();
      if (principal.implies(pdPerm)) {
        return true;
      }
    }
    catch (ClassCastException cce) {
      // Handle exception
    }
  }
  return false;
}
```

Module 4: Use Java Authentication and Authorization Service (JAAS) authorization in WebSphere Application Server

Data grid authentication

You can use the secure token manager plug-in to enable server-to-server authentication, which requires you to implement the SecureTokenManager interface.

The generateToken(Object) method takes an object protect, and then generates a token that cannot be understood by others. The verifyTokens(byte[]) method does the reverse process: it converts the token back to the original object.
A simple SecureTokenManager implementation uses a simple encoding algorithm, such as a XOR algorithm, to encode the object in serialized form and then use corresponding decoding algorithm to decode the token. This implementation is not secure and is easy to break.
WebSphere® eXtreme Scale default implementation
WebSphere eXtreme Scale provides an immediately available implementation for this interface. This default implementation uses a key pair to sign and verify the signature, and uses a secret key to encrypt the content. Every server has a JCEKS type keystore to store the key pair, a private key and public key, and a secret key. The keystore has to be the JCEKS type to store secret keys. These keys are used to encrypt and sign or verify the secret string on the sending end. Also, the token is associated with an expiration time. On the receiving end, the data is verified, decrypted, and compared to the receiver secret string. Secure Sockets Layer (SSL) communication protocols are not required between a pair of servers for authentication because the private keys and public keys serve the same purpose. However, if server communication is not encrypted, the data can be stolen by looking at the communication. Because the token expires soon, the replay attack threat is minimized. This possibility is significantly decreased if all servers are deployed behind a firewall.
The disadvantage of this approach is that the WebSphere eXtreme Scale administrators have to generate keys and transport them to all servers, which can cause security breach during transportation.

Local security programming

WebSphere® eXtreme Scale provides several security endpoints to allow you to integrate custom mechanisms. In the local programming model, the main security function is authorization, and has no authentication support . You must authenticate outside of WebSphere Application Server. However, there are provided plug-ins to obtain and validate Subject objects.

Authentication

In the local programming model, eXtreme Scale does not provide any authentication mechanism, but relies on the environment, either application servers or applications, for authentication. When eXtreme Scale is used in WebSphere Application Server or WebSphere Extended Deployment, applications can use the WebSphere Application Server security authentication mechanism. When eXtreme Scale is running in a Java™ 2 Platform, Standard Edition (J2SE) environment, the application has to manage authentications with Java Authentication and Authorization Service (JAAS) authentication or other authentication mechanisms. For more information about using JAAS authentication, see the JAAS reference guide. The contract between an application and an ObjectGrid instance is the javax.security.auth.Subject object. After the client is authenticated by the application server or the application, the application can retrieve the authenticated javax.security.auth.Subject object and use this Subject object to get a session from the ObjectGrid instance by calling the ObjectGrid.getSession(Subject) method. This Subject object is used to authorize accesses to the map data. This contract is called a subject passing mechanism. The following example illustrates the ObjectGrid.getSession(Subject) API.

```
/**
 * This API allows the cache to use a specific subject rather than the one
 * configured on the ObjectGrid to get a session.
 * @param subject
 * @return An instance of Session
 * @throws ObjectGridException
 * @throws TransactionCallbackException
 * @throws InvalidSubjectException the subject passed in is not valid based
 * on the SubjectValidation mechanism.
 */
public Session getSession(Subject subject)
throws ObjectGridException, TransactionCallbackException, InvalidSubjectException;
```

The ObjectGrid.getSession() method in the ObjectGrid interface can also be used to get a Session object:

```
/**
 * This method returns a Session object that can be used by a single thread at a time.
 * You cannot share this Session object between threads without placing a
 * critical section around it. While the core framework allows the object to move
 * between threads, the TransactionCallback and Loader might prevent this usage,
 * especially in J2EE environments. When security is enabled, this method uses the
 * SubjectSource to get a Subject object.
 *
 * If the initialize method has not been invoked prior to the first
 * getSession invocation, then an implicit initialization occurs.  This
 * initialization ensures that all of the configuration is complete before
 * any runtime usage is required.
 *
 * @see #initialize()
 * @return An instance of Session
 * @throws ObjectGridException
 * @throws TransactionCallbackException
 * @throws IllegalStateException if this method is called after the
 *         destroy() method is called.
 */
public Session getSession()
throws ObjectGridException, TransactionCallbackException;
```

As the API documentation specifies, when security is enabled, this method uses the SubjectSource plug-in to get a Subject object. The SubjectSource plug-in is one of the security plug-ins defined in eXtreme Scale to support propagating Subject objects. See Security-related plug-ins for more information. The getSession(Subject) method can be called on the local ObjectGrid instance only. If you call the getSession(Subject) method on a client side in a distributed eXtreme Scale configuration, an IllegalStateException results.

Security plug-ins

WebSphere eXtreme Scale provides two security plug-ins that are related to the subject passing mechanism: the SubjectSource and SubjectValidation plug-ins.

SubjectSource plug-in

The SubjectSource plug-in, represented by the com.ibm.websphere.objectgrid.security.plugins.SubjectSource interface, is a plug-in that is used to get a Subject object from an eXtreme Scale running environment. This environment can be an application using the ObjectGrid or an application server that hosts the application. Consider the SubjectSource plug-in an alternative to the subject passing mechanism. Using the subject passing mechanism, the application retrieves the Subject object and uses it to get the ObjectGrid session object. With the SubjectSource plug-in, the eXtreme Scale runtime retrieves the Subject object and uses it to get the session object. The subject passing mechanism gives the control of Subject objects to applications, while the SubjectSource plug-in mechanism frees applications from retrieving the Subject object. You can use the SubjectSource plug-in to get a Subject object that represents an eXtreme Scale client that is used for authorization. When the ObjectGrid.getSession method is called, the Subject getSubject throws an ObjectGridSecurityException if security is enabled. WebSphere eXtreme Scale provides a default implementation of this plug-in: com.ibm.websphere.objectgrid.security.plugins.builtins.WSSubjectSourceImpl. This implementation can be used to retrieve a caller subject or a RunAs subject from the thread when an application is running in WebSphere Application Server. You can configure this class in your ObjectGrid descriptor XML file as the SubjectSource implementation class when using eXtreme Scale in WebSphere Application Server. The following code snippet shows the main flow of the WSSubjectSourceImpl.getSubject method.

```
Subject s = null;
try {
  if (finalType == RUN_AS_SUBJECT) {
    // get the RunAs subject
    s = com.ibm.websphere.security.auth.WSSubject.getRunAsSubject();
  }
  else if (finalType == CALLER_SUBJECT) {
    // get the callersubject
    s = com.ibm.websphere.security.auth.WSSubject.getCallerSubject();
  }
}
catch (WSSecurityException wse) {
  throw new ObjectGridSecurityException(wse);
}

return s;
```

For other details, refer to the API documentation for the SubjectSource plug-in and the WSSubjectSourceImpl implementation.

SubjectValidation plug-in

The SubjectValidation plug-in, which is represented by the com.ibm.websphere.objectgrid.security.plugins.SubjectValidation interface, is another security plug-in. The SubjectValidation plug-in can be used to validate that a javax.security.auth.Subject, either passed to the ObjectGrid or retrieved by the SubjectSource plug-in, is a valid Subject that has not been tampered with.

The SubjectValidation.validateSubject(Subject) method in the SubjectValidation interface takes a Subject object and returns a Subject object. Whether a Subject object is considered valid and which Subject object is returned are all up to your implementations. If the Subject object is not valid, an InvalidSubjectException results.

You can use this plug-in if you do not trust the Subject object that is passed to this method. This case is rare considering that you trust the application developers who develop the code to retrieve the Subject object.

An implementation of this plug-in needs support from the Subject object creator because only the creator knows if the Subject object has been tampered with. However, some subject creator might not know if the Subject has been tampered with. In this case, this plug-in is not useful.

WebSphere eXtreme Scale provides a default implementation of SubjectValidation: com.ibm.websphere.objectgrid.security.plugins.builtins.WSSubjectValidationImpl. You can use this implementation to validate the WebSphere Application Server-authenticated subject. You can configure this class as the SubjectValidation implementation class when using eXtreme Scale in WebSphere Application Server. The WSSubjectValidationImpl implementation considers a Subject object valid only if the credential token that is associated with this Subject has not been tampered with. You can change other parts of the Subject object. The WSSubjectValidationImpl implementation asks WebSphere Application Server for the original Subject corresponding to the credential token and returns the original Subject object as the validated Subject object. Therefore, the changes made to the Subject contents other than the credential token have no effects. The following code snippet shows the basic flow of the WSSubjectValidationImpl.validateSubject(Subject).

```
// Create a LoginContext with scheme WSLogin and
// pass a Callback handler.
LoginContext lc = new LoginContext("WSLogin",
new WSCredTokenCallbackHandlerImpl(subject));

// When this method is called, the callback handler methods
// will be called to log the user in.
lc.login();

// Get the subject from the LoginContext
return lc.getSubject();
```

In the previous code snippet, a credential token callback handler object, WSCredTokenCallbackHandlerImpl, is created with the Subject object to validate. Then a LoginContext object is created with the login scheme WSLogin. When the lc.login method is called, WebSphere Application Server security retrieves the credential token from the Subject object and then returns the correspondent Subject as the validated Subject object.
For other details, refer to the Java APIs of SubjectValidation and WSSubjectValidationImpl implementation.

Plug-in configuration

You can configure the SubjectValidation plug-in and SubjectSource plug-in in two ways:

- **XML Configuration**You can use the ObjectGrid XML file to define an ObjectGrid and set these two plug-ins. Here is an example, in which the WSSubjectSourceImpl class is configured as the SubjectSource plug-in and the WSSubjectValidation class is configured as the SubjectValidation plug-in. Attention: In the following example, some lines of code are continued on the next line for publication purposes.

  ```
  <objectGrids>
          <objectGrid name="secureClusterObjectGrid" securityEnabled="true"
                  authorizationMechanism="AUTHORIZATION_MECHANISM_JAAS">
          <bean
  id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxslocalsec_SubjectSource"
  className="com.ibm.websphere.objectgrid.security.plugins.builtins.
          WSSubjectSourceImpl" />
                            <bean
  id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxslocalsec_SubjectValidation"
   className="com.ibm.websphere.objectgrid.security.plugins.builtins.
          WSSubjectValidationImpl" />
                            <bean
  id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_cxslocalsec_TransactionCallback"
  className="com.ibm.websphere.samples.objectgrid.
          HeapTransactionCallback" />
  ...
  </objectGrids>
  ```

- **Programming** If you want to create an ObjectGrid through APIs, you can call the following methods to set the SubjectSource or SubjectValidation plug-ins.

```
**
* Set the SubjectValidation plug-in for this ObjectGrid instance. A
* SubjectValidation plug-in can be used to validate the Subject object
* passed in as a valid Subject. Refer to {@link SubjectValidation}
* for more details.
* @param subjectValidation the SubjectValidation plug-in
*/
void setSubjectValidation(SubjectValidation subjectValidation);

/**
* Set the SubjectSource plug-in. A SubjectSource plug-in can be used
* to get a Subject object from the environment to represent the
* ObjectGrid client.
*
* @param source the SubjectSource plug-in
*/
void setSubjectSource(SubjectSource source);
```

Write your own JAAS authentication code

You can write you own Java Authentication and Authorization Service (JAAS) authentication code to handle the authentication. You need to write your own login modules and then configure the login modules for your authentication module.

The login module receives information about a user and authenticates the user. This information can be anything that can identify the user. For example, the information can be a user ID and password, client certificate, and so on. After receiving the information, the login module verifies that the information represents a valid subject and then creates a Subject object. Currently, several implementations of login modules are available to the public.

After a login module is written, configure this login module for the run time to use. You must configure a JAAS login module. This login module file contains the module and its authentication scheme. For example:

```
FileLogin
{
    com.acme.auth.FileLoginModule required
};
```

The authentication scheme is FileLogin and the login module is com.acme.auth.FileLoginModule. The required token indicates that the FileLoginModule module must validate this login or the entire scheme fails.

Setting the JAAS login module configuration file can be done in one of the following ways:

- Set the JAAS login module configuration file in the login.config.url property in the java.security file, for example:

  ```
  login.config.url.1=file:${java.home}/lib/security/file.login
  ```

- Set the JAAS login module configuration file from the command line by using the **-Djava.security.auth.login.config** Java virtual machine (JVM) arguments , for example, `-Djava.security.auth.login.config ==$JAVA_HOME/lib/security/file.login`

For more information, see Java SE security tutorial - Step 2.For more information, see Java SE security tutorial - Step 2.
If your code is running in WebSphere Application Server, you must configure the JAAS login in the administrative console and store this login configuration in the application server configuration. See Login configuration for Java Authentication and Authorization Service for details.

Troubleshooting

In addition to the logs and trace, messages, and release notes discussed in this section, you can use monitoring tools to figure out issues such as the location of data in the environment, the availability of servers in the data grid, and so on. If you are running in a WebSphere® Application Server environment, you can use Performance Monitoring Infrastructure (PMI). If you are running in a stand-alone environment, you can use a vendor monitoring tool, such as CA Wily Introscope or Hyperic HQ. You can also use and customize the **xscmd** utility to display textual information about your environment.

- Troubleshooting and support for WebSphere eXtreme Scale
  To isolate and resolve problems with your IBM products, you can use the troubleshooting and support information. This information contains instructions for using the problem-determination resources that are provided with your IBM products, including WebSphere eXtreme Scale .
- Enabling logging
  You can use logs to monitor and troubleshoot your environment.
- Collecting trace
  You can use trace to monitor and troubleshoot your environment. You must provide trace for a server when you work with IBM® support.
- Analyzing log and trace data
  You can use the log analysis tools to analyze how your runtime environment is performing and solve problems that occur in the environment.
- 8.5+ Troubleshooting the product installation
  IBM Installation Manager is a common installer for many IBM software products that you use to install this version of WebSphere eXtreme Scale.
- Troubleshooting client connectivity
  There are several common problems specific to clients and client connectivity that you can solve as described in the following sections.
- Troubleshooting cache integration
  Use this information to troubleshoot issues with your cache integration configuration, including HTTP session and dynamic cache configurations.

- Troubleshooting the JPA cache plug-in
  Use this information to troubleshoot issues with your JPA cache plug-in configuration. These problems can occur in both Hibernate and OpenJPA configurations.
- Troubleshooting IBM eXtremeMemory
  Use the following information to troubleshoot eXtremeMemory.
- Troubleshooting administration
  Use the following information to troubleshoot administration, including starting and stopping servers, using the **xscmd** utility, and so on.
- Troubleshooting multiple data center configurations
  Use this information to troubleshoot multiple data center configurations, including linking between catalog service domains.
- Troubleshooting high availability
  Use this information to troubleshoot high availability.
- Troubleshooting loaders
  Use this information to troubleshoot issues with your database loaders.
- Troubleshooting XML configuration
  When you configure eXtreme Scale, you can encounter unexpected behavior with your XML files. The following sections describe problems that can occur and solutions.
- Troubleshooting deadlocks
  The following sections describe some of the most common deadlock scenarios and suggestions on how to avoid them.
- Troubleshooting security
  Use this information to troubleshoot issues with your security configuration.
- Troubleshooting Liberty profile configurations
  Use this information to troubleshoot commonly experienced problems with the Liberty profile.
- IBM Support Assistant for WebSphere eXtreme Scale
  You can use the IBM Support Assistant to collect data, analyze symptoms, and access product information.

Troubleshooting and support for WebSphere eXtreme Scale

To isolate and resolve problems with your IBM products, you can use the troubleshooting and support information. This information contains instructions for using the problem-determination resources that are provided with your IBM products, including WebSphere® eXtreme Scale .

- Techniques for troubleshooting problems
  Troubleshooting is a systematic approach to solving a problem. The goal of troubleshooting is to determine why something does not work as expected and how to resolve the problem. Certain common techniques can help with the task of troubleshooting.
- Searching knowledge bases
  You can often find solutions to problems by searching IBM knowledge bases. You can optimize your results by using available resources, support tools, and search methods.
- Getting fixes
  A product fix might be available to resolve your problem.
- Contacting IBM Support
  IBM Support provides assistance with product defects, answers FAQs, and helps users resolve problems with the product.
- Exchanging information with IBM
  To diagnose or identify a problem, you might need to provide IBM Support with data and information from your system. In other cases, IBM Support might provide you with tools or utilities to use for problem determination.
- Subscribing to Support updates
  To stay informed of important information about the IBM products that you use, you can subscribe to updates.

Techniques for troubleshooting problems

Troubleshooting is a systematic approach to solving a problem. The goal of troubleshooting is to determine why something does not work as expected and how to resolve the problem. Certain common techniques can help with the task of troubleshooting.
The first step in the troubleshooting process is to describe the problem completely. Problem descriptions help you and the IBM technical-support representative know where to start to find the cause of the problem. This step includes asking yourself basic questions:

- What are the symptoms of the problem?
- Where does the problem occur?
- When does the problem occur?
- Under which conditions does the problem occur?
- Can the problem be reproduced?

The answers to these questions typically lead to a good description of the problem, which can then lead you to a problem resolution.

What are the symptoms of the problem?

When starting to describe a problem, the most obvious question is "What is the problem?" This question might seem straightforward; however, you can break it down into several more-focused questions that create a more descriptive picture of the problem. These questions can include:

- Who, or what, is reporting the problem?
- What are the error codes and messages?
- How does the system fail? For example, is it a loop, hang, crash, performance degradation, or incorrect result?

Where does the problem occur?

Determining where the problem originates is not always easy, but it is one of the most important steps in resolving a problem. Many layers of technology can exist between the reporting and failing components. Networks, the data grid, and servers are only a few of the components to consider when you are investigating problems.

The following questions help you to focus on where the problem occurs to isolate the problem layer:

- Is the problem specific to one platform or operating system, or is it common across multiple platforms or operating systems?
- Is the current environment and configuration supported?
- Do all users have the problem?
- (For multi-site installations.) Do all sites have the problem?

If one layer reports the problem, the problem does not necessarily originate in that layer. Part of identifying where a problem originates is understanding the environment in which it exists. Take some time to completely describe the problem environment, including the operating system and version, all corresponding software and versions, and hardware information. Confirm that you are running within an environment that is a supported configuration; many problems can be traced back to incompatible levels of software that are not intended to run together or have not been fully tested together.

When does the problem occur?

Develop a detailed timeline of events leading up to a failure, especially for those cases that are one-time occurrences. You can most easily develop a timeline by working backward: Start at the time an error was reported (as precisely as possible, even down to the millisecond), and work backward through the available logs and information. Typically, you need to look only as far as the first suspicious event that you find in a diagnostic log.

To develop a detailed timeline of events, answer these questions:

- Does the problem happen only at a certain time of day or night?
- How often does the problem happen?
- What sequence of events leads up to the time that the problem is reported?
- Does the problem happen after an environment change, such as upgrading or installing software or hardware?

Responding to these types of questions can give you a frame of reference in which to investigate the problem.

Under which conditions does the problem occur?

Knowing which systems and applications are running at the time that a problem occurs is an important part of troubleshooting. These questions about your environment can help you to identify the root cause of the problem:

- Does the problem always occur when the same task is being performed?
- Does a certain sequence of events need to happen for the problem to occur?
- Do any other applications fail at the same time?

Answering these types of questions can help you explain the environment in which the problem occurs and correlate any dependencies. Remember that just because multiple problems might have occurred around the same time, the problems are not necessarily related.

Can the problem be reproduced?

From a troubleshooting standpoint, the ideal problem is one that can be reproduced. Typically, when a problem can be reproduced you have a larger set of tools or procedures at your disposal to help you investigate. Consequently, problems that you can reproduce are often easier to debug and solve.

However, problems that you can reproduce can have a disadvantage: If the problem is of significant business impact, you do not want it to recur. If possible, re-create the problem in a test or development environment, which typically offers you more flexibility and control during your investigation.

- Can the problem be re-created on a test system?
- Are multiple users or applications encountering the same type of problem?
- Can the problem be recreated by running a single command, a set of commands, or a particular application?

Searching knowledge bases

You can often find solutions to problems by searching IBM knowledge bases. You can optimize your results by using available resources, support tools, and search methods.

About this task

You can find useful information by searching the information center for WebSphere® eXtreme Scale . However, sometimes you need to look beyond the information center to answer your questions or resolve problems.

Procedure

To search knowledge bases for information that you need, use one or more of the following approaches:

- Search for content by using the IBM® Support Assistant (ISA).

ISA is a no-charge software serviceability workbench that helps you answer questions and resolve problems with IBM software products. You can find instructions for downloading and installing ISA on the ISA website.

- Find the content that you need by using the IBM Support Portal.
  The IBM Support Portal is a unified, centralized view of all technical support tools and information for all IBM systems, software, and services. The IBM Support Portal lets you access the IBM electronic support portfolio from one place. You can tailor the pages to focus on the information and resources that you need for problem prevention and faster problem resolution. Familiarize yourself with the IBM Support Portal by viewing the demo videos (https://www.ibm.com/blogs/SPNA/entry/the_ibm_support_portal_videos) about this tool. These videos introduce you to the IBM Support Portal, explore troubleshooting and other resources, and demonstrate how you can tailor the page by moving, adding, and deleting portlets.

- Search for content about WebSphere eXtreme Scale by using one of the following additional technical resources:
  - WebSphere eXtreme Scale release notes
  - WebSphere eXtreme Scale Support website
  - WebSphere eXtreme Scale forum
- Search for content by using the IBM masthead search. You can use the IBM masthead search by typing your search string into the Search field at the top of any ibm.com® page.
- Search for content by using any external search engine, such as Google, Yahoo, or Bing. If you use an external search engine, your results are more likely to include information that is outside the ibm.com domain. However, sometimes you can find useful problem-solving information about IBM products in newsgroups, forums, and blogs that are not on ibm.com.
  Tip: Include "IBM" and the name of the product in your search if you are looking for information about an IBM product.

Getting fixes

A product fix might be available to resolve your problem.

Procedure

To find and install fixes:

1. Obtain the tools required to get the fix. Use the IBM Update Installer to install and apply various types of maintenance packages for WebSphere eXtreme Scale or WebSphere eXtreme Scale Client. Because the Update Installer undergoes regular maintenance, you must use the most current version of the tool.
2. Determine which fix you need. See the Recommended fixes for WebSphere eXtreme Scale to select the latest fix. When you select a fix, the download document for that fix opens.
3. Download the fix. In the download document, click the link for the latest fix in the "Download package" section.
4. Apply the fix. Follow the instructions in the "Installation Instructions" section of the download document.
5. Subscribe to receive weekly e-mail notifications about fixes and other IBM Support information.

- Getting fixes from Fix Central
  You can use Fix Central to find the fixes that are recommended by IBM Support for a variety of products, including WebSphere eXtreme Scale . With Fix Central, you can search, select, order, and download fixes for your system with a choice of delivery options. A WebSphere eXtreme Scale product fix might be available to resolve your problem.

Getting fixes from Fix Central

You can use Fix Central to find the fixes that are recommended by IBM Support for a variety of products, including WebSphere® eXtreme Scale . With Fix Central, you can search, select, order, and download fixes for your system with a choice of delivery options. A WebSphere eXtreme Scale product fix might be available to resolve your problem.

Procedure

To find and install fixes:

1. Obtain the tools that are required to get the fix. If it is not installed, obtain your product update installer. You can download the installer from Fix Central. This site provides download, installation, and configuration instructions for the update installer.
2. Select as the product, and select one or more check boxes that are relevant to the problem that you want to resolve.
3. Identify and select the fix that is required.
4. Download the fix.
   a. Open the download document and follow the link in the "Download Package" section.
   b. When downloading the file, ensure that the name of the maintenance file is not changed. This change might be intentional, or it might be an inadvertent change that is caused by certain web browsers or download utilities.
5. Apply the fix.
   a. Follow the instructions in the "Installation Instructions" section of the download document.
   b. For more information, see the "Installing fixes with the Update Installer" topic in the product documentation.
6. Optional: Subscribe to receive weekly e-mail notifications about fixes and other IBM Support updates.

Contacting IBM Support

IBM Support provides assistance with product defects, answers FAQs, and helps users resolve problems with the product.

Before you begin

After trying to find your answer or solution by using other self-help options, such as release notes, you can contact IBM Support. Before contacting IBM Support, your company or organization must have an active IBM maintenance contract, and you must be authorized to submit problems to IBM. For information about the types of available support, see the Support portfolio topic in the "*Software Support Handbook*".

Procedure

To contact IBM Support about a problem:

1. Define the problem, gather background information, and determine the severity of the problem. For more information, see the Getting IBM support topic in the *Software Support Handbook*.
2. Gather diagnostic information.
3. Submit the problem to IBM Support in one of the following ways:
   - With IBM® Support Assistant (ISA). For more information, see IBM Support Assistant for WebSphere eXtreme Scale.
   - Online through the IBM Support Portal: You can open, update, and view all of your service requests from the Service Request portlet on the Service Request page.
   - By phone: For the phone number to call in your region, see the Directory of worldwide contacts web page.

Results

If the problem that you submit is for a software defect or for missing or inaccurate documentation, IBM Support creates an Authorized Program Analysis Report (APAR). The APAR describes the problem in detail. Whenever possible, IBM Support provides a workaround that you can implement until the APAR is resolved and a fix is delivered. IBM publishes resolved APARs on the IBM Support website daily, so that other users who experience the same problem can benefit from the same resolution.

Exchanging information with IBM

To diagnose or identify a problem, you might need to provide IBM Support with data and information from your system. In other cases, IBM Support might provide you with tools or utilities to use for problem determination.

Sending information to IBM Support

To reduce the time that is required to resolve your problem, you can send trace and diagnostic information to IBM Support.

Procedure

To submit diagnostic information to IBM Support:

1. Open a problem management record (PMR).
2. Collect the diagnostic data that you need. Diagnostic data helps reduce the time that it takes to resolve your PMR. You can collect the diagnostic data manually or automatically:
   - Collect the data manually.
   - Collect the data automatically.
3. Compress the files by using the .zip or .tar file format.
4. Transfer the files to IBM. You can use one of the following methods to transfer the files to IBM:
   - IBM® Support Assistant
   - The Service Request tool
   - Standard data upload methods: FTP, HTTP
   - Secure data upload methods: FTPS, SFTP, HTTPS
   - E-mail

   If you are using a z/OS product and you use ServiceLink / IBMLink to submit PMRs, you can send diagnostic data to IBM Support in an e-mail or by using FTP.

   All of these data exchange methods are explained on the IBM Support website.

Receiving information from IBM Support

Occasionally an IBM technical-support representative might ask you to download diagnostic tools or other files. You can use FTP to download these files.

Before you begin

Ensure that your IBM technical-support representative provided you with the preferred server to use for downloading the files and the exact directory and file names to access.

Procedure

To download files from IBM Support:

1. Use FTP to connect to the site that your IBM technical-support representative provided and log in as `anonymous`. Use your e-mail address as the password.
2. Change to the appropriate directory:
    a. Change to the /fromibm directory.

    ```
    cd fromibm
    ```

    b. Change to the directory that your IBM technical-support representative provided.

    ```
    cd nameofdirectory
    ```

3. Enable binary mode for your session.

    ```
    binary
    ```

4. Use the **get** command to download the file that your IBM technical-support representative specified.

    ```
    get filename.extension
    ```

5. End your FTP session.

    ```
    quit
    ```

Subscribing to Support updates

To stay informed of important information about the IBM products that you use, you can subscribe to updates.

About this task

By subscribing to receive updates about the product, you can receive important technical information and updates for specific IBM Support tools and resources. You can subscribe to updates by using one of two approaches:

Social media subscriptions
: The following RSS feed is available for the product:

    - RSS feed for WebSphere® eXtreme Scale forum

    For general information about RSS, including steps for getting started and a list of RSS-enabled IBM web pages, visit the IBM Software Support RSS feeds site.

My Notifications
: With My Notifications, you can subscribe to Support updates for any IBM product. My Notifications replaces My Support, which is a similar tool that you might have used in the past. With My Notifications, you can specify that you want to receive daily or weekly e-mail announcements. You can specify what type of information you want to receive, such as publications, hints and tips, product flashes (also known as alerts), downloads, and drivers. My Notifications enables you to customize and categorize the products about which you want to be informed and the delivery methods that best suit your needs.

Procedure

To subscribe to Support updates:

1. Subscribe to the RSS feed for the WebSphere eXtreme Scale forum .
    a. On the subscription page, click the RSS feed icon.
    b. Select the option that you want to use to subscribe to the feed.
    c. Click Subscribe.
2. Subscribe to My Notifications by going to the IBM® Support Portal and click My Notifications in the Notifications portlet.
3. Sign in using your IBM ID and password, and click Submit.
4. Identify what and how you want to receive updates.
    a. Click the Subscribe tab.
    b. Select the appropriate software brand or type of hardware.
    c. Select one or more products by name and click Continue.
    d. Select your preferences for how to receive updates, whether by e-mail, online in a designated folder, or as an RSS or Atom feed.
    e. Select the types of documentation updates that you want to receive, for example, new information about product downloads and discussion group comments.
    f. Click Submit.

Results

Until you modify your RSS feeds and My Notifications preferences, you receive notifications of updates that you have requested. You can modify your preferences when needed; for example, if you stop using one product and begin using another product.

Enabling logging

You can use logs to monitor and troubleshoot your environment.

About this task

Logs are saved different locations and formats depending on your configuration.

Procedure

- **Enable logs in a stand-alone environment.**
  With stand-alone catalog servers, the logs are in the location where you run the start server command. For container servers, you can use the default location or set a custom log location:
  - **Default log location:** The logs are in the directory where the start server command was run. If you start the servers in the *wxs_home*/bin directory, the logs and trace files are in the logs/*<server_name>* directories in the bin directory.
  - **Custom log location:** To specify an alternate location for container server logs, create a properties file, such as server.properties, with the following contents:

    ```
    workingDirectory=<directory>
    traceSpec=
    systemStreamToFileEnabled=true
    ```

    The workingDirectory property is the root directory for the logs and optional trace file. WebSphere® eXtreme Scale creates a directory with the name of the container server with a SystemOut.log file, a SystemErr.log file, and a trace file. To use a properties file during container startup, use the -serverProps option and provide the server properties file location.
- **Enable logs in WebSphere Application Server.**
  See WebSphere Application Server: Enabling and disabling logging for more information.
- **Retrieve FFDC files.**
  FFDC files are for IBM® support to aid in debug. These files might be requested by IBM support when a problem occurs. These files are in a directory labeled, `ffdc`, and contain files that resemble the following:

  ```
  server2_exception.log
  server2_20802080_07.03.05_10.52.18_0.txt
  ```

What to do next

View the log files in their specified locations. Common messages to look for in the SystemOut.log file are start confirmation messages, such as the following example:

```
CWOBJ1001I: ObjectGrid Server catalogServer01 is ready to process requests.
```

For more information about a specific message in the log files, see Messages.

Collecting trace

You can use trace to monitor and troubleshoot your environment. You must provide trace for a server when you work with IBM® support.

About this task

Collecting trace can help you monitor and fix problems in your deployment of WebSphere® eXtreme Scale. How you collect trace depends on your configuration. See Server trace options for a list of the different trace specifications you can collect.

Procedure

- **Collect trace within a WebSphere Application Server environment.**
  If your catalog and container servers are in a WebSphere Application Server environment, see WebSphere Application Server: Working with trace for more information.
- **Collect trace with the stand-alone catalog or container server start command.**
  You can set trace on a catalog service or container server by using the -traceSpec and -traceFile parameters with the start server command. For example:

```
startOgServer.sh catalogServer -traceSpec ObjectGridPlacement=all=enabled -traceFile  /home/user1/logs/trace.log
```

The -traceFile parameter is optional. If you do not set a -traceFile location, the trace file goes to the same location as the system out log files.

For more information about these parameters, see startOgServer script .

- **Collect trace on the stand-alone catalog or container server with a properties file.**
  To collect trace from a properties file, create a file, such as a server.properties file, with the following contents:

  ```
  workingDirectory=<directory>
  traceSpec=<trace_specification>
  systemStreamToFileEnabled=true
  ```

  The workingDirectory property is the root directory for the logs and optional trace file. If the workingDirectory value is not set, the default working directory is the location used to start the servers, such as *wxs_home*/bin. To use a properties file during server startup, use the -serverProps parameter with the **startOgServer** command and provide the server properties file location.
  For more information about the server properties file and how to use the file, see Server properties file.
- **Collect trace on a stand-alone client.**
  You can start trace collection on a stand-alone client by adding system properties to the startup script for the client application. In the following example, trace settings are specified for the `com.ibm.samples.MyClientProgram` application:

  ```
  java -DtraceSettingsFile=MyTraceSettings.properties
  -Djava.util.logging.manager=com.ibm.ws.bootstrap.WsLogManager
  -Djava.util.logging.configureByServer=true com.ibm.samples.MyClientProgram
  ```

  Fore more information, see WebSphere Application Server: Enabling trace on client and stand-alone applications.
- **Collect trace with the ObjectGridManager interface.**
  You can also set trace during run time on an ObjectGridManager interface. Setting trace on an ObjectGridManager interface can be used to get trace on an eXtreme Scale client while it connects to an eXtreme Scale and commits transactions. To set trace on an ObjectGridManager interface, supply a trace specification and a trace log.

  ```
  ObjectGridManager manager = ObjectGridManagerFactory.getObjectGridManager();
  ...
  manager.setTraceEnabled(true);
  manager.setTraceFileName("logs/myClient.log");
  manager.setTraceSpecification("ObjectGridReplication=all=enabled");
  ```

  For more information about the ObjectGridManager interface, see Interacting with an ObjectGrid using the ObjectGridManager interface.
- **Collect trace on container servers with the xscmd utility.**
  To collect trace with the **xscmd** utility, use the -c setTraceSpec command. Use the **xscmd** utility to collect trace on a stand-alone environment during run time instead of during startup. You can collect trace on all servers and catalog services or you can filter the servers based on the ObjectGrid name, and other properties. For example, to collect ObjectGridReplication trace with access to the catalog service server, run:

  ```
  xscmd -c setTraceSpec -spec "ObjectGridReplication=all=enabled"
  ```

  You can also disable trace by setting the trace specification to `*=all=disabled`.

Results

Trace files are written to the specified location.

- Server trace options
  You can enable trace to provide information about your environment to IBM support.

Server trace options

You can enable trace to provide information about your environment to IBM® support.

Trace option components

WebSphere® eXtreme Scale trace is divided into several different components. You can specify the level of trace to use for a catalog server or container server. Common levels of trace include: all, debug, entryExit, and event.
An example trace string follows:

```
ObjectGridComponent=level=enabled
```

You can concatenate trace strings. Use the `*` (asterisk) symbol to specify a wildcard value, such as `ObjectGrid*=all=enabled`. If you need to provide a trace to IBM support, a specific trace string is requested. For example, if a problem with replication occurs, the `ObjectGridReplication=debug=enabled` trace string might be requested.

Trace specification

Table 1. Trace options. Trace options for WebSphere eXtreme Scale

Trace option	Description
ObjectGrid	General core cache engine.
ObjectGridCacheInvalidator	Near-cache invalidation
ObjectGridCatalogServer	General catalog service.
ObjectGridChannel	Static deployment topology communications.
ObjectGridClientInfo	DB2® client information.
ObjectGridClientInfoUser	DB2 user information.
ObjectgridCORBA	Dynamic deployment topology communications.
ObjectGridDataGrid	The AgentManager API.
ObjectGridDynaCache	The WebSphere eXtreme Scale dynamic cache provider.
ObjectGridEntityManager	The EntityManager API. Use with the Projector option.
ObjectGridEvictors	ObjectGrid built-in evictors.
ObjectGridJPA	Java™ Persistence API (JPA) loaders.
ObjectGridJPACache	JPA cache plug-ins.
ObjectGridLocking	ObjectGrid cache entry lock manager.
ObjectGridMBean	Management beans.
ObjectGridMonitor	Historical monitoring infrastructure.
ObjectGridNative	WebSphere eXtreme Scale native code trace, including eXtremeMemory native code.
ObjectGridOSGi	The WebSphere eXtreme Scale OSGi integration components.
ObjectGridPlacement	Catalog server shard placement service.
ObjectGridPubSub	Catalog and container server shard placement service.
ObjectGridQuery	ObjectGrid query.
ObjectGridReplication	Replication service.
ObjectGridRest	REST gateway.
ObjectGridRouting	Client/server routing details.
ObjectGridSecurity	Security trace.
ObjectGridSerializer	The DataSerializer plug-in infrastructure.
ObjectGridStats	ObjectGrid statistics.
ObjectGridTransactionManager	The WebSphere eXtreme Scale transaction manager.
ObjectGridWriteBehind	ObjectGrid write behind.
ObjectGridXM	General IBM eXtremeMemory trace.
ObjectGridXMEviction	eXtremeMemory eviction trace.
ObjectGridXMTransport	eXtremeMemory general transport trace.
ObjectGridXMTransportInbound	eXtremeMemory inbound specific transport trace.
ObjectGridXMTransportOutbound	eXtremeMemory outbound specific transport trace.
Projector	The engine within the EntityManager API.
QueryEngine	The query engine for the Object Query API and EntityManager Query API.
QueryEnginePlan	Query plan trace.
TCPChannel	The IBM eXtremeIO TCP/IP channel.
WXSRevision	Revision control for replication.
XsByteBuffer	WebSphere eXtreme Scale byte buffer trace.

Analyzing log and trace data

You can use the log analysis tools to analyze how your runtime environment is performing and solve problems that occur in the environment.

About this task

You can generate reports from the existing log and trace files in the environment. These visual reports can be used for the following purposes:

- **To analyze runtime environment status and performance:**
  - Deployment environment consistency
  - Logging frequency
  - Running topology versus configured topology
  - Unplanned topology changes
  - Partition replication status
  - Statistics of memory, throughput, processor usage, and so on
- **To troubleshoot problems in the environment:**
  - Topology views at specific points in time
  - Statistics of memory, throughput, processor usage during client failures
  - Current fix pack levels, tuning settings

- Log analysis overview
  You can use the **xsLogAnalyzer** tool to help troubleshoot issues in the environment.
- Running log analysis
  You can run the **xsLogAnalyzer** tool on a set of log and trace files from any computer.
- Creating custom scanners for log analysis
  You can create custom scanners for log analysis. After you configure the scanner, the results are generated in the reports when you run the **xsLogAnalyzer** tool. The custom scanner scans the logs for event records based on the regular expressions that you specified.
- Troubleshooting log analysis
  Use the following troubleshooting information to diagnose and fix problems with the **xsLogAnalyzer** tool and its generated reports.

Log analysis overview

You can use the **xsLogAnalyzer** tool to help troubleshoot issues in the environment.

All failover messages

Displays the total number of failover messages as a chart over time. Also displays a list of the failover messages, including the servers that have been affected

All eXtreme Scale critical messages

Displays message IDs along with the associated explanations and user actions, which can save you the time from searching for messages.

All exceptions

Displays the top five exceptions, including the messages and how many times they occurred, and what servers were affected by the exception.

Topology summary

Displays a diagram of how your topology is configured according to the log files. You can use this summary to compare to your actual configuration, possibly identifying configuration errors.

Topology consistency: Object Request Broker (ORB) comparison table

Displays ORB settings in the environment. You can use this table to help determine if the settings are consistent across your environment.

Event timeline view

Displays a timeline diagram of different actions that have occurred on the data grid, including life cycle events, exceptions, critical messages, and first-failure data capture (FFDC) events.

Running log analysis

You can run the **xsLogAnalyzer** tool on a set of log and trace files from any computer.

Before you begin

- Enable logs and trace. See Enabling logging and Collecting trace for more information.

- Collect your log files. The log files can be in various locations depending on how you configured them. If you are using the default log settings, you can get the log files from the following locations:
  - In a stand-alone installation: *wxs_install_root*/bin/logs/*<server_name>*
  - In an installation that is integrated with WebSphere® Application Server: *was_root*/logs/*<server_name>*
- Collect your trace files. The trace files can be in various locations depending on how you configured them. If you are using the default trace settings, you can get the trace files from the following locations:
  - In a stand-alone installation: If no specific trace value is set, the trace files are written to the same location as the system out log files.
  - In an installation that is integrated with WebSphere Application Server: *was_root*/profiles/*server_name*/logs.

  Copy the log and trace files to the computer from which you are planning to use the log analyzer tool.
- If you want to create custom scanners in your generated report, create a scanner specifications properties file and configuration file before you run the tool. For more information, see Creating custom scanners for log analysis.

Procedure

1. Run the **xsLogAnalyzer** tool.
   The script is in the following locations :
   - In a stand-alone installation: *wxs_install_root*/ObjectGrid/bin
   - In an installation that is integrated with WebSphere Application Server: *was_root*/bin

   Tip: If your log files are large, consider using the -startTime, -endTime, and -maxRecords parameters when you run the report to restrict the number of log entries that are scanned. Using these parameters when you run the report makes the reports easier to read and run more effectively. You can run multiple reports on the same set of log files.

   ```
   xsLogAnalyzer.sh|bat -logsRoot c:\myxslogs -outDir c:\myxslogs\out
   -startTime 11.09.27_15.10.56.089 -endTime 11.09.27_16.10.56.089 -maxRecords 100
   ```

   -logsRoot
   : Specifies the absolute path to the log directory that you want to evaluate (required).

   -outDir
   : Specifies an existing directory to write the report output. If you do not specify a value, the report is written to the root location of the **xsLogAnalyzer** tool.

   -startTime
   : Specifies the start time to evaluate in the logs. The date is in the following format: *year.month.day_hour.minute.second.millisecond*

   -endTime
   : Specifies the end time to evaluate in the logs. The date is in the following format: *year.month.day_hour.minute.second.millisecond*

   -trace
   : Specifies a trace string, such as `ObjectGrid*=all=enabled`.

   -maxRecords
   : Specifies the maximum number of records to generate in the report. The default is `100`. If you specify the value as 50, the first 50 records are generated for the specified time period.

2. Open the generated files. If you did not define an output directory, the reports are generated in a folder called report_*date_time*. To open the main page of the reports, open the index.html file.
3. Use the reports to analyze the log data. Use the following tips to maximize the performance of the report displays:
   - To maximize the performance of queries on the log data, use as specific information as possible. For example, a query for `server` takes much longer to run and returns more results than `server_host_name`.
   - Some views have a limited number of data points that are displayed at one time. You can adjust the segment of time that is being viewed by changing the current data, such as start and end time, in the view.

What to do next

For more information about troubleshooting the **xsLogAnalyzer** tool and the generated reports, see Troubleshooting log analysis.

Creating custom scanners for log analysis

You can create custom scanners for log analysis. After you configure the scanner, the results are generated in the reports when you run the **xsLogAnalyzer** tool. The custom scanner scans the logs for event records based on the regular expressions that you specified.

Procedure

1. Create a scanner specifications properties file that specifies the general expression to run for the custom scanner.
   a. Create and save a properties file. The file must be in the *loganalyzer_root*/config/custom directory. You can name the file as: you like. The file is used by the new scanner, so naming the scanner in the properties file is useful, for example: *my_new_server_scanner_spec*.properties.
   b. Include the following properties in the *my_new_server_scanner_spec*.properties file:

      ```
      include.regular_expression = REGULAR_EXPRESSION_TO_SCAN
      ```

      The *REGULAR_EXPRESSION_TO_SCAN* variable is a regular expression on which to filter the log files.
      Example: To scan for instances of lines that contain both the "`xception`" and "`rror`" strings regardless of the order, set the include.regular_expression property to the following value:

      ```
      include.regular_expression = (xception.+rror)|(rror.+xception)
      ```

      This regular expression causes events to be recorded if the string "`rror`" comes before or after the "`xception`" string.

Example:

To scan through each line in the logs for instances of lines that contain either the phrase "`xception`" or the phrase "`rror`" strings regardless of the order, set the include.regular_expression property to the following value:

```
include.regular_expression = (xception)|(rror)
```

This regular expression causes events to be recorded if the either the "`rror`" string or the "`xception`" string exist.

2. Create a configuration file that the **xsLogAnalyer** tool uses to create the scanner.
   a. Create and save a configuration file. The file must be in the *loganalyzer_root*/config/custom directory. You can name the file as *scanner_name*Scanner.config, where *scanner_name* is a unique name for the new scanner. For example, you might name the file serverScanner.config
   b. Include the following properties in the *scanner_name*Scanner.config file:

```
scannerSpecificationFiles = LOCATION_OF_SCANNER_SPECIFICATION_FILE
```

The *LOCATION_OF_SCANNER_SPECIFICATION_FILE* variable is the path and location of the specification file that you created in the previous step. For example: *loganalyzer_root*/config/custom/my_new_scanner_spec.properties. You can also specify multiple scanner specification files by using a semi-colon separated list:

```
scannerSpecificationFiles = LOCATION_OF_SCANNER_SPECIFICATION_FILE1;LOCATION_OF_SCANNER_SPECIFICATION_FILE2
```

3. Run the **xsLogAnalyzer** tool. For more information, see Running log analysis.

Results

After you run the **xsLogAnalyzer** tool, the report contains new tabs in the report for the custom scanners that you configured. Each tab contains the following views:

Charts
: A plotted graph that illustrates recorded events. The events are displayed in the order in which the events were found.

Tables
: A tabular representation of the recorded events.

Summary reports

Troubleshooting log analysis

Use the following troubleshooting information to diagnose and fix problems with the **xsLogAnalyzer** tool and its generated reports.

Procedure

- **Problem:** Out of memory conditions occur when you are using the **xsLogAnalyzer** tool to generate reports. An example of an error that might occur follows: `java.lang.OutOfMemoryError: GC overhead limit exceeded`.
  Solution: The **xsLogAnalyzer** tool runs within a Java virtual machine (JVM). You can configure the JVM to increase the heap size before you run the **xsLogAnalyzer** tool by specifying some settings when you run the tool. Increasing the heap size enables more event records to be stored in JVM memory. Start with a setting of 2048M, assuming the operating system has enough main memory. On the same command-line instance in which you are planning to run the **xsLogAnalyzer** tool, set the maximum JVM heap size:

  ```
  java -XmxHEAP_SIZEm
  ```

  The *HEAP_SIZE* value can be any integer and represents the number of megabytes that are allocated to JVM heap.
  For example, you might run `java -Xmx2048m`. If the out of memory messages continue, or you do not have the resources to allocate 2048m or more of memory, limit the number of events that are being held in the heap. You can limit the number of events in the heap up by passing the -maxRecords parameter to the .**xsLogAnalyzer** command
- **Problem:** When you open a generated report from the **xsLogAnalyzer** tool, the browser hangs or does not load the page.
  Cause: The generated HTML files are too large and cannot be loaded by the browser. These files are large because the scope of the log files that you are analyzing is too broad.

  Solution: Consider using the -startTime, -endTime, and -maxRecords parameters when you run the **xsLogAnalyzer** tool to restrict the number of log entries that are scanned. Using these parameters when you run the report makes the reports easier to read and run more effectively. You can run multiple reports on the same set of log files.

Troubleshooting installation

Use this information to troubleshoot issues with your installation and updates.

Procedure

- **Problem:** When you run the installation command from a remote computer, such as `\\mymachine\downloads\`, the following message displays: `CMD.EXE was started with the above path as the current directory. UNC paths are not supported. Defaulting to Windows directory.` As a result, the installation does not complete correctly.

Solution: Map the remote computer to a network drive. For example, in Windows, you can right-click My computer and choose Map Network Drive and include the uniform naming conventions (UNC) path to the remote computer. You can then run the installation script from the network drive successfully, for example: y:\mymachine\downloads\WXS\install.bat.

- **Problem:** The installation completes unsuccessfully.
  Solution: Check the log files to see where the installation failed. When the installation completes unsuccessfully, the logs are in the *wxs_install_root*/logs/wxs directory.

- **Problem:** A catastrophic failure occurs during the installation.
  Solution: Check the log files to see where the installation failed. When the installation fails when it is partially completed, the logs can generally be found in the *user_root*/wxs_install_logs/ directory.

- Windows **Problem:** If you are installing the WebSphere® eXtreme Scale Client on Windows, you might see the following text in the results of the installation:

  ```
  Success: The installation of the following product was successful:
  WebSphere eXtreme Scale Client.  Some configuration steps have errors.
  For more information, refer to the following log file:
  <WebSphere Application Server install root>\logs\wxs_client\install\log.txt"
  Review the installation log (log.txt) and review the deployment manager
  augmentation log.
  ```

  Solution: If you see a failure with the iscdeploy.sh file, you can ignore the error. This error does not cause any problems.
- Linux **Problem:**
  If you have a full installation and try to apply WebSphere eXtreme Scale Client only maintenance with the update installer, you see the following message:

  ```
  Prerequisite checking has failed. Click Back to select a different package,
  or click Cancel to exit.

  Failure messages are:

  Required feature wxs.client.primary is not found.
  ```

  If you have WebSphere eXtreme Scale Client installed and try to apply a full maintenance package with the update installer, you see the following message:

  ```
  Prerequisite checking has failed. Click Back to select a different package,
  or click Cancel to exit.

  Failure messages are:

  Required feature wxs.primary is not found.
  ```

  Solution: The maintenance package that you install must match the type of installation. Download and apply the maintenance package that applies to your installation type.
- Linux **Problem:** The installation hangs.
  Solution: Sometimes, when installing WebSphere eXtreme Scale on Linux as a non-root user, the installer can hang. This is likely because the maximum number of open files is set too low on your Linux operating system. You will need to raise the allowed limit in the /etc/limits.conf or /etc/security/limits.conf file (where the file is located depends on your specific Linux distribution) to at least 8192.

Using the Update Installer to install maintenance packages

Troubleshooting client connectivity

There are several common problems specific to clients and client connectivity that you can solve as described in the following sections.

Procedure

- **Problem:** If you are using the EntityManager API or byte array maps with the COPY_TO_BYTES copy mode, client data access methods result in various serialization-related exceptions or a NullPointerException exception.
  - The following error occurs when you are using the COPY_TO_BYTES copy mode:

    ```
    java.lang.NullPointerException
            at com.ibm.ws.objectgrid.map.BaseMap$BaseMapObjectTransformer2.inflateObject(BaseMap.java:5278)
            at com.ibm.ws.objectgrid.map.BaseMap$BaseMapObjectTransformer.inflateValue(BaseMap.java:5155)
    ```

  - The following error occurs when you are using the EntityManager API:

    ```
    java.lang.NullPointerException
                    at com.ibm.ws.objectgrid.em.GraphTraversalHelper.fluffFetchMD(GraphTraversalHelper.java:323)
                    at com.ibm.ws.objectgrid.em.GraphTraversalHelper.fluffFetchMD(GraphTraversalHelper.java:343)
                    at com.ibm.ws.objectgrid.em.GraphTraversalHelper.getObjectGraph(GraphTraversalHelper.java:102)
                    at
    com.ibm.ws.objectgrid.ServerCoreEventProcessor.getFromMap(ServerCoreEventProcessor.java:709)
                    at
    com.ibm.ws.objectgrid.ServerCoreEventProcessor.processGetRequest(ServerCoreEventProcessor.java:323)
    ```

  Cause: The EntityManager API and COPY_TO_BYTES copy mode use a metadata repository that is embedded in the data grid. When clients connect, the data grid stores the repository identifiers in the client and caches the identifiers for the duration of the client connection. If you restart the data grid, you

lose all metadata and the regenerated identifiers do not match the cached identifiers on the client.
Solution: If you are using the EntityManager API or the COPY_TO_BYTES copy mode, disconnect and reconnect all of the clients if the ObjectGrid is stopped and restarted. Disconnecting and reconnecting the clients refreshes the metadata identifier cache. You can disconnect clients by using the ObjectGridManager.disconnect method or the ObjectGrid.destroy method.

- **Problem:** The client hangs during a getObjectGrid method call.
  A client might seem to hang when calling the getObjectGrid method on the ObjectGridManager or throw an exception: com.ibm.websphere.projector.MetadataException. The EntityMetadata repository is not available and the timeout threshold is reached.

  Cause: The reason is the client is waiting for the entity metadata on the ObjectGrid server to become available.

  Solution: This error can occur when a container server has been started, but placement has not yet started. Take the following actions:
  - Examine the deployment policy for the ObjectGrid and verify that the number of active containers is greater than or equal to both the numInitialContainers and minSyncReplicas attributes in the deployment policy descriptor file.
  - Examine the setting for the placementDeferralInterval property in the container server server properties file to see how much time needs to pass before placement operations occur.
  - If you used the **xscmd -c suspendBalancing** command to stop the balancing of shards for a specific data grid and map set, use the **xscmd -c resumeBalancing** to start balancing again.

Related concepts:
Creating ObjectGrid instances with the ObjectGridManager interface

Troubleshooting cache integration

Use this information to troubleshoot issues with your cache integration configuration, including HTTP session and dynamic cache configurations.

Procedure

- **Problem:** HTTP session IDs are not being reused.
  Cause: You can reuse session IDs. If you create a data grid for session persistence in Version 7.1.1 or later, session ID reuse is automatically enabled. However, if you created prior configurations, this setting might already be set with the wrong value.

  Solution: Check the following settings to verify that you have HTTP session ID reuse enabled:
  - The `reuseSessionId` property in the splicer.properties file must be set to `true`.
  - The `HttpSessionIdReuse` custom property value must be set to `true`. This custom property might be set on one of the following paths in the WebSphere® Application Server administrative console:
    - Servers > *server_name* > Session management > Custom properties
    - Dynamic clusters > *dynamic_cluster_name* > Server template > Session management > Custom properties
    - Servers > Server Types > WebSphere application servers > *server_name*, and then, under Server Infrastructure, click Java and process management > Process definition > Java virtual machine > Custom properties
    - Servers > Server Types > WebSphere application servers > *server_name* > Web container settings > Web container

  If you update any custom property values, reconfigure eXtreme Scale session management so the splicer.properties file becomes aware of the change.
- **Problem:** When you are using a data grid to store HTTP sessions and the transaction load is high, a CWOBJ0006W message displays in the SystemOut.log file.

  ```
  CWOBJ0006W: An exception occurred:
  com.ibm.websphere.objectgrid.ObjectGridRuntimeException:
  java.util.ConcurrentModificationException
  ```

  This message occurs only when the replicationInterval parameter in the splicer.properties file is set to a value greater than zero and the Web application modifies a List object that was set as an attribute on the HTTPSession.

  Solution: Clone the attribute that contains the modified List object and put the cloned attribute into the session object.

Related tasks:

splicer.properties file

Troubleshooting the JPA cache plug-in

Use this information to troubleshoot issues with your JPA cache plug-in configuration. These problems can occur in both Hibernate and OpenJPA configurations.

Procedure

- **Problem:** The following exception displays: `CacheException: Failed to get ObjectGrid server.`
  With either an `EMBEDDED` or `EMBEDDED_PARTITION` ObjectGridType attribute value, the eXtreme Scale cache tries to obtain a server instance from the run time. In a Java™ Platform, Standard Edition environment, an eXtreme Scale server with embedded catalog service is started. The embedded catalog service tries to listen to port 2809. If that port is being used by another process, the error occurs.

  Solution: If external catalog service endpoints are specified, for example, with the objectGridServer.properties file, this error occurs if the host name or port is specified incorrectly. Correct the port conflict.

- **Problem:** The following exception displays: `CacheException: Failed to get REMOTE ObjectGrid for configured REMOTE ObjectGrid. objectGridName = [ObjectGridName], PU name = [persistenceUnitName]`
  This error occurs because the cache cannot get the ObjectGrid instance from the provided catalog service end points.

  Solution: This problem typically occurs because of an incorrect host name or port.

- **Problem:** The following exception displays: `CacheException: Cannot have two PUs [persistenceUnitName_1, persistenceUnitName_2] configured with same ObjectGridName [ObjectGridName] of EMBEDDED ObjectGridType`
  This exception results if you have many persistence units configured and the eXtreme Scale caches of these units are configured with the same ObjectGrid name and `EMBEDDED` ObjectGridType attribute value. These persistence unit configurations could be in the same or different persistence.xml files.

  Solution: You must verify that the ObjectGrid name is unique for each persistence unit when the ObjectGridType attribute value is `EMBEDDED`.

- **Problem:** The following exception displays: `CacheException: REMOTE ObjectGrid [ObjectGridName] does not include required BackingMaps [mapName_1, mapName_2,...]`
  With a REMOTE ObjectGrid type, if the obtained client-side ObjectGrid does not have complete entity backing maps to support the persistence unit cache, this exception occurs. For example, five entity classes are listed in the persistence unit configuration, but the obtained ObjectGrid only has two BackingMaps. Even though the obtained ObjectGrid might have 10 BackingMaps, if any one of the five required entity BackingMaps are not found in the 10 backing maps, this exception still occurs.

  Solution: Make sure that your backing map configuration supports the persistence unit cache.

Troubleshooting IBM eXtremeMemory

Use the following information to troubleshoot eXtremeMemory.

Procedure

Problem: If the shared resource, libstdc++.so.5, is not installed, then when you start the container server, IBM eXtremeMemory native libraries do not load.
Linux **Symptom:** On a Linux 64-bit operating system, if you try to start a container server with the enableXM server property set to `true`, and the `libstdc++.so.5` shared resource is not installed, you get an error similar to the following example:

```
00000000 Initialization W CWOBJ0006W: An exception occurred: java.lang.reflect.InvocationTargetException
        at sun.reflect.NativeConstructorAccessorImpl.newInstance0(Native Method)
        at sun.reflect.NativeConstructorAccessorImpl.newInstance(NativeConstructorAccessorImpl.java:56)
        at sun.reflect.DelegatingConstructorAccessorImpl.newInstance(DelegatingConstructorAccessorImpl.java:39)
        at java.lang.reflect.Constructor.newInstance(Constructor.java:527)
        at com.ibm.websphere.objectgrid.server.ServerFactory.initialize(ServerFactory.java:350)
        at com.ibm.websphere.objectgrid.server.ServerFactory$2.run(ServerFactory.java:303)
        at java.security.AccessController.doPrivileged(AccessController.java:202)
        at com.ibm.websphere.objectgrid.server.ServerFactory.getInstance(ServerFactory.java:301)
        at com.ibm.ws.objectgrid.InitializationService.main(InitializationService.java:302)

Caused by: com.ibm.websphere.objectgrid.ObjectGridRuntimeException: java.lang.UnsatisfiedLinkError:
        OffheapMapdbg (Not found in java.library.path)
        at com.ibm.ws.objectgrid.ServerImpl.<init&gt;(ServerImpl.java:1033)
... 9 more Caused by: java.lang.UnsatisfiedLinkError: OffheapMapdbg (Not found in java.library.path)
        at java.lang.ClassLoader.loadLibraryWithPath(ClassLoader.java:1011)
        at java.lang.ClassLoader.loadLibraryWithClassLoader(ClassLoader.java:975)

        at java.lang.J9VMInternals.initialize(J9VMInternals.java:200)
        at com.ibm.ws.objectgrid.ServerImpl.<init&gt;(ServerImpl.java:1028)
... 9 more
```

Cause: The shared resource `libstdc++.so.5` has not been installed.

Diagnosing the problem: To verify that the resource `libstdc++.so.5` is installed, issue the following command from the ObjectGrid/native directory of your installation:

```
ldd libOffheapMap.so
```

If you do not have the shared library installed, you get the following error:

```
ldd libOffheapMap.so
libstdc++.so.5 => not found
```

Resolving the problem: Use the package installer of your 64-bit Linux distribution to install the required resource file. The package might be listed as `compat-libstdc++-33.x86_64` or `libstdc++5`. After installing the required resource, verify that the `libstdc++5`package is installed by issuing the following command from the ObjectGrid directory of your installation:

```
ldd libOffheapMap.so
```

Troubleshooting administration

Use the following information to troubleshoot administration, including starting and stopping servers, using the **xscmd** utility, and so on.

Procedure

- **Problem:** Administration scripts are missing from the *profile_root*/bin directory of a WebSphere® Application Server installation.
  Cause: When you update the installation, new script files do not automatically get installed in the profiles.

  Solution: If you want to run a script from your *profile_root*/bin directory, unaugment and reaugment the profile with the latest release. For more information, see Unaugmenting a profile using the command prompt and Creating and augmenting profiles for WebSphere eXtreme Scale.

- **Problem:** When you are running a **xscmd** command, the following message is printed to the screen:

  ```
  java.lang.IllegalStateException: Placement service MBean not available.
  []
          at
  com.ibm.websphere.samples.objectgrid.admin.OGAdmin.main(OGAdmin.java:1449)
          at sun.reflect.NativeMethodAccessorImpl.invoke0(Native Method)
          at
  sun.reflect.NativeMethodAccessorImpl.invoke(NativeMethodAccessorImpl.java:60)
          at
  sun.reflect.DelegatingMethodAccessorImpl.invoke(DelegatingMethodAccessorImpl.java:37)
          at java.lang.reflect.Method.invoke(Method.java:611)
          at com.ibm.ws.bootstrap.WSLauncher.main(WSLauncher.java:267)
  Ending at: 2011-11-10 18:13:00.000000484
  ```

  Cause: A connection problem occurred with the catalog server.

  Solution: Verify that your catalog servers are running and are available through the network. This message can also occur when you have a catalog service domain defined, but less than two catalog servers are running. The environment is not available until two catalog servers are started.

- 8.5+ **Problem:** When you are running a **xscmd** command, the following message is printed to the screen:

  ```
  CWXSI0066E: Unmatched argument argument_name was detected.
  ```

  Cause: You entered a command format that the **xscmd** utility did not recognize.

  Solution: Check the format of the command. You might encounter this issue when running regular expressions with the **-c findbyKey** command. For more information, see Querying and invalidating data.

Related concepts:
Example: Configuring catalog service domains
Administering

Troubleshooting multiple data center configurations

Use this information to troubleshoot multiple data center configurations, including linking between catalog service domains.

Before you begin

You must use the **xscmd** utility to troubleshoot your multiple data center configurations. For more information, see Administering with the xscmd utility.

Procedure

- **Problem:** Data is missing in one or more catalog service domains. For example, you might run the **xscmd -c establishLink** command. When you look at the data for each linked catalog service domain, the data looks different, for example from the **xscmd -c showMapSizes** command.
  Solution: You can troubleshoot this problem with the **xscmd -c showLinkedPrimaries** command. This command prints each primary shard, and including which foreign primaries are linked.

  In the described scenario, you might discover from running the **xscmd -c showLinkedPrimaries** command that the first catalog service domain primary shards are linked to the second catalog service domain primary shards, but the second catalog service domain does not have links to the first catalog service domain. You might consider rerunning the **xscmd -c establishLink** command from the second catalog service domain to the first catalog service domain.

- **Problem:** The catalog service domains are not replicating data. The output of the command **showMapsizes** or **showDomainReplicationState** do not match between the catalog service domains as expected. The command **showLinkedPrimaries** shows links in the recovery state instead of the online state.
  Diagnosis: Investigate the multi-master links between the primary shards in the recovery state. The recovery state indicates that WebSphere® eXtreme Scale cannot successfully replicate between the primary shards in each catalog service domain. When a primary shard encounters an exception, it goes into an auto-recovery state and sends a ping to the foreign primary shard. If the ping is successful, replication starts again. If the ping fails, the primary

shard sleeps and pings again in the future. Each primary shard is responsible for maintaining replication with its foreign primary in the foreign domain. For example, the primary shard for partition 1 in domain 1 replicates directly with the primary shard for partition 1 in domain 2.

1. Review the output for the command **showLinkedPrimaries** and locate a shard in recovery state. Example output:

```
CWXSI0068I: Executing command: showLinkedPrimaries
CWXSI0091I: Verifying the primary shards have the correct number of links to foreign primary shards.

*** Displaying results for inventory data grid and aSet map set. Expected number of online links: 1.

*** Listing Primary Shards with the incorrect number of links for local domain:
domain1, Container: server0_C-0, Server: server0,
Host: myHost.rchland.ibm.com ***

Grid Name Map Set Name Partition Domain  Container      Status
--------- ------------ --------- ------  ---------      -------
inventory aSet         0         domain2 server20_C-1   recovery
inventory aSet         1         domain2 server20_C-1   recovery
```

2. Review the SystemOut or JVM logs and FFDC of a link in recovery state. In the showLinkedPrimaries example that is provided, take note of the first entry, that is partition `0`, for the grid inventory and map set `aSet`. The local primary shard for partition `0` runs on `server0` and the foreign primary shard for partition `0` runs on `server20`. To find out more information about the link, locate the SystemOut or JVM log file for `server0`. Search the file for the inventory grid for partition `0`. To aid in the search, the shard identification string is formatted as `objectGridName:mapSetName:partitionID` in the log. In this case, the shard identification string is `inventory:aSet:0`. You should search for several messages in the `CWOBJ1500-CWOBJ1599` range. The relevant messages for this showLinkedPrimaries example include `CWOBJ1511I`, `CWOBJ1542I`, `CWOBJ1550W`and `CWOBJ1551I`.
Example log messages:

```
ReplicatedPar I   CWOBJ1511I: inventory:aSet:0 (primary) is open for business.
PrimaryShardI I   CWOBJ1542I: Primary inventory:aSet:0 started or continued replicating
from foreign primary (domain2:server20_C-1). Replicating for maps: [movie, book]
PrimaryShardI W   CWOBJ1550W:
The primary (inventory:aSet:0) shard received exceptions while replicating from the primary shard on
the domain2:server20_C-1 primary container.
The primary shard continues to poll the primary shard.

CWOBJ1551I: Primary inventory:aSet:0successfully recovered and replicated after several exceptions from the
primary on domain2:server20_C-1.

If the primary shard automatically recovers, a CWOBJ1551I message occurs.
```

- **Problem**: The multimaster replication link was dismissed, but the foreign domain or collective could not be contacted. The link is in the DISMISSING_LINK state in the monitoring console, or the link is displayed in the DISMISSING_LINK state when you run the `xscmd -c showLinkedDomains -v` command. The foreign domain or collective cannot be restarted or contacted to resolve the dismiss link request. The link stays in DISMISSING_LINK state because the local domain tries again to connect to the foreign domain to complete the dismissal request.
Solution: Run the `xscmd -c dismissLink` command with the -force option to dismiss the link once with the foreign domain and then clean up the local domain.

Troubleshooting loaders

Use this information to troubleshoot issues with your database loaders.

Procedure

- **Problem:** The loader is unable to communicate with the database. A LoaderNotAvailableException exception occurs.
  Explanation: The loader plug-in can fail when it is unable to communicate to the database back end. This failure can happen if the database server or the network connection is down. The write-behind loader queues the updates and tries to push the data changes to the loader periodically. The loader must notify the ObjectGrid run time that there is a database connectivity problem by throwing a LoaderNotAvailableException exception.

  Solution: The Loader implementation must be able to distinguish a data failure or a physical loader failure. Data failure should be thrown or rethrown as a LoaderException or an OptimisticCollisionException, but a physical loader failure must be thrown or rethrown as a LoaderNotAvailableException. ObjectGrid handles these two exceptions differently:
  - If a LoaderException is caught by the write-behind loader, the write-behind loader considers the exception a failure, such as duplicate key failure. The write-behind loader unbatches the update, and tries the update one record at one time to isolate the data failure. If A {{LoaderException}}is caught again during the one record update, a failed update record is created and logged in the failed update map.
  - If a LoaderNotAvailableException is caught by the write-behind loader, the write-behind loader considers it failed because it cannot connect to the database end, for example, the database back-end is down, a database connection is not available, or the network is down. The write-behind loader waits for 15 seconds and then try the batch update to the database again.

  The common mistake is to throw a LoaderException while a LoaderNotAvailableException must be thrown. All the records queued in the write-behind loader become failed update records, which defeats the purpose of back-end failure isolation.
- **Problem:** When you are using an OpenJPA loader with DB2® in WebSphere® Application Server, a closed cursor exception occurs.
  The following exception is from DB2 in the org.apache.openjpa.persistence.PersistenceException log file:

  ```
  [jcc][t4][10120][10898][3.57.82] Invalid operation: result set is closed.
  ```

  Solution: By default, the application server configures the resultSetHoldability custom property with a value of `2` (CLOSE_CURSORS_AT_COMMIT). This property causes DB2 to close its resultSet/cursor at transaction boundaries. To remove the exception, change the value of the custom property to `1` (HOLD_CURSORS_OVER_COMMIT). Set the resultSetHoldability custom property on the following path in the WebSphere Application Server cell: Resources > JDBC provider > DB2 Universal JDBC Driver Provider > DataSources > *data_source_name* > Custom properties > New.

- **Problem** DB2 displays an exception: `The current transaction has been rolled back because of a deadlock or timeout. Reason code "2".. SQLCODE=-911, SQLSTATE=40001, DRIVER=3.50.152`
  This exception occurs because of a lock contention problem when you are running with OpenJPA with DB2 in WebSphere Application Server. The default isolation level for WebSphere Application Server is Repeatable Read (RR), which obtains long-lived locks with DB2.

  Solution:
  Set the isolation level to Read Committed to reduce the lock contention. Set the webSphereDefaultIsolationLevel data source custom property to set the isolation level to `2`(TRANSACTION_READ_COMMITTED) on the following path in the WebSphere Application Server cell: Resources > JDBC provider > *JDBC_provider* > Data sources > *data_source_name* > Custom properties > New. For more information about the webSphereDefaultIsolationLevel custom property and transaction isolation levels, see Requirements for setting data access isolation levels.

- **Problem:** When you are using the preload function of the JPALoader or JPAEntityLoader, the following CWOBJ1511 message does not display for the partition in a container server: `CWOBJ1511I: GRID_NAME:MAPSET_NAME:PARTITION_ID (primary) is open for business.`
  Instead, a TargetNotAvailableException exception occurs in the container server, which activates the partition that is specified by the preloadPartition property.

  Solution: Set the preloadMode attribute to `true` if you use a JPALoader or JPAEntityLoader to preload data into the map. If the preloadPartition property of the JPALoader and JPAEntityLoader is set to a value between `0` and `total_number_of_partitions - 1`, then the JPALoader and JPAEntityLoader try to preload the data from backend database into the map. The following snippet of code illustrates how the preloadMode attribute is set to enable asynchronous preload:

  ```
  BackingMap bm = og.defineMap( "map1" );
  bm.setPreloadMode( true );
  ```

  You can also set the preloadMode attribute by using an XML file as illustrated in the following example:

  ```
  <backingMap name="map1" preloadMode="true" pluginCollectionRef="map1"
                lockStrategy="OPTIMISTIC" />
  ```

Troubleshooting XML configuration

When you configure eXtreme Scale, you can encounter unexpected behavior with your XML files. The following sections describe problems that can occur and solutions.

Procedure

- **Problem:** Your deployment policy and ObjectGrid XML files must match.
  The deployment policy and ObjectGrid XML files must match. If they do not have matching ObjectGrid names and map names, errors occur.

If the backingMap list in an ObjectGrid XML file does not match the map references list in a deployment policy XML file, an error occurs on the catalog server.

For example, the following ObjectGrid XML file and deployment policy XML file are used to start a container process. The deployment policy file has more map references than are listed in the ObjectGrid XML file.

```
ObjectGrid.xml - incorrect example

<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="accounting">
            <backingMap name="payroll" readOnly="false" />
        </objectGrid>
    </objectGrids>
</objectGridConfig>

deploymentPolicy.xml - incorrect example

<?xml version="1.0" encoding="UTF-8"?>
<deploymentPolicy xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/deploymentPolicy ../deploymentPolicy.xsd"
 xmlns="http://ibm.com/ws/objectgrid/deploymentPolicy">
    <objectgridDeployment objectgridName="accounting">
        <mapSet name="mapSet1" numberOfPartitions="4" minSyncReplicas="1"
                                    maxSyncReplicas="2" maxAsyncReplicas="1">
            <map ref="payroll"/>
            <map ref="ledger"/>
        </mapSet>
    </objectgridDeployment>
</deploymentPolicy>
```

Messages: An error message occurs in the SystemOut.log file when the deployment policy is incompatible with the ObjectGrid XML file. For the preceding example, the following message occurs:

```
CWOBJ3179E: The map ledger reference in the mapSet mapSet1 of ObjectGrid accounting
deployment descriptor file does not reference a valid backing map from the ObjectGrid
XML.
```

If the deployment policy is missing map references to backingMaps that are listed in the ObjectGrid XML file, an error message occurs in the SystemOut.log file. For example:

```
CWOBJ3178E: The map ledger in ObjectGrid accounting referenced in the ObjectGrid XML
was not found in the deployment descriptor file.
```

Solution: Determine which file has the correct list and alter the relevant code accordingly.

- **Problem:** Incorrect ObjectGrid names between XML files also causes and error.
  The name of the ObjectGrid is referenced in both the ObjectGrid XML file and the deployment policy XML file.

  Message: An ObjectGridException occurs with a caused by exception of IncompatibleDeploymentPolicyException. An example follows.

  Caused by: com.ibm.websphere.objectgrid.IncompatibleDeploymentPolicyException: The objectgridDeployment with objectGridName "accountin" does not have a corresponding objectGrid in the ObjectGrid XML.

  The ObjectGrid XML file is the master list of ObjectGrid names. If a deployment policy has an ObjectGrid name that is not contained in the ObjectGrid XML file, an error occurs.

  Solution: Verify details such as the spelling of the ObjectGrid name. Remove any extra names, or add missing ObjectGrid names, to the ObjectGrid XML or deployment policy XML files. In the example message, the objectGridName is misspelled as "accountin" instead of "accounting".

- **Problem:** Some of the attributes in the XML file can only be assigned certain values. These attributes have acceptable values enumerated by the schema. The following list provides some of the attributes:
  - authorizationMechanism attribute on the objectGrid element
  - copyMode attribute on the backingMap element
  - lockStrategy attribute on the backingMap element
  - ttlEvictorType attribute on the backingMap element
  - type attribute on the property element
  - initialState on the objectGrid element
  - evictionTriggers on the backingMap element

  If one of these attributes is assigned an invalid value, XML validation fails. In the following example XML file, an incorrect value of INVALID_COPY_MODE is used:

```
INVALID_COPY_MODE example
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="accounting">
            <backingMap name="payroll" copyMode="INVALID_COPY_MODE"/>
        <objectGrid/>
   </objectGrids>
</objectGridConfig>
```

The following message appears in the log.

```
CWOBJ2403E: The XML file is invalid. A problem has been detected
with < null > at line 5. The error message is cvc-enumeration-valid:
Value 'INVALID_COPY_MODE' is not facet-valid with respect to enumeration
'[COPY_ON_READ_AND_COMMIT, COPY_ON_READ, COPY_ON_WRITE, NO_COPY, COPY_TO_BYTES]'.
It must be a value from the enumeration.
```

- **Problem:** Missing or incorrect attributes or tags in an XML file causes errors, such as the following example in which the ObjectGrid XML file is missing the closing < /objectGrid > tag:

```
missing attributes - example XML

<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
    <objectGrids>
        <objectGrid name="accounting">
            <backingMap name="payroll" />

   </objectGrids>
</objectGridConfig>
```

  Message:

```
CWOBJ2403E: The XML file is invalid. A problem has been detected with
< null > at line 7. The error message is The end-tag for element type "objectGrid"
must end with a '>' delimiter.
```

  An ObjectGridException about the invalid XML file occurs with the name of the XML file.

  Solution: Ensure that the necessary tags and attributes appear in your XML files with correct format.

- **Problem:** If an XML file is formatted with incorrect or missing syntax, the CWOBJ2403E appears in the log. For example, the following message is displayed when a quotation is missing on one of the XML attributes

```
CWOBJ2403E: The XML file is invalid. A problem has been detected with
< null > at line 7. The error message is Open quote is expected for attribute
"maxSyncReplicas" associated with an element type "mapSet".
```

  An ObjectGridException about the invalid XML file also occurs.

  Solution: Various solutions can be used for a given XML syntax error. Consult relevant documentation about XML script writing.

- **Problem:** Referencing a nonexistent plug-in collection causes an XML file to be invalid. For example, when using XML to define BackingMap plug-ins, the pluginCollectionRef attribute of the backingMap element must reference a backingMapPluginCollection. The pluginCollectionRef attribute must match the backingMapPluginCollection elements.
  Message:

  If the pluginCollectionRef attribute does not match any ID attributes of any of the backingMapPluginConfiguration elements, the following message, or one that is similar, is displayed in the log.

```
[7/14/05 14:02:01:971 CDT] 686c060e XmlErrorHandl E CWOBJ9002E:
This is an English only Error message: Invalid XML file. Line: 14; URI:
null; Message: Key 'pluginCollectionRef' with
value 'bookPlugins' not found for identity constraint of
element 'objectGridConfig'.
```

  The following XML file is used to produce the error. Notice that the name of the BackingMap book has its pluginCollectionRef attribute set to bookPlugins, and the single backingMapPluginCollection has an ID of collection1.

```
referencing a non-existent attribute XML - example

<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://ibm.com/ws/objectgrid/config../objectGrid.xsd"
 xmlns="http://ibm.com/ws/objectgrid/config">
   <objectGrids>
      <objectGrid name="bookstore">
         <backingMap name="book" pluginCollectionRef="bookPlugin" />
      </objectGrid>
   </objectGrids>
   <backingMapPluginCollections>
    <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txsxmlprob_collection1">
     <bean id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_txsxmlprob_Evictor"
       className="com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor" />
     </backingMapPluginCollection>
    </backingMapPluginCollections>
</objectGridConfig>
```

  Solution:

  To fix the problem, ensure that the value of each pluginCollectionRef matches the ID of one of the backingMapPluginCollection elements. Simply change the name of pluginCollectionRef to collection1 to not receive this error. Alternatively, change the ID of the existing backingMapPluginCollection to match the pluginCollectionRef, or add an additional backingMapPluginCollection with an ID that matches the pluginCollectionRef to correct the error.

- **Problem:** The IBM® Software Development Kit (SDK) Version 5 contains an implementation of some Java™ API for XML Processing (JAXP) function to use for XML validation against a schema. When using an SDK that does not contain this implementation, attempts to validate might fail.
  When you attempt to validate XML with an SDK that does not have the necessary implementation, the log contains the following error:

  ```
  XmlConfigBuild XML validation is enabled
  SystemErr R com.ibm.websphere.objectgrid
  SystemErr R at com.ibm.ws.objectgrid.ObjectGridManagerImpl.getObjectGridConfigurations
          (ObjectGridManagerImpl.java:182)
  SystemErr R at com.ibm.ws.objectgrid.ObjectGridManagerImpl.createObjectGrid(ObjectGridManagerImpl.java:309)
  SystemErr R at com.ibm.ws.objectgrid.test.config.DocTest.main(DocTest.java:128)
  SystemErr R Caused by: java.lang.IllegalArgumentException: No attributes are implemented
  SystemErr R at org.apache.crimson.jaxp.DocumentBuilderFactoryImpl.setAttribute(DocumentBuilderFactoryImpl.java:93)
  SystemErr R at com.ibm.ws.objectgrid.config.XmlConfigBuilder.<init>XmlConfigBuilder.java:133)
  SystemErr R at com.ibm.websphere.objectgrid.ProcessConfigXML$2.runProcessConfigXML.java:99)...
  ```

  The SDK that is used does not contain an implementation of JAXP function that is necessary to validate XML files against a schema.

  Solution: If you want to validate XML by using an SDK that does not contain JAXP implementation, download Apache Xerces, and include its Java archive (JAR) files in the classpath. To avoid this problem, after you download Xerces and include the JAR files in the classpath, you can validate the XML file successfully.

Troubleshooting deadlocks

The following sections describe some of the most common deadlock scenarios and suggestions on how to avoid them.

Before you begin

Implement exception handling in your application. For more information, see Implementing exception handling in locking scenarios for Java applications .
The following exception displays as a result:

```
com.ibm.websphere.objectgrid.plugins.LockDeadlockException: Message
```

This message represents the string that is passed as a parameter when the exception is created and thrown.

Procedure

- **Problem:**A LockTimeoutException exception occurs.
  Description: When a transaction or client asks for a lock to be granted for a specific map entry, the request often waits for the current client to release the lock before the request is submitted. If the lock request remains idle for an extended time, and a lock is never granted, LockTimeoutException exception is created to prevent a deadlock, which is described in more detail in the following section. You are more likely to see this exception when you configure a pessimistic locking strategy, because the lock never releases until the transaction commits.

  Retrieve more details:

  - The LockTimeoutException exception contains the getLockRequestQueueDetails method, which returns a string. You can use this method to see a detailed description of the situation that triggers the exception. The following is an example of code that catches the exception, and displays an error message.

    ```
    try {
        ...
    }
    catch (LockTimeoutException lte) {
        System.out.println(lte.getLockRequestQueueDetails());
    }
    ```

    If you receive the exception in an ObjectGridException exception catch block, the following code determines the exception and displays the queue details. It also uses the findRootCause utility method.

    ```
    try {
    ...
    }
    catch (ObjectGridException oe) {
        Throwable Root = findRootCause( oe );
        if (Root instanceof LockTimeoutException) {
            LockTimeoutException lte = (LockTimeoutException)Root;
            System.out.println(lte.getLockRequestQueueDetails());
        }
    }
    ```

Solution: A LockTimeoutException exception prevents possible deadlocks in your application. An exception of this type results when the exception waits a set amount of time. You can set the amount of time that the exception waits by setting the lock timeout value. If a deadlock does not actually exist in your application, adjust the lock timeout to avoid the LockTimeoutException.

For more information about setting the lock timeout value, see Configuring the lock timeout value in the ObjectGrid descriptor XML file. You can also configure the timeout value programmatically:

- Configuring and implementing locking in Java applications

.

- **Problem:** A deadlock occurs on a single key.
  Description: The following scenarios describe how deadlocks can occur when a single key is accessed with an S lock and later updated. When this action occurs from two transactions simultaneously, a deadlock occurs.

Table 1. Single key deadlocks scenario

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction.
2	get key1	get key1	S lock granted to both transactions for key1.
3	○ update key1		No U lock. Update performed in transactional cache.
4		○ update key1	No U lock. Update performed in the transactional cache
5	Commit transaction		Blocked: The S lock for key1 cannot be upgraded to an X lock because Thread 2 has an S lock.
6		Commit transaction	Deadlock: The S lock for key1 cannot be upgraded to an X lock because T1 has an S lock.

Table 2. Single key deadlocks, continued

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction.
2	get key1		S lock granted for key1
3	○ getForUpdate key1	get key1	S lock is upgraded to a U lock for key1.
4		get key1	S lock granted for key1.
5		○ getForUpdate key1	Blocked: T1 already has U lock.
6	Commit transaction		Deadlock: The U lock for key1 cannot be upgraded.
7		Commit transaction	Deadlock: The S lock for key1 cannot be upgraded.

Table 3. Single key deadlocks, continued

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction
2	get key1		S lock granted for key1.
3	○ getForUpdate key1		S lock is upgraded to a U lock for key1
4		get key1	S lock is granted for key1.
5		○ getForUpdate key1	Blocked: Thread 1 already has a U lock.
6	Commit transaction		Deadlock: The U lock for key1 cannot be upgraded to an X lock because Thread 2 has an S lock.

If the ObjectMap.getForUpdate is used to avoid the S lock, then the deadlock is avoided:

Table 4. Single key deadlocks, continued

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction.
2	○ getForUpdate key1		U lock granted to thread 1 for key1.
3		○ getForUpdate key1	U lock request is blocked.
4	○ update key1	<blocked>	
5	Commit transaction	<blocked>	The U lock for key1 can be successfully upgraded to an X lock.
6		<released>	The U lock is finally granted to key1 for thread 2.
7		○ update key2	U lock granted to thread 2 for key2.
8		Commit transaction	The U lock for key1 can successfully be upgraded to an X lock.

Solutions:

- Use the getForUpdate method instead of get to acquire a U lock instead of an S lock.
- Use a transaction isolation level of read committed to avoid holding S locks. Reducing the transaction isolation level increases the possibility of non-repeatable reads. However, non-repeatable reads from one client are only possible if the transaction cache is explicitly invalidated by the same

client.
    - Use the optimistic locking strategy. Using the optimistic lock strategy requires handling optimistic collision exceptions.
- **Problem:** A deadlock occurs on ordered multiple keys.
  Description: This scenario describes what happens if two transactions attempt to update the same entry directly and hold S locks to other entries.

Table 5. Ordered multiple key deadlock scenario

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction.
2	get key1	get key1	S lock granted to both transactions for key1.
3	get key2	get key2	S lock granted to both transactions for key2.
4	◦ update key1		No U lock. Update performed in transactional cache.
5		◦ update key2	No U lock. Update performed in transactional cache.
6.	Commit transaction		Blocked: The S lock for key 1 cannot be upgraded to an X lock because thread 2 has an S lock.
7		Commit transaction	Deadlock: The S lock for key 2 cannot be upgraded because thread 1 has an S lock.

You can use the ObjectMap.getForUpdate method to avoid the S lock, then you can avoid the deadlock:

Table 6. Ordered multiple key deadlock scenario, continued

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction.
2	◦ getForUpdate key1		U lock granted to transaction T1 for key1.
3		◦ getForUpdate key1	U lock request is blocked.
4	get key2	<blocked>	S lock granted for T1 for key2.
5	◦ update key1	<blocked>	
6	Commit transaction	<blocked>	The U lock for key1 can be successfully upgraded to an X lock.
7		<released>	The U lock is finally granted to key1 for T2
8		get key2	S lock granted to T2 for key2.
9		◦ update key2	U lock granted to T2 for key2.
10		Commit transaction	The U lock for key1 can be successfully upgraded to an X lock.

Solutions:
- Use the getForUpdate method instead of the get method to acquire a U lock directly for the first key. This strategy works only if the method order is deterministic.
- Use a transaction isolation level of read committed to avoid holding S locks. This solution is the easiest to implement if the method order is not deterministic. Reducing the transaction isolation level increases the possibility of non-repeatable reads. However, non-repeatable reads are only possible if the transaction cache is explicitly invalidated.
- Use the optimistic locking strategy. Using the optimistic lock strategy requires handling optimistic collision exceptions.

- **Problem:** A deadlock occurs from an out of order U lock
  Description: If the order in which keys are requested cannot be guaranteed, then a deadlock can still occur.

Table 7. Out of order with U lock scenario

	Thread 1	**Thread 2**	
1	Start transaction	Start transaction	Each thread establishes an independent transaction.
2	◦ getForUpdate key1	◦ getForUpdate key2	U locks successfully granted for key1 and key2.
3	get key2	get key1	S lock granted for key1 and key2.
4	◦ update key1	◦ update key2	
5	Commit transaction		The U lock cannot be upgraded to an X lock because T2 has an S lock.
6		Commit transaction	The U lock cannot be upgraded to an X lock because T1 has an S lock.

Solutions:
- Wrap all work with a single global U lock (mutex). This method reduces concurrency, but handles all scenarios when access and order are non-deterministic.
- Use a transaction isolation level of read committed to avoid holding S locks. This solution is the easiest to implement if the method order is not deterministic and provides the greatest amount of concurrency. Reducing the transaction isolation level increases the possibility of non-repeatable reads. However, non-repeatable reads are only possible if the transaction cache is explicitly invalidated.
- Use the optimistic locking strategy. Using the optimistic lock strategy requires handling optimistic collision exceptions.

Lock types

Troubleshooting security

Use this information to troubleshoot issues with your security configuration.

Procedure

- **Problem:** The client end of the connection requires Secure Sockets Layer (SSL), with the transportType setting set to `SSL-Required`. However, the server end of the connection does not support SSL, and has the transportType setting set to `TCP/IP`. As a result, the following exception gets chained to another exception in the log files:

  ```
  java.net.ConnectException: connect: Address is invalid on local machine, or
  port is not valid on remote machine
      at java.net.PlainSocketImpl.doConnect(PlainSocketImpl.java:389)
      at java.net.PlainSocketImpl.connectToAddress(PlainSocketImpl.java:250)
      at java.net.PlainSocketImpl.connect(PlainSocketImpl.java:237)
      at java.net.SocksSocketImpl.connect(SocksSocketImpl.java:385)
      at java.net.Socket.connect(Socket.java:540)
      at
  com.ibm.rmi.transport.TCPTransportConnection.createSocket(TCPTransportConnection.java:155)
      at
  com.ibm.rmi.transport.TCPTransportConnection.createSocket(TCPTransportConnection.java:167)
  ```

  The address in this exception could be a catalog server, container server, or client.
  Solution: See Configuring secure transport types for a table with the valid security configurations between clients and servers.

- When agent is used, the client sends the agent call to the server, and server sends the response back to the client to acknowledge the agent call. When the agent finishes processing, the server initiates a connection to send the agent results. This makes the container server a client from connect point of view. Therefore, if TLS or SSL is configured, make sure the client public certificate is imported in the server truststore.
- 8.5+ **Problem:** When users are authorized to access a WebSphere® eXtreme Scale data grid, those users might also be authorized to perform management operations using the **xscmd** command or the **stopOgServer** command. Most data grid deployers restrict administrative access to only a subset of the users who can access grid data.
  If you use the following command to access the data grid, you might also be authorized to perform administrative actions, such as listAllJMXAddresses:

  ```
  ./xscmd.sh -user <user> -password <password> <other_parameters>
  ```

  If this operation works for this user, then any **xscmd** operation might also be performed by the same user.
  Resolution: When eXtreme Scale components run with WebSphere Application Server, use the WebSphere Application Server administrative console to activate the security manager. Click Security > Global Security, and select the check boxes, Enable administrative security and Use Java 2 Security, to restrict application access to local resources.

  Access to the management operations is controlled by the WebSphere Application Server security manager and is granted only to the users who belong to the WebSphere Administrator role. The **xscmd** command must be run from the WebSphere Application Server directory.

  When eXtreme Scale components run in a stand-alone environment, additional steps are required to implement administrative security. You must run the catalog servers and container servers using the Java™ security manager, which requires a policy file.

  The policy file resembles the following example:
  Remember: There are typically MapPermission entries as well, as documented in Java SE security tutorial - Step 5.

  ```
  grant codeBase "file:${objectgrid.home}/lib/*" {
  permission java.security.AllPermission;
  };

  grant principal javax.security.auth.x500.X500Principal "CN=manager,O=acme,OU=OGSample"
       {
          permission javax.management.MBeanPermission "*",
  "getAttribute,setAttribute,invoke,queryNames,addNotificationListener,removeNotificationListener";
       };
  ```

  In this case, only the manager principal is authorized to do administrative operations using the **xscmd** command. Other lines can be added as necessary to give additional principals MBean permissions. A different type of principal is needed if you use LDAP authentication.

  Enter the following command: UNIX Linux

  ```
  startOgServer.sh <arguments> -jvmargs -Djava.security.auth.login.config=jaas.config -Djava.security.manager
  -Djava.security.policy="auth.policy" -Dobjectgrid.home=$OBJECTGRID_HOME
  ```

  Windows

  ```
  startOGServer.bat <arguments> -jvmargs -Djava.security.auth.login.config=jaas.config -Djava.security.manager
  -Djava.security.policy="auth.policy" -Dobjectgrid.home=%OBJCTGRID_HOME%
  ```

  You specify -Djava.security.policy in this case, instead of -Djava.security.auth.policy.

Troubleshooting Liberty profile configurations

8.5+ Use this information to troubleshoot commonly experienced problems with the Liberty profile.

About this task

To help you identify and resolve problems, the product has a unified logging component. See Analyzing log and trace data.

Details of known restrictions that apply when using the Liberty profile are provided in the following two topics in the WebSphere® Application Server Information Center:

- Liberty profile: Runtime environment known restrictions
- Liberty profile: Developer Tools known restrictions

Procedure

- **Problem:** You experience problems that are not readily explained.
  Solution: Check that your Java™ development kits at Java Version 6 or later, and are at a current service level. See Minimum supported Java levels in the Liberty profile: Runtime environment known restrictions topic for more information.
- **Problem:** The following security error is displayed when you attempt to access an application that redirects to an SSL port, and the SSL port is not available:

  ```
  CWWKS9105E: Could not determine the SSL port for automatic redirection
  ```

  Solution: The port might not be available because of a missing SSL configuration or some error in the SSL configuration definition. Check the SSL configuration in the server.xml file to make sure that it exists and is correct.

IBM Support Assistant for WebSphere eXtreme Scale

You can use the IBM® Support Assistant to collect data, analyze symptoms, and access product information.

IBM Support Assistant Lite

IBM Support Assistant Lite for WebSphere® eXtreme Scale provides automatic data collection and symptom analysis support for problem determination scenarios.
IBM Support Assistant Lite reduces the amount of time it takes to reproduce a problem with the proper Reliability, Availability, and Serviceability tracing levels set (trace levels are set automatically by the tool) to streamline problem determination. If you need further assistance, IBM Support Assistant Lite also reduces the effort required to send the appropriate log information to IBM Support.

IBM Support Assistant Lite is included in each installation of WebSphere eXtreme Scale Version 7.1.0

IBM Support Assistant

IBM® Support Assistant (ISA) provides quick access to product, education, and support resources that can help you answer questions and resolve problems with IBM software products on your own, without needing to contact IBM Support. Different product-specific plug-ins let you customize IBM Support Assistant for the particular products you have installed. IBM Support Assistant can also collect system data, log files, and other information to help IBM Support determine the cause of a particular problem.

IBM Support Assistant is a utility to be installed on your workstation, not directly onto the WebSphere eXtreme Scale server system itself. The memory and resource requirements for the Assistant could negatively affect the performance of the WebSphere eXtreme Scale server system. The included portable diagnostic components are designed for minimal impact to the normal operation of a server.

You can use IBM Support Assistant to help you in the following ways:

- To search through IBM and non-IBM knowledge and information sources across multiple IBM products to answer a question or solve a problem
- To find additional information through product-specific Web resources; including product and support home pages, customer news groups and forums, skills and training resources and information about troubleshooting and commonly asked questions
- To extend your ability to diagnose product-specific problems with targeted diagnostic tools available in the Support Assistant
- To simplify collection of diagnostic data to help you and IBM resolve your problems (collecting either general or product/symptom-specific data)
- To help in reporting of problem incidents to IBM Support through a customized online interface, including the ability to attach the diagnostic data referenced above or any other information to new or existing incidents

Finally, you can use the built-in Updater facility to obtain support for additional software products and capabilities as they become available. To set up IBM Support Assistant for use with WebSphere eXtreme Scale, first install IBM Support Assistant using the files provided in the downloaded image from the IBM Support Overview Web page at: http://www-947.ibm.com/support/entry/portal/Overview/Software/Other_Software/IBM_Support_Assistant. Next, use IBM Support Assistant to locate and install any product updates. You can also choose to install plug-ins available for other IBM software in your environment. More information and the latest version of the IBM Support Assistant are available from the IBM Support Assistant Web page at: http://www.ibm.com/software/support/isa/.

Reference

	Use the reference information to quickly access configuration file descriptions, API information, messages, and more.

- ObjectGrid interface
  The following methods allow you to interact with an ObjectGrid instance.
- BackingMap interface
  Each ObjectGrid instance contains a collection of BackingMap objects. Use the defineMap method or the createMap method of the ObjectGrid interface to name and add each BackingMap to an ObjectGrid instance. These methods return a BackingMap instance that is then used to define the behavior of an individual Map. A BackingMap can be considered as an in-memory cache of committed data for an individual map.
- ExceptionMapper interface
  When a user plug-in implementation throws an exception, eXtreme Scale checks certain exceptions defined in the throws contract. However, sometimes an unchecked exception contains a contract exception or the exception does not observe the contract appropriately. Therefore a mechanism is necessary to map the exception to the contract exception if possible, such as ExceptionMapper.
- 8.5+ Regular expression syntax
  A regular expression is a structured string that is used to match other strings. You can use regular expressions for data invalidation.
- Configuration files
  WebSphere® eXtreme Scale is configured by a collection of XML and properties files.
- Messages
  When you encounter a message in a log or other parts of the product interface, you can look up the message by its component prefix to find out more information.
- User interface settings
  This reference information describes settings that you can view and configure on the pages of the WebSphere Application Serveradministrative console and elsewhere.

ObjectGrid interface

The following methods allow you to interact with an ObjectGrid instance.

Create and initialize

See the ObjectGridManager interface topic for the required steps for creating an ObjectGrid instance. Two distinct methods exist to create an ObjectGrid instance: programmatically or with XML configuration files. See ObjectGridManager interface for more information.

Get or set and factory methods

Any set methods must be called before you initialize the ObjectGrid instance. If you call a set method after the initialize method is called, a java.lang.IllegalStateException exception results. Each of the getSession methods of the ObjectGrid interface also implicitly call the initialize method. Therefore, you must call the set methods before calling any of the getSession methods. The only exception to this rule is with the setting, adding, and removing of ObjectGridEventListener objects. These objects are allowed to be processed after the initialization processing has completed.

The ObjectGrid interface contains the following major methods.

Table 1. ObjectGrid interface. Major methods of ObjectGrid.

Method	Description
BackingMap defineMap(String name);	defineMap: is a factory method to define a uniquely named BackingMap. For more information about backing maps, see BackingMap interface.
BackingMap getMap(String name);	getMap: Returns a BackingMap previously defined by calling defineMap. By using this method, you can configure the BackingMap, if it is not already configured through XML configuration.
BackingMap createMap(String name);	createMap: Creates a BackingMap, but does not cache it for use by this ObjectGrid. Use this method with the setMaps(List) method of the ObjectGrid interface, which caches BackingMaps for use with this ObjectGrid. Use these methods when you are configuring an ObjectGrid with the Spring Framework.
void setMaps(List mapList);	setMaps: Clears any BackingMaps that have been previously defined on this ObjectGrid and replaces them with the list of BackingMaps that is provided.
public Session getSession() throws ObjectGridException, TransactionCallbackException;	getSession: Returns a Session, which provides begin, commit, rollback functionality for a Unit of Work. For more information about Session objects, see Session interface.
Session getSession(CredentialGenerator cg);	getSession(CredentialGenerator cg): Get a session with a CredentialGenerator object. This method can only be called by the ObjectGrid client in a client server environment.
Session getSession(Subject subject);	getSession(Subject subject): Allows the use of a specific Subject object rather than the one configured on the ObjectGrid to get a Session.
void initialize() throws ObjectGridException;	initialize: ObjectGrid is initialized and available for general use. This method is called implicitly when the getSession method is called, if the ObjectGrid is not in an initialized state.
void destroy();	destroy: The framework is disassembled and cannot be used after this method is called.

Method	Description
void setTxTimeout(int timeout);	setTxTimeout: Use this method to set the amount of time, in seconds, that a transaction that is started by a session that this ObjectGrid instance created is allowed for completion. If a transaction does not complete within the specified amount of time, the Session that started the transaction is marked as being "timed out". Marking a Session as timed out causes the next ObjectMap method that is invoked by the timed out Session to result in a com.ibm.websphere.objectgrid.TransactionTimeoutException exception. The Session is marked as rollback only, which causes the transaction to be rolled back even if the application calls the commit method instead of the rollback method after the TransactionTimeoutException exception is caught by the application. A timeout value of 0 indicates that the transaction is allowed unlimited amount of time to complete. The transaction does not time out if a time out value of 0 is used. If this method is not called, then any Session that is returned by the getSession method of this interface has a transaction timeout value set to 0 by default. An application can override the transaction timeout setting on a per Session basis by using the setTransactionTimeout method of the com.ibm.websphere.objectgrid.Session interface. You can also configure transaction timeout with the objectGrid.xml file in the distributed case.
int getTxTimeout();	getTxTimeout: Returns the transaction timeout value in seconds. This method returns the same value that is passed as the timeout parameter on the setTxTimeout method. If the setTxTimeout method was not called, then the method returns 0 to indicate that the transaction is allowed an unlimited amount of time to complete.
public int getObjectGridType();	Returns the type of ObjectGrid. The return value is equivalent to one of the constants declared on this interface: LOCAL, SERVER, or CLIENT.
public void registerEntities(Class[] entities);	Register one or more entities based on the class metadata. Entity registration is required prior to ObjectGrid initialization to bind an Entity with a BackingMap and any defined indices. This method may be called multiple times.
public void registerEntities(URL entityXML);	Registers one ore more entities from an entity XML file. Entity registration is required prior to ObjectGrid initialization to bind an Entity with a BackingMap and any defined indices. This method may be called multiple times.
void setQueryConfig(QueryConfig queryConfig);	Set the QueryConfig object for this ObjectGrid. A QueryConfig object provides query configurations for executing object queries over the maps in this ObjectGrid.
//Security	
void setSecurityEnabled()	setSecurityEnabled: Enables security. Security is disabled by default.
void setPermissionCheckPeriod(long period);	setPermissionCheckPeriod: This method takes a single parameter that indicates how often to check the permission that is used to allow a client access. If the parameter is 0, all methods ask the authorization mechanism, either JAAS authorization or custom authorization, to check if the current subject has permission. This strategy might cause performance issues depending on the authorization implementation. However, this type of authorization is available if it is required. Alternatively, if the parameter is less than 0, it indicates the number of milliseconds to cache a set of permissions before returning to the authorization mechanism to refresh them. This parameter provides much better performance, but if the backend permissions are changed during this time the ObjectGrid might allow or prevent access even though the backend security provider has been modified.
void setAuthorizationMechanism(int authMechanism);	setAuthorizationMechanism: Set the authorization mechanism. The default is SecurityConstants.JAAS_AUTHORIZATION.
setSubjectSource(SubjectSource ss);	setSubjectSource: Sets the SubjectSource plugin. This plug-in can be used to get a Subject object that represents the ObjectGrid client. This subject is used for ObjectGrid authorization. The SubjectSource.getSubject method is called by the ObjectGrid runtime when the ObjectGrid.getSession method is used to get a session and the security is enabled. This plug-in is useful for an already authenticated client: it can retrieve the authenticated Subject object and then pass to the ObjectGrid instance. Another authentication is not necessary.
setSubjectValidation(SubjectValidation sv);	setSubjectValidation: Sets the SubjectValidation plugin for this ObjectGrid instance. This plug-in can be used to validate that a javax.security.auth.Subject subject that is passed to the ObjectGrid is a valid subject that has not been tampered with. An implementation of this plug-in needs support from the Subject object creator, because only the creator knows if the Subject object has been tampered with. However, a subject creator might not know if the Subject has been tampered with. In this case, this plug-in should not be used.

Method	Description
void setObjectGridAuthorization (ObjectGridAuthorization ogAuthorization);	Sets the ObjectGridAuthorization for this ObjectGrid instance. Passing null to this method removes a previously set ObjectGridAuthorization object from an earlier invocation of this method and indicates that this <code>ObjectGrid</code> is not associated with a ObjectGridAuthorization object. This method should only be used when ObjectGrid security is enabled. If the ObjectGrid security is disabled, the provided ObjectGridAuthorization object will not be used. A ObjectGridAuthorization plug-in can be used to authorize access to the ObjectGrid and maps.

ObjectGrid interface: plug-ins

The ObjectGrid interface has several optional plug-in points for more extensible interactions.

```
void addEventListener(ObjectGridEventListener cb);
void setEventListeners(List cbList);
void removeEventListener(ObjectGridEventListener cb);
void setTransactionCallback(TransactionCallback callback);
int reserveSlot(String);
// Security related plug-ins
void setSubjectValidation(SubjectValidation subjectValidation);
void setSubjectSource(SubjectSource source);
```

- ObjectGridEventListener: An ObjectGridEventListener interface is used to receive notifications when significant events occur on the ObjectGrid. These events include ObjectGrid initialization, beginning of a transaction, ending a transaction, and destroying an ObjectGrid. To listen for these events, create a class that implements the ObjectGridEventListener interface and add it to the ObjectGrid. These listeners are associated with each Session. See Listeners and Session interface for more information.
- TransactionCallback: A TransactionCallback listener interface allows transactional events such as begin, commit and rollback signals to send to this interface. Typically, a TransactionCallback listener interface is used with a Loader. For more information, see TransactionCallback plug-in and Loaders. These events can then be used to coordinate transactions with an external resource or within multiple loaders.
- reserveSlot: Allows plug-ins on this ObjectGrid to reserve slots for use in object instances that have slots like TxID.
- SubjectValidation. If security is enabled, this plug-in can be used to validate a javax.security.auth.Subject class that is passed to the ObjectGrid.
- SubjectSource: If security is enabled, this plug-in can be used to get a Subject object that represents the ObjectGrid client. This subject is then used for ObjectGrid authorization.

For more information about plug-ins, see Java plug-ins overview.

BackingMap interface

Each ObjectGrid instance contains a collection of BackingMap objects. Use the defineMap method or the createMap method of the ObjectGrid interface to name and add each BackingMap to an ObjectGrid instance. These methods return a BackingMap instance that is then used to define the behavior of an individual Map. A BackingMap can be considered as an in-memory cache of committed data for an individual map.

Session interface

The Session interface is used to begin a transaction and to obtain the ObjectMap or JavaMap that is required for performing transactional interaction between an application and a BackingMap object. However, the transaction changes are not applied to the BackingMap object until the transaction is committed. A BackingMap can be considered as an in-memory cache of committed data for an individual map. For more information, see Using Sessions to access data in the grid.

The BackingMap interface provides methods for setting BackingMap attributes. Some of the set methods allow extensibility of a BackingMap through several custom designed plug-ins. See the following list of the set methods for setting attributes and providing custom designed plug-in support:

```
// For setting BackingMap attributes.
public void setReadOnly(boolean readOnlyEnabled);
public void setNullValuesSupported(boolean nullValuesSupported);
public void setLockStrategy( LockStrategy lockStrategy );
public void setCopyMode(CopyMode mode, Class valueInterface);
public void setCopyKey(boolean b);
public void setNumberOfBuckets(int numBuckets);
public void setNumberOfLockBuckets(int numBuckets);
public void setLockTimeout(int seconds);
public void setTimeToLive(int seconds);
public void setTtlEvictorType(TTLType type);
public void setEvictionTriggers(String evictionTriggers);

// For setting an optional custom plug-in provided by application.
public abstract void setObjectTransformer(ObjectTransformer t);
public abstract void setOptimisticCallback(OptimisticCallback checker);
public abstract void setLoader(Loader loader);
public abstract void setPreloadMode(boolean async);
public abstract void setEvictor(Evictor e);
public void setMapEventListeners( List /*MapEventListener*/ eventListenerList );
public void addMapEventListener(MapEventListener eventListener );
public void removeMapEventListener(MapEventListener eventListener );
public void addMapIndexPlugin(MapIndexPlugin index);
public void setMapIndexPlugins(List /\* MapIndexPlugin \*/ indexList );
public void createDynamicIndex(String name, boolean isRangeIndex,
```

```
String attributeName, DynamicIndexCallback cb);
public void createDynamicIndex(MapIndexPlugin index, DynamicIndexCallback cb);
public void removeDynamicIndex(String name);
```

A corresponding get method exists for each of the set methods listed.

BackingMap attributes

Each BackingMap has the following attributes that can be set to modify or control the BackingMap behavior:

backingMap attributes

copyKey
: Specifies if the a copy of the key is required when a map entry is created. Copying the key object allows the application to use the same key object for each ObjectMap operation. Set the value to `true` to copy the key object when a map entry is created. The default value is `false`. (Optional)

CopyMode
: Specifies if a get operation of an entry in the BackingMap instance returns the actual value, a copy of the value, or a proxy for the value. Set the CopyMode attribute to one of five values:

  `COPY_ON_READ_AND_COMMIT`
  : The default value is `COPY_ON_READ_AND_COMMIT`. Set the value to `COPY_ON_READ_AND_COMMIT` to ensure that an application never has a reference to the value object that is in the BackingMap instance. Instead, the application is always working with a copy of the value that is in the BackingMap instance. (Optional)

  `COPY_ON_READ`
  : Set the value to `COPY_ON_READ` to improve performance over the `COPY_ON_READ_AND_COMMIT` value by eliminating the copy that occurs when a transaction is committed. To preserve the integrity of the BackingMap data, the application commits to delete every reference to an entry after the transaction is committed. Setting this value results in an ObjectMap.get method returning a copy of the value instead of a reference to the value, which ensures changes that are made by the application to the value does not affect the BackingMap element until the transaction is committed.

  `COPY_ON_WRITE`
  : Set the value to `COPY_ON_WRITE` to improve performance over the `COPY_ON_READ_AND_COMMIT` value by eliminating the copy that occurs when ObjectMap.get method is called for the first time by a transaction for a given key. Instead, the ObjectMap.get method returns a proxy to the value instead of a direct reference to the value object. The proxy ensures that a copy of the value is not made unless the application calls a set method on the value interface.

  `NO_COPY`
  : Set the value to `NO_COPY` to allow an application to never modify a value object that is obtained using an ObjectMap.get method in exchange for performance improvements. Set the value to `NO_COPY` for maps associated with EntityManager API entities.

  `COPY_TO_BYTES`
  : Set the value to `COPY_TO_BYTES` to improve memory footprint for complex Object types and to improve performance when the copying of an Object relies on serialization to make the copy. If an Object is not Cloneable or a custom ObjectTransformer with an efficient copyValue method is not provided, the default copy mechanism is to serialize and inflate the object to make a copy. With the `COPY_TO_BYTES` setting, inflate is only performed during a read and serialize is only performed during commit.

  For more information about these settings, see Tuning the copy mode.

evictionTriggers
: Sets the types of additional eviction triggers to use. All evictors for the backing map use this list of additional triggers. To avoid an IllegalStateException, this attribute must be called before the ObjectGrid.initialize() method. Also, note that the ObjectGrid.getSession() method implicitly calls the ObjectGrid.initialize() method if the method has yet to be called by the application. Entries in the list of triggers are separated by semicolons. Current eviction triggers include MEMORY_USAGE_THRESHOLD. For more information, see Plug-ins for evicting cache objects. (Optional)

lockStrategy
: Specifies if the internal lock manager is used whenever a map entry is accessed by a transaction. Set this attribute to one of three values: `OPTIMISTIC`, `PESSIMISTIC`, or `NONE`. The default value is `OPTIMISTIC`. (Optional)
  The optimistic locking strategy is typically used when a map does not have a loader plug-in, is mostly read and not frequently written to or updated, and the locking is not provided by the persistence manager using eXtreme Scale as a side cache or by the application. An exclusive lock is obtained on a map entry that is inserted, updated, or removed at commit time. The lock ensures that the version information cannot be changed by another transaction while the transaction being committed is performing an optimistic version check.

  The pessimistic locking strategy is typically used for a map that does not have a loader plug-in, and locking is not provided by a persistence manager using eXtreme Scale as a side cache, by a loader plug-in, or by the application. The pessimistic locking strategy is used when the optimistic locking strategy fails too often because update transactions frequently collide on the same map entry.

  The no locking strategy indicates that the internal LockManager is not needed. Concurrency control is provided outside of eXtreme Scale, either by the persistence manager using eXtreme Scale as a side cache or application, or by the loader plug-in that uses database locks to control concurrency.

lockTimeout
: Sets the lock timeout that is used by the lock manager for the BackingMap instance. Set the lockStrategy attribute to `OPTIMISTIC` or `PESSIMISTIC` to create a lock manager for the BackingMap instance. To prevent deadlocks from occurring, the lock manager has a default timeout value of 15 seconds. If the timeout limit is exceeded, a LockTimeoutException exception occurs. The default value of 15 seconds is sufficient for most applications, but on a heavily loaded system, a timeout might occur when no deadlock exists. Use the lockTimeout attribute to increase the value from the default to prevent false timeout exceptions from occurring. Set the lockStrategy attribute to `NONE` to specify the BackingMap instance use no lock manager. (Optional)

name
: Specifies the name that is assigned to the backingMap instance. If this attribute is missing, the XML validation fails. (Required)

nullValuesSupported
: Set the value to `true` to support null values in the ObjectMap. When null values are supported, a get operation that returns null might mean that the value is null or that the map does not contain the key that is passed to the method. The default value is `true`. (Optional)

numberOfBuckets
: The BackingMap instance uses a hash map for implementation. The numberOfBuckets attribute specifies the number of buckets for the BackingMap instance to use. If multiple entries exist in the BackingMap, more buckets lead to better performance because the risk of collisions is lower as the number

of buckets increases. More buckets also lead to more concurrency. Specify a value of `0` to disable the near cache on a client. When you set the value to `0` for a client, set the value in the client override ObjectGrid XML descriptor file only. (Optional)

numberOfLockBuckets
: The lock manager uses a hash map to track entries that are locked by one or more transactions. The numberOfLockBuckets attribute sets the number of lock buckets that are used by the lock manager for the BackingMap instance. Set the lockStrategy attribute to `OPTIMISTIC` or `PESSIMISTIC` to create a lock manager for the BackingMap instance. If many entries exist, more lock buckets lead to better performance because the risk of collisions is lower as the number of buckets grows. More lock buckets also lead to more concurrency. Set the lockStrategy attribute to `NONE` to specify the BackingMap instance use no lock manager. (Optional)

pluginCollectionRef
: Specifies a reference to a backingMapPluginCollection plug-in. The value of this attribute must match the ID attribute of a backingMapCollection plug-in. Validation fails if no matching ID exists. Set the attribute to reuse BackingMap plug-ins. (Optional)

preloadMode
: Sets the preload mode if a loader plug-in is set for this BackingMap instance. The default value is `false`. If the attribute is set to `true`, the Loader.preloadMap(Session, BackingMap) method is invoked asynchronously. Otherwise, running the method is blocked when loading data so that the cache is unavailable until preload completes. Preloading occurs during initialization. (Optional)

readOnly
: Sets a BackingMap instance as read/write when you specify the attribute as `false`. When you specify the attribute as `true`, the BackingMap instance is read-only. (Optional)

template
: Specifies if dynamic maps can be used. Set this value to `true` if the BackingMap map is a template map. Template maps can be used to dynamically create maps after the ObjectGrid is started. Calls to Session.getMap(String) result in dynamic maps being created if the name passed to the method matches the regular expression specified in the name attribute of the backingMap. The default value is `false`. (Optional)

timeToLive
: Specifies in seconds how long each map entry is present. The default value of `0` means that the map entry is present forever, or until the application explicitly removes or invalidates the entry. Otherwise, the TTL evictor evicts the map entry based on this value. (Optional)

ttlEvictorType
: Specifies how the expiration time of a BackingMap entry is computed. Set this attribute to one of these values: `CREATION_TIME`, `LAST_ACCESS_TIME`, `LAST_UPDATE_TIME`, or `NONE`. The `CREATION_TIME` value indicates that an entry expiration time is the sum of the creation time of the entry plus the timeToLive attribute value. The `LAST_ACCESS_TIME` value indicates that an entry expiration time is the sum of the last access time of the entry (whether the entry was updated or merely read), plus the timeToLive attribute value. The `LAST_UPDATE_TIME` value indicates that an entry expiration time is the sum of the last update time of the entry plus the timeToLive attribute value. The `NONE` value, which is the default, indicates that an entry has no expiration time and is present in the BackingMap instance until the application explicitly removes or invalidates the entry. (Optional)

valueInterfaceClassName
: Specifies a class that is required when you set the CopyMode attribute to `COPY_ON_WRITE`. This attribute is ignored for all other modes. The `COPY_ON_WRITE` value uses a proxy when ObjectMap.get method calls are made. The proxy ensures that a copy of the value is not made unless the application calls a set method on the class that is specified as the valueInterfaceClassName attribute. (Optional)

viewRef
: Specifies that the backingMap is a view map. (Optional)

writeBehind
: Specifies that the write-behind support is enabled with write-behind parameters (Optional). Write-behind parameters consist of a maximum update time and a maximum key update count. The format of the write-behind parameter is "`[T(time)][;][C(count)]`". The database is updated when one of the following events occurs:

  - The maximum update time, specified in seconds, has passed since the last update.
  - The number of available updates in the queue map has reached the maximum update count.

  For more information, see Write-behind caching.

  Write-behind support is an extension of the Loader plug-in, which you use to integrate eXtreme Scale with the database. For example, consult the Configuring JPA loaders information about configuring a JPA loader.

The following example demonstrates how to define the someMap BackingMap in the someGrid ObjectGrid instance and set various attributes of the BackingMap by using the set methods of the BackingMap interface:

```
import com.ibm.websphere.objectgrid.BackingMap;
import com.ibm.websphere.objectgrid.LockStrategy;
import com.ibm.websphere.objectgrid.ObjectGrid;
import com.ibm.websphere.objectgrid.ObjectGridManagerFactory;

...

ObjectGrid og =
ObjectGridManagerFactory.getObjectGridManager().createObjectGrid("someGrid");
BackingMap bm = objectGrid.getMap("someMap");
bm.setReadOnly( true ); // override default of read/write
bm.setNullValuesSupported(false); // override default of allowing Null values
bm.setLockStrategy( LockStrategy.PESSIMISTIC ); // override default of OPTIMISTIC
bm.setLockTimeout( 60 ); // override default of 15 seconds.
bm.setNumberOfBuckets(251); // override default (prime numbers work best)
bm.setNumberOfLockBuckets(251); // override default (prime numbers work best)
```

BackingMap plug-ins

The BackingMap interface has several optional plug points for more extensible interactions with the ObjectGrid:

- **Evictor**: An evictor plug-in is a default mechanism that is provided for evicting cache entries and for creating custom evictors. The built in time-to-live evictor uses a time-based algorithm to decide when an entry in BackingMap must be evicted. Some applications might need to use a different algorithm for deciding when a cache entry needs to be evicted. The Evictor plug-in makes a custom designed Evictor available to the BackingMap to use. The Evictor plug-in is in addition to the built in time-to-live evictor. You can use the provided custom Evictor plug-in that implements well-known algorithms such as

"least recently used" or "least frequently used". Applications can either plug-in one of the provided Evictor plug-ins or it can provide its own Evictor plug-in. For more information, see Plug-ins for evicting cache objects.

- **ObjectTransformer**: An ObjectTransformer plug-in allows you to serialize, deserialize, and copy objects in the cache. The ObjectTransformer interface has been replaced by the DataSerializer plug-ins, which you can use to efficiently store arbitrary data in WebSphere eXtreme Scale so that existing product APIs can efficiently interact with your data. For more information, see ObjectTransformer plug-in.
- **OptimisticCallback**: An OptimisticCallback plug-in allows you to customize versioning and comparison operations of cache objects when you are using the optimistic lock strategy. The OptimisticCallback plug-in has been replaced by the ValueDataSerializer.Versionable interface, which you can implement when you use the DataSerializer plug-in with the COPY_TO_BYTES copy mode or when you use the @Version annotation with the EntityManager API. For more information, see Plug-ins for versioning and comparing cache objects.
- **MapEventListener**: A MapEventListener plug-in provides callback notifications and significant cache state changes that occur for a BackingMap. An application might want to know about BackingMap events such as a map entry eviction or a preload of a BackingMap completion. A BackingMap calls methods on the MapEventListener plug-in to notify an application of BackingMap events. An application can receive notification of various BackingMap events by using the setMapEventListener method to provide one or more custom designed MapEventListener plug-ins to the BackingMap. The application can modify the listed MapEventListener objects by using the addMapEventListener method or the removeMapEventListener method. For more information, see MapEventListener plug-in.
- **BackingMapLifecycleListener**: A BackingMapLifecycleListener plug-in provides BackingMap life cycle events for the BackingMap instance. The BackingMapLifecycleListener plug-in can be used as an optional mix-in interface for all other BackingMap plug-ins.
- **BackingMapPlugin**: A BackingMapPlugin is an optional mix-in interface that provides extended life cycle management events for all other BackingMap plug-ins.
- **Indexing**: Use the indexing feature, which is represented by the MapIndexplug-in plug-in, to build an index or several indexes on a BackingMap map to support non-key data access.
- **Loader**: A Loader plug-in on an ObjectGrid map acts as a memory cache for data that is typically kept in a persistent store on either the same system or some other system. (Server side only) For example, a Java database connectivity (JDBC) Loader can be used to move data in and out of a BackingMap and one or more relational tables of a relational database. A relational database does not need to be used as the persistent store for a BackingMap. The Loader can also be used to moved data between a BackingMap and a file, between a BackingMap and a Hibernate map, between a BackingMap and a Java 2 Platform, Enterprise Edition (JEE) entity bean, between a BackingMap and another application server, and so on. The application must provide a custom-designed Loader plug-in to move data between the BackingMap and the persistent store for every technology that is used. If a Loader is not provided, the BackingMap becomes a simple in-memory cache. For more information, see Plug-ins for communicating with databases.
- **MapSerializerPlugin**: A MapSerializerPlugin allows you to serialize and inflate Java objects and non-Java data in the cache. It is used with the DataSerializer mix-in interfaces, allowing robust and flexible options for high-performance applications.

ExceptionMapper interface

When a user plug-in implementation throws an exception, eXtreme Scale checks certain exceptions defined in the throws contract. However, sometimes an unchecked exception contains a contract exception or the exception does not observe the contract appropriately. Therefore a mechanism is necessary to map the exception to the contract exception if possible, such as ExceptionMapper.

Configuring the bean

Consider that a JPALoader must throw a LoaderNotAvailableException when the database server or network is not functional or the database runs out of resources. However, the JPA provider implementation normally just throws a generic PersistenceException with an SQLException, the SQL state or error code of which could indicate the database server problem or network problem. To further complicate the situation, different databases have different SQL state and error codes for such problems. So the exception-mapping mechanism has to be specific to the database.

The ExceptionMapper interface is used to solve the problem. It has a method Throwable map(Throwable original) to map the original exception to a consumable exception.

For example, to solve the stated problem, the implementation class could introspect the SQL state and error code of the java.sql.SQLException chained in the JPA exception. Then, it can throw a LoaderNotAvailableException if the SQL state or error code indicates the database server or network is not functional or the database runs out of resources.

Currently, the ExceptionMapper bean can only be configured in the JPATxCallback ObjectGrid beans. It is used to map all the exceptions received from the JPATxCallback and JPALoader or JPAEntityLoader beans.

To configure an ExceptionMapper, you have to use a Spring-style configuration for the ExceptionMapper bean inside of the JPATxCallback bean.

See Configuring JPA loaders for information about how to use Spring-style configuration for a JPALoader.

The following code is an example in which we map the JPA exceptions to a LoaderNotAvailableException if it indicates a database server problem or network problem. This ExceptionMapper implementation is for using a JPA provider with an MSSQL database. First, define a set of SQL error codes and SQL states that indicate the particular network problem or database server problem. In the map method, first check the SQL error code against a list of known error codes, then the SQL states, and finally the message. If one of them matches, throw a LoaderNotAvaliableException.

Code example

```
public class JPAMSSQLExceptionMapper implements ExceptionMapper {

    static Set<Integer> loaderNotAvailableSQLErrorSet = new HashSet<Integer>();

    static Set<String> loaderNotAvailableSQLStateSet = new HashSet<String>();

    static {
        addInitialMaps();
    }
```

```
    public C3P0MSSQLExceptionMapper() {
        System.out.println("C3P0MSSQLExceptionMapper is constructed");
    }

    /**
     * @internal
     * This method is used to add intial maps to the hash, this is used
     * internally, and it is not for public view
     */
    private static void addInitialMaps() {
        //  http://msdn.microsoft.com/en-us/library/cc645603.aspx
        loaderNotAvailableSQLErrorSet.add(new Integer(230));
        loaderNotAvailableSQLErrorSet.add(new Integer(6002));

        // http://white-box.us/2009/03/08/sql-92-sqlstate-codes/
        /*
         * 08001 SQL client unable to establish SQL connection
         * 08002 connection name in use
         * 08003 connection does not exist
         * 08004 SQL server rejected SQL connection
         * 08006 connection failure
         * 08007 transaction resolution unknown
         */
        loaderNotAvailableSQLStateSet.add("08000");
        loaderNotAvailableSQLStateSet.add("08001");
        loaderNotAvailableSQLStateSet.add("08002");
        loaderNotAvailableSQLStateSet.add("08003");
        loaderNotAvailableSQLStateSet.add("08004");
        loaderNotAvailableSQLStateSet.add("08006");
        loaderNotAvailableSQLStateSet.add("08007");

        // http://msdn.microsoft.com/en-us/library/ms714687.aspx
        loaderNotAvailableSQLStateSet.add("08S01");
        loaderNotAvailableSQLStateSet.add("HY000");
    }

    private static Pattern[] sqlServerMessagePatterns = new Pattern[] {
            Pattern.compile("The TCP/IP connection to the host .* has failed.*"), Pattern.compile(".*Connection
reset.*") };

    private static Pattern[] sqlExceptionMessagePatterns = new Pattern[] { Pattern
            .compile(".*Connections could not be acquired from the underlying database.*") };

    private static String connection_reset = "Connection reset";

    public Throwable map(Throwable originalEx) {

        Throwable cause = originalEx;

        while (cause != null) {
            // keep looping to check the next chained exception
            if (cause instanceof SQLException) {
                // Only check if the exception is an SQLException

                SQLException sqle = (SQLException) cause;

                // If the loader not available SQL state set contains this SQL state, then
                // we return a LoaderNotAvailableException with the original exception chained in it.
                if (loaderNotAvailableSQLStateSet.contains(sqle.getSQLState())) {
                    return new LoaderNotAvailableException(originalEx);
                }

                // If the loader not available SQL error code set contains this error code, then
                // we return a LoaderNotAvailableException with the original exception chained in it
                if (loaderNotAvailableSQLErrorSet.contains(new Integer(sqle.getErrorCode()))) {
                    return new LoaderNotAvailableException(originalEx);
                }

                String msg = sqle.getMessage();
                for (int i=0; i<sqlExceptionMessagePatterns.length; i++) {
                    if (sqlExceptionMessagePatterns[i].matcher(msg).matches()) {
                        return new LoaderNotAvailableException(originalEx);
                    }
                }

            } else if (cause.getClass().getName().equals("com.microsoft.sqlserver.jdbc.SQLServerException")) {
                String msg = cause.getMessage();
                for (int i=0; i<sqlServerMessagePatterns.length; i++) {
                    if (sqlServerMessagePatterns[i].matcher(msg).matches()) {
                        return new LoaderNotAvailableException(originalEx);
                    }
                }
                System.out.println("msg " + msg + " does not match");
            }

            // Get the next chained exception
            Throwable newCause = cause.getCause();

            // Safe-guard check to avoid indefinite loop if the exception chains itself
            if (newCause == cause) {
```

```
                // Always return the original exception if cannot map it.
                return originalEx;
            } else {
                cause = newCause;
            }
        }

        // Always retrun the original exception if cannot map it.
        return originalEx;
    }
```

xscmd utility reference

You can use the following list of commands as a reference when you are using the **xscmd** utility.

General command parameters

The general format of **xscmd** utility commands follows. The optional parameters are in square brackets [ ].
8.5

```
Usage: xscmd -c <cmdName> | -h <cmdName> | -lc [<cmdGroupName>] | -lcg
             [-cgc <className>] [-ca <support>] [-sp
             <profileName>] [-ks <filePath>] [-ts <filePath>] [-trf
             <filePath>] [-prot <protocol>] [-cxpv <provider>] [-trs
             <traceSpec>] [-al <alias>] [-pwd <password>] [-tsp <password>]
             [-cep <endpoints>] [-ksp <password>] [-arc <integer>] [-tt
             <type>] [-tst <type>] [-ssp <profileName>] [-kst <type>] [-cgp
             <property>] [-user <username>]

Options:
  -al,--alias <alias>                    Alias name in the keystore.

  -arc,--authRetryCount <integer>        The retry count for authentication if
                                         the credential is expired. If the
                                         value is set to 0, then
                                         authentication retries do not occur.

  -c,--command <cmdName>                 Specifies the name of the command to
                                         execute

  -ca,--credAuth <support>               Set the client credential
                                         authentication support [Never,
                                         Supported, Required].

  -cep,--catalogEndPoints <endpoints>    Specifies one or more catalog service
                                         endpoints in the format
                                         <host>[:<listenerPort>][,<host>[:<liste
                                         nerPort>]]. Default endpoint:
                                         localhost:2809

  -cgc,--credGenClass <className>        Specifies the name of the class that
                                         implements the CredentialGenerator
                                         interface. This class is used to get
                                         credentials for clients.

  -cgp,--credGenProps <property>         Specifies the properties for the
                                         CredentialGenerator implementation
                                         class. The properties are set to the
                                         object with the setProperties(String)
                                         method.

  -cxpv,--contextProvider <provider>     Context provider.  Examples: IBMJSSE2,
                                         IBMJSSE, IBMJSSEFIPS.

  -h,--help <cmdName>                    Invokes general command-line help

  -ks,--keyStore <filePath>              Absolute path to keystore. Example:
                                         /etc/test/security/server.public

  -ksp,--keyStorePassword <password>     Specifies the password to the keystore.

  -kst,--keyStoreType <type>             Keystore type. Example: JKS, JCEK,
                                         PKCS12.

  -lc,--listCommands <cmdGroupName>      List all commands for a command group

  -lcg,--listCommandGroups               List all command groups

  -prot,--protocol <protocol>            Protocol.  Examples: SSL, SSLv2,
                                         SSLv3, TLS, TLSv1.

  -pwd,--password <password>             eXtreme Scale password security
                                         credential

  -sp,--secProfile <profileName>         Specifies a profile name.
```

-ssp,--saveSecProfile <profileName>	Save security parameter values in security profile.
-trf,--traceFile <filePath>	Specifies the absolute path to the generated trace file for xscmd command output
-trs,--traceSpec <traceSpec>	Specifies the trace specification for xscmd command output
-ts,--trustStore <filePath>	Absolute path to truststore. Example: /etc/test/security/server.public
-tsp,--trustStorePassword <password>	Truststore password
-tst,--trustStoreType <type>	Truststore type. Examples: JKS, JCEK, PKCS12.
-tt,--transportType <type>	Transport layer security configuration type. Examples: TCP/IP, SSL-Supported, SSL-Required.
-user,--username <username>	eXtreme Scale user name security credential

Restriction: You can use FIPS data encryption with the TLSv1 protocol only.

All commands

The full list of **xscmd** utility commands follows.
Note: Column names may change (except for a column type and position), and new columns may be added to the end of a table if a command is enhanced as appropriate.
For further help and parameters for a specific command run **xscmd -h command_name**. If you plan on developing a customized script with these commands, then you should redirect the standard error path to a null device by running the following: `./xscmd.sh -c commandName -Options 2> /dev/null`

Examples

The following examples demonstrate how to run a command from the **xscmd** utility:

```
./xscmd.sh -lc * This command lists all available commands
```

```
./xscmd.sh -h showMapSizes * This command lists help for the showMapSizes command
```

Important: The output and usage of the following commands are subject to change in the future. If a command is marked with an asterisk (*) it means that only the output of the command is subject to change:

- listHosts
- showPlacement
- placementServiceStatus
- showDomainReplicationState
- showReplicationState
- *osgiAll
- *osgiCheck
- *osgiCurrent
- *osgiUpdate
- *showLinkedPrimaries
- *triggerPlacement

Regular expression syntax

8.5+ A regular expression is a structured string that is used to match other strings. You can use regular expressions for data invalidation.

Regular expression examples

Regular expression	Description
.	

	Finds any one character.
`.*`	Finds any one character zero or more times.
`A.*`	Finds all strings that start with "A".
`.*A`	Finds all strings that end with "A".
`A?`	Finds "A", zero or one time.
`A*`	Finds "A", zero or many times.
`A+`	Finds "A", one time or many times.
`A?B*C+`	Finds any one character, followed by zero or one A, followed by zero or many Bs, followed by one or many Cs
`[ABC].*`	Finds strings that start with the letters "A", or "B", or "C".
`.*ABC.*`	Finds strings with the string "ABC" somewhere in the string.
`(ABC|DEF).*`	Finds strings that start with the string "ABC" or "DEF".

See the java.util.regex.Pattern API documentation for the full regular expression syntax.

Configuration files

WebSphere® eXtreme Scale is configured by a collection of XML and properties files.

- Server properties file
  The server properties file contains several properties that define different settings for your server, such as trace settings, logging, and security configuration. The server properties file is used by both catalog service and container servers in both stand-alone servers and servers that are hosted in WebSphere Application Server.
- Client properties file
  Create a properties file based on your requirements for WebSphere eXtreme Scale client processes.
- REST data service properties file
  To configure the REST data service, edit the properties file for REST and define the required entity schema for a data grid.
- ObjectGrid descriptor XML file
  To configure WebSphere eXtreme Scale, use an ObjectGrid descriptor XML file and the ObjectGrid API.
- Deployment policy descriptor XML file
  To configure a deployment policy, use a deployment policy descriptor XML file.
- Entity metadata descriptor XML file
  The entity metadata descriptor file is an XML file that is used to define an entity schema for WebSphere eXtreme Scale. Define all of the entity metadata in the XML file, or define the entity metadata as annotations on the entity Java™ class file. The primary use is for entities that cannot use Java annotations.
- Security descriptor XML file
  Use a security descriptor XML file to configure an eXtreme Scale deployment topology with security enabled. You can use the elements in this file to configure different aspects of security.
- Spring descriptor XML file
  Use a Spring descriptor XML file to configure and integrate eXtreme Scale with Spring.
- Liberty profile configuration files
  You can specify server properties and Liberty web feature properties for WebSphere eXtreme Scale applications that run in the Liberty profile.

Troubleshooting XML configuration

Server properties file

The server properties file contains several properties that define different settings for your server, such as trace settings, logging, and security configuration. The server properties file is used by both catalog service and container servers in both stand-alone servers and servers that are hosted in WebSphere® Application Server.

- Server properties
  - General server properties
  - Container server properties
  - Catalog server properties
- Security server properties
  - General security properties
  - Transport layer security properties
    - Secure Sockets Layer (SSL) properties
  - Authentication properties

Sample server properties file

You can use the sampleServer.properties file that is in the *wxs_home*/properties directory to create your properties file.

Specifying a server properties file

Specifying a setting by using one of the items later in the list overrides the previous setting. For example, if you specify a system property value for the server properties file, the properties in that file override the values in the objectGridServer.properties file that is in the class path.

- For servers that run in WebSphere Application Server:
  - Use a well-named file in the class path, for example *was_root*/properties. If you put this well-named file in the current directory, the file is not found unless the current directory is in the class path. The name that is used follows:

    ```
    objectGridServer.properties
    ```

  - Specify a system property that specifies a file in the system current directory. Put the file in the *was_root*/properties directory. The file cannot be in the class path:

    ```
    -Dobjectgrid.server.props=file_name
    ```

- For servers that run in the Liberty profile:
  - In server.xml file, specify a server properties file by setting the serverProps attribute of the xsServer element; for example:

    ```
    <xsServer ... serverProps="${server.config.dir}/server.properties" ... />
    ```

    For eXtreme Scale servers that run in the Liberty profile, specify a server properties file to configure security. You can configure other properties in the server.xml file. For more information, see Liberty profile configuration files.

- For stand-alone servers:
  - Use a well-named file in the class path, for example *wxs_home*/properties. If you put this well-named file in the current directory, the file is not found unless the current directory is in the class path. The name that is used follows:

    ```
    objectGridServer.properties
    ```

  - Specify the server properties file as a parameter when you run the start server command. You can specify an absolute path or a path that is relative to the directory from which you run the start server command.

    ```
    -serverProps file_name
    ```

- For embedded, stand alone servers:
  Use the embedded server API. Use the ServerFactory.getServerProperties and ServerFactory.getCatalogServerProperties methods. The data in the object is populated with the data from the properties files.

Server properties

General properties

diskOverflowCapBytes
: Specifies the maximum amount of disk space that is used by this server for disk overflow, in bytes. The default value specifies that there is no limit on how much is stored on disk.
Default: `Long.MAX_VALUE`

diskStoragePath
: Specifies the absolute path to a directory location used for storing overflow content.

diskOverflowMinDiskSpaceBytes
: Specifies that entries are not moved to disk if there is less than this amount of space free in diskStoragePath, in bytes.
Default: `0`

diskOverflowEnabled
: Enables the native overflow disk feature. You must enable eXtreme Memory for this feature to work.
Default: `false`

enableMBeans
: Enables ObjectGrid container Managed Beans (MBean). This property applies to both the container server and the catalog service.
Default: `true`

exitJVMOnTeardown
: Specifies whether the JVM is also stopped when the eXtreme Scale server is stopped in an OSGi framework. By default, the JVM continues to run when each server in an OSGi framework is stopped in the **xscmd** utility with the **-c teardown** command. If you want to stop the JVM as well, set this property to `true`.
Default: `false`

haManagerPort
: Specifies the port that is used by the high availability (HA) manager for heartbeat communication between peer container servers. The haManagerPort port is only used for peer-to-peer communication between container servers that are in same domain. If the haManagerPort property is not defined, then an ephemeral port is used. In WebSphere Application Server, this setting is inherited by the high availability manager port configuration.
Default: `A dynamic port is chosen`.

JMXConnectorPort
: Defines the Secure Sockets Layer (SSL) port to which the Java™ Management Extensions (JMX) service binds. Only required if an SSL transport protocol is needed for JMX data.

JMXServicePort

Required only for WebSphere eXtreme Scale in a stand-alone environment. Specifies the port number on which the MBean server listens for communication with Java Management Extensions (JMX).
Default: `1099`

jvmStatsFileName
Specifies the file name of the CSV statistics file for the JVM.
Default: `jvmstats`

jvmStatsLoggingEnabled
When set to `true`, enables log data for the JVM to be written to a CSV file.
Default: `true`

jvmStatsWriteRate
Specifies the write rate of the CSV statistics files for the JVM in writes per second.
Default: `10`

listenerHost
Specifies the host name to which the Object Request Broker (ORB) transport protocol binds for communication. The value must be a fully qualified domain name or IP address. If your configuration involves multiple network cards, set the listener host and port to the IP address for which to bind. By setting the listener and host port, it allows the transport mechanism in the JVM know which IP address to use. If you do not specify which IP address to use, symptoms such as connection timeouts, unusual API failures, and clients that seem to hang can occur.

listenerPort (catalog server)
Specifies the port number to which the Object Request Broker transport protocol binds for communication.
Default: `2809`

Note: When a data grid server is run inside and the ORB transport protocol is being used, another port ORB_LISTENER_ADDRESS must also be opened. The BOOTSTRAP_ADDRESS port forwards requests to this port.

listenerPort (container server)
Specifies the port number to which the ORB transport protocol binds for communication.
Default: An ephemeral port is chosen.

Note: When a data grid server is run inside WebSphere Application Server and the ORB transport protocol is being used, another port ORB_LISTENER_ADDRESS must also be opened. The BOOTSTRAP_ADDRESS port forwards requests to this port.

listenerPort (client)
Specifies the port number to which the ORB transport protocol binds for communication. This setting configures the client to communicate with the catalog and container service. If a listener is not configured with the ORB transport protocol, an ephemeral port is chosen at startup. This port can vary each time the client application is started.
Default: An ephemeral port is chosen.

Note: When a data grid client is run inside WebSphere Application Server and the ORB transport protocol is being used, another port ORB_LISTENER_ADDRESS must also be opened. The BOOTSTRAP_ADDRESS port forwards requests to this port.

mapStatsFileName
Specifies the file name of the CSV statistics file for the map.
Default: `mapstats`

mapStatsLoggingEnabled
When set to `true`, enables log data for the maps on the server to be written to a CSV file.
Default: `true`

mapStatsWriteRate
Specifies the write rate of the CSV statistics files for the map in writes per second.
Default: `10`

maxJVMStatsFiles
Indicates the maximum number of CSV statistics files that are generated for the JVM.
Default: `5`

maxJVMStatsFileSize
Indicates the maximum file size, in megabytes, of the CSV statistics files for the JVM.
Default: `100`

maxMapStatsFileSize
Indicates the maximum file size, in megabytes, of the CSV statistics files for the map.
Default: `100`

maxOGStatsFiles
Indicates the maximum number of CSV statistics files that are generated for the ObjectGrid instance.
Default: `5`

maxOGStatsFileSize
Indicates the maximum file size, in megabytes, of the CSV statistics files for the ObjectGrid instance.
Default: `100`

maxMapStatsFiles
Indicates the maximum number of CSV statistics files that are generated for the map.
Default: `5`

maxThreads
Specifies the maximum number of threads that are used by the internal thread pool in the run time for built-in evictor and DataGrid operations.

Default: `50`

minThreads
: Specifies the minimum number of threads that are used by the internal thread pool in the run time for built-in evictor and DataGrid operations.
Default: `10`

ogStatsFileName
: Specifies the file name of the CSV statistics file for the ObjectGrid instance.
Default: `ogstats`

ogStatsLoggingEnabled
: When set to `true`, enables log data for the ObjectGrid instance on the server to be written to a CSV file.
Default: `false`

ogStatsWriteRate
: Specifies the write rate of the CSV statistics files for the ObjectGrid instance in writes per second.
Default: `10`

serverName
: Sets the server name that is used to identify the server. This property applies to both the container server and the catalog service.

systemStreamToFileEnabled
: Enables the container to write the SystemOut, SystemErr, and trace output to a file. If this property is set to `false`, output is not written to a file and is instead written to the console.
Default: `true`

traceFile
: Specifies a file name to write trace information. This property applies to both the container server and the catalog service.

  Example: ../logs/c4Trace.log

  Restriction: The traceFile property is not supported in the Liberty profile.

traceSpec
: Enables trace and the trace specification string for the container server. Trace is disabled by default. This property applies to both the container server and the catalog service. Examples:

  - `ObjectGrid=all=enabled`
  - `ObjectGrid*=all=enabled`

  Restriction: The traceSpec property is not supported in the Liberty profile.

workingDirectory
: Specifies the location to where the container server output is written. When this value is not specified, the output is written to a log directory within the current directory. This property applies to both the container server and the catalog service.
Default: No value is defined.

zoneName
: Set the name of the zone to which the server belongs. This property applies to both the container server and the catalog service.

Container server properties

catalogServiceEndPoints
: Specifies the end points to connect to the catalog service domain. This value must be in the form `host:port,host:port`. The host value is the listenerHost value and the port value is the listenerPort value of the catalog server. This property applies to a container server only.

enableXM
: When set to `true`, enables IBM® eXtremeMemory on the server and configures the server to use IBM eXtremeIO for synchronous and asynchronous replication. Cache entries for maps that are compatible with eXtremeMemory are stored in native memory instead of on the Java heap. All container servers in the data grid must use the same value for the enableXM property.
Default:`false`

maxXMSize
: Sets the maximum amount of memory, in megabytes, used by the server for eXtremeMemory storage.
Default: 25% of the total memory on the system.

memoryThresholdPercentage
: Sets the memory threshold for memory-based eviction. The percentage specifies the maximum heap to be used in the Java virtual machine (JVM) before eviction occurs. The default value is `-1`, which indicates that the memory threshold is not set. If the memoryThresholdPercentage property is set, the MemoryPoolMXBean value is set with the provided value. For more information, see MemoryPoolMXBean interface in the Java API specification. However, eviction occurs only if eviction is enabled on an evictor. To enable memory-based eviction, see Plug-ins for evicting cache objects. This property applies to a container server only.
Default:`-1`

statsSpec
: Specifies the statistics specification for the container server.
Examples:

  `all=disabled`: Disables all statistics.

  `all=enabled`: Enables all statistics.

  For more information about enabling statistics, see Enabling statistics.

Catalog service properties

8.5+ allowableShardOverrage

8.5+ Specifies the percentage of container servers that a zone must have compared to the other zones in a multi-zone deployment before all the replica shards are placed in that zone. If the percentage of container servers in the zone is below the specified value, only a relative subset of the replicas available are placed. After the percentage exceeds the specified value, all the replicas are placed. Primary shards are always placed. For example, the allowableShardOverrage value is set to 0.75 (75 percent). If zone1 has two container servers, and zone2 has three container servers, the percentage of the container servers between the zones is 2/3 (67 percent). Because this percentage is less than the allowableShardOverrage value of 75 percent, not all the replicas for the data grid are necessarily placed until the zones have an equal number of container servers.

catalogClusterEndPoints

For stand-alone configurations only. Specifies a list of catalog service domain end points for the catalog service. This property specifies the catalog service end points to start the catalog service domain. Use the following comma-separated format:

```
serverName:hostName:clientPort:peerPort,<serverName:hostName:clientPort:peerPort>
```

serverName

Specifies the name of the catalog server.

hostName

Specifies the host name for the computer where the server is launched.

clientPort

Specifies the port that is used for peer catalog service communication.

peerPort

This value is the same as the haManagerPort. Specifies the port that is used for peer catalog service communication.

This property applies to the catalog service only. If you start more catalog servers, they must include the same servers in the catalogClusterEndPoints property. The order of the list can be different, but the servers that are contained in the list must be the same for each catalog server. Do not put any spaces in the list.

domainName

For stand-alone configurations only. Specifies the domain name that is used to uniquely identify this catalog service domain to clients when routing to multiple domains. This property applies to the catalog service only.

enableQuorum

Enables quorum for the catalog service. Quorum is used to ensure that most of the catalog service domain is available before partitions are moved to the available container servers. To enable quorum, set the value to `true` or `enabled`. The default value is `disabled`. This property applies to the catalog service only. For more information, see Catalog server quorums.

<*foreignDomain*>.endpoints

Specifies the connection information for the catalog servers of the foreign domains, such as domain B:
For example:

```
B.endPoints=hostB1:2809, hostB2:2809
```

If a foreign domain has multiple catalog servers, specify all of them.

foreignDomains

Specifies the names of catalog service domains to which you want to link in a multi-master replication topology. You can specify multiple catalog service domains with a comma-separated list. This property applies to the catalog service only.

```
foreignDomains=domain2,domain3,domain4
```

Restriction: The foreignDomains property is not supported in the Liberty profile.

heartBeatFrequencyLevel

Specifies how often a server failover is detected. An aggressive heartbeat interval can be useful when the processes and network are stable. If the network or processes are not optimally configured, heartbeats might be missed, which can result in a false failure detection. The heartbeat frequency level is a trade-off between use of resources and failure discovery time. The more frequent a heartbeat occurs, then more resources are used. However, failures are discovered more quickly. This property applies to the catalog service only.

Table 1. Valid heartbeat values

Value	Action	Description
-1	Aggressive	Specifies an aggressive heartbeat level. With this value, failures are detected more quickly, but more processor and network resources are used. This level is more sensitive to missing heartbeats when the server is busy. Failovers are typically detected within 5 seconds.
0	Typical (default)	Specifies a heartbeat level at a typical rate. With this value, failover detection occurs at a reasonable rate without overusing resources. Failovers are typically detected within 30 seconds.
1	Relaxed	Specifies a relaxed heartbeat level. With this value, a decreased heartbeat frequency increases the time to detect failures, but also decreases processor and network use. Failovers are typically detected within 180 seconds.

isCatalog

For stand-alone configurations only. When set to `true`, the server process automatically starts a catalog service.
Default: `false`

placementDeferralInterval

Specifies the interval in milliseconds for deferring the balancing and placement of shards on the container servers. Placement does not start until after the time specified in the property has passed. Increasing the deferral interval lowers processor utilization, but the placement of work items is completed over time. A decrease in the deferral interval increases short-term processor usage, but the placement of work items is more immediate and expedited.
If multiple container servers are starting in succession, the deferral interval timer is reset if a new container server starts within the given interval. For example, if a second container server starts 10 seconds after the first container server, placement does not start until 15 seconds after the second container server started. However, if a third container server starts 20 seconds after the second container server, placement has already begun on the first two container servers.

When container servers become unavailable, placement is triggered as soon as the catalog server learns of the event so that recovery can occur as quickly as possible.

Default: 15000 ms (15 seconds)

Security server properties

The server properties file is also used to configure eXtreme Scale server security. You use a single server property file to specify both the basic properties and the security properties.

General security properties

credentialAuthentication

Indicates whether this server supports credential authentication. Choose one of the following values:

- `Never`: The server does not support credential authentication.
- `Supported`: The server supports the credential authentication if the client also supports credential authentication.
- `Required`: The client requires credential authentication.

See Authenticating application clients for details about credential authentication.

securityEnabled

Enables the container server security when set to `true`. The default value is `false`. When you want authentication to the data grid, this property must match the securityEnabled property that is specified in the objectGridSecurity.xml file, which is provided to the catalog server. When you are running with transport security only (the transportType property is set to either SSL-Supported or SSL-Required), it is not necessary to set the securityEnabled property to `true` in the objectGridSecurity.xml file.

Transport layer security settings

transportType

Specifies the server transport type. Use one of the following values:

- `TCP/IP`: Indicates that the server supports TCP/IP connections only.
- `SSL-Supported`: Indicates that the server supports both TCP/IP and Secure Sockets Layer (SSL) connections. (Default)
- `SSL-Required`: Indicates that the server requires SSL connections.

SSL configuration properties

alias

Specifies the alias name in the keystore. This property is used if the keystore has multiple key pair certificates and you want to select one of the certificates.
Default: No value is defined.

clientAuthentication

By default, the server does not authenticate the client and this property is set to false. When set to true, the server expects to receive and authenticate the client credential during the SSL handshake.
Valid values: `true` or `false`

contextProvider

Specifies the name of the context provider for the SSL or TLS implementation. If you indicate a value that is not valid, a security exception result that indicates that the context provider type is incorrect.
Valid values: `IBMJSSE2`, `IBMJSSE`, `IBMJSSEFIPS`, and so on.
Note: Use the `IBMJSSE2` value when you have a Java runtime environment that is provided by IBM. The values, `IBMJSSE` and `IBMJSSEFIPS`, are deprecated. If you use SSL security with the ORB transport and a JRE that is not provided by IBM, then see the documentation from your JRE vendor for an appropriate context provider setting.

customSecureTokenManagerProps

Specifies the custom SecureTokenManager implementation class properties. This property is used only if the secureTokenManagerType value is `custom`. The value is set to the SecureTokenManager Object with the setProperties(String) method.

customTokenManagerClass

Specifies the name of your SecureTokenManager implementation class, if you specified the SecureTokenManagerType property value as `custom`. The implementation class must have a default constructor to be instantiated.

keyStore

Specifies a fully qualified path to the keystore file.
Example: etc/test/security/client.private

Important: The directory path does not support Windows backslashes. If you have used backslashes, you must escape any backslash (\ ) characters in the path. For example, if you want to use the path C:\opt\ibm, enter C:\\opt\\ibm in the properties file. Windows directories with spaces are not supported.

keyStorePassword

Specifies the string password to the keystore. You can encode this value or use the actual value.

keyStoreType

Indicates the type of keystore. If you indicate a value that is not valid, a runtime security exception results.
Valid values: `JKS`, `JCEK`, `PKCS12`, and so on.

Important: The directory path does not support Windows backslashes. If you have used backslashes, you must escape any backslash (\ ) characters in the path. For example, if you want to use the path C:\opt\ibm, enter C:\\opt\\ibm in the properties file. Windows directories with spaces are not supported.

protocol

Indicates the type of security protocol to use for the client. Set this protocol value that is based on the Java Secure Socket Extension (JSSE) provider you use. If you indicate a value that is not valid, a security exception result that indicates that the protocol value is incorrect.
Valid values: `SSL`, `SSLv2`,`SSLv3`, `TLS`, `TLSv1`.

SecureTokenManager

The SecureTokenManager setting is used for protecting the secret string for server mutual authentications and for protecting the single sign-on token.

secureTokenManagerType
Specifies the type of SecureTokenManager setting. You must use the same secureTokenManagerType setting in all of the servers in the catalog service domain, and all servers in linked catalog service domains. You can use one of the following settings:

- `none`: Indicates that no secure token manager is used. A secure token manager is required to protect the authenticationSecret attribute value when it is transmitted over the network. This setting also disables the use of a single sign-on token.
- `default`: Indicates that a token manager that is supplied with the WebSphere eXtreme Scale product is used. You must provide a SecureToken keystore configuration.
- `custom`: Indicates that you have your own token manager that you specified with the SecureTokenManager implementation class.

trustStore
Specifies a fully qualified path to the truststore file.
Example: etc/test/security/server.public

Important: The directory path does not support Windows backslashes. If you have used backslashes, you must escape any backslash (\ ) characters in the path. For example, if you want to use the path C:\opt\ibm, enter C:\\opt\\ibm in the properties file. Windows directories with spaces are not supported.

trustStorePassword
Specifies a string password to the truststore. You can encode this value or use the actual value.

trustStoreType
Indicates the type of truststore. If you indicate a value that is not valid, a runtime security exception results.
Valid values: `JKS`, `JCEK`, `PKCS12`, and so on.

Secure token keystore configuration
The secure token keystore configuration is only needed when secureTokenManager=default.

secureTokenKeyStore
Specifies the file path name for the keystore that stores the public-private key pair and the secret key.

secureTokenKeystorePassword
Specifies the password for the keystore that stores the public-private key pair and the secret key.

secureTokenKeyStoreType
Specifies the keystore type, for example, JCEKS. You can set this value that is based on the Java Secure Socket Extension (JSSE) provider that you use. However, the keystore must support secret keys.

secureTokenKeyPairAlias
Specifies the alias of the public-private key pair that is used for signing and verifying.

secureTokenKeyPairPassword
Specifies the password to protect the key pair alias that is used for signing and verifying.

secureTokenSecretKeyAlias
Specifies the secret key alias that is used for ciphering.

secureTokenSecretKeyPassword
Specifies the password to protect the secret key.

secureTokenCipherAlgorithm
Specifies the algorithm that is used for providing a cipher. You can set this value that is based on the Java Secure Socket Extension (JSSE) provider that you use.

secureTokenSignAlgorithm
Specifies the algorithm that is used for signing the object. You can set this value that is based on the JSSE provider that you use.

Authentication string

authenticationSecret
Specifies the secret string to challenge the server. When a server starts, it must present this string to the president server or catalog server. If the secret string matches what is in the president server, this server is allowed to join in. All of the servers in a catalog service domain, and the servers in any linked catalog service domains must use the same value this setting. The authenticationSecret value must be a long, hard to guess string. Do not use the authenticationSecret value that is in the sampleServer.properties in production deployments.

StatsSpec class

Client properties file

Create a properties file based on your requirements for WebSphere® eXtreme Scale client processes.

Sample client properties file

You can use the sampleClient.properties file that is in the *wxs_home*/properties directory to create your properties file.

Specifying a client properties file

You can specify the client properties file in one of the following ways. Specifying a setting by using one of the items later in the list overrides the previous setting. For example, if you specify a system property value for the client properties file, the properties in that file override the values in the objectGridClient.properties file that is in the class path.

1. As a well-named file anywhere in the WebSphere Application Server class path. Putting this file in the system current directory is not supported:

   `objectGridClient.properties`

2. As a system property in either a stand-alone or WebSphere Application Server configuration. This value can specify a file in the system current directory, but not a file in the class path:

   `-Dobjectgrid.client.props=`*`file_name`*

   Note: In a WebSphere Application Server configuration, the client properties file must be in the classpath if you want to specify a particular client properties file to use with the system property; for example, *was_root*/properties or *profile_root*/properties, depending on whether you want the properties file to apply to a specific profile, or the entire installation.
3. As a programmatic override using the ClientClusterContext.getClientProperties method. The data in the object is populated with the data from the properties files. You cannot configure security properties with this method.

Client properties

Client properties

listenerHost
: Specifies the host name to which the Object Request Broker (ORB) transport protocol binds for communication. If your configuration involves multiple network cards, set the listener host and port to let the transport mechanism in the JVM know the IP address for which to bind. If you do not specify which IP address to use, symptoms such as connection timeouts, unusual API failures, and clients that seem to hang can occur.

  Default: `localhost`

  Valid values: port number

listenerPort
: Specifies the port number to which the Object Request Broker transport protocol binds for communication.
  Note: When a data grid server is run inside and the ORB transport protocol is being used, another port ORB_LISTENER_ADDRESS must also be opened. The BOOTSTRAP_ADDRESS port forwards requests to this port.
  Default: `2809`

  Valid values: fully qualified domain name or IP address

preferLocalProcess
: This property is not currently used. It is reserved for future use.

preferLocalHost
: This property is not currently used. It is reserved for future use.

preferZones
: Specifies a list of preferred routing zones. Each specified zone is separated by a comma in the form: `preferZones=ZoneA,ZoneB,ZoneC`
  Default: no value

  Valid value: comma-separated list of preferred zones

requestRetryTimeout
: Specifies how long to continue processing a request (in milliseconds) after an exception occurs.
  Default: -1

  Valid values:

  - A value of `0` indicates that the request should fail fast and skip over the internal retry logic.
  - A value of `-1` indicates that the request retry timeout is not set, meaning that the request duration is governed by the transaction timeout. (Default). The following levels of checking the request retry timeout are used to determine the default behavior:
    - Session instance requestRetryTimeout value
    - Client properties file requestRetryTimeout value
    - If neither of the previous values are set, then the lowest value between the transaction timeout value and 30 seconds is selected. For example, if the transaction timeout value has the default value of 10 minutes, then the request times out at 30 seconds. Alternatively, if you set the transaction timeout value to 20 seconds, then the request times out after 20 seconds.
  - A value over `0` indicates the request entry timeout value in milliseconds. Exceptions that are not successfully created are returned. Even when exceptions, such as DuplicateException, are tried again, they are also returned when they do not succeed. The transaction timeout is still used as

the maximum time to wait.

Security client properties

General security properties

securityEnabled

Enables WebSphere eXtreme Scale client security. This setting must match with the securityEnabled setting in theWebSphere eXtreme Scale server properties file. If the settings do not match, the client connection to the data grid fails.
Default: `false`

Valid values: `true`, `false`

Credential authentication configuration properties

credentialAuthentication

Specifies the client credential authentication support.
Use one of the following valid values:

Default: `Supported`

Valid values:

- `Never`: The client does not support credential authentication.
- `Supported`: The client supports credential authentication if the server also supports credential authentication. (Default)
- `Required`: The client requires credential authentication.

authenticationRetryCount

Specifies the number of times that authentication is tried if the credential is expired. If the value is set to `0`, attempts to authenticate are not tried again.
Default: `3`

Valid values: Integer value greater than or equal to `0`

credentialGeneratorClass

Specifies the name of the class that implements the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface. To specify this property, the credentialAuthentication property must be set to `Supported` or `Required`. This class is used to get credentials for clients.
Several built-in classes support this interface; for example:

- com.ibm.websphere.objectgrid.security.plugins.builtins.UserPasswordCredentialGenerator. A user ID and password separated by a space are required for this class.
- com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator

You can also create a custom class, as described in the eXtreme Scale API reference

Default: no value

Valid values: class name

credentialGeneratorProps

Specifies the properties for the CredentialGenerator implementation class. The properties are set to the object with the setProperties(String) method. Specify this property when the credentialAuthentication property is set to `Supported` or `Required`, and the credentialGeneratorClass requires properties.
Default: `SSL-Supported`

Valid values: `SSL-Supported`, `TCP/IP`, or `SSL-Required`

Transport layer security configuration properties

transportType

Specifies the client transport type. The possible values are:
Default: `SSL-Supported`

Valid values:

- `TCP/IP`: Indicates that the client only supports TCP/IP connections.
- `SSL-Supported`: Indicates that the client supports both TCP/IP and Secure Sockets Layer (SSL) connections. (Default)
- `SSL-Required`: Indicates that the client requires SSL connections.

SSL configuration properties

alias

Specifies the alias name in the keystore. This property is used if the keystore has multiple key pair certificates and you want to select one of the certificates. It is only required if client certificate authentication is configured on the server.
Default: no value

Valid value: alias name in keystore

contextProvider

Specifies the name of the context provider for the trust service. If you indicate a value that is not valid, a security exception results that indicates that the context provider type is incorrect.
Default: no value

Valid values: `IBMJSSE2`. If you are using a JRE from another vendor, see your vendor documentation for valid JSSE providers. A value must be specified if SSL is used.

keyStore
Specifies a fully qualified path to the keystore file. A value must be specified if SSL is used. The keyStore is not used unless client certificate authentication is configured on the server. If client certificate authentication is not used, you can specify the trustStore value for keyStore.
Default: no value

Valid values: fully qualified path to keystore
Important: The keyStore directory path does not support Windows backslashes. If you have used backslashes, you must escape any backslash (\ ) characters in the path. For example, if you want to use the path C:\opt\ibm, enter C:\\opt\\ibm in the properties file. Windows directories with spaces are not supported.
Example: etc/test/security/client.private

keyStorePassword
Specifies the string password to the keystore. A value must be specified if SSL is used. You can encode this value or use the actual value.

keyStoreType
Indicates the type of keystore. A value must be specified if SSL is used. If you indicate a value that is not valid, a runtime security exception occurs.
Default: no value

Valid values: `JKS`, `JCEK`, `PKCS12`, and so on.

protocol
Indicates the type of security protocol to use for the client. Set this protocol value based on which security provider you use. If you indicate a value that is not valid, a security exception results that indicates that the protocol value is incorrect. A value for protocol must be specified if SSL or TLS is used. If you are using a JRE from another vendor, see your vendor documentation for valid protocols.
Default:`SSL_TLS`. When you specify this default value, the server accepts either the SSL or TLS protocol from the client.

Valid values: When the IBM Runtime Environment is used, the following values are valid: `SSL`, `SSLv2`, `SSLv3`, `TLS`, `TLSv1`, , and `SSL_TLS`.

trustStoreType
Indicates the type of truststore. A value must be specified if SSL is used. If you indicate a value that is not valid, a runtime security exception results.
Valid values: `JKS`, `JCEKS`, `PKCS12`, and so on.

trustStore
Specifies a fully qualified path to the truststore file. A value must be specified if SSL is used.
Example: etc/test/security/server.public

trustStorePassword
Specifies a string password to the truststore. You can encode this value or use the actual value. A value must be specified if SSL is used.

REST data service properties file

To configure the REST data service, edit the properties file for REST and define the required entity schema for a data grid.

The REST data service properties file is the main configuration file for the eXtreme Scale REST data service. This file is a Java™ property file with key-value pairs. By default, the REST data service runtime environment looks for a well-named wxsRestService.properties file in the classpath. The file can also be explicitly defined by using the system property: wxs.restservice.props.

```
-Dwxs.restservice.props=/usr/configs/dataservice.properties
```

When the REST data service is loaded, the property file used is displayed in the log files:

```
CWOBJ4004I: The eXtreme Scale REST data service properties files were loaded: [/usr/configs/RestService.properties]
```

The REST data service properties file supports the following properties:

Table 1. Properties for the REST data service

Property	Description

catalogServiceEndPoints	The required comma-delimited list of hosts and ports of a catalog service domain in the format: `<host:port>`. This is optional if using WebSphere® Application Server integrated with WebSphere eXtreme Scale to host the REST data service. See Starting a stand-alone catalog service for more information.
	`catalogServiceEndPoints=`
	`server1:2809,server2:2809`

objectGridNames	The required names of the data grids to expose to the REST service. At least one ObjectGrid name is required. Separate multiple ObjectGrid names using a comma: `ECommerceGrid,InventoryGrid`
objectGridClientXML	The optional name of the ObjectGrid client override XML file. The name specified here will be loaded from the classpath. The default is: /META-INF/objectGridClient.xml.
ogClientPropertyFile	The optional name of the ObjectGrid client property file. This file contains security properties that are required for enabling ObjectGrid client security. If the "securityEnabled" attribute is set in the property file, security will be enabled on the ObjectGrid client used by the REST service. The "credentialGeneratorProps" must also be set in the property file to a value in the format of "user:pass" or a value of {xor_encoded user:pass}
loginType	The type of authentication used by the REST Service when ObjectGrid client security is enabled. If ObjectGrid client security is not enabled, this property is ignored. If ObjectGrid client security is enabled and loginType is set to `basic`, the REST service will: • Use the credentials specified in the 'credentialGeneratorProps' property of the ObjectGrid client property file for ObjectGrid operations at service initialization. • Use HTTP BASIC authentication for per request ObjectGrid session operations If ObjectGrid client security is enabled and loginType is set to `none` the REST service will: • Use the credentials specified in the 'credentialGeneratorProps' property of the ObjectGrid client property file for ObjectGrid operations at service initialization. • Use the credentials specified in the 'credentialGeneratorProps' property of the ObjectGrid client property file for per request ObjectGrid session operations.
traceFile	The optional name of the file to redirect the trace output to. The default is logs/trace.log.
traceSpec	The optional trace specification that the eXtreme Scale runtime server should initially use. The default is `*=all=disabled`. To trace the entire REST data service, use: `ObjectGridRest*=all=enabled`
verboseOutput	If set to `true`, REST data service clients receive additional diagnostic information when failures occur. The default is `false`. This optional value should be set to false for production environments as sensitive information may be revealed.
maxResultsPerCollection	The optional maximum number of results that will be returned in a query. The default value is `unlimited`. Any positive integer is a valid value.
wxsRestAccessRightsFile	The optional name of the eXtreme Scale REST service access rights property file which specifies the access rights for the service operations and the ObjectGrid entities. If this property is specified, the REST service will try to load the file from the path specified, else it will try to load the file from its classpath.

WebSphere eXtreme Scale configuration

The eXtreme Scale REST data service interacts with eXtreme Scale using the EntityManager API. An entity schema is defined for an eXtreme Scale data grid and the metadata for the entities is automatically consumed by the REST data service. See Defining an entity schema for details about configuring an entity schema.

For example, you can define an entity representing a Person in an eXtreme Scale data grid as follows:

```
@Entity
public class Person {
                @Id String taxId;
                String firstName;
                String lastName;
}
```

Tip: The annotations used here are in the com.ibm.websphere.projector.annotations package.
The REST service automatically creates an ADO.NET Entity Data Model for Data Services (EDMX) document, which is available using the $metadata URI:

```
http://localhost:8080/wxsrestservice/restservice/NorthwindGrid/$metadata
```

After the data grid is configured and running, configure and package an eXtreme Scale client. For details on configuring the eXtreme Scale REST data service client package, see the packaging and deployment information in Installing the REST data service.

Entity model

WebSphere eXtreme Scale entities are modeled using the entity annotations or an entity metadata descriptor file. For details on how to configure an entity schema, see Defining an entity schema. The eXtreme Scale REST service uses the entity metadata to automatically create an EDMX model for the data service.

This version of the WebSphere eXtreme Scale REST data service has the following schema restrictions:

- When defining entities in a partitioned data grid, all entities must have a direct or indirect single valued association to the root entity (a key association). The WCF data service client runtime environment must be able to access every entity directly through its canonical address. Therefore, the key of the root entity that is used for partition routing (the schema root) must be part of the key in the child entity.
  For example:

```
@Entity(schemaRoot=true)
public class Person {
    @Id String taxId;
    String firstName;
    String lastName;
    @OneToMany(mappedBy="person")
    List<Address> addresses;

}

@Entity
public class Address {
    @Id int addrId;
    @Id @ManyToOne Person person;
    String street;
}
```

- Bi-directional and uni-directional associations are supported. However, uni-directional associations may not always work from a Microsoft WCF Data Services client since they can only be navigated in one direction and the Microsoft specification requires all associations to be bi-directional.
- Referential constraints are not supported. The WebSphere eXtreme Scale runtime environment does not validate keys between entities. Associations between entities must be managed by the client.
- Complex types are not supported. The EntityManager API does not support embeddable attributes. All attributes are expected to be simple type attributes (see the simple attribute types listed below). Non-simple type attributes are treated as a binary object from the perspective of the client.
- Entity inheritance is not supported. The EntityManager API does not support inheritance.
- Media Resources and Media Links are not supported. The HasStream attribute of the EntityType in the Conceptual Schema Definition Language Document for Data Services is never used.

Mapping between EDM data types and Java data types

The OData protocol defines the following list of Entity Data Model (EDM) types in its abstract type system. The following topics describe how the eXtreme Scale REST adapter chooses the EDM type based on the basic type defined in the entity. For details on EDM types, see: MSDN Library: Abstract Type System.

The following EDM types are available in WCF Data Services:

- Edm.Binary
- Edm.Boolean
- Edm.Byte
- Edm.DateTime
- Edm.Time
- Edm.Decimal
- Edm.Double
- Edm.Single
- Edm.Float
- Edm.Guid *
- Edm.Int16
- Edm.Int32
- Edm.Int64
- Edm.SByte
- Edm.String

The EDM type: Edm.Guid is not supported by the eXtreme Scale REST data service.

Mapping Java types to EDM types

The eXtreme Scale REST data service automatically converts basic entity types into EDM types. The type mapping can be seen by displaying the Entity Data Model Extensions (EDMX) metadata document using the $metadata URI. The EDM type is used by clients to read and write data to the REST data service.

Table 2. Java types mapped to EDM types. The table shows the mapping from the Java type defined for an entity to the EDM data type. When retrieving data using a query, the data will be represented with these types:

Java Type	EDM Type
boolean java.lang.Boolean	Edm.Boolean
byte java.lang.Byte	Edm.SByte
short java.lang.Short	Edm.Int16

Java Type	EDM Type
int java.lang.Integer	Edm.Int32
long java.lang.Long	Edm.Int64
float java.lang.Float	Edm.Single
double java.lang.Double	Edm.Double
java.math.BigDecimal	Edm.Decimal
java.math.BigInteger	java.math.BigInteger
java.lang.String	Edm.String
char	char
java.lang.Character	java.lang.Character
Char[]	Char[]
java.lang.Character[]	java.lang.Character[]
java.util.Calendar	Edm.DateTime
java.util.Date	java.util.Date
java.sql.Date	java.sql.Date
java.sql.Timestamp	java.sql.Timestamp
java.sql.Time	java.sql.Time
Other types	Edm.Binary

Mapping from EDM types to Java types

For Update requests and Insert requests, the payload specifies the data to be updated or inserted into the eXtreme Scale REST data service. The service can automatically convert compatible data types to the data types defined in the EDMX document. The REST data service converts the XML encoded string representations of the value into the correct type using the following two-step process:

1. A type check is performed to make sure the EDM type is compatible with the Java type. An EDM type is compatible with a Java type if the data supported by the EDM type is a subset of the data supported by the Java type. For example, Edm.int32 type is compatible with a Java long type, but Edm.int32 type is not compatible with a Java short type.
2. A target Java type object will be created which represents the string value in the payload.

Table 3. Compatible EDM type to Java type

EDM Type	Java Type
Edm.Boolean	boolean java.lang.Boolean
Edm.SByte	byte java.lang.Byte short java.lang.Short int java.lang.Integer long java.lang.Long float java.lang.Float double java.lang.Double java.math.BigDecimal java.math.BigInteger char java.lang.Character

EDM Type	Java Type
Edm.Byte, Edm.Int16	short java.lang.Short int java.lang.Integer long java.lang.Long float java.lang.Float double java.lang.Double java.math.BigDecimal java.math.BigInteger char java.lang.Character
Edm.Int32	int java.lang.Integer long java.lang.Long float java.lang.Float double java.lang.Double java.math.BigDecimal java.math.BigInteger
Edm.Int64	long java.lang.Long double java.lang.Double java.math.BigDecimal java.math.BigInteger
Edm.Double	double java.lang.Double java.math.BigDecimal
Edm.Decimal	double java.lang.Double java.math.BigDecimal java.math.BigInteger
Edm.Single	float java.lang.Float double java.lang.Double java.math.BigDecimal

EDM Type	Java Type
Edm.String	java.lang.String char java.lang.Character Char[] java.lang.Character[] java.math.BigDecimal java.math.BigInteger
Edm.DateTime	java.util.Calendar java.util.Date java.sql.Date java.sql.Time java.sql.Timestamp
Edm.Time	java.sql.Time java.sql.Timestamp

Mapping temporal types

Java includes five temporal types for storing date, time or both: java.util.Date, java.sql.Date, java.sql.Time, java.sql.Timestamp and java.util.Calendar. All of these types are expressed in the entity data model as Edm.DateTime. The eXtreme Scale REST data service automatically converts and normalizes the data depending on the Java type. This topic describes several issues that developers must be aware of when using any temporal type.

Time zone differences

In WCF Data Services, the descriptions of time values in the Edm.DateTime type are always expressed using the Coordinated Universal Time (UTC) standard, which is the internationally recognized name for Greenwich Mean Time (GMT). Coordinated Universal Time is the time as measured at zero degrees longitude, the UTC origin point. Daylight saving time is not applicable to UTC.

Converting between entity and EDM types

When a client sends a request to the REST data service, the date and time is represented as a GMT time zone time, like the following example:

```
"2000-02-29T21:30:30.654123456"
```

The REST data service will then construct the appropriate Java temporal type instance and insert it into the entity in the data grid.

When a client requests a property which is a Java temporal type from the eXtreme Scale REST data service, the value is always normalized as a GMT time zone value. For example, if an entity java.util.Date is constructed as follows:

```
Calendar c = Calendar.getInstance();
c.clear();
c.set(2000, 1, 29, 21, 30, 30);
Date d = c.getTime();
```

The date and time are represented using the default time zone of the Java process because Calendar.getInstance() will create a Calendar object with local time zone. If the local time zone is CST, then the date, when retrieved from the REST data service will be the GMT representation of the time: `"2000-03-01T03:30:30"`

java.sql.Date normalization

An eXtreme Scale entity can define an attribute with Java type java.sql.Date. This data type does not include the time and is normalized by the REST data service. This means that the eXtreme Scale runtime environment does not store any hours, minutes, seconds, or milliseconds information in the java.sql.Date attribute. Regardless of the time zone offset, the date is always represented as a local date.

For example, if the client updates a java.sql.Date property with the value “2009-01-01T03:00:00”, the REST data service, which is in the CST time zone (-06:00), will simply create a java.sql.Date instance of which the time is set to “2009-01-01T00:00:00” of the local CST time. There is no time zone conversion done to create the java.sql.Date value. When the REST service client retrieves the value of this attribute, it will be displayed as “2009-01-01T00:00:00Z”. If a time zone conversion were done, the value would be displayed as having the date of “2008-12-31”, which would be incorrect.

java.sql.Time normalization

Similar to java.sql.Date, the java.sql.Time values are normalized and do not include date information. This means that the eXtreme Scale run time does not store the year, month or day. The time is stored using the GMT time from the epoch January 1, 1970, which is consistent with the java.sql.Time implementation.

For example, if the client updates a java.sql.Time property with the value "2009-01-01T03:00:00", the REST data service, will create a java.sql.Time instance with the milliseconds set to 3*60*60*1000, which is equal to 3 hours. When the rest service retrieves the value, it will be displayed as "1970-01-01:03:00:00Z".

Associations

Associations define the relationship between two peer entities. The eXtreme Scale REST service reflects the associations modeled with entities defined with eXtreme Scale annotated entities or entities defined using an entity descriptor XML file.

Association maintenance

The eXtreme Scale REST data service does not support referential integrity constraints. The client should ensure that references are updated when entities are removed or added. If a target entity of an association is removed from the data grid, but the link between the source and target entity is not removed, then the link is broken. The eXtreme Scale REST data service and EntityManager API tolerates broken links and logs the broken links as CWPRJ1022W warnings. Broken associations are removed from the request payload.

Use a batch request to group association updates in a single transaction to avoid broken links. See the following section for details on batch requests.

The ADO.NET Entity Data Model ReferentialConstraint element is not used by the eXtreme Scale REST data service.

Association multiplicity

Entities can have multi-valued associations or single-valued associations. Multi-valued associations, or collections, are one-to-many or many-to-many associations. Single-valued associations are one-to-one or many-to-one associations.

In a partitioned data grid, all entities should have a single-valued key-association path to a root entity. Another section of this topic shows how to define a key association. Because the root entity is used to partition the entity, many-to-many associations are not allowed for partitioned data grids. For an example on how to model a relational entity schema for a partitioned data grid, see Scalable data model in eXtreme Scale.

The following example describes how the EntityManager API association types, modeled using annotated Java classes map to the ADO.NET Entity Data Model:

```
@Entity
public class Customer {
    @Id String customerId;
    @OneToOne TaxInfo taxInfo;
    @ManyToOne Address homeAddress;
    @OneToMany Collection<Order> orders;
    @ManyToMany Collection<SalesPerson> salespersons;
}

<Association Name="Customer_TaxInfo">
    <End Type="Model1.Customer" Role="Customer" Multiplicity="1" />
    <End Type="Model1.TaxInfo " Role="TaxInfo" Multiplicity="1" />
</Association>
<Association Name="Customer_Address">
    <End Type="Model1.Customer" Role="Customer" Multiplicity="1" />
    <End Type="Model1.Address" Role="TaxInfo" Multiplicity="*" />
</Association>
<Association Name="Customer_Order">
    <End Type="Model1.Customer" Role="Customer" Multiplicity="*" />
    <End Type="Model1.Order" Role="TaxInfo" Multiplicity="1" />
</Association>
<Association Name="Customer_SalesPerson">
    <End Type="Model1.Customer" Role="Customer" Multiplicity="*" />
    <End Type="Model1.SalesPerson" Role="TaxInfo" Multiplicity="*" />
</Association>
```

Bi-directional and uni-directional associations

Entities associations can be uni-directional or bi-directional. By specifying the "mappedBy" attribute on the @OneToOne, @OneToMany or @ManyToMany annotation or the "mapped-by" attribute on the one-to-one, one-to-many or many-to-many XML attribute tag, the entity becomes bi-directional. The OData protocol currently requires all entities to be bi-directional, allowing clients to generate navigation paths in both directions. The eXtreme Scale EntityManager API allows modeling uni-directional associations which can save memory and simplify maintenance of the associations. If a uni-directional association is used, the REST data services client must only navigate through the association using the defined association.

For example: If a uni-directional many-to-one association is defined between Address and Country, the following URI is not allowed:

/restservice/CustomerGrid/Country('USA')/addresses

Key associations

Single-valued associations (one-to-one and many-to-one) can also be included as all or part of the entities key. This is known as a key-association.

Key associations are required when using a partitioned data grid. The key association must be defined for all child entities in a partitioned entity schema. The OData protocol requires that all entities are directly addressable. This means that the key in the child entity must include the key used for partitioning.

In the following example, Customer has a one-to-many association to Order. The Customer entity is the root entity and the customerId attribute is used to partition the entity. Order has included the Customer as part of its identity:

```
@Entity(schemaRoot="true")
public class Customer {
    @Id String customerId;
    @OneToMany(mappedBy="customer") Order orders
}

@Entity
public class Order {
    @Id int orderId;
    @Id @ManyToOne Customer customer;
    java.util.Date orderDate;
}
```

When the REST data service generates the EDMX document for this model, the Customer key fields are automatically included as part of the Order entity:

```
<EntityType Name="Order">
<Key>
```

```
    <PropertyRef Name="orderId"/>
    <PropertyRef Name="customer_customerId"/>
</Key>

<Property Name="orderId" Type="Edm.Int64" Nullable="false"/>
<Property Name="customer_customerId" Type="Edm.String"
    Nullable="false"/>
<Property Name="orderDate" Type="Edm.DateTime" Nullable="true"/>
<NavigationProperty Name="customer"
    Relationship="NorthwindGridModel.Customer_orders"
    FromRole="Order" ToRole="Customer"/>

<NavigationProperty Name="orderDetails"
    Relationship="NorthwindGridModel.Order_orderDetails"
    FromRole="Order" ToRole="OrderDetail"/>
</EntityType>
```

When an entity is created, the key must never change. This means if the key association between a child entity and its parent must change, the child entity must be removed and re-created with a different parent. In a partitioned data grid, this will require two different batch change sets since the move will likely involve more than one partition.

Cascading operations

The EntityManager API allows a flexible cascade policy. Associations can be marked to cascade a persist, remove, invalidate or merge operation. Such cascade operations can happen on one or both sides of a bi-directional association.

The OData protocol only allows cascade delete operations on the single-side of the association. The CascadeType.REMOVE annotation or cascade-remove XML attribute cannot be defined on both sides of a one-to-one bi-directional association or on the many-side of a one-to-many association. The following example illustrates a valid Cascade.REMOVE bi-directional association:

```
@Entity(schemaRoot="true")
public class Customer {
    @Id String customerId;
    @OneToMany(mappedBy="customer", cascade=CascadeType.REMOVE)
    Order orders
}

@Entity
public class Order {
    @Id int orderId;
    @Id @ManyToOne Customer customer;
    java.util.Date orderDate;
}
```

The resulting EDMX association looks as follows:

```
<Association Name="Customer_orders">
    <End Type="NorthwindGridModel.Customer" Role="Customer"
        Multiplicity="1">
        <OnDelete Action="Cascade"/>
    </End>
    <End Type="NorthwindGridModel.Order" Role="Order"
        Multiplicity="*"/>
</Association>
```

ObjectGrid descriptor XML file

To configure WebSphere® eXtreme Scale, use an ObjectGrid descriptor XML file and the ObjectGrid API.

In the following sections, sample XML files are provided to illustrate various configurations. Each element and attribute of the XML file is defined. Use the ObjectGrid descriptor XML schema to create the descriptor XML file. See objectGrid.xsd file for an example of the ObjectGrid descriptor XML schema.

A modified version of the original companyGrid.xml file is used. The following companyGridSingleMap.xml file is like the companyGrid.xml file. The companyGridSingleMap.xml file has one map, and the companyGrid.xml file has four maps. The elements and attributes of the file are described in detail following the example.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
                xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
                xmlns="http://ibm.com/ws/objectgrid/config">

                <objectGrids>
                                <objectGrid name="CompanyGrid">
```

```
                                        <backingMap name="Customer"/>
                                </objectGrid>
                        </objectGrids>
</objectGridConfig>
```

objectGridConfig element

The objectGridConfig element is the top-level element of the XML file. Write this element in your eXtreme Scale XML document as shown in the preceding example. This element sets up the namespace of the file and the schema location. The schema is defined in the objectGrid.xsd file.

- Number of occurrences: One
- Child element: objectGrids element and backingMapPluginCollections element

objectGrids element

The objectGrids element is a container for all the objectGrid elements. In the companyGridSingleMap.xml file, the objectGrids element contains one objectGrid, the CompanyGrid objectGrid.

- Number of occurrences: One or more
- Child element: objectGrid element

objectGrid element

Use the objectGrid element to define an ObjectGrid. Each of the attributes on the objectGrid element corresponds to a method on the ObjectGrid interface.

- Number of occurrences: One to many
- Child element: bean element, backingMap element, and querySchema element

Attributes

name
: Specifies the name that is assigned to ObjectGrid. The XML validation fails if this attribute is missing. (Required)

securityEnabled
: Enables security at the ObjectGrid level, which enables the access authorizations to the data in the map, when you set the attribute to `true`. The default is `true`. (Optional)

authorizationMechanism
: Sets the authorization mechanism for the element. You can set the attribute to one of two values: `AUTHORIZATION_MECHANISM_JAAS` or `AUTHORIZATION_MECHANISM_CUSTOM`. The default is `AUTHORIZATION_MECHANISM_JAAS`. You must set the securityEnabled attribute to `true` for the authorizationMechanism attribute to take effect. (Optional)

permissionCheckPeriod
: Specifies an integer value in seconds that indicates how often to check the permission that is used to allow a client access. The default is `0`. When you set the attribute value `0`, every get, put, update, remove, or evict method call asks the authorization mechanism, either Java™ Authentication and Authorization Service (JAAS) authorization or custom authorization, to check if the current subject has permission. A value greater than 0 indicates the number of seconds to cache a set of permissions before returning to the authorization mechanism to refresh. You must set the securityEnabled attribute to `true` for the permissionCheckPeriod attribute to take effect. (Optional)

accessByCreatorOnlyMode
: Specifies if a user (represented by the Principal objects associated with it) other than the creator of a cache entry can access, update or delete that entry. The default value is `disabled` when not specified, allowing any user access to the cache entry. Valid values also include `complement` and `supersede`. The `complement` value enables creator-only access, and also enforces map authorization. The `supersede` value enables creator-only access, and disables map authorization. (Optional)

txTimeout
: Specifies the amount of time in seconds that a transaction is allowed for completion. If a transaction does not complete in this amount of time, the transaction is marked for rollback and a `TransactionTimeoutException` exception results. If you set the value to `0`, the default setting of 10 minutes is used as the transaction timeout. (Optional)

txIsolation
: Sets the default transaction isolation level for all sessions created by the ObjectGrid. Define one of the following values:

  - `REPEATABLE_READ` (default): Specifies that dirty reads and non-repeatable reads are prevented; phantom reads can occur. This level prohibits a transaction from reading an uncommitted cache entry. It also prohibits the following scenario: one transaction reads an entry, a second transaction alters the entry, and the first transaction rereads the entry, getting different values the second time (a "non-repeatable read").
  - `READ_UNCOMMITTED`: Specifies that dirty reads, non-repeatable reads and phantom reads can occur. Cache entries can be changed by one transaction and read by another transaction before any changes in that entry have been committed. If any of the changes are rolled back, the second transaction retrieves an entry that is not valid.
  - `READ_COMMITTED`: Specifies that dirty reads are prevented; non-repeatable reads and phantom reads can occur. This level only prohibits a transaction from reading a cache entry that has uncommitted changes.

entityMetadataXMLFile
: Specifies the path to the entity descriptor XML file that defines the entity schema. Define entities before you start the catalog server so that each entity can bind with a backing map.

  - **For a relative directory:** Specify the location relative to the location of the objectgrid.xml file.
  - **For an absolute path:** Specify the location with a URL format, such as file:// or http://.

  (Optional)

```
<objectGrid
(1)     name="objectGridName"
```

```
(2)     securityEnabled="true" | "false"
(3)     authorizationMechanism="AUTHORIZATION_MECHANISM_JASS" | "AUTHORIZATION_MECHANISM_CUSTOM"
(4)     permissionCheckPeriod="permission_check_period"
(5)     txTimeout="seconds"
(6)     entityMetadataXMLFile="URL"
/>
```

In the following example, the companyGridObjectGridAttr.xml file demonstrates one way to configure the attributes of an objectGrid element. Security is enabled, the authorization mechanism is set to JAAS, and the permission check period is set to 45 seconds. The file also registers entities by specifying an entityMetadataXMLFile attribute.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlnc:xsi="http:www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid" securityEnabled="true"
                        authorizationMechanism="AUTHORIZATION_MECHANISM_JASS"
                        permissionCheckPeriod="45"
                        entityMetadataXMLFile="companyGridEntities.xml">
                        <backingMap name="Customer"/>
                </objectGrid>
        </objectGrids>
</objectGridConfig>
```

The following code sample demonstrates the programmatic approach to achieving the same configuration as the companyGridObjectGridAttr.xml file in the preceding example.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);

companyGrid.setSecurityEnabled();
companyGrid.setAuthorizationMechanism(SecurityConstants.AUTHORIZATION_MECHANISM_JAAS);
companyGrid.setPermissionCheckPeriod(45);
companyGrid.registerEntities(new URL("file:companyGridEntities.xml"));
```

backingMap element

The backingMap element is used to define a BackingMap instance on an ObjectGrid. Each of the attributes on the backingMap element corresponds to a method on the BackingMap interface. For details, see BackingMap interface.

- Number of occurrences: Zero to many
- Child element: timeBasedDBUpdate element

backingMap attributes

copyKey
: Specifies if the a copy of the key is required when a map entry is created. Copying the key object allows the application to use the same key object for each ObjectMap operation. Set the value to `true` to copy the key object when a map entry is created. The default value is `false`. (Optional)

CopyMode
: Specifies if a get operation of an entry in the BackingMap instance returns the actual value, a copy of the value, or a proxy for the value. Set the CopyMode attribute to one of five values:

  `COPY_ON_READ_AND_COMMIT`
  : The default value is `COPY_ON_READ_AND_COMMIT`. Set the value to `COPY_ON_READ_AND_COMMIT` to ensure that an application never has a reference to the value object that is in the BackingMap instance. Instead, the application is always working with a copy of the value that is in the BackingMap instance. (Optional)

  `COPY_ON_READ`
  : Set the value to `COPY_ON_READ` to improve performance over the `COPY_ON_READ_AND_COMMIT` value by eliminating the copy that occurs when a transaction is committed. To preserve the integrity of the BackingMap data, the application commits to delete every reference to an entry after the transaction is committed. Setting this value results in an ObjectMap.get method returning a copy of the value instead of a reference to the value, which ensures changes that are made by the application to the value does not affect the BackingMap element until the transaction is committed.

  `COPY_ON_WRITE`
  : Set the value to `COPY_ON_WRITE` to improve performance over the `COPY_ON_READ_AND_COMMIT` value by eliminating the copy that occurs when ObjectMap.get method is called for the first time by a transaction for a given key. Instead, the ObjectMap.get method returns a proxy to the value instead of a direct reference to the value object. The proxy ensures that a copy of the value is not made unless the application calls a set method on the value interface.

  `NO_COPY`
  : Set the value to `NO_COPY` to allow an application to never modify a value object that is obtained using an ObjectMap.get method in exchange for performance improvements. Set the value to `NO_COPY` for maps associated with EntityManager API entities.

  `COPY_TO_BYTES`
  : Set the value to `COPY_TO_BYTES` to improve memory footprint for complex Object types and to improve performance when the copying of an Object relies on serialization to make the copy. If an Object is not Cloneable or a custom ObjectTransformer with an efficient copyValue method is not provided, the default copy mechanism is to serialize and inflate the object to make a copy. With the `COPY_TO_BYTES` setting, inflate is only performed during a read and serialize is only performed during commit.

  For more information about these settings, see Tuning the copy mode.

evictionTriggers
: Sets the types of additional eviction triggers to use. All evictors for the backing map use this list of additional triggers. To avoid an IllegalStateException, this attribute must be called before the ObjectGrid.initialize() method. Also, note that the ObjectGrid.getSession() method implicitly calls the

ObjectGrid.initialize() method if the method has yet to be called by the application. Entries in the list of triggers are separated by semicolons. Current eviction triggers include MEMORY_USAGE_THRESHOLD. For more information, see Plug-ins for evicting cache objects. (Optional)

lockStrategy
: Specifies if the internal lock manager is used whenever a map entry is accessed by a transaction. Set this attribute to one of three values: `OPTIMISTIC`, `PESSIMISTIC`, or `NONE`. The default value is `OPTIMISTIC`. (Optional)

  The optimistic locking strategy is typically used when a map does not have a loader plug-in, is mostly read and not frequently written to or updated, and the locking is not provided by the persistence manager using eXtreme Scale as a side cache or by the application. An exclusive lock is obtained on a map entry that is inserted, updated, or removed at commit time. The lock ensures that the version information cannot be changed by another transaction while the transaction being committed is performing an optimistic version check.

  The pessimistic locking strategy is typically used for a map that does not have a loader plug-in, and locking is not provided by a persistence manager using eXtreme Scale as a side cache, by a loader plug-in, or by the application. The pessimistic locking strategy is used when the optimistic locking strategy fails too often because update transactions frequently collide on the same map entry.

  The no locking strategy indicates that the internal LockManager is not needed. Concurrency control is provided outside of eXtreme Scale, either by the persistence manager using eXtreme Scale as a side cache or application, or by the loader plug-in that uses database locks to control concurrency.

lockTimeout
: Sets the lock timeout that is used by the lock manager for the BackingMap instance. Set the lockStrategy attribute to `OPTIMISTIC` or `PESSIMISTIC` to create a lock manager for the BackingMap instance. To prevent deadlocks from occurring, the lock manager has a default timeout value of 15 seconds. If the timeout limit is exceeded, a LockTimeoutException exception occurs. The default value of 15 seconds is sufficient for most applications, but on a heavily loaded system, a timeout might occur when no deadlock exists. Use the lockTimeout attribute to increase the value from the default to prevent false timeout exceptions from occurring. Set the lockStrategy attribute to `NONE` to specify the BackingMap instance use no lock manager. (Optional)

name
: Specifies the name that is assigned to the backingMap instance. If this attribute is missing, the XML validation fails. (Required)

nullValuesSupported
: Set the value to `true` to support null values in the ObjectMap. When null values are supported, a get operation that returns null might mean that the value is null or that the map does not contain the key that is passed to the method. The default value is `true`. (Optional)

numberOfBuckets
: The BackingMap instance uses a hash map for implementation. The numberOfBuckets attribute specifies the number of buckets for the BackingMap instance to use. If multiple entries exist in the BackingMap, more buckets lead to better performance because the risk of collisions is lower as the number of buckets increases. More buckets also lead to more concurrency. Specify a value of `0` to disable the near cache on a client. When you set the value to `0` for a client, set the value in the client override ObjectGrid XML descriptor file only. (Optional)

numberOfLockBuckets
: The lock manager uses a hash map to track entries that are locked by one or more transactions. The numberOfLockBuckets attribute sets the number of lock buckets that are used by the lock manager for the BackingMap instance. Set the lockStrategy attribute to `OPTIMISTIC` or `PESSIMISTIC` to create a lock manager for the BackingMap instance. If many entries exist, more lock buckets lead to better performance because the risk of collisions is lower as the number of buckets grows. More lock buckets also lead to more concurrency. Set the lockStrategy attribute to `NONE` to specify the BackingMap instance use no lock manager. (Optional)

pluginCollectionRef
: Specifies a reference to a backingMapPluginCollection plug-in. The value of this attribute must match the ID attribute of a backingMapCollection plug-in. Validation fails if no matching ID exists. Set the attribute to reuse BackingMap plug-ins. (Optional)

preloadMode
: Sets the preload mode if a loader plug-in is set for this BackingMap instance. The default value is `false`. If the attribute is set to `true`, the Loader.preloadMap(Session, BackingMap) method is invoked asynchronously. Otherwise, running the method is blocked when loading data so that the cache is unavailable until preload completes. Preloading occurs during initialization. (Optional)

readOnly
: Sets a BackingMap instance as read/write when you specify the attribute as `false`. When you specify the attribute as `true`, the BackingMap instance is read-only. (Optional)

template
: Specifies if dynamic maps can be used. Set this value to `true` if the BackingMap map is a template map. Template maps can be used to dynamically create maps after the ObjectGrid is started. Calls to Session.getMap(String) result in dynamic maps being created if the name passed to the method matches the regular expression specified in the name attribute of the backingMap. The default value is `false`. (Optional)

timeToLive
: Specifies in seconds how long each map entry is present. The default value of `0` means that the map entry is present forever, or until the application explicitly removes or invalidates the entry. Otherwise, the TTL evictor evicts the map entry based on this value. (Optional)

ttlEvictorType
: Specifies how the expiration time of a BackingMap entry is computed. Set this attribute to one of these values: `CREATION_TIME`, `LAST_ACCESS_TIME`, `LAST_UPDATE_TIME`, or `NONE`. The `CREATION_TIME` value indicates that an entry expiration time is the sum of the creation time of the entry plus the timeToLive attribute value. The `LAST_ACCESS_TIME` value indicates that an entry expiration time is the sum of the last access time of the entry (whether the entry was updated or merely read), plus the timeToLive attribute value. The `LAST_UPDATE_TIME` value indicates that an entry expiration time is the sum of the last update time of the entry plus the timeToLive attribute value. The `NONE` value, which is the default, indicates that an entry has no expiration time and is present in the BackingMap instance until the application explicitly removes or invalidates the entry. (Optional)

valueInterfaceClassName
: Specifies a class that is required when you set the CopyMode attribute to `COPY_ON_WRITE`. This attribute is ignored for all other modes. The `COPY_ON_WRITE` value uses a proxy when ObjectMap.get method calls are made. The proxy ensures that a copy of the value is not made unless the application calls a set method on the class that is specified as the valueInterfaceClassName attribute. (Optional)

viewRef
: Specifies that the backingMap is a view map. (Optional)

writeBehind
: Specifies that the write-behind support is enabled with write-behind parameters (Optional). Write-behind parameters consist of a maximum update time and a maximum key update count. The format of the write-behind parameter is "`[T(time)][;][C(count)]`". The database is updated when one of the following events occurs:

  - The maximum update time, specified in seconds, has passed since the last update.
  - The number of available updates in the queue map has reached the maximum update count.

For more information, see Write-behind caching.

Write-behind support is an extension of the Loader plug-in, which you use to integrate eXtreme Scale with the database. For example, consult the Configuring JPA loaders information about configuring a JPA loader.

```
<backingMap
(1)                     name="objectGridName"
(2)                     readOnly="true" | "false"
(3)                     template="true" | "false"
(4)                     pluginCollectionRef="reference to backingMapPluginCollection"
(5)                     numberOfBuckets="number of buckets"
(6)                     preloadMode="true" | "false"
(7)                     lockStrategy="OPTIMISTIC" | "PESSIMISTIC" | "NONE"
(8)                     numberOfLockBuckets="number of lock buckets"
(9)                     lockTimeout="lock timeout"
(10)                    copyMode="COPY_ON_READ_AND_COMMIT" | "COPY_ON_READ" | "COPY_ON_WRITE"
                                                   | "NO_COPY" | "COPY_TO_BYTES"
(11)                    valueInterfaceClassName="value interface class name"
(12)                    copyKey="true" | "false"
(13)                    nullValuesSupported="true" | "false"
(14)                    ttlEvictorType="CREATION_TIME" | "LAST_ACCESS_TIME" | "LAST_UPDATE_TIME" | NONE"
(15)                    timeToLive="time to live"
(16)                    streamRef="reference to a stream"
(17)                    viewRef="reference to a view"
(18)                    writeBehind="write-behind parameters"
/>
```

In the following example, the companyGridBackingMapAttr.xml file is used to demonstrate a sample backingMap configuration.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid">
                        <backingMap name="Customer" readOnly="true"
                                        numberOfBuckets="641" preloadMode="false"
                                        lockStrategy="OPTIMISTIC" numberOfLockBuckets="409"
                                        lockTimeout="30" copyMode="COPY_ON_WRITE"

valueInterfaceClassName="com.ibm.websphere.samples.objectgrid.CounterValueInterface"
                                        copyKey="true" nullValuesSupported="false"
                                        ttlEvictorType="LAST_ACCESS_TIME" timeToLive="3000"/>
                </objectGrid>
        </objectGrids>
</objectGridConfig>
```

The following sample code demonstrates the programmatic approach to achieve the same configuration as the companyGridBackingMapAttr.xml file in the preceding example:

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);

BackingMap customerMap = companyGrid.defineMap("Customer");
customerMap.setReadOnly(true);
customerMap.setNumberOfBuckets(641);
customerMap.setPreloadMode(false);
customerMap.setLockStrategy(LockStrategy.OPTIMISTIC);
customerMap.setNumberOfLockBuckets(409);
customerMap.setLockTimeout(30);

// when setting copy mode to COPY_ON_WRITE, a valueInterface class is required
customerMap.setCopyMode(CopyMode.COPY_ON_WRITE,
        com.ibm.websphere.samples.objectgrid.CounterValueInterface.class);
customerMap.setCopyKey(true);
customerMap.setNullValuesSupported(false);
customerMap.setTtlEvictorType(TTLType.LAST_ACCESS_TIME);
customerMap.setTimeToLive(3000); // set time to live to 50 minutes
```

bean element

Use the bean element to define plug-ins. You can attach plug-ins to objectGrid and BackingMap elements.

- Number of occurrences within the objectGrid element: Zero to many
- Number of occurrences within the backingMapPluginCollection element: Zero to many
- Child element: property element

Attributes

id

Specifies the type of plug-in to create. (Required)
The valid plug-ins for a bean that is a child element of the objectGrid element are included in the following list:

- TransactionCallback plug-in
- ObjectGridEventListener plug-in
- SubjectSource plug-in

- SubjectValidation plug-in

The valid plug-ins for a bean that is a child element of the backingMapPluginCollection element are included in the following list:

- Loader plug-in
- ObjectTransformer plug-in
- OptimisticCallback plug-in
- Evictor plug-in
- MapEventListener plug-in
- MapIndex plug-in

className
: Specifies the name of the class or spring bean to instantiate to create the plug-in. The class must implement the plug-in type interface. For example, if you specify `ObjectGridEventListener` as the value for the id attribute, the className attribute value must refer to a class that implements the ObjectGridEventListener interface. The className or osgiService is required.

osgiService
: Specifies the name of the OSGi service to look up in the OSGi service manager. When running in the Eclipse Equinox OSGi framework with the Eclipse Gemini or Apache Aries Blueprint container, plug-ins can be defined using an OSGi Blueprint XML file. The other bean properties are not typically used when using an osgiService name, since the bean properties are configured in the Blueprint configuration file. See Configuring OSGi-enabled plug-ins using the ObjectGrid descriptor XML file for more information. The className or osgiService is required.

```
<bean
(1)     id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_TransactionCallback"
| "ObjectGridEventListener" |"SubjectSource" |
     "SubjectValidation" | "Loader" | "ObjectTransformer" |
    "OptimisticCallback" | "Evictor" | "MapEventListener" | "MapIndexPlugin"
(2)     className="class name" | "(spring)bean name"
/>
```

In the following example, the companyGridBean.xml file is used to demonstrate how to configure plug-ins using the bean element. An ObjectGridEventListener plug-in is added to the CompanyGrid ObjectGrid. The className attribute for this bean is the com.ibm.websphere.objectgrid.plugins.builtins.TranPropListener class. This class implements the com.ibm.websphere.objectgrid.plugins.ObjectGridEventListener interface as required.

A BackingMap plug-in is also defined in the companyGridBean.xml file. An evictor plug-in is added to the Customer BackingMap instance. Because the bean ID is Evictor, the className attribute must specify a class that implements the com.ibm.websphere.objectgrid.plugins.Evictor interface. The com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor class implements this interface. The backingMap references its plug-ins using the pluginCollectionRef attribute.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid">
                        bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_ObjectGridEventListener"
                                className="com.ibm.websphere.objectgrid.plugins.builtins.TranPropListener"/>
                        <backingMap name="Customer"
                                pluginCollectionRef="customerPlugins"/>
                </objectGrid>
        </objectGrids>
        <backingMapPluginCollections>
                <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_customerPlugins">
                        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_Evictor"
                                        className="com.ibm.websphere.objectGrid.plugins.builtins.LRUEvictor/>
                </backingMapPluginCollection>
        </backingMapPluginCollections>
</objectGridConfig>
```

The following code sample demonstrates the programmatic approach to achieving the same configuration as the companyGridBean.xml file in the preceding example.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);
TranPropListener tranPropListener = new TranPropListener();
companyGrid.addEventListener(tranPropListener);

BackingMap customerMap = companyGrid.defineMap("Customer");
Evictor lruEvictor = new com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor();
customerMap.setEvictor(lruEvictor);
```

For more details about using plug-ins, consult Java plug-ins overview.

property element

Use the property element to add properties to plug-ins. The name of the property must correspond to a set method on the class referenced by the containing bean.

- Number of occurrences: Zero to many
- Child element: None

Attributes

name
: Specifies the name of the property. The value that is assigned to this attribute must correspond to a set method on the class that is provided as the className attribute on the containing bean. For example, if you set the className attribute of the bean to `com.ibm.MyPlugin`, and the name of the property that is provided is `size`, the `com.ibm.MyPlugin` class must have a setSize method. (Required)

type
: Specifies the type of the property. The type is passed to the set method that is identified by the name attribute. The valid values are the Java primitives, the java.lang counterparts, and java.lang.String. The name and type attributes must correspond to a method signature on the className attribute of the bean. For example, if you set the name as `size` and the type as `int`, a setSize(int) method must exist on the class that is specified as the className attribute for the bean. (Required)

value
: Specifies the value of the property. This value is converted to the type that is specified by the type attribute, and is then used as a parameter in the call to the set method that is identified by the name and type attributes. The value of this attribute is not validated in any way. (Required)

description
: Describes the property. (Optional)

```
<bean
(1)     name="name"
(2)     type="java.lang.String" | "boolean" | "java.lang.Boolean" | "int" |
                        "java.lang.Integer" | "double" | "java.lang.Double" | "byte" |
                        "java.lang.Byte" | "short" | "java.lang.Short" | "long" |
                        "java.lang.Long" | "float" | "java.lang.Float" | "char" |
                        "java.lang.Character"
(3)     value="value"
(4)     description="description"
/>
```

In the following example, the companyGridProperty.xml file is used to demonstrate how to add a property element to a bean. In this example, a property with the name maxSize and type int is added to an evictor. The com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor class has a method signature that matches the setMaxSize(int) method. An integer value of 499 is passed to the setMaxSize(int) method on the com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor class.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid">
                        <backingMap name="Customer"
                                pluginCollectionRef="customerPlugins"/>
                </objectGrid>
        </objectGrids>
        <backingMapPluginCollections>
                <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_customerPlugins">
                        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_Evictor"
                                        className="com.ibm.websphere.objectGrid.plugins.builtins.LRUEvictor>
                                        <property name="maxSize" type="int" value="449"
                                                description="The maximum size of the LRU Evictor"/>
                        </bean>
                </backingMapPluginCollection>
        </backingMapPluginCollections>
</objectGridConfig>
```

The following code sample demonstrates the programmatic approach to achieving the same configuration as the companyGridProperty.xml file in the preceding example.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);

BackingMap customerMap = companyGrid.defineMap("Customer");

LRUEvictor lruEvictor = new com.ibm.websphere.objectgrid.plugins.builtins.LRUEvictor();
// if the XML file is used instead,
// the property that was added would cause the following call to occur
lruEvictor.setMaxSize(449);
customerMap.setEvictor(lruEvictor);
```

backingMapPluginsCollections element

The backingMapPluginsCollections element is a container for all the backingMapPluginCollection elements. In the companyGridProperty.xml file in the preceding section, the backingMapPluginCollections element contains one backingMapPluginCollection element with the ID `customerPlugins`.

- Number of occurrences: Zero to one
- Child element: backingMapPluginCollection element

backingMapPluginCollection element

The backingMapPluginCollection element defines the BackingMap plug-ins, and is identified by the id attribute. Specify the pluginCollectionRef attribute to reference the plug-ins. When configuring several BackingMaps plug-ins similarly, each BackingMap can reference the same backingMapPluginCollection element.

- Number of occurrences: Zero to many
- Child element: bean element

Attributes

id

Identifies the backingMapPluginCollection, and is referenced by the pluginCollectionRef attribute of the backingMap element. Each ID must be unique. If the value of a pluginCollectionRef attribute does not match the ID of one backingMapPluginCollection element, XML validation fails. Any number of backingMap elements can reference a single backingMapPluginCollection element. (Required)

```
<backingMapPluginCollection
(1)                     id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_id"
/>
```

In the following example, the companyGridCollection.xml file is used to demonstrate how to use the backingMapPluginCollection element. In this file, the Customer BackingMap uses the customerPlugins backingMapPluginCollection to configure the Customer BackingMap with an LRUEvictor. The Item and OrderLine BackingMaps reference the collection2 backingMapPluginCollection. These BackingMaps each have an LFUEvictor set.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid">
                        <backingMap name="Customer"
                                pluginCollectionRef="customerPlugins"/>
                        <backingMap name="Item" pluginCollectionRef="collection2"/>
                        <backingMap name="OrderLine"
                                pluginCollectionRef="collection2"/>
                        <backingMap name="Order"/>
                </objectGrid>
        </objectGrids>
        <backingMapPluginCollections>
                <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_customerPlugins">
                        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_Evictor"
                                        className="com.ibm.websphere.objectGrid.plugins.builtins.LRUEvictor/>
                </backingMapPluginCollection>
                <backingMapPluginCollection
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_collection2">
                        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_Evictor"
                                        className="com.ibm.websphere.objectgrid.plugins.builtins.LFUEvictor/>
                        <bean
id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsogref_OptimisticCallback"

className="com.ibm.websphere.samples.objectgrid.EmployeeOptimisticCallBackImpl"/>
                </backingMapPluginCollection>
                </backingMapPluginCollections>
</objectGridConfig>
```

The following code sample demonstrates the programmatic approach to achieving the same configuration as the companyGridCollection.xml file in the preceding example.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();

ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);
BackingMap customerMap = companyGrid .defineMap("Customer");
LRUEvictor customerEvictor = new LRUEvictor();
customerMap.setEvictor(customerEvictor);

BackingMap itemMap = companyGrid.defineMap("Item");
LFUEvictor itemEvictor = new LFUEvictor();
itemMap.setEvictor(itemEvictor);

BackingMap orderLineMap = companyGrid.defineMap("OrderLine");
LFUEvictor orderLineEvictor = new LFUEvictor();
orderLineMap.setEvictor(orderLineEvictor);

BackingMap orderMap = companyGrid.defineMap("Order");
```

querySchema element

The querySchema element defines relationships between BackingMaps and identifies the type of object in each map. This information is used by ObjectQuery to translate query language strings into map access calls. For more information, see Configuring an ObjectQuery schema.

- Number of occurrences: Zero to one
- Child element: mapSchemas element, relationships element

mapSchemas element

Each querySchema element has one mapSchemas element that contains one or more mapSchema elements.

- Number of occurrences: One
- Child element: mapSchema element

mapSchema element

A mapSchema element defines the type of object that is stored in a BackingMap and instructions on how to access the data.

- Number of occurrences: One or more
- Child element: None

Attributes

mapName
: Specifies the name of the BackingMap to add to the schema. (Required)

valueClass
: Specifies the type of object that is stored in the value portion of the BackingMap. (Required)

primaryKeyField
: Specifies the name of the primary key attribute in the valueClass attribute. The primary key must also be stored in the key portion of the BackingMap. (Optional)

accessType
: Identifies how the query engine introspects and accesses the persistent data in the valueClass object instances. If you set the value to `FIELD`, the class fields are introspected and added to the schema. If the value is `PROPERTY`, the attributes that are associated with get and is methods are used. The default value is `PROPERTY`. (Optional)

```
<mapSchema
(1)                     mapName="backingMapName"
(2)                     valueClass="com.mycompany.OrderBean"
(3)                     primaryKeyField="orderId"
(4)                     accessType="PROPERTY" | "FIELD"
/>
```

In the following example, the companyGridQuerySchemaAttr.xml file is used to demonstrate a sample mapSchema configuration.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid">
                        <backingMap name="Order"/>
                        <backingMap name="Customer"/>

                        <querySchema>
                                <mapSchemas>
                                        <mapSchema mapName="Order"
                                                valueClass="com.mycompany.OrderBean"
                                                primaryKeyField="orderNumber"
                                                accessType="FIELD"/>
                                        <mapSchema mapName="Customer"
                                                valueClass="com.mycompany.CustomerBean"
                                                primaryKeyField="id"
                                                accessType="FIELD"/>
                                </mapSchemas>
                        </querySchema>
                </objectGrid>
        </objectGrids>
</objectGridConfig>
```

The following code sample demonstrates the programmatic approach to achieving the same configuration as the companyGridQuerySchemaAttr.xml file in the preceding example.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);
companyGrid.defineMap("Order");
companyGrid.defineMap("Customer");

// Define the schema
QueryConfig queryCfg = new QueryConfig();
queryCfg.addQueryMapping(new QueryMapping(
    "Order", OrderBean.class.getName(), "orderNumber", QueryMapping.FIELD_ACCESS));
queryCfg.addQueryMapping(new QueryMapping(
    "Customer", CustomerBean.class.getName(), "id", QueryMapping.FIELD_ACCESS));
companyGrid.setQueryConfig(queryCfg);
```

relationships element

Each querySchema element has zero or one relationships element that contains one or more relationship elements.

- Number of occurrences: Zero or one
- Child element: relationship element

relationship element

A relationship element defines the relationship between two BackingMaps and the attributes in the valueClass attribute that bind the relationship.

- Number of occurrences: One or more
- Child element: None

Attributes

source
: Specifies the name of the valueClass of the source side of a relationship. (Required)

target
: Specifies the name of the valueClass of the target side of a relationship. (Required)

relationField
: Specifies the name of the attribute in the source valueClass that refers to the target. (Required)

invRelationField
: Specifies the name of the attribute in the target valueClass that refers to the source. If this attribute is not specified, the relationship is one directional. (Optional)

```
<mapSchema
(1)                     source="com.mycompany.OrderBean"
(2)                     target="com.mycompany.CustomerBean"
(3)                     relationField="customer"
(4)                     invRelationField="orders"
/>
```

In the following example, the companyGridQuerySchemaWithRelationshipAttr.xml file is used to demonstrate a sample mapSchema configuration that includes a bidirectional relationship.

```
<?xml version="1.0" encoding="UTF-8"?>
<objectGridConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/config ../objectGrid.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config">

        <objectGrids>
                <objectGrid name="CompanyGrid">
                        <backingMap name="Order"/>
                        <backingMap name="Customer"/>

                        <querySchema>
                                <mapSchemas>
                                        <mapSchema mapName="Order"
                                                valueClass="com.mycompany.OrderBean"
                                                primaryKeyField="orderNumber"
                                                accessType="FIELD"/>
                                        <mapSchema mapName="Customer"
                                                valueClass="com.mycompany.CustomerBean"
                                                primaryKeyField="id"
                                                accessType="FIELD"/>
                                </mapSchemas>
                                <relationships>
                                        <relationship
                                                source="com.mycompany.OrderBean"
                                                target="com.mycompany.CustomerBean"
                                                relationField="customer"/>
                                                invRelationField="orders"/>
                                </relationships>
                        </querySchema>
                </objectGrid>
        </objectGrids>
</objectGridConfig>
```

The following code sample demonstrates the programmatic approach to achieving the same configuration as the companyGridQuerySchemaWithRelationshipAttr.xml file in the preceding example.

```
ObjectGridManager objectGridManager = ObjectGridManagerFactory.getObjectGridManager();
ObjectGrid companyGrid = objectGridManager.createObjectGrid("CompanyGrid", false);
companyGrid.defineMap("Order");
companyGrid.defineMap("Customer");

// Define the schema
QueryConfig queryCfg = new QueryConfig();
queryCfg.addQueryMapping(new QueryMapping(
    "Order", OrderBean.class.getName(), "orderNumber", QueryMapping.FIELD_ACCESS));
queryCfg.addQueryMapping(new QueryMapping(
    "Customer", CustomerBean.class.getName(), "id", QueryMapping.FIELD_ACCESS));
queryCfg.addQueryRelationship(new QueryRelationship(
     OrderBean.class.getName(), CustomerBean.class.getName(), "customer", "orders"));
companyGrid.setQueryConfig(queryCfg);
```

stream element

The stream element represents a stream to the stream query engine. Each attribute of the stream element corresponds to a method on the StreamMetadata interface.

- Number of occurrences: One to many
- Child element: basic element

Attributes

name
: Specifies the name of the stream. Validation fails if this attribute is not specified. (Required)

valueClass
: Specifies the class type of the value that is stored in the stream ObjectMap. The class type is used to convert the object to the stream events and to generate an SQL statement if the statement is not provided. (Required)

sql
: Specifies the SQL statement of the stream. If this property is not provided, a stream SQL is generated by reflecting the attributes or accessor methods on the valueClass attribute or by using the tuple attributes of the entity metadata. (Optional)

access
: Specifies the type to access the attributes of the value class. If you set the value to `FIELD`, the attributes are directly retrieved from the fields using Java reflection. Otherwise, accessor methods are used to read the attributes. The default value is `PROPERTY`. (Optional)

```
<stream
(1)     name="streamName"
(2)     valueClass="streamMapClassType"
(3)     sql="streamSQL create stream stockQuote
                        keyed by t ( transactionvolume INTEGER, price DECIMAL (9,2), issue VARCHAR(100) );"
(4)     access="PROPERTY" | "FIELD"
/>
```

view element

The view element represents a stream query view. Each stream element corresponds to a method on the ViewMetadata interface.

- Number of occurrences: One to many
- Child element: basic element, ID element

Attributes

name
: Specifies the name of the view. Validation fails if this attribute is not specified. (Required)

sql
: Specifies the SQL of the stream, which defines the view transformation. Validation fails if this attribute is not specified. (Required)

valueClass
: Specifies the class type of the value that is stored in this view of the ObjectMap. The class type is used to convert view events into the correct tuple format that is compatible with this class type. If the class type is not provided, a default format following the column definitions in the Stream Processing Technology Structured Query Language (SPTSQL) is used. If an entity metadata is defined for this view map, do not use the valueClass attribute. (Optional)

access
: Specifies the type to access the attributes of the value class. If you set the access type to `FIELD`, the column values are directly set to the fields using Java reflection. Otherwise, accessor methods are used to set the attributes. The default value is `PROPERTY`. (Optional)

```
<view
(1)                     name="viewName"
(2)                     valueClass="viewMapValueClass"
(3)                     sql="viewSQL CREATE VIEW last5MinuteAvgPrice AS
                                        SELECT issue, avg(price) as totalVolume
                                    FROM (SELECT * FROM stockQuote FETCH LATEST 5 MINUTES) group by issue;"/>
(4)                     access="PROPERTY" | "FIELD"
/>
```

basic element

The basic element is used to define a mapping from the attribute name in the value class or entity metadata to the column that is defined in the SPTSQL.

- Number of occurrences: Zero to many
- Child element: None

```
<basic
(1)                     name="attributeName"
(2)                     column="columnName"
/>
```

id element

The id element is used for a key attribute mapping.

- Number of occurrences: Zero to many
- Child element: None

```
<id
(1)                     name="idName"
(2)                     column="columnName"
/>
```

objectGrid.xsd file

Use the ObjectGrid descriptor XML schema to configure WebSphere® eXtreme Scale.

See the ObjectGrid descriptor XML file for descriptions of the elements and attributes defined in the objectGrid.xsd file. For information about the Spring objectgrid.xsd file, see Spring descriptor XML file.

```

Deployment policy descriptor XML file

To configure a deployment policy, use a deployment policy descriptor XML file.

In the following sections, the elements and attributes of the deployment policy descriptor XML file are defined. See the deploymentPolicy.xsd file for the corresponding deployment policy XML schema.

Figure 1. Elements in the deploymentPolicy.xml file

```
<?xml version="1.0" encoding="UTF-8"?>
<deploymentPolicy xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/deploymentPolicy ../deploymentPolicy.xsd"
        xmlns="http://ibm.com/ws/objectgrid/deploymentPolicy">
        <objectgridDeployment objectgridName="myGrid">
                <mapSet
                                name="mapSetName"
                                numberOfPartitions="numberOfPartitions"
                                minSyncReplicas="minimumNumber"
                                maxSyncReplicas="maximumNumber"
                                maxAsyncReplicas="maximumNumber"
                                replicaReadEnabled="true|false"
                                numInitialContainers="numberOfInitialContainersBeforePlacement"
                                autoReplaceLostShards="true|false"
                                developmentMode="true|false"
                                placementStrategy="FIXED_PARTITIONS|PER_CONTAINER">
                                <map ref="backingMapReference" />

                                        <zoneMetadata>
                                                <shardMapping
                                                        shard="shardType"
                                                        zoneRuleRef="zoneRuleRefName" />

                                                                name="zoneRuleName"
                                                                exclusivePlacement="true|false" >
                                                                <zone name="ALPHA" />
                                                                <zone name="BETA" />
                                                                <zone name="GAMMA" />
                                                </zoneRule>
                                        </zoneMetadata>
                        </mapSet>
```

```
            </objectgridDeployment>
        </deploymentPolicy>
```

deploymentPolicy element

The deploymentPolicy element is the top-level element of the deployment policy XML file. This element sets up the namespace of the file and the schema location. The schema is defined in the deploymentPolicy.xsd file.

- **Number of occurrences:** One
- **Child element:** objectgridDeployment

objectgridDeployment element

The objectgridDeployment element is used to reference an ObjectGrid instance from the ObjectGrid XML file. Within the objectgridDeployment element, you can divide your maps into map sets.

- **Number of occurrences:** One or more
- **Child element:** mapSet

Attributes

objectgridName
: Specifies the name of the ObjectGrid instance to deploy. This attribute references an objectGrid element that is defined in the ObjectGrid XML file. (Required)

For example, the objectgridName attribute is set as `CompanyGrid` in the companyGridDpReplication.xml file. The objectgridName attribute references the `CompanyGrid` that is defined in the companyGrid.xml file. Read about the ObjectGrid descriptor XML file, which you must couple with the deployment policy file for each ObjectGrid instance.

mapSet element

The mapSet element is used to group maps together. The maps within a mapSet element are partitioned and replicated similarly. Each map must belong to only one mapSet element.

- **Number of occurrences:** One or more
- **Child elements:**
  - map
  - zoneMetadata

Attributes

name
: (Required) Specifies the name of the mapSet. This attribute must be unique within the objectgridDeployment element.

numberOfPartitions
: (Optional) Specifies the number of partitions for the mapSet element. The default value is 1. The number must be appropriate for the number of container servers that host the partitions. (Optional)

minSyncReplicas
: Specifies the minimum number of synchronous replicas for each partition in the mapSet. The default value is 0. Shards are not placed until the domain can support the minimum number of synchronous replicas. To support the minSyncReplicas value, you need one more container server than the minSyncReplicas value. If the number of synchronous replicas falls below the minSyncReplicas value, write transactions are no longer allowed for that partition.
  In the following configurations, when the minSyncReplicas value is set to a value greater than `0`, transactions are rejected from the data grid because a replica is expected:

  - Only one zone is available in a multiple zone configuration
  - Only one host is available and the developmentMode attribute is set to `false`.
  - If the allowableShardOverrage property is configured, transactions for a particular partition are rejected until the second zone has a number of container servers over the configured percentage.

maxSyncReplicas
: Specifies the maximum number of synchronous replicas for each partition in the mapSet. The default value is 0. No other synchronous replicas are placed for a partition after a domain reaches this number of synchronous replicas for that specific partition. Adding container servers that can support this ObjectGrid can result in an increased number of synchronous replicas if your maxSyncReplicas value is not already met. (Optional)

maxAsyncReplicas
: Specifies the maximum number of asynchronous replicas for each partition in the mapSet. The default value is 0. After the primary and all synchronous replicas are placed for a partition, asynchronous replicas are placed until the maxAsyncReplicas value is met. (Optional)

replicaReadEnabled
: If this attribute is set to `true`, read requests are distributed between a partition primary and its replicas. If the replicaReadEnabled attribute is `false`, read requests are routed to the primary only. The default value is false. (Optional)

numInitialContainers
: Specifies the number of container servers that are required before initial placement occurs for the shards in this mapSet element. The default value is `1`. This attribute can help save process and network bandwidth when you are bringing a data grid online from a cold start. (Optional)
  You can also use the placementDeferralInterval property and the **xscmd -c suspendBalancing** command to delay the initial placement of shards on the container servers.
  Starting a container server sends an event to the catalog service. The first time that the number of active container servers is equal to the numInitialContainers value for a mapSet element, the catalog service places the shards from the mapSet, if the minSyncReplicas value can also be

satisfied. After the numInitialContainers value is met, each container server-started event can trigger a rebalancing of unplaced and previously placed shards. If you know approximately how many container servers you are going to start for this mapSet element, you can set the numInitialContainers value close to that number to avoid the rebalancing after every container server start. Placement occurs only when you reach the numInitialContainers value that is specified in the mapSet element.
To override the numInitialContainers value, for example, when you are performing maintenance on your servers and want shard placement to continue running, you can use the **xscmd -c triggerPlacement** command. This override is temporary and is applied when you run the command. After you run the command, all subsequent placement runs use the numInitialContainers value.

autoReplaceLostShards
: Specifies if lost shards are placed on other container servers. The default value is `true`. When a container server is stopped or fails, the shards that are running on the container server are lost. A lost primary shard causes one of its replica shards to be promoted to the primary shard for the corresponding partition. Because of this promotion, one of the replicas is lost. If you want lost shards to remain unplaced, set the autoReplaceLostShards attribute to `false`. This setting does not affect the promotion chain, but only the replacement of the last shard in the chain. (Optional)

developmentMode
: With this attribute, you can influence where a shard is placed in relation to its peer shards. The default value is `true`. When the developmentMode attribute is set to `false`, no two shards from the same partition are placed on the same computer. When the developmentMode attribute is set to `true`, shards from the same partition can be placed on the same server. In either case, no two shards from the same partition are ever placed in the same container server. (Optional)

placementStrategy
: There are two placement strategies. The default strategy is to use a fixed partition strategy. By setting the attribute placementStrategy to `FIXED_PARTITIONS`, the number of primary shards that are placed across available container servers is equal to the number of partitions that are defined, and increased by the number of replicas. The other strategy is to use a per container strategy. By setting placementStrategy to `PER_CONTAINER`, the number of primary shards that are placed on each container server is equal to the number of partitions that are defined, with an equal number of replicas that are placed on other container servers. (Optional)

map element

Each map in a mapSet element references one of the backingMap elements that is defined in the corresponding ObjectGrid XML file. Every map in a distributed eXtreme Scale environment can belong to only one mapSet element.

- **Number of occurrences:** One or more
- **Child element:** None

Attributes

ref
: Provides a reference to a backingMap element in the ObjectGrid XML file. Each map in a mapSet element must reference a backingMap element from the ObjectGrid XML file. The value that is assigned to the ref attribute must match the name attribute of one of the backingMap elements in the ObjectGrid XML file. (Required)

zoneMetadata element

You can place shards into zones. With zones, you can control how eXtreme Scale places shards on a grid. Java virtual machines that host an eXtreme Scale server can be tagged with a zone identifier. The deployment file can include one or more zone rules, and these zone rules are associated with a shard type. The zoneMetadata element is a receptacle of zone configuration elements. Within the zoneMetadata element, zones can be defined and shard placement behavior can be influenced.

For more information, see Zones for replica placement.

- **Number of occurrences:** Zero or one
- **Child elements:**
  - shardMapping
  - zoneRule

Attributes: None

shardMapping element

The shardMapping element is used to associate a shard type with a zone rule. Placement of the shard is influenced by the mapping to the zone rule.

- **Number of occurrences:** Zero or one
- **Child elements:** None

Attributes

shard
: Specify the name of a shard with which to associate the zoneRule. (Required)

zoneRuleRef
: Specify the name of a zoneRule with which to associate the shard. (Optional)

zoneRule element

A zone rule specifies the possible set of zones in which a shard can be placed. The zoneRule element is used to specify a set of zones that a set of shard types can be placed within. The zone rule can also be used to determine how shards are grouped across the zones with the exclusivePlacement attribute.

- **Number of occurrences:** One or more

- **Child elements:** zone

Attributes

name
: Specify the name of the zone rule that you defined previously, as the zoneRuleRef in a shardMapping element. (Required)

exclusivePlacement
: An exclusive setting indicates that each shard type mapped to this zone rule is placed in a different zone in the zone list. An inclusive setting indicates that after a shard is placed in a zone from the list, then the other shard types that are mapped to this zone rule are also placed in that zone. At least 3 zones are required when you use an exclusive setting with 3 shards that are mapped to the same zone rule. The 3 shards include the primary, and 2 synchronous replicas. (Optional)

zone element

The zone element is used to name a zone within a zone rule. Each zone that is named must correspond to a zone name that is used to start servers.

Example

In the following example, the mapSet element is used to configure a deployment policy. The value is set to `mapSet1`, and is divided into 10 partitions. Each of these partitions must have at least one synchronous replica available and no more than two synchronous replicas. Each partition also has an asynchronous replica if the environment can support it. All synchronous replicas are placed before any asynchronous replicas are placed. Additionally, the catalog service does not attempt to place the shards for the mapSet1 element until the domain can support the minSyncReplicas value. Supporting the minSyncReplicas value requires two or more container servers: one for the primary and two for the synchronous replica.

```
<?xml version="1.0" encoding="UTF-8"?>
<deploymentPolicy xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
        xsi:schemaLocation="http://ibm.com/ws/objectgrid/deploymentPolicy ../deploymentPolicy.xsd"
        xmlns="http://ibm.com/ws/objectgrid/deploymentPolicy">

        <objectgridDeployment objectgridName="CompanyGrid">
                <mapSet name="mapSet1" numberOfPartitions="10"
                        minSyncReplicas="1" maxSyncReplicas="2" maxAsyncReplicas="1"
                        numInitialContainers="10" autoReplaceLostShards="true"
                        developmentMode="false" replicaReadEnabled="true">
                        <map ref="Customer"/>
                        <map ref="Item"/>
                        <map ref="OrderLine"/>
                        <map ref="Order"/>
                </mapSet>
        </objectgridDeployment>

</deploymentPolicy>
```

Only 2 container servers are required to satisfy the replication settings. However, the numInitialContainers attribute requires 10 available container servers before the catalog service attempts to place any of the shards in this mapSet element. After the domain has 10 container servers that are able to support the CompanyGrid ObjectGrid, all shards in the mapSet1 element are placed.
When the autoReplaceLostShards attribute is set to true, any shard in this mapSet element that is lost as the result of container server failure is automatically replaced on another container server. This replacement occurs only if a container server is available to host the lost shard. Shards from the same partition cannot be placed on the same server for the mapSet1 element because the developmentMode attribute is set to `false`. Read-only requests are distributed across the primary shard and its replicas for each partition because the replicaReadEnabled value is `true`.

The companyGridDpMapSetAttr.xml file uses the ref attribute on the map to reference each of the backingMap elements from the companyGrid.xml file.

For more examples, see Zone-preferred routing.

    </xsd:complexType>

</xsd:schema>
```

Entity metadata descriptor XML file

The entity metadata descriptor file is an XML file that is used to define an entity schema for WebSphere® eXtreme Scale. Define all of the entity metadata in the XML file, or define the entity metadata as annotations on the entity Java™ class file. The primary use is for entities that cannot use Java annotations.

Use XML configuration to create entity metadata that is based on the XML file. When used in conjunction with annotation, some of the attributes that are defined in the XML configuration override the corresponding annotations. If you can override an element, the override is explicitly in the following sections. See emd.xsd file for an example of the entity metadata descriptor XML file.

id element

The id element implies that the attribute is a key. At a minimum, at least one id element must be specified. You can specify multiple id keys for use as a compound key.

Attributes

name
: Specifies the name of the attribute. The attribute must exist in the Java file.

alias
: Specifies the element alias. The alias value is overridden if used in conjunction with an annotated entity.

basic element

The basic element implies that the attribute is a primitive type or wrappers to primitive types:

- java.lang.String
- java.math.BigInteger
- java.math.BigDecimal
- java.util.Date
- java.util.Calendar
- java.sql.Date
- java.sql.Time
- java.sql.Timestamp
- byte[]
- Byte[]
- char[]
- Character[]
- Java Platform, Standard Edition Version 5 enum

It is not necessary to specify any attribute as basic. The basic element attributes are automatically configured using reflection.

Attributes

name
: Specifies the name of the attribute in the class.

alias
: Specifies the element alias. The alias value is overridden if used in conjunction with an annotated entity.

fetch
: Specifies the fetch type. Valid values include: `LAZY` or `EAGER`.

id-class element

The id_class element specifies a compound key class, which helps to find entities with compound keys.

Attributes

class-name
: Specifies the class name, which is an id-class, to use with the id-class element.

transient element

The transient element implies that it is ignored and not processed. It also can be overridden if used in conjunction with annotated entities.

Attributes

name
: Specifies the name of the attribute, which is ignored.

version element

Attributes

name
: Specifies the name of the attribute, which is ignored.

cascade-type element

Child elements

- **cascade-all**: Cascades the all operation to associations.
- **cascade-persist**: Cascades the persist operation to associations.
- **cascade-remove**: Cascades the remove operation to associations.
- **cascade-merge**: Currently not used.
- **cascade-refresh**: Currently not used.

one-to-one element

Attributes

name
: Specifies the name of the class, which has a one-to-one relationship.

alias
: Specifies a name alias.

target-entity
: Specifies the association class. This value is a fully-qualified class name.

fetch
: Specifies the fetch type. Valid values include: `LAZY` or `EAGER`.

mapped-by
: Specifies the field that owns the relationship. The mapped-by element is only specified on the inverse (non-owning) side of the association.

id
: Identifies the association as key.

Child elements

- **cascade**: cascade-type element

one-to-many element

Attributes

name
: Specifies the name of the attribute in the class.

alias
: Specifies a name alias.

target-entity
: Specifies the association class. This value is a fully-qualified class name.

fetch
: Specifies the fetch type. Valid values include: `LAZY` or `EAGER`.

mapped-by
: Specifies the field that owns the relationship. The mapped-by element is only specified on the inverse (non-owning) side of the association.

Child elements

- **order-by**
- **cascade**: cascade-type element

many-to-one element

Attributes

name
: Specifies the name of the attribute in the class.

alias
: Specifies a name alias.

target-entity
: Specifies the class to which this attribute refers. This value is a fully-qualified class name.

fetch
: Specifies the fetch type. Valid values include: `LAZY` or `EAGER`.

id
: Identifies the association as a key.

Child elements

- **cascade**: cascade-type element

many-to-many element

Attributes

name
: Specifies the name of the attribute in the class.

alias
: Specifies a name alias.

target-entity
: Specifies the class to which this attribute refers. This value is a fully-qualified class name.

fetch
: Specifies the fetch type. Valid values include: `LAZY` or `EAGER`.

mapped-by
: Specifies the field that owns the relationship. The mapped-by element is only specified on the inverse (non-owning) side of the association.

Child elements

- **order-by**
- **cascade**: cascade-type element

attributes element

Child elements

- id element
- basic element
- version element
- many-to-one element
- one-to-many element
- one-to-one element
- many-to-many element
- transient element

Entity element

Attributes

name(required)
: Specifies the name of the attribute in the class.

class-name
: Specifies the fully-qualified class name.

access
: Specifies the access type. The valid values are `PROPERTY` or `FIELD`.

schemaRoot
: Specifies that this entity is the schema root and is used as a parent class for partitioned data.

Child elements

- **description:** Specifies a description.
- id-class element
- attributes element

entity-mappings element

Child elements

- **description:** Specifies a description.
- Entity element

entity-listener element

Attributes

class-name (required)
: Specifies the name of the listener class.

Child elements

- PrePersist element
- PostPersist element
- PreRemove element
- PreUpdate element
- PostUpdate element
- PostLoad element

PrePersist element

Attributes

method-name (required)
: Specifies the lifecycle callback method for the PrePersist event.

PostPersist element

Attributes

method-name (required)
: Specifies the lifecycle callback method for the PostPersist event.

PreRemove element

Attributes

method-name (required)
: Specifies the lifecycle callback method for the PreRemove event.

PreUpdate element

Attributes

method-name (required)
Specifies the lifecycle callback method for the PreUpdate event.

PostUpdate element

Attributes

method-name (required)
Specifies the lifecycle callback method for the PostUpdate event.

PostLoad element

Attributes

method-name (required)
Specifies the lifecycle callback method for the PostLoad event.

```

Security descriptor XML file

Use a security descriptor XML file to configure an eXtreme Scale deployment topology with security enabled. You can use the elements in this file to configure different aspects of security.

securityConfig element

The securityConfig element is the top-level element of the ObjectGrid security XML file. This element sets up the namespace of the file and the schema location. The schema is defined in the objectGridSecurity.xsd file.

- Number of occurrences: One
- Child elements: security

security element

Use the security element to define an ObjectGrid security.

- Number of occurrences: One
- Child elements: authenticator, adminAuthorization, and systemCredentialGenerator

Attributes

securityEnabled
: Enables security for the grid when set to true. The default value is false. If the value is set to false, grid-wide security is disabled. For more information, see Data grid security. (Optional)

singleSignOnEnabled
: Enables a client to connect to any server after it has authenticated with one of the servers when the value is set to `true`. Otherwise, a client must authenticate with each server before the client can connect. The default value is false. (Optional)

loginSessionExpirationTime
: Specifies the amount of time in seconds before the login session expires. If the login session expires, the client must authenticate again. (Optional)

adminAuthorizationEnabled
: Enables administrative authorization. If the value is set to true, all of the administrative tasks need authorization. The authorization mechanism that is used is specified by the value of the adminAuthorizationMechanism attribute. The default value is false. (Optional)

adminAuthorizationMechanism
: Indicates which authorization mechanism to use. WebSphere® eXtreme Scale supports two authorization mechanisms, Java™ Authentication and Authorization Service (JAAS) and custom authorization. The JAAS authorization mechanism uses the standard JAAS policy-based approach. To specify JAAS as the authorization mechanism, set the value to AUTHORIZATION_MECHANISM_JAAS. The custom authorization mechanism uses a user-plugged-in AdminAuthorization implementation. To specify a custom authorization mechanism, set the value to AUTHORIZATION_MECHANISM_CUSTOM. For more information on how these two mechanisms are used, see Authorizing application clients. (Optional)

The following security.xml file is a sample configuration to enable the data grid security.

security.xml

```
<?xml version="1.0" encoding="UTF-8"?>
<securityConfig xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
```

```
    xsi:schemaLocation="http://ibm.com/ws/objectgrid/config/security ../objectGridSecurity.xsd"
        xmlns="http://ibm.com/ws/objectgrid/config/security">

    <security securityEnabled="true" singleSignOnEnabled="true"
        loginSessionExpirationTime="20"
        adminAuthorizationEnabled="true"
        adminAuthorizationMechanism="AUTHORIZATION_MECHANISM_JAAS" >

        <authenticator className ="com.ibm.websphere.objectgrid.security.plugins.
                                        builtins.WSTokenAuthenticator">
        </authenticator>

        <systemCredentialGenerator className ="com.ibm.websphere.objectgrid.security.
                                        plugins.builtins.WSTokenCredentialGenerator">
            <property name="properties" type="java.lang.String" value="runAs"
                                                        description="Using runAs subject" />
        </systemCredentialGenerator>

    </security>
</securityConfig>
```

authenticator element

Authenticates clients to eXtreme Scale servers in the data grid. The class that is specified by the className attribute must implement the com.ibm.websphere.objectgrid.security.plugins.Authenticator interface. The authenticator can use properties to call methods on the class that is specified by the className attribute. See property element for more information on using properties.
In the previous security.xml file example, the com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenAuthenticator class is specified as the authenticator. This class implements the com.ibm.websphere.objectgrid.security.plugins.Authenticator interface.

- Number of occurrences: zero or one
- Child element: property

Attributes

className
: Specifies a class that implements the com.ibm.websphere.objectgrid.security.plugins.Authenticator interface. Use this class to authenticate clients to the servers in the eXtreme Scale grid. (Required)

adminAuthorization element

Use the adminAuthorization element to set up administrative access to the data grid.

- Number of occurrences: zero or one
- Child element: property

Attributes

className
: Specifies a class that implements the com.ibm.websphere.objectgrid.security.plugins.AdminAuthorization interface. (Required)

systemCredentialGenerator element

Use a systemCredentialGenerator element to set up a system credential generator. This element only applies to a dynamic environment. In the dynamic configuration model, the dynamic container server connects to the catalog server as an eXtreme Scale client and the catalog server can connect to the eXtreme Scale container server as a client too. This system credential generator is used to represent a factory for the system credential.

- Number of occurrences: zero or one
- Child element: property

Attributes

className
: Specifies a class that implements the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface. (Required)

See the previous security.xml file for an example of how to use a systemCredentialGenerator class. In this example, the system credential generator is a com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator class, which retrieves the RunAs Subject object from the thread.

property element

Calls set methods on the authenticator and adminAuthorization classes. The name of the property corresponds to a set method on the className attribute of the authenticator or adminAuthorization element.

- Number of occurrences: zero or more
- Child element: property

Attributes

name
: Specifies the name of the property. The value that is assigned to this attribute must correspond to a set method on the class that is provided as the className attribute on the containing bean. For example, if the className attribute of the bean is set to com.ibm.MyPlugin, and the name of the property

that is provided is size, then the com.ibm.MyPlugin class must have a setSize method. (Required)

type
: Specifies the type of the property. The type of the parameter is passed to the set method that is identified by the name attribute. The valid values are the Java primitives, their java.lang counterparts, and java.lang.String. The name and type attributes must correspond to a method signature on the className attribute of the bean. For example, if the name is size and the type is int, then a setSize(int) method must exist on the class that is specified as the className attribute for the bean. (Required)

value
: Specifies the value of the property. This value is converted to the type that is specified by the type attribute, and is then used as a parameter in the call to the set method that is identified by the name and type attributes. The value of this attribute is not validated in any way. The plug-in implementor must verify that the value passed in is valid. (Required)

description
: Provides a description of the property. (Optional)

See objectGridSecurity.xsd file for more information.

                        <xsd:enumeration value="AUTHORIZATION_MECHANISM_CUSTOM" />
                </xsd:restriction>
        </xsd:simpleType>

</xsd:schema>
```

Spring descriptor XML file

Use a Spring descriptor XML file to configure and integrate eXtreme Scale with Spring.

In the following sections, each element and attribute of the Spring objectgrid.xsd file is defined. The Spring objectgrid.xsd file is in the ogspring.jar file and the ObjectGrid namespace com/ibm/ws/objectgrid/spring/namespace. See the Spring objectgrid.xsd file for an example of the descriptor XML schema.

register element

Use the register element to register the default bean factory for the ObjectGrid.

- Number of occurrences: Zero to many
- Child element: None

Attributes

id
: Specifies the name of the default bean directory for a particular ObjectGrid.

gridname
: Specifies the name of the ObjectGrid instance. The value assigned to this attribute must correspond to a valid ObjectGrid configured in the ObjectGrid descriptor file.

```
<register
        id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsxsdelements_register id"
        gridname="ObjectGrid name"
/>
```

server element

Use the server element to define a server, which can host a container, a catalog service, or both.

- Number of occurrences: Zero to many
- Child element: None

Attributes

id
: Specifies the name of the eXtreme Scale server.

tracespec
: Indicates the type of trace and enables trace and trace specification for the server.

tracefile
: Provides the path and name of the trace file to create and use.

statspec
: Indicates the statistic specification for the server.

jmxport
: Specifies the port that is used by the high availability (HA) manager for heartbeat communication between peer container servers. The haManagerPort port is only used for peer-to-peer communication between container servers that are in same domain. If the haManagerPort property is not defined, then

an ephemeral port is used. In WebSphere® Application Server, this setting is inherited by the high availability manager port configuration.

isCatalog
: Specifies whether the particular server hosts a catalog service. The default value is `false`.

name
: Specifies the name of the server.

haManagerPort
: Specifies the port that is used by the high availability (HA) manager for heartbeat communication between peer container servers. The haManagerPort port is only used for peer-to-peer communication between container servers that are in same domain. If the haManagerPort property is not defined, then an ephemeral port is used. In WebSphere Application Server, this setting is inherited by the high availability manager port configuration.

listenerHost
: Specifies the host name to which the Object Request Broker (ORB) transport protocol binds for communication. The value must be a fully qualified domain name or IP address. If your configuration involves multiple network cards, set the listener host and port to the IP address for which to bind. By setting the listener and host port, it allows the transport mechanism in the JVM know which IP address to use. If you do not specify which IP address to use, symptoms such as connection timeouts, unusual API failures, and clients that seem to hang can occur.

listenerPort
: Specifies the port number to which the Object Request Broker transport protocol binds for communication.

maximumThreadPoolSize
: Sets the maximum number of threads in the pool.

memoryThresholdPercentage
: Sets the memory threshold (percentage of max heap) for memory-based eviction.

minimumThreadPoolSize
: Sets the minimum number of threads in the pool.

workingDirectory
: The property that defines which directory the ObjectGrid server uses for all default settings.

zoneName
: Defines the zone to which this server belongs.

enableSystemStreamToFile
: Defines whether SystemOut and SystemErr is sent to a file.

enableMBeans
: Determines whether the ObjectGrid registers MBeans in this process.

serverPropertyFile
: Loads the server properties from a file.

catalogServerProperties
: Specifies the catalog server that hosts server.

```
<server
        id="_dcs_markdown_workspace_Transform_htmlout_0_com.ibm.websphere.extremescale.doc_rxsxsdelements_server id"
        tracespec="the server trace specification"
        tracefile="the server trace file"
        statspec="the server statistic specification"
        jmxport="JMX port number"
        isCatalog="true"|"false"
        name="the server name"
        haManagerPort="the haManager port"
        listenerHost="the orb binding host name"
        listenerPort="the orb binding listener port"
        maximumThreadPoolSize="the number of maximum threads"
        memoryThresholdPercentage="the memory threshold (percentage of max heap)"
        minimumThreadPoolSize="the number of minimum threads"
        workingDirectory="location for the working directory"
        zoneName="the zone name"
        enableSystemStreamToFile="true"|"false"
        enableMBeans="true"|"false"
        serverPropertyFile="location of the server properties file."
        catalogServerProperties="the catalog server properties reference"
/>
```

catalog element

Use the catalog element to route to container servers in the data grid.

- Number of occurrences: Zero to many
- Child element: None

Attributes

host
: Specifies the host name of the workstation where the catalog service is running.

port
: Specifies the port number paired with the host name to determine the catalog service port to which the client can connect.

```
<catalog
        host="catalog service host name"
        port="catalog service port number"
/>
```

catalogServerProperties element

Use the catalog server properties element to define a catalog service.

- Number of occurrences: Zero to many
- Child element: foreignDomains element

Attributes

catalogServerEndPoint
: Specifies the connection properties for the catalog server.

enableQuorum
: Determines whether to enable quorum.

heartBeatFrequencyLevel
: Sets the heartbeat frequency level.

domainName
: Defines the domain name used to uniquely identify this catalog service domain to clients when routing to multiple catalog service domains.

clusterSecurityURL
: Sets the location of the security file specific to the catalog service.

```
<catalogServerProperties
        catalogServerEndPoint="a catalog server endpoint reference"
        enableQuorum="true"|"false"
        heartBeatFrequencyLevel="
                HEARTBEAT_FREQUENCY_LEVEL_TYPICAL|
                HEARTBEAT_FREQUENCY_LEVEL_RELAXED|
                HEARTBEAT_FREQUENCY_LEVEL_AGGRESSIVE"
        domainName="the domain name used to uniquely identify this catalog service domain"
        clusterSecurityURL="the The cluster security file location.">
        <foreignDomains>
                <foreignDomain name="name_of_foreign_domain_1">
                        <endPoint host="catalog server host 1" port="2809"/>
                        <endPoint host="catalog server host 2" port="2809"/>
                </foreignDomain>
                <foreignDomain name="name_of_foreign_domain_2">
                        <endPoint host="catalog server host 3" port="2809"/>
                        <endPoint host="catalog server host 4" port="2809"/>
                </foreignDomain>
        </foreignDomains>
</catalogServerProperties>
```

foreignDomains element

Use the foreignDomains element to connect to a list of other catalog service domains. You must include the name of each catalog service domain and the end points for the catalog servers within each catalog service domain.

- Number of occurrences: Zero to many
- Parent element: catalogServerProperties element
- Child element: foreignDomain element

foreignDomain element

Indicates the name of the catalog service domain to connect. This name is defined with the domainName attribute on the catalogServiceProperties element.

- Number of occurrences: One to many
- Parent element: foreignDomains element
- Child element: endPoint element
- **Attributes**

  name
  : Specifies the name that identifies the foreign catalog service domain.

endPoint element

Indicates a list of catalog service end points for a specified foreign catalog service domain.

- Number of occurrences: One to many
- Parent element: foreignDomain element
- Child element: None
- **Attributes**

  host
  : Specifies the host name of one of the catalog servers in the catalog service domain.

  port
  : Specifies the port of one of the catalog servers in the catalog service domain.

catalog server endpoint element

Use the catalog server endpoint element to create a catalog server endpoint to be used by a catalog server element.

- Number of occurrences: Zero to many
- Child element: None

Attributes

serverName
: Specifies the name that identifies the process that you are launching.

hostName
: Specifies the host name for the machine where the server is launched.

clientPort
: Specifies the port used for peer catalog cluster communication.

peerPort
: Specifies the port used for peer catalog cluster communication.

```
<catalogServerEndPoint
        name="catalog server endpoint name"
        host=""
        clientPort=""
        peerPort=""
/>
```

container element

Use the container element to store the data itself.

- Number of occurrences: Zero to many
- Child element: None

Attributes

objectgridxml
: Specifies the path and name of the descriptor XML file to use that specifies characteristics for the ObjectGrid, including maps, locking strategy, and plug-ins.

deploymentxml
: Specifies the path and name of the XML file that is used with the descriptor XML file. This file determines partitioning, replication, number of initial containers, and other settings.

server
: Specifies the server on which the container is hosted.

```
<server
        objectgridxml="the objectgrid descriptor XML file"
        deploymentxml ="the objectgrid deployment descriptor XML file "
        server="the server reference "
/>
```

JPALoader element

Use the JPALoader element to synchronize the ObjectGrid cache with an existing backend data store when using the ObjectMap API.

- Number of occurrences: Zero to many
- Child element: None

Attributes

entityClassName
: Enables usage of JPAs such as EntityManager.persist and EntityManager.find. The entityClassName attribute is required for the JPALoader.

preloadPartition
: Specifies the partition number at which the map preload is started. If the value is less than 0, or greater than (totalNumberOfPartition – 1), the map preload is not started.

```
<JPALoader
        entityClassName="the entity class name"
        preloadPartition ="int"
/>
```

JPATxCallback element

Use the JPATxCallback element to coordinate JPA and ObjectGrid transactions.

- Number of occurrences: Zero to many
- Child element: None

Attributes

persistenceUnitName
: Creates a JPA EntityManagerFactory and locates the JPA entity metadata in the persistence.xml file. The persistenceUnitName attribute is required.

jpaPropertyFactory
: Specifies the factory to create a persistence property map to override the default persistence properties. This attribute references a bean.

exceptionMapper
: Specifies the ExceptionMapper plug-in that can be used for JPA-specific or database-specific exception mapping functions. This attribute references a bean.

```
<JPATxCallback
        persistenceUnitName="the JPA persistence unit name"
        jpaPropertyFactory ="JPAPropertyFactory bean reference"
        exceptionMapper="ExceptionMapper bean reference"
/>
```

JPAEntityLoader element

Use the JPAEntityLoader element to synchronize the ObjectGrid cache with an existing backend data store when using the EntityManager API.

- Number of occurrences: Zero to many
- Child element: None

Attributes

entityClassName
: Enables usage of JPAs such as EntityManager.persist and EntityManager.find. The entityClassName attribute is optional for the JPAEntityLoader element. If the element is not configured, the entity class configured in the ObjectGrid entity map is used. The same class must be used for the ObjectGrid EntityManager and for the JPA provider.

preloadPartition
: Specifies the partition number at which the map preload is started. If the value is less than 0, or greater than (totalNumberOfPartition – 1) the map preload is not launched.

```
<JPAEntityLoader
        entityClassName="the entity class name"
        preloadPartition ="int"
/>
```

LRUEvictor element

Use the LRUEvictor element to decide which entries to evict when a map exceeds its maximum number of entries.

- Number of occurrences: Zero to many
- Child element: None

Attributes

maxSize
: Specifies the total entries in a queue until the evictor must intervene.

sleepTime
: Sets the time in seconds between the eviction sweep over map queues to determine any necessary actions on the map.

numberOfLRUQueues
: Specifies the setting of how many queues the evictor must scan to avoid having a single queue that is the size of the entire map.

```
<LRUEvictor
        maxSize="int"
        sleepTime ="seconds"
        numberOfLRUQueues ="int"
/>
```

LFUEvictor element

Use the LFUEvictor element to determine which entries to evict when a map exceeds its maximum number of entries.

- Number of occurrences: Zero to many
- Child element: None

Attributes

maxSize
: Specifies the total entries that are allowed in each heap until the evictor must act.

sleepTime
: Sets the time in seconds between eviction sweeps over map heaps to determine any necessary actions on the map.

numberOfHeaps
: Specifies the setting of how many heaps the evictor must scan to avoid having a single heap that is the size of the entire map.

```
<LFUEvictor
        maxSize="int"
        sleepTime ="seconds"
        numberOfHeaps ="int"
/>
```

HashIndex element

Use the HashIndex element with Java™ reflection to dynamically introspect objects stored in a map when the objects are updated.

- Number of occurrences: Zero to many
- Child element: None

Attributes

name
Specifies the name of the index, which must be unique for each map.
attributeName
Specifies the name of the attribute to index. For field-access indexes, the attribute name is equivalent to the field name. For property-access indexes, the attribute name is the JavaBeans compatible property name.
rangeIndex
Indicates whether range indexing is enabled. The default value is `false`.
fieldAccessAttribute
Used for non-entity maps. The getter method is used to access the data. The default value is `false`. If you specify the value as `true`, the object is accessed using the fields directly.
POJOKeyIndex
Used for non-entity maps. The default value is `false`. If you specify the value as `true`, the index introspects the object in the key part of the map. This inspection is useful when the key is a composite key and the value does not have an embedded key. If you do not set the value or you specify the value as `false`, the index introspects the object in the value part of the map.

```
<HashIndex
        name="index name"
        attributeName="attribute name"
        rangeIndex ="true"|"false"
        fieldAccessAttribute ="true"|"false"
        POJOKeyIndex ="true"|"false"
/>
```

Liberty profile configuration files

You can specify server properties and Liberty web feature properties for WebSphere® eXtreme Scale applications that run in the Liberty profile.

Use the following files to configure eXtreme Scale servers that run in the Liberty profile:

- Liberty profile server properties
  Use the options from the server properties file to configure WebSphere eXtreme Scale servers that run in the Liberty profile.
- Liberty profile web feature properties
  Specify the web feature for your server definition to identify web-based applications and add functions, such as session replication.
- Liberty profile webApp feature properties
  Specify the webApp feature to extend the Liberty profile web application. Add the webApp feature when you want to replicate HTTP session data for fault

tolerance.
- Liberty profile xsWebGrid feature properties
  Specify the webGrid feature to automatically start a container that hosts clients for HTTP session replication.
- Liberty profile xsDynacacheApp feature properties
  Specify Liberty profile to host the data grid, which you can configure as a dynamic cache provider with this feature.

Liberty profile server properties

Use the options from the server properties file to configure WebSphere® eXtreme Scale servers that run in the Liberty profile.

The server properties file contains several properties that define different settings for your server, such as security configuration. The server properties file is used by both catalog service and container servers in both stand-alone servers and servers that are hosted in WebSphere Application Server.

Configure the server.xml file using the same configuration that you might use for a stand-alone server configuration. In the server.xml file, specify the file path to the properties file in a serverProps attribute inside the com.ibm.ws.xs.server.config element. See the following example from the server.xml file:

```
<server>
...
<com.ibm.ws.xs.server.config ... serverProps="/path/to/myServerProps.properties" ... />
</server>
```

Some properties that were formerly configurable in a stand-alone environment must be configured using the Liberty profile configuration instead of the eXtreme Scale configuration mechanisms.

- Logging and tracing settings must be specified using the logging element in the server.xml file, rather than being specified in the eXtreme Scale server properties file or com.ibm.ws.xs.server.config element.
- The working directory, like logging and tracing, is a server-wide setting, and therefore, they must be specified in a server-wide way.

If the previous settings are specified incorrectly, eXtreme Scale logs a warning message, which indicates that the settings are ignored.

Liberty profile web feature properties

Liberty profile web feature properties

Specify the web feature for your server definition to identify web-based applications and add functions, such as session replication.

The web feature is deprecated. Use the webApp feature when you want to replicate HTTP session data for fault tolerance.

You can set the following attributes on the `xsWebAppV85` element of the server.xml file:

Parameters

objectGridType
: A string value that is set to `REMOTE`, which specifies that session data is stored outside of the server on which the web application is running.

objectGridName
: A string value that defines the name of the ObjectGrid instance used for a particular web application. The default name is session.

  This property must reflect the objectGridName in both the ObjectGrid XML and deployment XML files used to start the eXtreme Scale container servers.

catalogHostPort
: The catalog server can be contacted to obtain a client side ObjectGrid instance. The value must be of the form `host:port<,host:port>`. The host is the listener host on which the catalog server is running. The port is the listener port for that catalog server process. This list can be arbitrarily long and is used for bootstrapping only. The first viable address is used. It is optional inside WebSphere® Application Server if the catalog.services.cluster property is configured.

replicationInterval
: An integer value (in seconds) that defines the time between writing of updated sessions to ObjectGrid. The default is `10` seconds. Possible values are from 0 to 60. 0 means that updated sessions are written to the ObjectGrid at the end of servlet service method call for each request. A higher replicationInterval value improves performance because fewer updates are written to the data grid. However, a higher value makes the configuration less fault tolerant.

This setting applies only when objectGridType is set to `REMOTE`.

sessionTableSize
: An integer value that defines the number of session references kept in memory. The default is `1000`.

  This setting pertains only to a `REMOTE` topology.

  Sessions are evicted from the in-memory table based on least recently used (LRU) logic. When a session is evicted from the in-memory table, it is invalidated from the web container. However, the data is not removed from the grid, so subsequent requests for that session can still retrieve the data. This value must be set higher than the web container maximum thread pool value, which reduces contention on the session cache.

fragmentedSession
: A string value of either `true` or `false`. The default value is `true`. Use this setting to control whether the product stores session data as a whole entry, or stores each attribute separately.

  Set the fragmentedSession parameter to `true` if the web application session has many attributes or attributes with large sizes. Set fragmentedSession to `false` if a session has few attributes, because all the attributes are stored in the same key in the data grid.

  In the previous, filter-based implementation, this property was referred to as persistenceMechanism, with the possible values of ObjectGridStore (fragmented) and ObjectGridAtomicSessionStore (not fragmented).

securityEnabled
: A string value of either `true` or `false`. The default value is `false`. This setting enables eXtreme Scale client security. It must match the securityEnabled setting in the eXtreme Scale server properties file. If the settings do not match, an exception occurs.

credentialAuthentication
: Indicates if credential authentication is enforced or supported.

  Never
  : No client certificate authentication is enforced.

  Required
  : Credential authentication is always enforced. If the server does not support credential authentication, the client cannot to connect to the server.

  Supported
  : (Default) Credential authentication is enforced only if both the client and server support credential authentication.

authenticationRetryCount
: Specifies the name of the class that implements the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface. This class is used to get credentials for clients. The default value is `0`.

credentialGeneratorClass
: The name of the class that implements the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator interface. This class is used to obtain credentials for clients.

credentialGeneratorProps
: The properties for the CredentialGenerator implementation class. The properties are set to the object with the setProperties(String) method. The credentialGeneratorProps value is used only if the value of the credentialGeneratorClass property is not null.

objectGridXML
: The file location of the objectgrid.xml file.

objectGridDeploymentXML
: Specifies the location of the objectGrid deployment policy XML file.

cookieDomain
: Specifies if you require sessions to be accessible across hosts. Set the value to the name of the common domain between the hosts.

cookiePath
: The default path is `"/"`.

reuseSessionID
: Set to `true` if the underlying web container reuses session IDs across requests to different hosts. The default value is `false`. The value of this property must be the same as the value in the web container. If you are using WebSphere Application Server and configuring eXtreme Scale HTTP session persistence using the administrative console or **wsadmin** tool scripting, the web container custom property `HttpSessionIdReuse=true` is added by default. The reuseSessionID is also set to `true`. If you do not want the session IDs to be reused, set the `HttpSessionIdReuse=false` custom property on the web container custom property before you configure eXtreme Scale session persistence.

shareSessionsAcrossWebApps
: Specifies if sessions are shared across web applications, specified as a string value of either `true` or `false`. The default is `false`. The servlet specification states that HTTP Sessions cannot be shared across web applications. An extension to the servlet specification is provided to allow this sharing.

useURLEncoding
: Set to `true` if you want to enable URL rewriting. The default value is `false`, which indicates that cookies are used to store session data. The value of this parameter must be the same as the web container settings for session management.

useCookies
: The default value is `false`.

Messages

When you encounter a message in a log or other parts of the product interface, you can look up the message by its component prefix to find out more information.

Finding messages

When you encounter a message in a log, copy the message number with its letter prefix and number and search in the information center (for example, `CWOBJ1526I`). When you search for the message, you can find an additional explanation of the message and possible actions you can take to resolve the problem.

To open the information center table of contents to the location of this reference information, click the Show in Table of Contents () button on your information center border.

  MEMORY_COLLECTION_THRESHOLD_EXCEEDED_CWOBJ0039=CWOBJ0039W: Memory collection threshold exceeded. Current heap memory usage: {0}.
- CWOBJ0040E
  CWOBJ0040=CWOBJ0040E: Hash based data structure over run for {0} with {1} elements in the data structure. Examine the hashCode method on this class for better distribution.
- CWOBJ0041W
  RANGE_INDEX_NOT_SUPPORTED_CWOBJ0041=CWOBJ0041W: The rangeIndex property of HashIndex plug-in cannot be set to true for a composite index: {0}. The rangeIndex property setting will be ignored.
- CWOBJ0042E
  EXCEPTION_MAPPER_THROWABLE_IGNORED_CWOBJ0042=CWOBJ0042E: The ExceptionMapper implementation class {0} threw an unexpected exception with the following message: {1}. This exception is ignored.
- CWOBJ0043W
  CATALOG_CONFIG_PROBLEM_CELL_PROPERTY_CWOBJ0043=CWOBJ0043W: The {0} is formatted improperly but was corrected: {1}
- CWOBJ0044E
  FORMAT_ERROR_INITIALIZE_CATALOG_CWOBJ0044=CWOBJ0044E: Invalid data in the {0}: {1}. The exception is: {2}
- CWOBJ0045W
  ERROR_CREATING_MBEAN_CWOBJ0045=CWOBJ0045W: An exception occurred while creating an MBean with ObjectName: {0}. The exception is: {1}.
- CWOBJ0046I
  MEMORY_THRESHOLD_DEFAULT_PERCENT_USED_CWOBJ0046=CWOBJ0046I: The Java MemoryMXPool bean was not set (current value = 0). During initialization, the memoryThresholdPercentage property is set to default value of {0}.
- CWOBJ0047I
  DEVELOPMENT_MODE_ENABLED_CWOBJ0047=CWOBJ0047I: Development mode is enabled for one or more MapSets for ObjectGrids: {0}. For a production deployment, set the development mode attribute in the deployment policy file to false.
- CWOBJ0048E
  START_PROCESS_IN_WAS_CWOBJ0048=CWOBJ0048E: Starting stand-alone WebSphere eXtreme Scale server processes in a WebSphere Application Server 6.0.x deployment is not supported.
- CWOBJ0049W
  WAS_NOT_AUGMENTED_CWOBJ0049=CWOBJ0049W: This profile is not augmented with WebSphere eXtreme Scale. WebSphere eXtreme Scale container servers will therefore not start automatically.
- CWOBJ0050W
  INVALID_PORT_BOOTSTRAP_OVERRIDE_CWOBJ0050=CWOBJ0050W: Invalid listenerPort {0} defined in the {1}. Overriding it with the bootstrap address port (BOOTSTRAP_ADDRESS) {2}.
- CWOBJ0051W
  WAS_NOT_AUGMENTED_CWOBJ0051=CWOBJ0051W: This profile is not augmented with WebSphere eXtreme Scale. A catalog service will therefore not start automatically.
- CWOBJ0052I
  ORB_CHANNELFRAMEWORK_CWOBJ0052=CWOBJ0052I: The IBM ORB TransportMode property was set to ChannelFramework.
- CWOBJ0053I
  ORB_SEVERSOCKETQUEUEDEPTH_OVERRIDE_CWOBJ0053=CWOBJ0053I: The IBM ORB ServerSocketQueueDepth property was set to {0} to run with correctly with the ChannelFramework TransportMode.
- CWOBJ0054I
  WXS_PROPERTY_CWOBJ0054=CWOBJ0054I: The value of the "{0}" property is "{1}".
- CWOBJ0055W
  ORB_CHANNELFRAMEWORK_CWOBJ0055=CWOBJ0055W: The IBM ORB TransportMode property was set to ChannelFramework in the server properties file, but the existing orb.properties file already had a TransportMode set. The TransportMode will not be overridden.
- CWOBJ0056I
  ORB_PROPERTY_OVERRIDE_CWOBJ0056=CWOBJ0056I: The Object Request Broker (ORB) property, {0}, with the value, {1}, is being overridden with the value, {2}.
- CWOBJ0057E
  CATALOG_VERSION_DOWN_LEVEL_CWOBJ0057=CWOBJ0057E: The WebSphere eXtreme Scale catalog server version is {0}, and the client or container server version is {1}.
- CWOBJ0058I
  SAME_GRID_DIFFERENT_MAPSETS_CWOBJ0058=CWOBJ0058I: A deployment policy conflict was detected. Additional mapsets were found for ObjectGrid {0}.
- CWOBJ0059I
  DEFAULT_TRANSACTION_TIMEOUT_CWOBJ0059=CWOBJ0059I: The transaction time out value was not configured or was set to 0 for ObjectGrid {0}. With this configuration, transactions never time out. The transaction time out is being set to 600 seconds.
- CWOBJ0060W
  JVM_SHUTDOWN_HOOK_NOT_ORDERED_CWOBJ0060=CWOBJ0060W: The JVM shutdown hook is not ordered. The ORB shutdown hook might execute before eXtreme Scale shutdown hook executes. This may cause connectivity problem during the XS shutdown process.
- CWOBJ0061W
  TRANSACTION_ROLLED_BACK_CWOBJ0061W=CWOBJ0061W: The transaction with TxID, {0}, that was last running on thread, {1}, on shard {2} has

exceeded the configured transaction timeout value and was been marked rollback-only. This might be caused by lock contention or application deadlock, or your transaction timeout value is set too small.

- CWOBJ0062I
  ORB_PROPERTY_CWOBJ0062=CWOBJ0062I: The value of the "{0}" ORB property is "{1}".
- CWOBJ0063I
  ORB_DEFAULT_PROPERTY_SET_CWOBJ0063=CWOBJ0063I: The {0} property was not configured. The {0} property is being set to {1}.
- CWOBJ0064I
  MEMORY_THRESHOLD_USER_OVERRIDE_CWOBJ0064=CWOBJ0064I: The memoryThresholdPercentage property is provided in a server properties file, which overrides any previously set values.
- CWOBJ0065W
  HASHINDEX_ATTRIBUTE_NOT_FOUND_IN_SERIALIZER_METADATA_CWOBJ0065=CWOBJ0065W: The HashIndex, "{0}", for map "{1}" is enabled for multi-type access. The {2} attribute "{3}" was not defined in the {4} descriptor for the configured DataSerializer plug-in.
- CWOBJ0066W
  TRANSACTION_ROLLED_BACK_STATE_CWOBJ0066W=CWOBJ0066W: The {0} transaction has been marked rollback-only due to a state change of ObjectGrid {1} on shard {2} that forced transaction completion. This could be caused by an administrator changing the availability state of the ObjectGrid instance or termination of the ObjectGrid instance.
- CWOBJ0067W
  JMX_SSL_ENABLED_WITHOUT_PORT_CWOBJ0067W=CWOBJ0067W: SSL is enabled for JMX connections to this server. However, the JMXServicePort property was not provided.
- CWOBJ0068I
  JMX_SERVICE_URL_CWOBJ0068I=CWOBJ0068I: MBeanServer started with JMX URL {0}.
- CWOBJ0069W
  GRID_NOT_OFFHEAP_ELIGIBLE_CWOBJ0069=CWOBJ0069W: OffHeap is enabled but one of the BackingMaps for ObjectGrid "{0}" does not have a CopyMode of COPY_TO_BYTES or COPY_TO_BYTES_RAW. All BackingMaps for an ObjectGrid must be configured with either COPY_TO_BYTES or COPY_TO_BYTES_RAW to use OffHeap.
- CWOBJ0070W
  GC_POLICY_WARNING_CWOBJ0070W=CWOBJ0070W: The IBM implementation of the JVM is using a garbage collection policy that might affect performance.
- CWOBJ0071W
  MAX_HEAP_WARNING_CWOBJ0071W=CWOBJ0071W: The maximum heap size of {1} bytes surpasses the recommended maximum heap size of {0} bytes.
- CWOBJ0072I
  COMMAND_RUNAS_SUBJECT_CWOBJ0072I=CWOBJ0072I: The WebSphere eXtreme Scale command runtime is using the {0} Subject RunAs type.
- CWOBJ0080W
  NO_OBJECTGRID_XML_SPECIFIED_CWOBJ0080W=CWOBJ0080W: No objectgrid.xml specified for container, {0}. Will not process.
- CWOBJ0081I
  STARTING_CONTAINER_CWOBJ0081I=CWOBJ0081I: Starting container specified at: {0} with name, "{1}".
- CWOBJ0082W
  UNABLE_TO_LOAD_SERVER_PROPS_FILE_CWOBJ0082W=CWOBJ0082W: Unable to load properties from server properties file, {0}.
- CWOBJ0083W
  UNRECOGNIZED_SERVER_PROPERTY_CWOBJ0083W=CWOBJ0083W: Unrecognized XS server property specified: {0} Ignoring.
- CWOBJ0084W
  UNSUPPORTED_MULTI_PARAMETER_PROPERTY_CWOBJ0084W=CWOBJ0084W: Unsupported multi-parameter property: {0} - ignoring.
- CWOBJ0085W
  UNKNOWN_PARAMETER_TYPE_CWOBJ0085W=CWOBJ0085W: Unknown parameter type ({0}) while setting config property, {1} - ignoring.
- CWOBJ0086W
  FAILED_TO_SET_PROPERTY_CWOBJ0086W=CWOBJ0086W: Failed to set user property ({0}) : {1}.
- CWOBJ0087W
  PROPERTY_CHANGE_SERVER_RESTART_CWOBJ0087W=CWOBJ0087W: Property, {0}, has changed from {1} to {2} but will not take effect until the server is restarted.
- CWOBJ0088W
  UNRECOGNIZED_WEB_APP_CONFIG_PROPERTY_CWOBJ0088W=CWOBJ0088W: Unrecognized XS Web App Configuration property specified: {0} Ignoring.
- CWOBJ0900I
  CWOBJ0900=CWOBJ0900I: The ObjectGrid runtime component is started for server {0}.
- CWOBJ0901E
  CWOBJ0901=CWOBJ0901E: {0} system property is required to start ObjectGrid runtime component for server: {1}.
- CWOBJ0902W
  CWOBJ0902=CWOBJ0902W: An error prevented the ObjectGrid runtime component from starting for server: {0}.
- CWOBJ0903I
  INTERNAL_OBJECTGRID_VERSION_CWOBJ0903=CWOBJ0903I: The internal version of WebSphere eXtreme Scale is {0}.
- CWOBJ0904E
  FILES_DO_NOT_EXIST_CWOBJ0904=CWOBJ0904E: {0} exists but the following file or files are missing: {1}. Cannot start the ObjectGrid runtime component for server: {2}.
- CWOBJ0905I
  FILES_NOT_FOUND_CWOBJ0905=CWOBJ0905I: WebSphere eXtreme Scale did not find object grid configuration files packaged with application {0}.
- CWOBJ0910I
  CWOBJ0910=CWOBJ0910I: The ObjectGrid runtime component is stopped for server {0}.
- CWOBJ0912E
  CWOBJ0912=CWOBJ0912E: The application {0} has ObjectGrid configuration files that will not be used because application {1} is currently running an ObjectGrid server instance.
- CWOBJ0913I
  LOADED_PROPERTY_FILES_CWOBJ0913=CWOBJ0913I: Server property files have been loaded: {0}.
- CWOBJ0915I
  ORB_VERSION_USED_CWOBJ0915=CWOBJ0915I: ORB version used is {0}.

- CWOBJ0917I
  ORB_LISTENING_CWOBJ0917=CWOBJ0917I: {0} ORB is listening on host and port {1}:{2}.
- CWOBJ0918W
  NON_OBJECTGRID_CONFIG_OBJECT_CWOBJ0918=CWOBJ0918W: The list that was supplied to override client-side ObjectGrid settings for domain/cluster {0} contains an element that is not an ObjectGridConfiguration object. This element will be removed from the List: {1}
- CWOBJ0919W
  SERVER_PROPERTY_NOT_FOUND_CWOBJ0919=CWOBJ0919W: The server property file {0} cannot be found. All server properties are set to the default values.
- CWOBJ0920I

CWOBJ0001E

ILLEGAL_STATE_EXCEPTION_CWOBJ0001=CWOBJ0001E: Method, {0}, was called after initialization completed.

Explanation

After initialization completes, certain method invocations are no longer accepted.

User response

Configuration methods must be called before initialization. Restructure the code so the configuration is completed before the runtime object is initialized. For example, on ObjectGrid, methods such as defineMap, setTransactionCallback, or setSecurityEnabled must be called before an ObjectGrid is used.

CWOBJ0047I

DEVELOPMENT_MODE_ENABLED_CWOBJ0047=CWOBJ0047I: Development mode is enabled for one or more MapSets for ObjectGrids: {0}. For a production deployment, set the development mode attribute in the deployment policy file to false.

Explanation

Development mode allows primary and replica shards for the same partition to be placed on the same machine. When using one or two machines to develop code, this behavior is acceptable. However, when running in production, allowing placement of a primary and its replicas on the same machine risks data loss in case of whole machine failure.

User response

If you are in production phase or test phase consider changing development mode to false. The default is true. Otherwise, no action is required. See the Deployment policy descriptor XML file article in the information center for more information about the developmentMode setting.

CWOBJ0055W

ORB_CHANNELFRAMEWORK_CWOBJ0055=CWOBJ0055W: The IBM ORB TransportMode property was set to ChannelFramework in the server properties file, but the existing orb.properties file already had a TransportMode set. The TransportMode will not be overridden.

Explanation

The TransportMode set in the server properties file will not override a TransportMode set in the orb.properties file.

User response

Review the TransportMode set in the orb.properties file. If it is set to Pluggable or SSL or Transport Security settings are used, the ChannelFramework Transport mode will not be used. To remove the warning, adjust the setting in one of the files.

CWOBJ0061W

TRANSACTION_ROLLED_BACK_CWOBJ0061W=CWOBJ0061W: The transaction with TxID, {0}, that was last running on thread, {1}, on shard {2} has exceeded the configured transaction timeout value and was been marked rollback-only. This might be caused by lock contention or application deadlock, or your transaction timeout value is set too small.

Explanation

WebSphere eXtreme Scale automatically marks a transaction rollback-only, when it has exceeded its configured transaction timeout value. This might be caused by lock contention or application deadlock, or your transaction timeout value is set too small.

User response

Examine the application logic to determine whether a lock contention can be avoided. If a deadlock situation exists, remove that logic. If the transaction timeout value is too small and your application expects a long transaction, increase the transaction timeout value appropriately.

Configuring Object Request Brokers

CWOBJ0063I

ORB_DEFAULT_PROPERTY_SET_CWOBJ0063=CWOBJ0063I: The {0} property was not configured. The {0} property is being set to {1}.

Explanation

The listed property was not set in an orb.properties file. For some properties, if a value is not set for a timeout, it is set by the ORB to infinite and requests will not time out. The server sets a default value to allow requests to time out in the event of a problem. Other default settings are suggested starting points.

User response

No action is required, or set a specific value. See ORB properties in the information center for more information on changing the ORB properties and values.
Related tasks:

CWOBJ0065W

HASHINDEX_ATTRIBUTE_NOT_FOUND_IN_SERIALIZER_METADATA_CWOBJ0065=CWOBJ0065W: The HashIndex, "{0}", for map "{1}" is enabled for multi-type access. The {2} attribute "{3}" was not defined in the {4} descriptor for the configured DataSerializer plug-in.

Explanation

The configured attribute was not found in the data descriptor for the configured DataSerializer plug-in, which allows multiple attribute types to be indexed with the same attribute name. For example, the attribute name is "id" and its type can be Integer or String.

User response

This message might indicate that the attribute path is defined incorrectly, or the data descriptor is missing a required attribute. Verify that the attribute path is defined correctly.

CWOBJ0066W

TRANSACTION_ROLLED_BACK_STATE_CWOBJ0066W=CWOBJ0066W: The {0} transaction has been marked rollback-only due to a state change of ObjectGrid {1} on shard {2} that forced transaction completion. This could be caused by an administrator changing the availability state of the ObjectGrid instance or termination of the ObjectGrid instance.

Explanation

eXtreme Scale automatically marks a transaction rollback-only when it does not end normally during some instances. When an administrator needs to quiesce activity to bring the data grid into the offline or preload state, if the transaction does not end normally in the allowed time, the transaction is marked rollback-only.

User response

The administrator should wait for a period of inactivity to change the state of the data grid. Alternatively, you can manually end or put client applications and their transactions into an inactive state before you change the state of the data grid.

CWOBJ1124W

DIFFERENT_CATALOG_SERVER_TIMESTAMPS_CWOBJ1124W=CWOBJ1124W: The container server database timestamps are normalized with different catalog servers {0} and {1}. Make sure the clocks of these two servers are synchronized.

Explanation

The container server database timestamps are normalized with different catalog servers. This normally happens when a catalog server fails over when container servers are started.

User response

Synchronize the time clocks between all the catalog servers. If the clocks are far apart, an out of date primary shard might be chosen.
Related tasks:
Configuring
Administering

CWOBJ1125W

CONTAINER_NOT_REGISTERED_CWOBJ1125W=CWOBJ1125W: The server was unable to register container, {0}, with the catalog server due to an exception. {1}

Explanation

The server timed out or received an error from the primary catalog service while starting containers to initiate shard placement. This is usually due to network problems or heavy workload on the catalog server.

User response

Restart the server.
Related tasks:

Configuring
Administering
Controlling the lifecycle of an ObjectGrid with the ObjectGridManager interface

CWOBJ1129W

SHARDS_LEFT_ON_TERMINATE_CWOBJ1129=CWOBJ1129W: Some of the shards were not removed before the container terminate completed on {0} container. Shards left: {1}

Explanation

A call to terminate the container attempted to destroy all of the shards on the container, but shards still remained on the container. A shard destroy could have failed or a new shard could have been placed during the terminate. Any shards placed on the terminating container will be failed over to other containers.

User response

Verify the placement using the administrative tools, for example review placementStatus data.

Analyzing log and trace data

CWOBJ1506E

POSSIBLE_NETWORK_PARTITION_CWOBJ1506=CWOBJ1506E: More than one primary replication group member exists in this group ({1}). Only one primary can be active. ({0}).

Explanation

There may have been a temporary network partition or brown out condition and now there is more than one primary active.

User response

No additional placement or routing updates will be done. Restart the servers that were network partitioned.
Related tasks:
Configuring
Administering

CWOBJ1508E

CANNOT_SEND_MESSAGE_CWOBJ1508=CWOBJ1508E: An exception occurred when attempting to send message ({0}) from sender ({1}) to receiver ({2}): {3}.

Explanation

A problem occurred while attempting to send a message between replication group members.

User response

Review the error message listed. If there is a configuration problem, correct it and restart the replica server. Otherwise, verify the correct placement of primaries and replicas using the logs. See the Logs and Trace section in the information center for JVM log location, or the ManagementGateway Interface.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1509E

CANNOT_SERIALIZE_MESSAGE_CWOBJ1509=CWOBJ1509E: An exception occurred when attempting to serialize message ({0}): {1}.

Explanation

An exception occurred while serialing an internal message.

User response

Review the error message listed. If there is a configuration problem, correct it and restart the replica server.
Related tasks:
Configuring
Administering

CWOBJ1510E

CANNOT_DESERIALIZE_MESSAGE_CWOBJ1510=CWOBJ1510E: An exception occurred when attempting to inflate message ({0}): {1}.

Explanation

An exception occurred while inflating an internal message.

User response

Review the error message listed. If there is a configuration problem, correct it and restart the replica server.
Related tasks:
Configuring
Administering
Controlling the lifecycle of an ObjectGrid with the ObjectGridManager interface

CWOBJ1511I

OPEN_FOR_BUSINESS_CWOBJ1511=CWOBJ1511I: {0} ({1}) is open for business.

Explanation

Specified replication group member is now ready to accept requests.

User response

No action is required.
Related tasks:
Configuring
Administering
Controlling the lifecycle of an ObjectGrid with the ObjectGridManager interface

CWOBJ1513E

SYNCH_REPLICATION_FAILED_CWOBJ1513=CWOBJ1513E: Synchronous replication failed on {0} ({1}). This member is no longer active.

Explanation

A problem was encountered that prevented synchronous replication from successfully completing.

User response

Review previous messages in the log. See the Logs and Trace section in the information center for JVM log location to help diagnose the problem. Restart the specified server to replace the removed replica.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1514I

PRIMARY_DOWNGRADED_CWOBJ1514=CWOBJ1514I: Primary ({0}) is being downgraded to either a replica or standby.

Explanation

This is not a normal operation, but ObjectGrid processing can continue.

User response

Verify the correct placement of primaries and replicas using the logs. See the Logs and Trace section in the information center for JVM log location, or the ManagementGateway Interface.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1515I

MIN_CONFIG_NOT_MET_CWOBJ1515=CWOBJ1515I: Minimum configuration requirements not satisfied for replication group ({0}).

Explanation

The necessary primary and replica configuration requirements were not met with the recent replication group member change.

User response

Wait for additional resources to be started and recognized for this configuration.
Related concepts:
Shard life cycles
Related tasks:
Configuring
Administering
Configuring zones for replica placement

CWOBJ1516E

CANNOT_ACTIVATE_OBJECTGRID_CWOBJ1516=CWOBJ1516E: An exception occurred when attempting to activate the replication process for ObjectGrid ({0}): {1}.

Explanation

While attempting to start a primay replication group member, an exception occurred during the activation processing.

User response

The primary will continue to run. Verify the correct placement of primaries and replicas using the logs. See the Logs and Trace section in the information center for JVM log location, or the ManagementGateway Interface. Restart the server if the primary continues to have errors.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1518E

CANNOT_COMMIT_REPLICA_CHANGES_CWOBJ1518=CWOBJ1518E: An exception occurred when attempting to commit replica transaction ({0}) for primary transaction ({1}) on Replica ({2}): {3}.

Explanation

There was an exception while committing data on the replica.

User response

If the exception indicates that there is a configuration problem on the replica, correct the problem and restart the replica server. Otherwise, the replica will rollback the failed transaction.
Related concepts:
Shard life cycles
Related tasks:
Configuring
Administering
Configuring zones for replica placement

CWOBJ1519E

CANNOT_ROLLBACK_REPLICA_CHANGES_CWOBJ1519=CWOBJ1519E: An exception occurred when attempting to rollback the LogSequences for replica ({0}): {1}

Explanation

After a transaction failed to commit on a replica, the rollback also failed on the replica.

User response

If the exception indicates that there is a configuration problem on the replica, correct the problem and restart the replica server.
Related concepts:
Shard life cycles
Related tasks:
Configuring
Administering
Configuring zones for replica placement

CWOBJ1524I

LISTENER_REREGISTER_CWOBJ1524=CWOBJ1524I: Replica listener {0} must re-register with the primary. Reason: {1}

Explanation

The replica will deregister and reregister the primary. It will get a new snapshot of the data and then continue processing new transactions. This happens when an error occurs on the replica.

User response

If the replica enters peer mode successfully, no immediate action is neccessary (CWOBJ1526I). To look for the cause, check on the reason for the reregister. If there is an error inflating the key, verify that the server for the replica has the correct classpath and the correct code to deserialize the object. Also, verify that the hashcode() and equals() methods are correct for the key or keys being used if a custom key is used. Otherwise, contact IBM Software Support.
Related concepts:
Shard life cycles

Related tasks:

CWOBJ1525I

CHECKPRELOADSTATE_EXCEPTION_CWOBJ1525=CWOBJ1525I: A ReplicaPreloadController ({0}) for map {1} threw an unexpected exception in method checkPreloadState {2}

Explanation

When promoting from replica to primary an exception occurred when the ReplicaPreloadController was called to determine the state of the replica. The exception is ignored and preload is performed on the map.

User response

Examine the stack trace to determine the cause of the problem. Fix the problem in your implementation or contact IBM Software Support if the problem does not appear to be in your implementation.
Related concepts:
Shard life cycles
Related tasks:

Administering
Configuring zones for replica placement

CWOBJ1526I

ENTERING_PEER_MODE_CWOBJ1526=CWOBJ1526I: Replica {0} entering peer mode after {1} seconds, replicating from primary on {2}

Explanation

This is an informational message on how long it took for a replica to enter peer mode where both primary and replica have the same data.

User response

No action is required.
Related concepts:
Shard life cycles
Related tasks:
Configuring
Administering
Configuring zones for replica placement

CWOBJ1527W

FAILED_ENTERING_PEER_MODE_CWOBJ1527=CWOBJ1527W: Replica {0} failed to enter peer mode after {1} seconds

Explanation

The replica failed to enter peer mode. Look for additional messages that point to the specific cause of the failure. Possible reasons may include a timeout or data failing to copy from the primary.

User response

Review the action recommended by the specific message for timeout, bad data copy or other reason.
Related concepts:
Shard life cycles
Related tasks:
Configuring
Administering
Configuring zones for replica placement

CWOBJ1531I

CLOSED_FOR_BUSINESS_CWOBJ1531=CWOBJ1531I: {0} ({1}) stopped on this server.

Explanation

Specified shard stopped running on this server and moved to another server if another is available.

User response

No action is required.
Related tasks:
Configuring
Administering
Controlling the lifecycle of an ObjectGrid with the ObjectGridManager interface

CWOBJ1532I

SHARD_TRANSITION_CWOBJ1532=CWOBJ1532I: {0} (moving from server {1} ({2}), promoting {3} to {4}) in transition.

Explanation

Specified shard is in a transitional state. The message indicates the state of the shard, the state the shard will become after transition completes and where the shard was running before it failed over to the current server. For a moving primary, if there is an existing replica, it will be promoted. If there is no replica, a new replica will be placed and promoted. If there are no replicas to promote and no primary to take over from, a new primary will be started. This is indicated by promoting an inactive shard.

User response

No action is required.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1533E

REPLICA_IN_PEER_MODE_CWOBJ1533=CWOBJ1533E: {0}:{1} is already in peer mode.

Explanation

Specified replica is in peer mode and attempted to enter peer mode again.

User response

Review the logs. See the Logs and Trace section in the information center for JVM log location for any additional error messages. Verify that the replica does not have additional messages after the CWOBJ1533E message. Placement can also be verified using wsadmin or xsAdmin and the PlacementServiceMBean.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1535E

REPLICA_FAIL_ON_PEER_MODE_BAD_TRAN_CWOBJ1535=CWOBJ1535E: {0}:{1} Replica map failed to enter peer mode. A transaction threw an error while copying data from the primary. Error received: {2}

Explanation

There was an error on the replica while it copied existing data from the primary.

User response

Review the error message received. Also review any other log messages for related errors from the application. If there is an error inflating the key, verify that the server for the replica has the correct classpath. Also, verify that the hashcode() and equals() methods are correct for the key or keys being used if a custom key is used. Restart the servers or use the triggerPlacement method on the PlacementServiceMBean Mbean to replace the replica. See the Life cycle, recovery, and failure events section in the information center for more information on the triggerPlacement method.
Related concepts:
Shard life cycles

CWOBJ1536E

REPLICA_FAIL_ON_PEER_MODE_ORDERING_CWOBJ1536=CWOBJ1536E: {0}:{1} Replica map failed to enter peer mode. Received incorrect ordering data from the primary, data copy cannot complete.

Explanation

The data that the replica received from the primary was in the incorrect order.

User response

Use the triggerPlacement method on the PlacementServiceMBean Mbean to place the failed replica again. See the Life cycle, recovery, and failure events section in the information center for more information on the triggerPlacement method.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1537E

REPLICA_FAIL_TO_REREGISTER_CWOBJ1537=CWOBJ1537E: {0} exceeded the maximum number of times to reregister ({1}) without successful transactions.

Explanation

The replica attempted to reregister several times in a row due to errors, but failed to successfully commit any data before the next reregister. The replica will stop attempting to reregister.

User response

Look why the replica had to reregister by finding CWOBJ1524I messages in the logs. See the Logs and Trace section in the information center for JVM log location. Check for configuration or application errors that would prevent the replica from working correctly, such as classpath issues, errors deserializing the data, and so on. Restart the servers or use the triggerPlacement method on the PlacementServiceMBean Mbean to replace the replica. See the Life cycle, recovery, and failure events section in the information center for more information on the triggerPlacement method.
Related tasks:

CWOBJ1538E

PRIMARY_REJECT_SAME_REPLICA_CWOBJ1538=CWOBJ1538E: {0} received a {1} replica with the same container name as the local container. The replica will not be placed. Container: {2}.

Explanation

The primary shard received a new replica, but the new replica is located on the same container as the primary which is an illegal placement. The replica will be rejected.

User response

Use XSAdmin to review where the primary and replica should have been placed. Otherwise, contact IBM Software Support.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1539W

CLIENT_REPLICA_SERIALIZATION_ERROR_CWOBJ1539=CWOBJ1539W: Unable to serialize client listener data to send to replica, the client listener may not failover: {0}

Explanation

The client replica is serialized and sent over to server replicas to be saved in the event of failover. If there is an error during serialization, the server replicas will not be able to failover the client replica.

User response

Review the error and correct any classpath issues or custom application errors. Otherwise, contact IBM Software Support.
Related concepts:
Class loader and classpath considerations
Related tasks:
Configuring
Administering

CWOBJ1540E

CREATING_CLIENT_REPLICA_TIMED_OUT_CWOBJ1540=CWOBJ1540E: Creating a client replica map times out after {0} ms.

Explanation

The replica did not enter peer mode before the timeout was met. It was not able to copy the primary's existing data and then start to receive data in realtime.

User response

Review the client log for errors copying data.
Related concepts:
Shard life cycles
Related tasks:

Configuring zones for replica placement

CWOBJ1541E

REPLICA_FAIL_ON_PRIOR_MAP_CWOBJ1541=CWOBJ1541E: {0}:{1} Replica map failed to enter peer mode because a previous map failed to enter peer mode. The entire replica cannot continue to enter peer mode. The prior exception was {2}.

Explanation

There was an error on a previous map entering peer mode. The replica cannot finish entering peer mode with some failed maps. Any other maps will fail as well and the replica will not be successfully placed at this time.

User response

Review the previous errors in the log for the failed map. See the Logs and Trace section in the information center for JVM log location. Correct any configuration or network problems. Restart the servers or use the triggerPlacement method on the PlacementServiceMBean Mbean to replace the replica. See the Life cycle, recovery, and failure events section in the information center for more information on the triggerPlacement method.

CWOBJ1542I

FOREIGN_PRIMARY_REPLICATING_CWOBJ1542=CWOBJ1542I: Primary {0} started or continued replicating from {3} primary ({1}). Replicating for maps: {2}

Explanation

A primary shard started or restarted replicating to another primary.

User response

No action is required.
Related tasks:
Configuring
Administering
Enabling logging

CWOBJ1543I

REPLICA_REPLICATING_CWOBJ1543=CWOBJ1543I: The {0} {1} started or continued replicating from the primary on {3}. Replicating for maps: {2}

Explanation

A replica shard started or restarted replicating.

User response

No action is required.
Related concepts:
Shard life cycles
Related tasks:
Configuring
Administering
Configuring zones for replica placement

CWOBJ1544I

FOREIGN_PRIMARY_REPLICATING_CWOBJ1544=CWOBJ1544I: Primary {0} stopped replicating from {2} primary ({1}).

Explanation

A primary shard stopped replicating from another primary.

User response

No action is required.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1545W

REPLICA_NOT_PLACED_CWOBJ1545=CWOBJ1545W: Primary {0} could not place a ({1}) on {2}. The remote container did not respond or returned an error.

Explanation

The primary shard attempted to add a replica on a remote container. Either the remote container was not running or the remote container returned an error creating a replica shard.

User response

Verify that the remote container listed in the message is running. If the container stopped or failed while the primary attempted to place a replica on it, another placement event should occur. If the replica shard is not automatically replaced, placement of the shard can be intiated by using the triggerPlacement method on the PlacementServiceMBean Mbean. If there was an error on the remote container, the JVM logs should container the message key CWOBJ1209E.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1546W

FOREIGN_PRIMARY_NOT_ADDED_CWOBJ1546=CWOBJ1546W: Primary {0} could not initiate replication to a {2} primary on {1}. The remote container did not respond or returned an error.

Explanation

The primary shard attempted to start replication with a another primary. Either the remote container was not running or the remote container returned an error instead of a reference to the other primary shard.

User response

Verify that the remote container listed in the message is running. If the container stopped or failed while the primary attempted to contact it, another placement event should occur. If there was an error on the remote container, the JVM logs should container the message key CWOBJ1209E.
Related tasks:

CWOBJ1548W

ENTERING_PEER_MODE_CWOBJ1548=CWOBJ1548W: Replica shard {0} did not enter peer mode, and the replication from the primary shard in the {1} container failed.

Explanation

This is an informational message on how long it took for a replica to enter peer mode where both primary and replica have the same data.

User response

No action is required.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1549I

COPY_FROM_REPLICA_CWOBJ1549=CWOBJ1549I: The transitioning primary shard ({0}) did not finish copying data from the previous primary shard on the {1} primary container. The transitioning primary shard will replicate from the existing {2} shard on the {3} replica container.

Explanation

A new primary shard attempted to replicate data from the previous primary shard, but did not finish. To recover, the new primary shard will copy data from an existing replica shard.

User response

No action is required.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1550W

ERROR_REPLICATING_FROM_PRIMARY_CWOBJ1550=CWOBJ1550W: The {1} ({0}) shard received exceptions while replicating from the primary shard on the {2} primary container. The {1} shard will continue to poll the primary shard. Exception received: {3}

Explanation

The replica or foreign primary shard received exceptions from the primary shard. Replication will continue until the shard is successful or stopped.

User response

Check the JVM logs of the shard for a later message, which indicates that the replica recovered. Alternatively, use xsadmin to review the map sizes or revisions to verify that the shard recovered and matches the primary shard. If the errors continue, review the exception printed to the JVM log or in the FFDC logs.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1551I

RECOVERED_REPLICATING_FROM_PRIMARY_CWOBJ1551=CWOBJ1551I: The {1} ({0}) shard successfully recovered and replicated after several exceptions from the primary shard on the {2} primary container.

Explanation

The replica or foreign primary shard was able to start replicating successfully from the primary shard again after a period of several exceptions from the primary shard.

User response

Review the exception previously printed in the JVM or FFDC log. Otherwise, no action is required.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1552W

REPLICA_NOT_REPLICATING_CWOBJ1552=CWOBJ1552W: The {0} {1} could not start replicating from the primary on {3}. Could not replicate for maps, {2}, because {4}.

Explanation

A replica shard was not able to start replication for the listed maps.

User response

Review the JVM logs for additional shard replication or shard stopping messages. If the shard is not stopping, also review the FFDC logs for additional exceptions.
Related tasks:
Configuring
Administering

CWOBJ1555E

REPLICA_INITIALIZATION_FAIL_CWOBJ1555=CWOBJ1555E: The {0} ({1}) shard failed to initialize. The shard was added by a primary shard on the {2} primary container. The initialization exception is {3}

Explanation

A replica shard was placed on the container server, but there was an error initializing the shard and the shard cannot be started succesfully.

User response

The failed replica will be stopped and primary shard for the partition will notify the catalog server that the replica could not be placed. The replica will be placed again if shards are rebalanced, such as a container stopping or starting, or when the triggerPlacement command is used on the administrative tools.
Related tasks:

CWOBJ1556I

REPLICA_ORPHANED_CWOBJ1556=CWOBJ1556I: The {0} ({1}) shard is orphaned and does not have a valid primary shard. The last primary shard for this {0} shard is on {2} primary container. This shard will be stopped.

Explanation

A replica shard removal was missed. The removal was likely missed when the primary shard for this shard was terminated before completing the removal work. The replica shard completes its own cleanup when it no longer has a valid primary shard.

User response

No action is required.
Related tasks:
Configuring
Administering
Enabling logging
Analyzing log and trace data

CWOBJ1557W

REPLICA_RECEIVED_OLD_PRIMARY_TRAN_CWOBJ1557=CWOBJ1557W: The {0} ({1}) shard received a transaction from a primary shard on the {2} primary container. The current primary shard is on the {3} primary container. The primary on the {2} primary container is an old primary and should be stopped.

Explanation

The shard received a transaction from a primary shard that is not the current primary shard. A re-register action may take place if an exception occurs on the replica. The old primary shard is delayed stopping or the new primary was unable to contact it to stop it.

User response

Verify the old primary on the listed container is stopped. If the replica shard performs a re-register, verify that the maps for the shard entered peer mode successfully.

CWOBJ1617E

NO_JNDI_NAME_SUPPLIED_BIND_CWOBJ1617=CWOBJ1617E: No JNDI name was supplied while doing a bind. The bind will not complete.

Explanation

A JNDI name is need for binding objects. The eXtreme Scale name service uses the following default naming convention: "objectgrid/second name"

User response

Supply a JNDI name for the bind and try the operation again.
Related tasks:
Configuring
Administering

CWOBJ1619E

NO_JNDI_NAME_SUPPLIED_RESOLVE_CWOBJ1619=CWOBJ1619E: No name was supplied while doing a JNDI resolve.

Explanation

A name is need for resolving objects. The eXtreme Scale name service uses the following default naming convention: "objectgrid/second name"

User response

Supply a name for the resolve and try the operation again.
Related tasks:
Configuring
Administering

CWOBJ1620I

REPLACE_SERVER_CWOBJ1620=CWOBJ1620I: Replacing target for wrongly routed request due to changes in the server. The new target is {0}.

Explanation

Old routing target replaced with new target.

User response

If the intended replication group is out of service, restart the servers in the replication group.
Related tasks:
Configuring
Administering

CWOBJ1621E

UNABLE_TO_RESOVLE_JNDI_CWOBJ1621=CWOBJ1621E: Unable to resolve JNDI name {0}.

Explanation

The eXtreme Scale name service uses the following default naming convention: "objectgrid/second name". The supplied name was not found in the name space.

User response

Correct any spelling errors and try the operation again.
Related tasks:
Configuring
Administering

CWOBJ1630I

DOMINO_MODE_CWOBJ1630=CWOBJ1630I: Replication group cannot serve this request {0}.

Explanation

Routing is refused due to the unavailable service such as the Domino effect

User response

No action is required.
Related tasks:
Configuring
Administering

CWOBJ1632E

NULL_ID_CWOBJ1632=CWOBJ1632E: Original request does not have a valid ID; no way to forward this request.

Explanation

No way to forward this request because the original request does not have a valid ID.

User response

Contact IBM Software Support.
Related tasks:
Configuring
Administering

CWOBJ3105E

WB_LOADER_LOADER_NOT_AVAILABLE_CWOBJ3105E=CWOBJ3105E: The write-behind loader for ObjectGrid {0}, map {1} on partition {2} received an {3} error.

Explanation

The write-behind loader catches a LoaderNotAvailableException. The write-behind loader will try to update the loader again at the next interval.

User response

Examine the exception to find the root problem and correct it. Most likely, the network is down, database is down, or the database ran out of resources.
Related tasks:
Configuring
Administering

CWOBJ3106W

WB_LOADER_LONG_TRAN_CWOBJ3106W=CWOBJ3106W: The write-behind loader for ObjectGrid {0}, map {1} on partition {2} {3} a {4} ms long transaction when removing the data from the queue map and batch updating to the loader. Within this eXtreme Scale transaction, the loader batch update takes {5} ms. The possible causes are: 1) The data store backend cannot keep up. Considering tuning database and using connection pool. 2) The write-behind parameter update count is too big or update time is too long. Consider decreasing the write-behind parameter value.

Explanation

The write-behind loader transaction takes a long time to complete. This normally indicates some tuning is needed. The possible causes are: 1) The data store backend cannot keep up. Considering tuning database and using connection pool. 2) The write-behind parameter update count is too big or update time is too long. Consider decreasing the write-behind parameter value.

User response

Tune database and use connection pool. And consider decreasing the write-behind parameter value.

Administering

CWOBJ6408W

SHARD_SCOPE_THREADLOCAL_WARNING_CWOBJ6408=CWOBJ6408W: In the Spring framework, the thread local {0} value for the custom shard scope is not null. It is {1}.

Explanation

In the Spring framework, always clear the thread local {0} value for the custom shard scope in a finally block.

User response

Add the code to clear the thread local value in a finally block.
Related tasks:
Configuring
Administering

CWOBJ6409W

SERVICE_DESTROY_FAILED_CWOBJ6409=CWOBJ6409W: When a new OSGi service is used, the destroy() call on the old service instance {0} throws an exception with the following message: {1}

Explanation

The destroy() call on the old OSGi service fails with an exception. WebSphere eXtreme Scale runtime logs this exception and continues the processing.

User response

For details about the exception stack, check the FFDC directory. Check the destroy() method implementation to see why an exception was thrown. Make sure the error condition is handled in the destroy() method because the eXtreme Scale runtime environment will not throw this exception again.
Related tasks:
Configuring

CWOBJ6410E

SERVICE_UPDATE_FAILED_CWOBJ6410=CWOBJ6410E: The update for the {0} OSGi service of the {1} ObjectGrid to service ranking {2} failed. The failure is logged and ignored. Error: {3}

Explanation

The OSGi service ranking update failed.

User response

Use OSGi administrative functions to update the OSGi service to a workable service.
Related tasks:
Configuring
Administering

CWOBJ6411W

REPOSITORY_SERVICE_RANKING_USED_CWOBJ6411=CWOBJ6411W: For the {0} ObjectGrid, the OSGi metadata repository is currently using service ranking {1} for service {2}, which is not the highest service ranking {3} for this JVM. The ObjectGrid instance uses service ranking {4} for this service.

Explanation

By default, the highest ranking service available in the JVM is used. However, the other JVMs use a lower ranking service. To be consistent, this JVM attempts to use the lower ranking service too.

User response

Determine why the other JVMs do not have the highest ranking service as this JVM does.
Related tasks:

Administering

CWOBJ6412W

MULTI_BLUEPRINT_SERVICE_FOUND_CWOBJ6412=CWOBJ6412W: The following OSGi blueprint container classes are found: {0}.

Explanation

Typically, install only one blueprint container in an OSGi container.

User response

Check the installed bundles of the OSGi container to see why multiple OSGi blueprint container classes are installed. Install one blueprint container to avoid conflicts.
Related tasks:
Configuring
Administering

CWOBJ6413W

NUMBER_SERVICES_NOT_MATCH_AFTER_UPDATE_CWOBJ6413=CWOBJ6413W: After updating the {0} OSGi service from the old service ranking {1} to the new service ranking {2}, the number of service instances is changed from {3} to {4}.

Explanation

One possible explanation is that the new service might be referencing a bean that is using a different scope.

User response

Check the plug-in service bundle to make sure the scope of the bean referenced by the service does not change between different versions.
Related tasks:
Configuring
Administering

CWOBJ6414W

SERVER_PROPERTIES_UPDATED_CWOBJ6414=CWOBJ6414W: The server property file is updated to {0} using OSGi Configuration Admin while the eXtreme Scale server is running. The update does not take effect until the server is restarted.

Explanation

Server property file update is ignored while the server is running. However, if the server is restarted, the new configured server property file will be used.

User response

Determine why the server property file was updated. Make sure that an operation error does not exist.
Related tasks:
Configuring
Administering

CWOBJ6415E

BUNDLE_RESTART_NOT_ALLOWED_CWOBJ6415=CWOBJ6415E: Restarting the eXtreme Scale (XS) bundles is not allowed.

Explanation

The Object Request Broker (ORB) does not allow for dynamic starting and stopping of its consumers which prevents XS from being restarted without also restarting the Java Virtual Machine (JVM).

User response

Exit the current JVM and restart the process with the XS bundle.

CWOBJ7100E

STATS_COLLECTOR_CWOBJ7100=CWOBJ7100E: Could not locate internal ObjectGrid information map for the following shard:{0}. Ensure that the grid and mapset is appropriately enabled for historic statistics monitoring.

Explanation

Statistic monitoring infrastructure injects a very small information map into each ObjectGrid enabled for historic stats monitoring in order to provide and track information about active shards. If the information map can not be located, historic statistics monitoring will fail for that shard.

User response

Ensure that the grid and mapset is appropriately enabled for historic statistic monitoring. Review the statsSpec setting in server properties file. See the Managed MBean usage overview section in the information center for more information on using statistics.

CWPRJ1001E

INVALID_SUBSET_ATTRIBUTE_MISSING_CWPRJ1001E=CWPRJ1001E: Invalid subset attribute. Attribute does not exist on superset entity. Entity={0}, Entity Class={1}, Attribute={2}

Explanation

The specified entity attribute or association must be defined on the subset entity.

User response

Review the metadata for the entity attribute and verify that the name and type match the superset entity.
Related reference:
Deprecated properties and APIs

CWPRJ1002E

INVALID_SUBSET_ATTRIBUTE_EXTRA_CWPRJ1002E=CWPRJ1002E: Invalid subset attribute. Extra attribute defined: Entity={0}, Entity Class={1}, Attribute={2}

Explanation

The specified entity attribute or association does not exist on the superset entity.

User response

Review the metadata for the entity attribute and verify that the name and type match the superset entity and all key attributes are defined.
Related reference:
Deprecated properties and APIs

CWPRJ1003E

INVALID_SUBSET_ATTRIBUTE_TYPEMISMATCH_CWPRJ1003E=CWPRJ1003E: Invalid subset attribute. Attribute or association type mismatch: Entity={0}, Entity Class={1}, Attribute={2}

Explanation

The specified entity attribute or association exists on the supserset entity, but is of a different type or cardinality.

User response

Review the metadata for the entity attribute and verify that the name and type match the superset entity.
Related reference:
Deprecated properties and APIs

CWPRJ1004E

INVALID_ASSOCIATION_KEY_CARDINALITY_CWPRJ1004E=CWPRJ1004E: Invalid association. Associations that are also keys can only have uni-directional OneToOne or ManyToOne relationships.

Explanation

Entities cannot use multi-valued associations as keys. All keys must be attributes or uni-directional OneToOne or ManyToOne relationships.

User response

Review the metadata for the entity key associations and verify that the entity does not use OneToMany or ManyToMany associations.
Related reference:
Deprecated properties and APIs

CWPRJ1005E

ERROR_RESOLVING_ASSOCIATION_CWPRJ1005E=CWPRJ1005E: Error resolving entity association. Entity={0}, association={1}.

Explanation

The specified entity association is not valid. The metadata processor was unable to create the entity because of this error.

User response

Check the nested exception message for details on how to resolve the error and resubmit the operation.
Related reference:

Deprecated properties and APIs

CWPRJ1025E

MULTIPLE_ENTITY_ACCESSTYPE_CWPRJ1025E=CWPRJ1025E: Unable to determine entity access type. Both fields and properties are annotated.

Explanation

Annotated entities can only have annotations specified on the field or property methods, but not both.

User response

Review the entity annotations and verify that the entity metadata annotations are only specified on the fields or get method of each attribute.
Related reference:
Deprecated properties and APIs

CWPRJ1026E

MISSING_ATTRIBUTES_CWPRJ1026E=CWPRJ1026E: No attributes or associations defined.

Explanation

All entities must have at least 1 attribute or association defined.

User response

Verify that the class or entity metadata definition is valid and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1027E

MISSING_ENTITYCLASS_XML_CWPRJ1027E=CWPRJ1027E: Entity class: {0} does not exist in entity descriptor file: {1}.

Explanation

The specified entity class could not be found.

User response

Verify that the class or entity metadata definition is valid and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1029E

MULTIPLE_SCHEMAROOTS_CWPRJ1029E=CWPRJ1029E: Multiple schema root references detected for Entity class: {0}, First Root Class: {1}, Second Root Class: {2}.

Explanation

Entities may only reference one schema root entity explicitly or implictly via its composite key.

User response

Verify that only one schema root entity is reachable from the key associations of the entity class and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1030E

INVALID_COMPOSITE_INDEX_DEFINITION_CWPRJ1030E=CWPRJ1030E: Invalid composite index definition for entity: {0}. Either composite index name: {1} or attributeNames: {2} is empty or is not unique for the entity: {0}.

Explanation

The specified composite index definition is invalid. The composite index name and attributeNames cannot be empty and must be unique.

User response

Verify that the composite index definition is valid, resolve the error and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1031E

COLLECTION_ATTRIBUTE_NOT_SUPPORTED_CWPRJ1031E=CWPRJ1031E: The multi-valued association: {0} is not supported in composite HashIndex: {1} for entity: {2}.

Explanation

A HashIndex configured as a composite index cannot include multi-valued associations such as collections.

User response

Verify that the attribute names of the composite HashIndex definition only include attributes and single-valued associations; then resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1032E

EM_CLASSLESS_NOID_CWPRJ1032E=CWPRJ1032E: The Entity configuration {0} does not contain a valid id.

Explanation

The specified entity did not contain a valid id.

User response

Verify that there is at least one field marked with an id annotation or an association with id set to true.
Related reference:
Deprecated properties and APIs

CWPRJ1033E

EM_CLASSLESS_MIXED_CONFIGURATION_CWPRJ1033E=CWPRJ1033E: The Entity configuration {0} contains both a class reference and a classless identifier marked with an @ symbol.

Explanation

The Entity configuration contains both entities with class references and those with classless identifiers.

User response

Verify that the entity configuration is either completely classless or all classes are present and referenced.
Related reference:
Deprecated properties and APIs

CWPRJ1100E

INVALID_ATTRIBUTE_CWPRJ1100E=CWPRJ1100E: Invalid attribute or association: {0}.

Explanation

The specified attribute is invalid.

User response

Review the exception text, resolve the error and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1101E

MISSING_FIELD_CWPRJ1101E=CWPRJ1101E: Field is undefined for class: {0}.

Explanation

The specified field does not exist on the specified class.

User response

Verify that the entity class specified in the entity metadata definition includes the specified field or that the field name is spelled correctly and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1102E

MISSING_PROPERTY_CWPRJ1102E=CWPRJ1102E: Property is undefined for class: {0}.

Explanation

The specified property does not exist on the specified class.

User response

Verify that the entity class specified in the entity metadata definition includes the specified property get and set methods or that the property name is spelled correctly and resubmit the operation. The property methods must follow the naming conventions defined in the JavaBeans Introspector API: http://java.sun.com/j2se/1.4.2/docs/api/java/beans/Introspector.html.
Related reference:
Deprecated properties and APIs

CWPRJ1103E

MISSING_ASSOCIATION_TARGET_ENTITY_CWPRJ1103E=CWPRJ1103E: The target entity is undefined.

Explanation

The target entity type could not be determined.

User response

The target entity type of an association must be explicitly set on the association metadata if it cannot be determined by the field or property type.
Related reference:
Deprecated properties and APIs

CWPRJ1104E

DUPLICATE_FIELDPROPERTY_CWPRJ1104E=CWPRJ1104E: Attribute is defined more than once.

Explanation

An attribute or association must have a unique name and cannot be defined more than one time for a single entity.

User response

Review the XML definition for the entity and verify that there is a different name for each element: basic, one-to-one, many-to-one, one-to-many or many-to-many.
Related reference:
Deprecated properties and APIs

CWPRJ1105E

MULTIPLE_INVERSE_ASSOCIATIONS_CWPRJ1105E=CWPRJ1105E: The target association has more than one inverse relationship to this entity and is missing the MappedBy relationship definition. Source entity: {0}, Inverse entity: {1}, Duplicate attributes: {2}

Explanation

A bi-directional relationship between two entities must have one field or property defined with the mappedBy annotation parameter or XML attribute.

User response

Verify that the class or entity metadata definition is valid and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1108E

INVALID_INVERSE_ASSOCIATION_TYPE_CWPRJ1108E=CWPRJ1108E: The inverse target association references an invalid entity type. Inverse, target entity: {0}, association name: {1}

Explanation

The inverse side of a bi-directional relationship between two entities has an invalid target entity type defined.

User response

Verify that the class type for both ends of the bi-directional relationship match the respective entity class and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1109E

INVALID_ENTITY_DEFINITION_MISSING_TARGET_CWPRJ1109E=CWPRJ1109E: The target entity type of {0} is not defined.

Explanation

An entity has an association to another entity, but the target entity does not exist in the metadata repository.

User response

Verify that the entity association name and type matches a defined entity and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1110E

INVALID_INVERSE_KEY_ASSOCIATION_CWPRJ1110E=CWPRJ1110E: An association that is also a key must not have an inverse association. Inverse, target entity: {0}, association name: {1}

Explanation

An entity key may have a one-to-one or many-to-one association to another entity, but the target entity must not have an bi-directional relationship to the same entity.

User response

Remove the association from the target entity and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1111E

INVERSE_ASSOCIATION_TYPE_MISMATCH_CWPRJ1111E=CWPRJ1111E: The inverse target association must match the source target type. Inverse, target entity: {0}, association name: {1}

Explanation

The inverse side of a bi-directional relationship between two entities has a target type that does not match the source type.

User response

Verify that the class type for both ends of the bi-directional relationship match the respective entity class and resubmit the operation.
Related reference:
Deprecated properties and APIs

CWPRJ1112E

TARGET_ENTITY_NOT_DEFINED_CWPRJ1112E=CWPRJ1112E: Target entity not defined for field or property: {0}.

Explanation

The target Entity for the association is not defined.

User response

Verify that the target entity is defined.
Related reference:
Deprecated properties and APIs

CWPRJ1113E

ENTITY_ATTRIBUTE_MISSING_CARDINALITY_CWPRJ1113E=CWPRJ1113E: Attribute {0} is an entity type but a relationship to the entity is not defined.

Explanation

The attribute type must declare the relationship cardinality.

User response

Define the cardinality of the entity relationship using the OneToOne or ManyToOne annotation or in the entity descriptor file.
Related reference:
Deprecated properties and APIs

CWPRJ1114E

ENTITY_ATTRIBUTE_NOT_SERIALIZABLE_CWPRJ1114E=CWPRJ1114E: Attribute {0} of type {1} is not serializable.

Explanation

All attribute types must be serializable.

User response

Verify that the attribute implements the java.io.Serializable or java.io.Externalizable interfaces.
Related reference:
Deprecated properties and APIs

CWPRJ1115E

INVALID_MANY_ASSOCIATION_TYPE_CWPRJ1115E=CWPRJ1115E: Invalid OneToMany or ManyToMany association type of: {0}.

Explanation

All multi-valued association types must be of type: java.util.Collection, java.util.List or java.util.Set.

User response

Change the attribute type to one of the supported data types.

Deprecated properties and APIs

CWPRJ1200I

PROJECTOR_INSTRUMENTATION_ENABLED_CWPRJ1200I=CWPRJ1200I: Projector entity class instrumentation is enabled. The instrumentation mode is {0}.

Explanation

Projector entity class instrumentation is enabled. Java classes in the configured transformation domain may be transformed to support field-access entities.

User response

None.
Related reference:
Deprecated properties and APIs

CWPRJ1201E

FIELD_ACCESS_ENTITY_NOT_INSTRUMENTED_CWPRJ1201E=CWPRJ1201E: Field-access entity not instrumented. Entity class={0}.

Explanation

This error occurs when the Projector Java instrumentation agent is enabled but the field-access entity class is not included in instrumentation domain, or the field-access entity class is included in instrumentation domain, but is not in the field-access entity domain. The field-access entity domain is an optional configuration. When specified, all field-access entity classes must included in the field-access entity domain.

User response

Verify that the field-access entity class is included in instrumentation domain if no field-access entity domain is defined. If field-access entity domain is defined, ensure the entity class is included.

Deprecated properties and APIs

CWPRJ1202W

PROXY_UNAVAILABLE_CWPRJ1202W=CWPRJ1202W: Entity proxy support is unavailable.

Explanation

Proxies cannot be created for managed entities because the CGLIB library is not installed or is incompatible. The absence of proxy support may degrade performance.

User response

Review the FFDC logs for details on why the CGLIB was unable to load and verify that a supported CGLIB library version is installed in the classpath.

Related reference:
Deprecated properties and APIs

CWPRJ1300E

MULTIPLE_METHODS_PER_TYPE_CWPRJ1300E=CWPRJ1300E: Multiple methods listen to the same event {0} in class {1}.

Explanation

Only one method can listen to one particular lifecycle event in one entity or entity listener class definition.

User response

Remove extra methods.
Related reference:
Deprecated properties and APIs

CWPRJ1301E

ENTITY_CALLBACK_NO_PARAM_CWPRJ1301E=CWPRJ1301E: Entity lifecycle callback method, {0}, defined in the entity class {1} must have no parameters.

Explanation

The entity lifecycle callback method defined in an entity class should not have parameters.

User response

Redefine the entity lifecycle callback method to remove the parameters.
Related reference:
Deprecated properties and APIs

CWPRJ1302E

LISTENER_CALLBACK_ONE_PARAM_CWPRJ1302E=CWPRJ1302E: Entity lifecycle callback method, {0}, defined in the entity listener class {1} must have only one parameter.

Explanation

The lifecycle callback method defined in an entity listener class should have just one parameter.

User response

Redefine the entity lifecycle callback method in the listener class to have just one parameter.
Related reference:
Deprecated properties and APIs

CWPRJ1303E

LISTENER_UNASSIGNABLE_TYPE_CWPRJ1303E=CWPRJ1303E: The parameter of the entity callback method, {0}, is not assignable to entity {1}.

Explanation

The parameter of a lifecycle callback method defined in an entity listener should be the same type as the entity type or a super type of the entity type.

User response

Redefine the entity lifecycle callback method to make sure the parameter type is the entity type or its super type.
Related reference:
Deprecated properties and APIs

CWPRJ1304E

NO_SUCH_CALLBACK_METHOD_CWPRJ1304E=CWPRJ1304E: The method name {0} with parameter {1} does not exist in the class {2}.

Explanation

The configured callback method name does not exist in the specified entity or entity listener class.

User response

Verify that the entity lifecycle callback or listener method name specified in the entity metadata matches a valid method name in the specified class. If the method is a callback method defined the entity class, verify that the method does not define any arguments. If the class is a listener method, verify that the method includes one argument of type Object or of a specific entity class type.
Related reference:
Deprecated properties and APIs

CWPRJ1305E

UNEXPECTED_CALLBACK_EXCEPTION_CWPRJ1305E=CWPRJ1305E: Unexpected exception encounted when invoking the lifecycle callback method {0}: {1}

Explanation

A runtime exception is caught during the invocation of the lifecycle callback method.

User response

Inspect the exception and the lifecycle callback method to determine the cause of the exception.
Related reference:
Deprecated properties and APIs

CWPRJ5000I

INSTRUMENTATION_ENABLED_CWPRJ5000I=CWPRJ5000I: Java instrumentation mechanism is enabled. The instrumentation mode is {0}.

Explanation

Java instrumentation mechanism is enabled. Java classes in the configured transformation domain may be transformed to support field-access entities.

User response

None.

SESN: WebSphere eXtreme Scale messages for the WebSphere eXtreme Scale HTTP Session manager

When you encounter a message in a log or other parts of the product interface, look up the message by its message ID to find out more information.

- SESN0006E
  SessionContext.createWhenStop=SESN0006E: Attempted to create a session while the WebSphere Application Server was stopping.
- SESN0007E
  SessionContext.accessWhenStop=SESN0007E: Attempted to access a session while the WebSphere Application Server was stopping.
- SESN0008E
  SessionContext.unauthAccessError=SESN0008E: A user authenticated as {0} has attempted to access a session owned by {1}.
- SESN0012E
  SessionData.putValErr1=SESN0012E: Null key entered. The HttpSession.putValue or HttpSession.setAttribute method was called from a servlet or JSP with a null key.
- SESN0013E
  SessionData.putValErr2=SESN0013E: Null value entered for key {0}. The HttpSession.putValue method was called from a servlet or JSP with a null value.
- SESN0066E
  SessionContext.responseAlreadyCommitted=SESN0066E: The response is already committed to the client. The session cookie cannot be set.
- SESN0116W
  SessionContext.maxSessionIdLengthExceeded=SESN0116W: Session identifier {0} has exceeded the max length limit of {1}.
- SESN0117I
  SessionContextRegistry.globalSessionsEnabled=SESN0117I: Global sessions is enabled for Web modules running with the Web container-level session management configuration.
- SESN0118W
  SessionContextRegistry.globalSessionTBWWarning=SESN0118W: Time-based write is enabled with global sessions. Accessing a global session from more than one server or cluster may result in loss of session data integrity.
- SESN0119W
  SessionContextRegistry.globalSessionM2MWarning=SESN0119W: Memory-to-memory replication is enabled with global sessions. Accessing a global session from more than one server or cluster may result in loss of session data integrity.
- SESN0120I
  SessionContextRegistry.SessionNotGlobalForWebApp=SESN0120I: Web module {0} will not participate in global sessions because the Web container-level session management configuration has been overridden.
- SESN0121E
  SessionContext.CrossoverOnRetrieve=SESN0121E: Session crossover detected in Web application {0}. Session {1} was retrieved when session {2} was expected -
- SESN0122E
  SessionContext.CrossoverOnReference=SESN0122E: Session crossover detected in Web application {0}. Session {1} was referenced by method {2} when session {3} was expected -
- SESN0123E
  SessionContext.CrossoverOnReturn=SESN0123E: Session crossover detected in Web application {0}. Session {1} was returned to the client when session {2} was expected -
- SESN0124W
  SessionContext.DebugCrossoverEnabled=SESN0124W: Session crossover detection is enabled.
- SESN0169I
  SessionContext.propertyFound=SESN0169I: Session Manager found the custom property {0} with value {1}.
- SESN0170W
  SessionContext.invalidPropertyFound=SESN0170W: Session Manager found the custom property {0} with a non-numeric value {1} so it will be ignored.
- SESN0171W
  SessionContext.valueOutOfRange=SESN0171W: Session Manager found the custom property {0} with out-of-range value {1} so it will use {2}.
- SESN0172I
  SessionIdGeneratorImpl.UsingDefaultSecureRandom=SESN0172I: Using the default SecureRandom implementation for ID generation.
- SESN0175I
  SessionContextRegistry.existingContext=SESN0175I: Will use an existing session context for application key {0}
- SESN0176I
  SessionContextRegistry.newContext=SESN0176I: Will create a new session context for application key {0}
- SESN0194W
  SessionProperties.serverLevelConfigOnly=SESN0194W: Session Manager found custom property {0} with value {1}. It cannot override server level configuration with value {2}. It will be ignored.
- SESN0195I
  SessionProperties.propertyFoundButAlreadySet=SESN0195I: Session Manager found custom property {0} with value {1}. Because it is the same as the server level configuration property, it will be used.
- SESN0196W
  Store.createSessionIdAlreadyExists=SESN0196W: The Id Generator generated an id that already exists.

Related tasks:
Configuring HTTP session managers

SESN0006E

SessionContext.createWhenStop=SESN0006E: Attempted to create a session while the WebSphere Application Server was stopping.

Explanation

This error occurs when a session request is received while the Application Server is stopping.

User response

Restart the Application Server.
Related tasks:
Configuring HTTP session managers

SESN0007E

SessionContext.accessWhenStop=SESN0007E: Attempted to access a session while the WebSphere Application Server was stopping.

Explanation

This error occurs when a session request is received while the Application Server is stopping.

User response

Retart the Application Server.
Related tasks:
Configuring HTTP session managers

SESN0008E

SessionContext.unauthAccessError=SESN0008E: A user authenticated as {0} has attempted to access a session owned by {1}.

Explanation

The Session Security Integration feature has detected an attempt to access a session by an unauthorized user.

User response

No user action is required.
Related tasks:
Configuring HTTP session managers

SESN0012E

SessionData.putValErr1=SESN0012E: Null key entered. The HttpSession.putValue or HttpSession.setAttribute method was called from a servlet or JSP with a null key.

Explanation

The HttpSession.putValue or HttpSession.setAttribute method cannot be called with a null key.

User response

Fix the servlet or JSP to pass a non-null key.
Related tasks:
Configuring HTTP session managers

SESN0013E

SessionData.putValErr2=SESN0013E: Null value entered for key {0}. The HttpSession.putValue method was called from a servlet or JSP with a null value.

Explanation

The HttpSession.putValue method cannot be called with a null value.

User response

Fix the servlet or JSP to pass a non-null value.
Related tasks:
Configuring HTTP session managers

SESN0066E

SessionContext.responseAlreadyCommitted=SESN0066E: The response is already committed to the client. The session cookie cannot be set.

Explanation

The response is already committed to client so the session cookie cannot be sent to client.

User response

Correct the application to access the HTTP session before writing anything to the response.
Related tasks:
Configuring HTTP session managers

SESN0116W

SessionContext.maxSessionIdLengthExceeded=SESN0116W: Session identifier {0} has exceeded the max length limit of {1}.

Explanation

The value specified for the SessionIdentifierMaxLength property has been exceeded.

User response

Only set this property if absolutely necessary. If this property is required, set it to the largest value that your installation can tolerate. If still experiencing this problem, it is likely due to repeated failovers. Investigate and fix the root cause of the failovers.
Related tasks:
Configuring HTTP session managers

SESN0117I

SessionContextRegistry.globalSessionsEnabled=SESN0117I: Global sessions is enabled for Web modules running with the Web container-level session management configuration.

Explanation

This message is for informational purposes only.

User response

If global sessions is not desired, disable global sessions by setting the Servlet21SessionCompatibility property to false.
Related tasks:
Configuring HTTP session managers

SESN0118W

SessionContextRegistry.globalSessionTBWWarning=SESN0118W: Time-based write is enabled with global sessions. Accessing a global session from more than one server or cluster may result in loss of session data integrity.

Explanation

The time-based write feature is enabled with global sessions. Unless all Web modules that access the session are in the same server or cluster, session data integrity may be lost.

User response

Disable the time-based write if Web modules that access global sessions are split across servers or clusters.
Related tasks:
Configuring HTTP session managers

SESN0119W

SessionContextRegistry.globalSessionM2MWarning=SESN0119W: Memory-to-memory replication is enabled with global sessions. Accessing a global session from more than one server or cluster may result in loss of session data integrity.

Explanation

The memory-to-memory replication feature is enabled with global sessions. Unless all Web modules that access the session are in the same server or cluster, session data integrity may be lost.

User response

Disable memory-to-memory replication if Web Modules that access global sessions are split across servers or clusters.
Related tasks:
Configuring HTTP session managers

SESN0120I

SessionContextRegistry.SessionNotGlobalForWebApp=SESN0120I: Web module {0} will not participate in global sessions because the Web container-level session management configuration has been overridden.

Explanation

The specified Web module will not participate in global sessions because the Web container-level session management configuration has been overridden either at the enterprise application- or Web module-level.

User response

If you want the Web module to participate in global sessions, disable the session management configuration that is specified at the enterprise application- or the Web module-level and restart the server.
Related tasks:
Configuring HTTP session managers

SESN0121E

SessionContext.CrossoverOnRetrieve=SESN0121E: Session crossover detected in Web application {0}. Session {1} was retrieved when session {2} was expected -

Explanation

A call to the request.getSession method returned a session other than the requested session.

User response

If the problem persists, see problem determination information on the WebSphere Application Server Support page at http://www.ibm.com/software/webservers/appserv/was/support/.
Related tasks:
Configuring HTTP session managers

SESN0122E

SessionContext.CrossoverOnReference=SESN0122E: Session crossover detected in Web application {0}. Session {1} was referenced by method {2} when session {3} was expected -

Explanation

An application referenced a session other than the session associated with the request.

User response

If the problem persists, see problem determination information on the WebSphere Application Server Support page at http://www.ibm.com/software/webservers/appserv/was/support/.
Related tasks:
Configuring HTTP session managers

SESN0123E

SessionContext.CrossoverOnReturn=SESN0123E: Session crossover detected in Web application {0}. Session {1} was returned to the client when session {2} was expected -

Explanation

A cookie or URL was returned to the client containing a session ID that is not associated with the request.

User response

If the problem persists, see problem determination information on the WebSphere Application Server Support page at http://www.ibm.com/software/webservers/appserv/was/support/.
Related tasks:
Configuring HTTP session managers

SESN0124W

SessionContext.DebugCrossoverEnabled=SESN0124W: Session crossover detection is enabled.

Explanation

Checks for session crossover are being initiated.

User response

For better performance, you may choose to disable these checks by setting the Web container custom property DebugSessionCrossover=false.
Related tasks:
Configuring HTTP session managers

SESN0169I

SessionContext.propertyFound=SESN0169I: Session Manager found the custom property {0} with value {1}.

Explanation

Session Manager will use the specified property and value to control behavior.

User response

Verify that the specified property and value will result in the desired behavior.
Related tasks:
Configuring HTTP session managers

SESN0170W

SessionContext.invalidPropertyFound=SESN0170W: Session Manager found the custom property {0} with a non-numeric value {1} so it will be ignored.

Explanation

Session Manager expected the specified property to contain a numeric value. The property will be ignored.

User response

Correct the specified property value to make it a valid number.
Related tasks:
Configuring HTTP session managers

SESN0171W

SessionContext.valueOutOfRange=SESN0171W: Session Manager found the custom property {0} with out-of-range value {1} so it will use {2}.

Explanation

Session Manager expected the specified property to have a value within a certain range. Session Manager will use the closest valid value.

User response

Correct the specified property value to make it within the documented range.
Related tasks:
Configuring HTTP session managers

SESN0172I

SessionIdGeneratorImpl.UsingDefaultSecureRandom=SESN0172I: Using the default SecureRandom implementation for ID generation.

Explanation

Session Manager is using the java default SecureRandom implementation for session ID generation.

User response

No action is required.
Related tasks:
Configuring HTTP session managers

SESN0175I

SessionContextRegistry.existingContext=SESN0175I: Will use an existing session context for application key {0}

Explanation

An existing session context is going to be shared for this application key.

User response

No action is required.
Related tasks:
Configuring HTTP session managers

SESN0176I

SessionContextRegistry.newContext=SESN0176I: Will create a new session context for application key {0}

Explanation

A new session context will be created for this application key.

User response

No action is required.
Related tasks:
Configuring HTTP session managers

SESN0194W

SessionProperties.serverLevelConfigOnly=SESN0194W: Session Manager found custom property {0} with value {1}. It cannot override server level configuration with value {2}. It will be ignored.

Explanation

The custom property can only be set at the server level configuration. The property will be ignored.

User response

Remove the custom property from the application/module level configuration. Change the server level configuration if applicable.
Related tasks:
Configuring HTTP session managers

SESN0195I

SessionProperties.propertyFoundButAlreadySet=SESN0195I: Session Manager found custom property {0} with value {1}. Because it is the same as the server level configuration property, it will be used.

Explanation

The custom property can only be set at the server level configuration. Since it is the same as the server level configuration property, it will be used.

User response

No action is required.
Related tasks:
Configuring HTTP session managers

SESN0196W

Store.createSessionIdAlreadyExists=SESN0196W: The Id Generator generated an id that already exists.

Explanation

The Id Generator generated an id that already exists. We will create another id.

User response

No action is required.

SSLC: WebSphere eXtreme Scale messages for SSL channel security

When you encounter a message in a log or other parts of the product interface, look up the message by its message ID to find out more information.

- SSLC0001W
  invalid.security.level=SSLC0001W: {0} in an invalid security level. Default of high will be used.
- SSLC0002E
  invalid.security.properties=SSLC0002E: The SSL channel cannot be started due to the following incorrect settings: {0}
- SSLC0003E
  security.repertoire.not.found=SSLC0003E: Alias {0} does not map to a known security repertoire.
- SSLC0004W
  provider.not.fips.enabled=SSLC0004W: FIPS support has been requested, but the specified provider {0} might not support it.
- SSLC0005E
  no.pkcs.keystore=SSLC0005E: Unable to get a PKCS keystore.
- SSLC0006E
  unable.to.read.config=SSLC0006E: Error reading the SSL channel configuration, exception: {0}
- SSLC0007W
  security.ssl.config.initialization.warning.invalidkeystoretype=SSLC0007W: The keystore or truststore type specified is invalid. Automatically adjusting to use the correct type, however, please correct the SSL configuration for performance reasons.
- SSLC0008E
  handshake.failure=SSLC0008E: Unable to initialize SSL connection. Unauthorized access was denied or security settings have expired. Exception is {0}.
- SSLC0009E
  hwcrypto.not.supported=SSLC0009E: Hardware crypto is not supported.
- SSLC0010E
  empty.keystore=SSLC0010E: Keystore file exists, but is empty: {0}
- SSLC0011E
  no.keystore.and.hwcrypto=SSLC0011E: No keystore specified and no hardware crypto defined.
- SSLC0012E
  null.truststore=SSLC0012E: Invalid truststore name of null.
- SSLC0013E
  invalid.keystore.password=SSLC0013E: Invalid password for keystore {0}. Internal exception {1}.

Related concepts:
Security

SSLC0001W

invalid.security.level=SSLC0001W: {0} in an invalid security level. Default of high will be used.

Explanation

Valid values for security level are low, medium and high.

User response

Ensure that the security level is set to a valid value.
Related concepts:
Security

SSLC0002E

invalid.security.properties=SSLC0002E: The SSL channel cannot be started due to the following incorrect settings: {0}

Explanation

One or more settings for security in the SSL channel were not valid.

User response

The SSL channel security settings should be modified to the correct values.
Related concepts:
Security

SSLC0003E

security.repertoire.not.found=SSLC0003E: Alias {0} does not map to a known security repertoire.

Explanation

If a configuration alias is specified on the SSL channel, it must map to a security repertoire.

User response

The SSL channel configuration must be updated to reference a valid security repertoire.
Related concepts:
Security

SSLC0004W

provider.not.fips.enabled=SSLC0004W: FIPS support has been requested, but the specified provider {0} might not support it.

Explanation

Not enough information is available to determine if the specified provider is FIPS enabled.

User response

Verify that the specified provider has the appropriate FIPS support.
Related concepts:
Security

SSLC0005E

no.pkcs.keystore=SSLC0005E: Unable to get a PKCS keystore.

Explanation

The token information provided did not identify a valid PKCS keystore.

User response

Review and update the token information to identify a valid PKCS keystore.
Related concepts:

Security

SSLC0006E

unable.to.read.config=SSLC0006E: Error reading the SSL channel configuration, exception: {0}

Explanation

An exception was created when reading the SSL channel configuration.

User response

Problems in the SSL channel configuration should be fixed.
Related concepts:
Security

SSLC0007W

security.ssl.config.initialization.warning.invalidkeystoretype=SSLC0007W: The keystore or truststore type specified is invalid. Automatically adjusting to use the correct type, however, please correct the SSL configuration for performance reasons.

Explanation

The keystore or truststore type specified is not valid.

User response

Modify the SSL configuration so that the keystore or truststore type is a valid type. You can check the keystore and truststore types by loading them in WebSphere's IKeyMan tool.
Related concepts:
Security

SSLC0008E

handshake.failure=SSLC0008E: Unable to initialize SSL connection. Unauthorized access was denied or security settings have expired. Exception is {0}.

Explanation

A new connection failed to complete a successful secure handshake.

User response

Check security settings. The certificate might have expired. Alternatively, an unauthorized client connection might have been denied.
Related concepts:
Security

SSLC0009E

hwcrypto.not.supported=SSLC0009E: Hardware crypto is not supported.

Explanation

Support for hardware cryptography cards is not available.

User response

Change the security settings to disable the use of hardware cryptography.
Related concepts:
Security

SSLC0010E

empty.keystore=SSLC0010E: Keystore file exists, but is empty: {0}

Explanation

The keystore from the configuration was found, but had no contents.

User response

Replace the current keystore file with valid keystore.
Related concepts:
Security

SSLC0011E

no.keystore.and.hwcrypto=SSLC0011E: No keystore specified and no hardware crypto defined.

Explanation

A keystore or hardware cryptography setting is required in the security configuration, but neither exist.

User response

Update the security settings to specify a keystore or to enable hardware cryptography.
Related concepts:
Security

SSLC0012E

null.truststore=SSLC0012E: Invalid truststore name of null.

Explanation

The truststore name is not present in the security configuration.

User response

Update the security settings to specify a valid truststore file.
Related concepts:
Security

SSLC0013E

invalid.keystore.password=SSLC0013E: Invalid password for keystore {0}. Internal exception {1}.

Explanation

The password provided for the keystore is not compatible.

User response

Check the keystore password in the security settings, or specify a new keystore and password.

Security

TCPC: WebSphere eXtreme Scale messages for the TCP channel component

When you encounter a message in a log or other parts of the product interface, look up the message by its message ID to find out more information.

- TCPC0001I
  TCP_CHANNEL_STARTED=TCPC0001I: TCP Channel {0} is listening on host {1} port {2}.
- TCPC0002I
  TCP_CHANNEL_STOPPED=TCPC0002I: TCP Channel {0} has stopped listening on host {1} port {2}.
- TCPC0003E
  BIND_ERROR=TCPC0003E: TCP Channel {0} initialization failed. The socket bind failed for host {1} and port {2}. The port may already be in use.
- TCPC0004W
  MAX_CONNS_EXCEEDED=TCPC0004W: TCP Channel {0} has exceeded the maximum number of open connections {1}.
- TCPC0005W
  THREAD_DISPATCH_FAILED=TCPC0005W: TCP Channel {0} could not obtain thread from thread pool {1}.

- TCPC0006E
  LOCAL_HOST_UNRESOLVED=TCPC0006E: TCP Channel {0} initialization failed. The host {1} and port {2} could not be resolved.
- TCPC0007E
  PORT_NOT_ACCEPTING=TCPC0007E: TCP Channel {0} listening on host {1} port {2} has stopped accepting connections.
- TCPC0801E
  MAX_OPEN_CONNECTIONS_INVALID=TCPC0801E: The maximum number of open connections {0} is not valid. Valid values must be no less than {1} and no greater than {2}.
- TCPC0802E
  INACTIVITY_TIMEOUT_INVALID=TCPC0802E: The inactivity time out of {0} is not valid. Valid values must be no less than {1} and no greater than {2}.
- TCPC0803E
  ADDRESS_EXCLUDE_LIST_INVALID=TCPC0803E: An entry in the address exclude list for the TCP Channel {0} was not valid. Valid values consist of a valid String.
- TCPC0804E
  ADDRESS_INCLUDE_LIST_INVALID=TCPC0804E: An entry in the address include list for the TCP Channel {0} was not valid. Valid values consist of a valid String.
- TCPC0805E
  HOST_NAME_EXCLUDE_LIST_INVALID=TCPC0805E: An entry in the host name exclude list for the TCP Channel {0} was not valid. Valid values consist of a valid String.
- TCPC0806E
  HOST_NAME_INCLUDE_LIST_INVALID=TCPC0806E: An entry in the host name include list for the TCP Channel {0} was not valid. Valid values consist of a valid String.
- TCPC0807E
  NOT_VALID_CUSTOM_PROPERTY=TCPC0807E: TCPChannel {0} custom property {1} has an value of {2}. This value is not valid.
- TCPC0808E
  CONFIG_VALUE_NUMBER_EXCEPTION=TCPC0808E: TCP Channel {0} has been configured with an incorrect number value for a property, Property Name: {1} Value: {2}
- TCPC0809E
  CONFIG_VALUE_NOT_VALID_STRING=TCPC0809E: TCP Channel {0} has been constructed with incorrect configuration property value, Name: {1} Value: {2}
- TCPC0810E
  CONFIG_VALUE_NOT_VALID_NULL_STRING=TCPC0810E: TCP Channel {0} has been constructed with a null configuration property value, Name: {1}
- TCPC0811E
  CONFIG_VALUE_NOT_VALID_BOOLEAN2=TCPC0811E: TCP Channel {0} has been constructed with incorrect configuration property value, Name: {1} Value: {2} Valid Range: 0 - False, 1 - True
- TCPC0812E
  CONFIG_VALUE_NOT_VALID_INT=TCPC0812E: TCP Channel {0} has been constructed with incorrect configuration property value, Name: {1} Value: {2} Valid Range: Minimum {3}, Maximum {4}
- TCPC0813W
  CONFIG_KEY_NOT_VALID=TCPC0813W: TCP Channel {0} has been constructed with incorrect configuration property, Property Name: {1} Value: {2}
- TCPC0814W
  UNRECOGNIZED_CUSTOM_PROPERTY=TCPC0814W: The TCP Channel {0} has a custom property configured which is not a recognized property, Property Name: {1}
- TCPC0815E
  NEW_CONFIG_VALUE_NOT_EQUAL=TCPC0815E: An attempt to update TCP Channel {0} failed because a property which can not be updated at runtime has been given a new value that is different from the current value. Propery Name: {1} Current Value: {2} Failed Updated Value: {3}
- TCPC0816E
  UPDATED_CONFIG_NOT_IMPLEMENTED=TCPC0816E: An attempt to update TCP Channel {0} failed.
- TCPC0817E
  NO_ENDPOINT_NAME=TCPC0817E: No Endpoint Name was assigned to TCP Channel {0}.
- TCPC0818E
  USER_ID_NOT_VALID=TCPC0818E: Configured user ID to switch to after starting was not valid. User ID: {0}
- TCPC0819E
  GROUP_ID_NOT_VALID=TCPC0819E: Configured group ID to switch to after starting was not valid. Group ID: {0}

Trace options

TCPC0001I

TCP_CHANNEL_STARTED=TCPC0001I: TCP Channel {0} is listening on host {1} port {2}.

Explanation

The specified TCP Channel has been started and is now listening for requests.

User response

Informational message only, no action required.
Related reference:
Trace options

TCPC0002I

TCP_CHANNEL_STOPPED=TCPC0002I: TCP Channel {0} has stopped listening on host {1} port {2}.

Explanation

The specified TCP Channel has been stopped and is no longer listening for requests.

User response

Information message only, no action required.
Related reference:
Trace options

TCPC0003E

BIND_ERROR=TCPC0003E: TCP Channel {0} initialization failed. The socket bind failed for host {1} and port {2}. The port may already be in use.

Explanation

The socket bind operation failed. Common cause is that the port number is already in use.

User response

Check that the TCP Channel has been configured to use the correct port number.
Related reference:
Trace options

TCPC0004W

MAX_CONNS_EXCEEDED=TCPC0004W: TCP Channel {0} has exceeded the maximum number of open connections {1}.

Explanation

The specified TCP Channel has exceeded the maximum number of open connections and is refusing some connections.

User response

If more connections are required, use either the admin application or the command line scripting tool to update the maximum number of connections allowed.
Related reference:
Trace options

TCPC0005W

THREAD_DISPATCH_FAILED=TCPC0005W: TCP Channel {0} could not obtain thread from thread pool {1}.

Explanation

The specified TCP Channel could not obtain a thread from the specified thread pool. Processing of subsequent requests may be delayed.

User response

If CPU is not fully utilized, increase the maximum number of threads in the thread pool. Otherwise, reduce the number of incoming requests.
Related reference:
Trace options

TCPC0006E

LOCAL_HOST_UNRESOLVED=TCPC0006E: TCP Channel {0} initialization failed. The host {1} and port {2} could not be resolved.

Explanation

The host name specified could not be resolved. The host name was specified incorrectly or has not been defined on this system.

User response

Check that the TCP Channel has been configured to use the correct host name.
Related reference:
Trace options

TCPC0007E

PORT_NOT_ACCEPTING=TCPC0007E: TCP Channel {0} listening on host {1} port {2} has stopped accepting connections.

Explanation

The specified TCP Channel can no longer accept connections for a port. The port appears to be disabled.

User response

To use the port, enable the port and restart the application.
Related reference:
Trace options

TCPC0801E

MAX_OPEN_CONNECTIONS_INVALID=TCPC0801E: The maximum number of open connections {0} is not valid. Valid values must be no less than {1} and no greater than {2}.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0802E

INACTIVITY_TIMEOUT_INVALID=TCPC0802E: The inactivity time out of {0} is not valid. Valid values must be no less than {1} and no greater than {2}.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0803E

ADDRESS_EXCLUDE_LIST_INVALID=TCPC0803E: An entry in the address exclude list for the TCP Channel {0} was not valid. Valid values consist of a valid String.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0804E

ADDRESS_INCLUDE_LIST_INVALID=TCPC0804E: An entry in the address include list for the TCP Channel {0} was not valid. Valid values consist of a valid String.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0805E

HOST_NAME_EXCLUDE_LIST_INVALID=TCPC0805E: An entry in the host name exclude list for the TCP Channel {0} was not valid. Valid values consist of a valid String.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0806E

HOST_NAME_INCLUDE_LIST_INVALID=TCPC0806E: An entry in the host name include list for the TCP Channel {0} was not valid. Valid values consist of a valid String.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0807E

NOT_VALID_CUSTOM_PROPERTY=TCPC0807E: TCPChannel {0} custom property {1} has an value of {2}. This value is not valid.

Explanation

A custom property was specified with a value that is outside the range of valid values.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0808E

CONFIG_VALUE_NUMBER_EXCEPTION=TCPC0808E: TCP Channel {0} has been configured with an incorrect number value for a property, Property Name: {1} Value: {2}

Explanation

A TCP Channel configuration property value is not a valid number

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0809E

CONFIG_VALUE_NOT_VALID_STRING=TCPC0809E: TCP Channel {0} has been constructed with incorrect configuration property value, Name: {1} Value: {2}

Explanation

A TCP Channel property value is not within the valid range for this property

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0810E

CONFIG_VALUE_NOT_VALID_NULL_STRING=TCPC0810E: TCP Channel {0} has been constructed with a null configuration property value, Name: {1}

Explanation

A TCP Channel property value is not within the valid range for this property

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0811E

CONFIG_VALUE_NOT_VALID_BOOLEAN2=TCPC0811E: TCP Channel {0} has been constructed with incorrect configuration property value, Name: {1} Value: {2} Valid Range: 0 - False, 1 - True

Explanation

A TCP Channel property value is not within the valid range for this property

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0812E

CONFIG_VALUE_NOT_VALID_INT=TCPC0812E: TCP Channel {0} has been constructed with incorrect configuration property value, Name: {1} Value: {2} Valid Range: Minimum {3}, Maximum {4}

Explanation

A TCP Channel property value is not within the valid range for this property

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0813W

CONFIG_KEY_NOT_VALID=TCPC0813W: TCP Channel {0} has been constructed with incorrect configuration property, Property Name: {1} Value: {2}

Explanation

A TCP Channel configuration property which is not recognized has been used.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0814W

UNRECOGNIZED_CUSTOM_PROPERTY=TCPC0814W: The TCP Channel {0} has a custom property configured which is not a recognized property, Property Name: {1}

Explanation

A custom property was specified incorrectly.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0815E

NEW_CONFIG_VALUE_NOT_EQUAL=TCPC0815E: An attempt to update TCP Channel {0} failed because a property which can not be updated at runtime has been given a new value that is different from the current value. Propery Name: {1} Current Value: {2} Failed Updated Value: {3}

Explanation

A TCP Channel property value was given a new value during an attempt to update the configuration, but this property can not be updated with a new value at runtime.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0816E

UPDATED_CONFIG_NOT_IMPLEMENTED=TCPC0816E: An attempt to update TCP Channel {0} failed.

Explanation

A TCP Channel could not be updated because the new configuration was not a valid configuration.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0817E

NO_ENDPOINT_NAME=TCPC0817E: No Endpoint Name was assigned to TCP Channel {0}.

Explanation

No additional information.

User response

Correct the configuration error.
Related reference:
Trace options

TCPC0818E

USER_ID_NOT_VALID=TCPC0818E: Configured user ID to switch to after starting was not valid. User ID: {0}

Explanation

No additional information.

User response

Change configured user id to a new value.
Related reference:
Trace options

TCPC0819E

GROUP_ID_NOT_VALID=TCPC0819E: Configured group ID to switch to after starting was not valid. Group ID: {0}

Explanation

No additional information.

User response

Change configured group id to a new value.

WSBB: WebSphere eXtreme Scale messages for the XsByteBuffer component

When you encounter a message in a log or other parts of the product interface, look up the message by its message ID to find out more information.

- WSBB0861E
  NOT_VALID_CUSTOM_PROPERTY=WSBB0861E: The custom property {0} has an value of {1}. This value is not valid.
- WSBB0862W
  UNRECOGNIZED_CUSTOM_PROPERTY=WSBB0862W: The custom property {0} specified for the XsByteBuffer Component is not valid.
- WSBB0863E
  CONFIG_VALUE_NUMBER_EXCEPTION=WSBB0863E: The XsByteBuffer Component caught a NumberFormatException processing property, Property Name: {0} Value: {1}
- WSBB0864E
  POOL_MISMATCH=WSBB0864E: The XsByteBuffer Pool Sizes and Pool Depths specification do not have the same number of entries, Sizes: {0} Depths: {1}

WSBB0861E

NOT_VALID_CUSTOM_PROPERTY=WSBB0861E: The custom property {0} has an value of {1}. This value is not valid.

Explanation

A custom property was specified with a value that is outside the range of valid values.

User response

Correct the configuration error.

WSBB0862W

UNRECOGNIZED_CUSTOM_PROPERTY=WSBB0862W: The custom property {0} specified for the XsByteBuffer Component is not valid.

Explanation

A custom property was specified incorrectly.

User response

Correct the configuration error.

WSBB0863E

CONFIG_VALUE_NUMBER_EXCEPTION=WSBB0863E: The XsByteBuffer Component caught a NumberFormatException processing property, Property Name: {0} Value: {1}

Explanation

A XsByteBuffer configuration property value is not a valid number

User response

Correct the configuration error.

WSBB0864E

POOL_MISMATCH=WSBB0864E: The XsByteBuffer Pool Sizes and Pool Depths specification do not have the same number of entries, Sizes: {0} Depths: {1}

Explanation

The Pool Sizes or Pool Depths were specified incorrectly.

User response

Correct the configuration error.

User interface settings

This reference information describes settings that you can view and configure on the pages of the WebSphere® Application Serveradministrative console and elsewhere.

To open the Table of Contents to the location of this reference information, click the Show in table of contents () button on the information center border. For example, if you found this page from the information center search or from an internet search engine, such as Google, click the button to make the information center show you the location of this page in the information center navigation tree. You will be able to browse the contents indented under this navigation entry.

- eXtreme Scale session management settings
  You can configure your WebSphere Application Server applications to use WebSphere eXtreme Scale or a WebSphere DataPower® XC10 Appliance for session persistence.
- Catalog service domain collection
  Use this page to manage catalog service domains. Catalog service domains define a group of catalog servers that manage the placement of shards and monitors the health of container servers in your data grid.
- Catalog service domain settings
  Use this page to manage the settings for a specific catalog service domain. Catalog service domains define a group of catalog servers that manage the placement of shards and monitors the health of container servers in your data grid. You can define a catalog service domain that is in the same cell as your deployment manager. You can also define remote catalog service domains if your WebSphere eXtreme Scale configuration is in a different cell or your data grid is made up of Java™ SE processes.
- Client security properties
  Use this page to configure client security for a catalog service domain. These settings apply to all the servers in your catalog service domain. These properties can be overridden by specifying a splicer.properties file with the com.ibm.websphere.xs.sessionFilterProps custom property or by splicing the application EAR file.
- Catalog service domain custom properties
  You can further edit the configuration of the catalog service domain by defining custom properties.

eXtreme Scale session management settings

You can configure your WebSphere® Application Server applications to use WebSphere eXtreme Scale or a WebSphere DataPower® XC10 Appliance for session persistence.

You can edit these settings in the enterprise application installation wizard, or on the application or server detail pages:

- Version 6.1: Applications > Install new application
- Version 6.1: Applications > Enterprise Applications > *application_name*
- Version 6.1: Servers > Application servers > *server_name* > Web container settings > Session management
- Version 7.0: Applications > New application > New Enterprise Application, and choose the Detailed path for creating the application.
- Version 7.0: Applications > Application Types > WebSphere enterprise applications > *application_name* > Web Module properties > Session management > Session management settings
- Version 7.0: Servers > Server Types > WebSphere application servers > *server_name* > Container settings > Session management settings

Enable session management

Enables session management to use WebSphere eXtreme Scale embedded or remote data grid or a WebSphere DataPower XC10 Appliance for session persistence.

Manage session persistence by

Specifies how session persistence is managed. You can choose one of the following options:

- WebSphere DataPower XC10 Appliance
- Remote eXtreme Scale data grid
- Embedded eXtreme Scale data grid

The remaining settings that you configure depend on the session persistence mechanism you choose.

WebSphere DataPower XC10 Appliance specific settings

The following settings are specific to configuring the WebSphere DataPower XC10 Appliance for session persistence.

IP or host name of the WebSphere DataPower XC10 Appliance

Specifies the IP or host name of the appliance to use for persisting sessions.

IBM® WebSphere DataPower XC10 Appliance administrative credentials

Specifies the User name and Password that you use to log in to the DataPower XC10 Appliance user interface. Click Test Connection... to test the connection to your appliance.

Session persistence preference

Specifies the data grid on which sessions are persisted. You can choose one of the following options:

- Persist sessions in a new data grid on the IBM WebSphere DataPower XC10 Appliance. You can then specify a Data grid name.
- Persist sessions in an existing data grid on the IBM WebSphere DataPower XC10 Appliance. You can then enter or browse for an Existing data grid name.

Remote eXtreme Scale data grid configuration

The following settings are specific to configuring the remote eXtreme Scale grid for session persistence.

Catalog service domain that manages the remote session data grid

Specifies the catalog service domain that you want to use to manage your sessions.

If no catalog service domains are displayed, or you want to create a new catalog service domain, click System administration > WebSphere eXtreme Scale > Catalog service domains.

Remote data grid in which to store session information

Specifies the name of the data grid in the catalog service domain in which you want to store your session information. The list of active remote grids is populated when you select a catalog service. The remote data grid must already exist in the eXtreme Scale configuration.

Embedded eXtreme Scale data grid configuration

The following settings are specific to configuring an embedded eXtreme Scale configuration. In the embedded eXtreme Scale scenario, the eXtreme Scale processes are hosted by WebSphere Application Server processes.

eXtreme Scale embedded data grid configuration

- Use default ObjectGrid configuration
- Specify custom ObjectGrid configuration files

Full path to objectgrid.xml file to copy into configuration
: Specifies the full path to the objectgrid.xml file for the configuration that you want to use.

Full path to objectgriddeployment.xml file to copy into configuration
: Specifies the full path to the objectgriddeployment.xml file for the configuration that you want to use.

Catalog service domain collection

Use this page to manage catalog service domains. Catalog service domains define a group of catalog servers that manage the placement of shards and monitors the health of container servers in your data grid.

To view this administrative console page, click System administration > WebSphere eXtreme Scale > Catalog service domains. To create a new catalog service domain, click New. To delete a catalog service domain, select the catalog service domain you want to remove and click Delete.

Test Connection

When you click the Test connection button, all of the defined catalog service domain end points are queried one by one, if any one end point is available, returns a message that indicates that the connection to the catalog service domain was successful. You can use this button to test that you have configured the connection and security information correctly.

Set Default

Defines the catalog service domain that is used as the default. Select one catalog service domain as the default and click Set default. Only one catalog service domain can be selected as the default.

Name

Specifies the name for the catalog service domain.

Default

Specifies which catalog service domain in the list is the default. The default catalog service domain is indicated with the following icon:  .

Catalog service domain settings

Use this page to manage the settings for a specific catalog service domain. Catalog service domains define a group of catalog servers that manage the placement of shards and monitors the health of container servers in your data grid. You can define a catalog service domain that is in the same cell as your deployment manager. You can also define remote catalog service domains if your WebSphere® eXtreme Scale configuration is in a different cell or your data grid is made up of Java™ SE processes.

To view this administrative console page, click System administration > WebSphere eXtreme Scale > Catalog service domains > *catalog_service_domain_name*.

Related tasks:
Configuring eXtreme Scale connection factories
Configuring catalog servers and catalog service domains

Client properties file

Test connection

When you click the Test connection button, all of the defined catalog service domain end points are queried one by one, if any one end point is available, returns a message that indicates that the connection to the catalog service domain was successful. You can use this button to test that you have configured the connection and security information correctly.

Name

Specifies the name of the catalog service domain.

Enable this catalog service domain as the default unless another catalog service domain is explicitly specified

If you select this check box, the selected catalog service domain becomes the default catalog service domain for the cell. Each server profile in the cell that is augmented with the WebSphere eXtreme Scale profile belongs to the selected catalog service domain.

For WebSphere eXtreme Scale, all eXtreme Scale containers that are embedded in Java EE application modules connect to the default domain. Clients can connect to the default domain using the ServerFactory.getServerProperties().getCatalogServiceBootstrap() API to retrieve the catalog service endpoints to use when calling the ObjectGridManager.connect() API.

If you change the default domain to point to a different set of catalog servers, then all containers and clients refer to the new domain after they are restarted.

Catalog servers

Specifies a list of catalog servers that belong to this catalog service domain.

Click New to add a catalog server to the list. This catalog server must already exist in the eXtreme Scale configuration. You can also edit or delete a server from the list by selecting the endpoint and then clicking Edit or Delete. Define the following properties for each catalog server endpoint:

Catalog server endpoint
: Specifies the name of the existing application server or remote server on which the catalog service is running. A catalog service domain cannot contain a mix of existing application servers and remote server endpoints.

  - Existing application server: Specifies the path of an application server, node agent, or deployment manager in the cell. A catalog service starts automatically in the selected server. Select from the list of the existing application servers. All of the application servers that you define within the catalog service domain must be in the same core group.
  - Remote server: Specifies the host name of the remote catalog server.
    For WebSphere eXtreme Scale remote endpoints: Specifies the host name of the remote catalog server process. You must start the remote servers with the **startOgServer** script or the embedded server API.

Client Port
: Specifies the port that is used for communication between the catalog servers in the catalog service domain. This value is required for catalog servers that are running in WebSphere Application Server processes. You can set the value to any port that is not being used by another process.

Listener Port
: Specifies the port that is used for communication with clients. This value is required for remote endpoints and must match the value used when the catalog service was started. The listener port is used by clients and containers to communicate with the catalog service.
For WebSphere eXtreme Scale remote endpoints: Defines the Object Request Broker (ORB) listener port for containers and clients to communicate with the catalog service through the ORB. For WebSphere Application Server endpoints, the listener port value is inherited from the BOOTSTRAP_ADDRESS port configuration.

Status

Table 1. Catalog server endpoint status

Icon	Definition
	Unknown
	Started
	Stopped

Client security properties

Use this page to configure client security for a catalog service domain. These settings apply to all the servers in your catalog service domain. These properties can be overridden by specifying a splicer.properties file with the com.ibm.websphere.xs.sessionFilterProps custom property or by splicing the application EAR file.

To view this administrative console page, click System administration > WebSphere eXtreme Scale > Catalog service domains > *catalog_service_domain_name* > Client security properties.

Enable client security

Specifies that client security is enabled for the catalog server. The server properties file that is associated with the selected catalog server must have a matching securityEnabled setting in the server properties file. If these settings do not match, an exception results.

Credential authentication

Indicates if credential authentication is enforced or supported.

Never
: No client credential authentication is enforced.

Required
: Credential authentication is always enforced. If the server does not support credential authentication, the client cannot to connect to the server.

Supported
: Credential authentication is enforced only if both the client and server support credential authentication.

Authentication retry count

Specifies the number of times that authentication gets tried again if the credential is expired.

If you do not want to try authentication again, set the value to `0`.

Credential generator class

Indicates the com.ibm.websphere.objectgrid.security.plugins.CredentialGenerator implementation class, so the client retrieves the credential from the CredentialGenerator object.

You can choose from two predefined credential generator classes, or you can specify a custom credential generator. If you choose a custom credential generator, you must indicate the name of the credential generator class.

- com.ibm.websphere.objectgrid.security.plugins.builtins.UserPasswordCredentialGenerator
- com.ibm.websphere.objectgrid.security.plugins.builtins.WSTokenCredentialGenerator

- Custom credential generator

Subject type

Specifies if you are using the J2EE caller or the J2EE runAs subject type. You must specify this value when you choose the WSTokenCredentialGenerator credential generator.

- **runAs**: The subject contains the principal of the J2EE run as identity and the J2EE run as credential.
- **caller**: The subject contains the principal of the J2EE caller and the J2EE caller credential.

User ID

Specify a user ID when you are using the UserPasswordCredentialGenerator credential generator implementation.

Password

Specify a password when you are using the UserPasswordCredentialGenerator credential generator implementation.

Credential generator properties

Specifies the properties for a custom CredentialGenerator implementation class. The properties are set in the object with the setProperties(String) method. The credential generator properties value is used only when a value is specified for the Credential generator class field.

Catalog service domain custom properties

You can further edit the configuration of the catalog service domain by defining custom properties.

To view this administrative console page, click System administration > WebSphere eXtreme Scale > Catalog service domains > Custom properties. To create a new custom property, click New.

Name

Specifies the name of the custom property for the catalog service domain.

Value

Specifies a value for the custom property for the catalog service domain.

Glossary

This glossary includes terms and definitions for various IBM business process management products.

The following cross-references are used in this glossary:

- See refers you from a term to a preferred synonym, or from an acronym or abbreviation to the defined full form.
- See also refers you to a related or contrasting term.

To view glossaries for other IBM products, go to www.ibm.com/software/globalization/terminology (opens in new window).

A

A2A
: See application to application.

abstract schema
: Part of the deployment descriptor for an entity bean that is used to define the bean relationships, persistent fields, or query statements.

abstract test
: A component or unit test that is used to test Java interfaces, abstract classes, and superclasses; that cannot be run on its own; and that does not include a test suite. See also component test.

abstract type
: A type that can never be instantiated and whose members are exposed only in instances of concrete types that are derived from it.

Abstract Window Toolkit (AWT)
: In Java programming, a collection of GUI components that were implemented using native-platform versions of the components. These components provide that subset of functionality which is common to all operating system environments. (Sun) See also Standard Widget Toolkit, Swing Set.

access bean
: An enterprise bean wrapper that is typically used by client programs, such as JSP files and servlets. Access beans hide the complexity of using enterprise beans and improve the performance of reading and writing multiple EJB properties.

access control

In computer security, the process of ensuring that users can access only those resources of a computer system for which they are authorized.

access control list (ACL)
In computer security, a list associated with an object that identifies all the subjects that can access the object and their access rights.

access ID
The unique identification of a user used during authorization to determine if access is permitted to the resource.

access intent
Metadata that optimizes and controls the runtime behavior of an entity bean with respect to concurrency control, resource management, and database access strategies.

access intent policy
A grouping of access intents that governs a type of data access pattern for enterprise bean persistence.

accessor
In computer security, an object that uses a resource. Users and groups are accessors.

access point group
A collection of core groups that defines the set of core groups in the same cell or in different cells that communicate with each other.

access privilege
An authority that relates to a request for a type of access to data.

access right
See permission.

accounting
The process of collecting and reporting information about the use of services to apportion cost.

ACID transaction
A transaction involving multiple resource managers using the two-phase commit process to ensure atomic, consistent, isolated, and durable (ACID) properties.

ACL
See access control list.

action

1. An activity that is run on a transition or a transaction. See also processing action.
2. In a business rule, the event that results from the evaluation of the condition.
3. A business process that is generated in response to the processing of an event or a rule.
4. A series of processing steps, such as document validation and transformation.

Action class
In Struts, the superclass of all action classes.

action column
The action part of a decision table.

action mapping
A Struts configuration file entry that associates an action name with an Action class, a form bean, and a local forward.

action object
A subset of fields in the definition of an action.

action phrase
In the vocabulary, a phrase that specifies an action to be executed. An action phrase corresponds to a method that has no return value in the business object model (BOM).

action rule

1. A rule in which the action is always performed. See also if-then rule, rule set.
2. A business rule that can be edited in the rule editor. Action rules, decision tables, and decision trees are different representations of business rules.

action rule template
A partly completed action rule that can be used to create a series of rules with the same structure.

action service
A service that triggers a process or notification to inform users about a situation.

action service handler
An entity that is responsible for the invocation mechanism of one or more action services.

action set

1. The leaf of a branch in a decision tree. Action sets consist of one or more actions to be carried out when the conditions defined in the rule are met.
2. In Eclipse, a group of commands that a perspective contributes to the main toolbar and menu bar.

action task
In a rule flow, a task that contains rule action statements. These action statements are executed each time the task is called.

activation
In Java, the process of transferring an enterprise bean from secondary storage to memory. (Sun) See also passivation.

activation condition
A Boolean expression in a node within a business process that specifies when processing is to begin.

active change set
A change that is in the Draft, Pending, or Approved state.

active option set
In an option set group, the option set that a new scenario uses or that a scenario in progress switches to, if switching becomes necessary.

active site analytics
The instrumentation of pages with metadata that is embedded in themes and skins to provide data to website analytics and search engine optimization tools.

activity

1. An action designed to achieve a particular business process. An activity is performed on a set of targets on a specific schedule.
2. An element of a process, such as a task, a subprocess, a loop, or a decision. Activities are represented as nodes in process diagrams.
3. A unit of work or a building block that performs a specific, discrete task. See also task.

4. Work that a company or organization performs using business processes. An activity can be atomic or non-atomic (compound). The types of activities that are a part of a process model are process, subprocess, and task.
5. A logical unit of work that can be completed by a person or a system while the process runs.

Activity Decision Flow (ADF)
: The format in which models are exported from WebSphere Business Integration Workbench into WebSphere Business Modeler.

actuator
: A device that causes mechanical motion.

adapter
: An intermediary software component that allows two other software components to communicate with one another.

adapter foundation classes (AFC)
: A common set of services for all resource adapters. The adapter foundation classes conform to, and extend, the Java 2 Connector Architecture JCA 1.5 specification.

adapter object
: An object used in the TX Programming Interface that represents a resource adapter.

Address Resolution Protocol (ARP)
: A protocol that dynamically maps an IP address to a network adapter address in a local area network.

ADF
: See Activity Decision Flow.

ad hoc start event
: An event that is triggered by a user's interaction with the process, such as through the process portal. The ad hoc start event requires an active process to be triggered. See also start event.

administrative agent
: A program that provides administrative support without requiring a direct connection to a database.

administrator
: A person responsible for administrative tasks such as access authorization and content management. Administrators can also grant levels of authority to users.

Advanced Integration service
: A service that represents and interacts with a corresponding service in Integration Designer. See also integration service, service.

Advanced Program-to-Program Communication (APPC)
: An implementation of the SNA LU 6.2 protocol that allows interconnected systems to communicate and share the processing of programs.

AFC
: See adapter foundation classes.

after-image
: A business object that contains all of the entity data after changes have been made to it during an update operation. An after-image contains the complete business object rather than only the primary key and those elements that were changed. See also delta business object.

agenda
: A logical workspace where rule instances that have conditions matching objects in the working memory are put.

agent
: A process that performs an action on behalf of a user or other program without user intervention or on a regular schedule, and reports the results back to the user or program.

aggregate interface
: The logical grouping of ethernet interfaces, connected to the same subnet, that provide higher levels of availability and bandwidth from the networking substrate. See also link aggregation.

aggregate metric
: A metric that is calculated by finding the average, maximum, minimum, sum, or number of occurrences of an instance metric across multiple runs of a process. Examples of aggregate metrics are an average order amount, a maximum order amount, a minimum order amount, the total order amount, or the number of occurrences of $500 for an order amount. See also measure, metric.

aggregation
: The structured collection of data objects for subsequent presentation within a portal.

alarm listener
: A type of asynchronous bean that is called when a high-speed transient alarm expires.

alert
: A message or other indication that signals an event or an impending event.

algorithm mapping
: A process by which service providers can define the mapping of Uniform Resource Identifier (URI) algorithms to cryptographic algorithms that are used for XML digital signature and XML encryption.

alias
: An assumed or actual association between two data entities, or between a data entity and a pointer.

annotate
: To add metadata to an object to describe services and data.

annotation
: An added descriptive comment or explanatory note.

anonymous user
: A user who does not use a valid user ID and password to log into a site. See also authenticated user, registered user.

AP
: See application program.

APAR
: See authorized program analysis report.

API
: See application programming interface.

API content model
: A model that describes how XML documents, and their extended metadata, are represented.

API stub
: A piece of glue code that enables the binder to resolve zRule Execution Server for z/OS API calls that COBOL applications make. For example, HBRBSTUB is an API stub that is used for COBOL applications that run as batch applications and HBRCSTUB is an API stub that is used for COBOL applications that

run as CICS applications. See also glue code.

APPC

See Advanced Program-to-Program Communication.

applet

A program that performs a specific task and is typically portable between operating systems. Often written in Java, applets can be downloaded from the Internet and run in a web browser.

applet client

A client that runs within a browser-based Java runtime environment, and is capable of interacting with enterprise beans directly instead of indirectly through a servlet.

appliance

A drop-in network device, including hardware and firmware, that simplifies IT deployment for a specific set of business requirements.

application

One or more computer programs or software components that provide a function in direct support of a specific business process or processes. See also application server.

application assembly

The process of creating an enterprise archive (EAR) file containing all the files related to an application as well as an Extensible Markup Language (XML) deployment descriptor for the application.

application client

In Java EE, a first-tier client component that runs in its own Java virtual machine. Application clients have access to some Java EE platform APIs, for example JNDI, JDBC, RMI-IIOP, and JMS. (Sun)

application client module

A Java archive (JAR) file that contains a client that accesses a Java application. The Java application runs inside a client container and can connect to remote or client-side Java EE resources.

Application Client project

A structure and hierarchy of folders and files that contain a first-tier client component that runs in its own Java virtual machine.

application delivery notification

A delivery notification that is passed to an application. Typically, an application delivery notification is based on a network delivery notification, but has been modified in some way by the service that exchanges data directly with the application. See also network delivery notification.

application edition

A unique deployment of a particular application. Multiple editions of the same application have the same application name, while edition names are unique.

application edition manager

An autonomic manager that manages interruption-free production application deployments.

application infrastructure virtualization

The pool of application server resources that separates applications from the physical infrastructure on which they run. As a result, workload can be dynamically placed and migrated across the application server pool.

application LT

A logical terminal (LT) that is used by one or more applications, but that is not used for LT sessions.

application placement controller

An autonomic manager that can start and stop application instances on servers to meet the fluctuating demand of work requests and varying service policy definitions.

application policy

A collection of policies and attributes governing access to applications.

application program (AP)

A complete, self-contained program, such as a text editor or a web browser, that performs a specific task for the user, in contrast to system software, such as the operating system kernel, server processes, and program libraries.

application programming interface (API)

An interface that allows an application program that is written in a high-level language to use specific data or functions of the operating system or another program.

Application Response Measurement (ARM)

An application programming interface (API), developed by a group of technology vendors, that can be used to monitor the availability and performance of business transactions within and across diverse applications and systems.

Application Response Measurement agent (ARM agent)

An agent that monitors software that is implemented using the Application Response Measurement standard.

application server

A server program in a distributed network that provides the execution environment for an application program. See also application.

application-specific component

The component of a connector that contains code tailored to a particular application or technology. The application-specific component can respond to requests and implement an event-notification mechanism that detects and responds to events initiated by an application or external programmatic entity.

application-specific information

Part of the metadata of a business object that enables the connector to interact with its application (for example, Ariba Buyer) or a data source (for example, a web servlet). See also metadata.

application to application (A2A)

A data transformation from the output of one application to the input of another application.

application virtualization

The separation of an application from the underlying operating environment, which improves portability, compatibility, and manageability of the application.

area

A representation of the physical space within the location to be monitored. Areas are the container for all zones. See also location.

ARFM

See autonomic request flow manager.

ARM

1. See Application Response Measurement.
2. See automatic restart manager.

ARM agent
See Application Response Measurement agent.
ARP
See Address Resolution Protocol.
artifact

1. A graphical object that provides supporting information about the process or elements within the process without directly affecting the semantics of the process.
2. An entity that is used or produced by a software development process. Examples of artifacts are models, source files, scripts, and binary executable files.

aspect-oriented connectivity
A form of connectivity that implements or enforces cross-cutting aspects in service-oriented architecture (SOA), such as security, management, logging, and auditing, by removing such aspects from the concern of the service requesters and providers.
assertion

1. A concept in the meta-model that is used to specify a policy requirement and evaluating endpoints at run time. An assertion is also used to describe the capabilities of an endpoint.
2. A logical expression specifying a program state that must exist or a set of conditions that program variables must satisfy at a particular point during program execution.

asset
A collection of artifacts that provide a solution to a specific business problem. Assets can have relationships and variability or extension points to other assets.
assisted lifecycle server
A representation of a server that is created outside of the administrative domain but can be managed in the administrative console.
assistive technology
Hardware or software that is used to increase, maintain, or assist the functional capabilities of people with disabilities.
associated type
An object that refers to a source object. See also referenced type.
association

1. In enterprise beans, a relationship that exists between two container-managed persistence (CMP) entity beans. There are two types of association: one-to-one and one-to-many.
2. For XML documents, the linkage of the document itself to the rules that govern its structure, which might be defined by a Document Type Definition (DTD) or an XML schema.
3. A connecting object that is used to link information and artifacts with flow objects. An association is represented as a dotted graphical line with an arrowhead to represent the direction of flow.

asymmetric algorithm
See public key algorithm.
asymmetric cryptography
See public key cryptography.
asynchronous
Pertaining to events that are not synchronized in time or do not occur in regular or predictable time intervals.
asynchronous bean
A Java object or an enterprise bean that a Java Platform, Enterprise Edition (Java EE) application can run asynchronously.
asynchronous messaging
A method of communication between programs in which a program places a message on a message queue, then proceeds with its own processing without waiting for a reply to its message.
asynchronous replica
A shard that receives updates after the transaction commits. This method is faster than a synchronous replica, but introduces the possibility of data loss because the asynchronous replica can be several transactions behind the primary shard. See also synchronous replica.
atomic activity
An activity that is not broken down to a finer level of process model detail. It is a leaf in the tree-structure hierarchy of process activities.
attribute

1. A set of factors that are used as variables to determine the score of an entity. The value of an attribute can be a natural number, a floating point number, a Boolean value, a character, or a character string. An attribute can be the result of the execution of another rule or a combination of other attributes.
2. A characteristic or trait of an entity that describes the entity; for example, the telephone number of an employee is one of the employee attributes. See also entity, identity.
3. In markup languages such as SGML, XML, and HTML, a name-value pair within a tagged element that modifies features of the element.
4. A property, quality, or characteristic whose value contributes to the specification of an element or program function. For example, "cost" or "location" are attributes that can be assigned to a resource.

attribute list
A linked list that contains extended information that is used to make authorization decisions. Attribute lists consist of a set of name = value pairs.
audit log
A log file containing a record of system events and responses.
augment
To convert a profile to another kind of profile. For example, a server profile can be modified to become a bus profile. See also unaugment.
authenticated user
A portal user who has logged in to the portal with a valid account (user ID and password). Authenticated users have access to all public places. See also anonymous user, registered user.
authentication

A security service that provides proof that a user of a computer system is genuinely who that person claims to be. Common mechanisms for implementing this service are passwords and digital signatures.

authentication alias
An alias that authorizes access to resource adapters and data sources. An authentication alias contains authentication data, including a user ID and password.

authenticator key
A set of alphanumeric characters used for the authentication of a message sent via the SWIFT network.

authorisation
A document that authorizes one SWIFTNet destination to send messages to or receive messages from another SWIFTNet destination.

authorization

1. The process of granting a user, system, or process either complete or restricted access to an object, resource, or function.
2. In computer security, the right granted to a user to communicate with or make use of a computer system.

authorization policy
A policy whose policy target is a business service and whose contract contains one or more assertions that grant permission to run a channel action.

authorization table
A table that contains the role to user or group mapping information that identifies the permitted access of a client to a particular resource.

authorized program analysis report (APAR)
A request for correction of a defect in a supported release of a program supplied by IBM.

autodiscovery
The discovery of service artifacts in a file system, external registry, or another source.

automatic application installation project
A monitored directory to which the addition of a fully composed EAR, WAR, EJB JAR, or stand-alone RAR file triggers automatic deployment and publication to a target server. Deletion of an EAR or Java EE module file from this directory triggers automatic uninstalling. See also monitored directory.

automatic restart management
The facilities that detect failures and manage server restarts.

automatic restart manager (ARM)
A z/OS recovery function that can automatically restart batch jobs and started tasks after they or the system on which they are running end unexpectedly.

automatic transition
A transition that occurs on completion of the activity within the originating state.

automatic variable
A variable that a user can declare as an instance of a specific business object model (BOM) class.

autonomic request flow manager (ARFM)
An autonomic manager that controls request prioritization in the on-demand router.

availability

1. The time periods during which a resource is accessible. For example, a contractor might have an availability of 9 AM to 5 PM every weekday, and 9 AM to 3 PM on Saturdays.
2. The condition allowing users to access and use their applications and data.

AWT
See Abstract Window Toolkit.

Axis
An implementation of SOAP on which Java web services can be implemented.

B

B2B
See business-to-business.

B2C
See business-to-consumer.

B2E
See business-to-employee.

BA
See basic authentication.

back-end system
An IMS in a multisystem environment that accepts transactions from the front-end system, calls application programs for transaction processing, and routes replies back to the front-end system for response to the terminal.

background processing
A mode of program execution in which the shell does not wait for program completion before prompting the user for another command.

BAL
See Business Action Language.

BAM
See business activity monitoring.

bank identifier code (BIC)
A code used to uniquely identify a bank, logical terminal, or branch within a SWIFT network.

BAPI
See Business Application Programming Interface.

base
The core product, for which features can be separately ordered and installed.

base classes
See adapter foundation classes.

base configuration
The part of a storage management subsystem (SMS) configuration that contains general storage management attributes, such as the default management class, default unit, and default device geometry. It also identifies the systems, system groups, or both the systems and system groups that an SMS

configuration manages.

baseline
: See snapshot.

base object
: An object that defines a common set of attributes; more complex objects are then built from a base object, inheriting the common attribute set.

basic analysis
: A type of analysis that displays a report for the values of one or more business measures during a specific period of time.

basic authentication (BA)
: An authentication method that uses a user name and a password.

basic type
: A type whose values have no identity (that is, they are pure values). Basic types include Integer, Boolean, and Text.

batch application
: An application that is implemented as part of a bundle or Java archive file and deployed as an archive file.

batch job
: A predefined group of processing actions submitted to the system to be performed with little or no interaction between the user and the system.

bean
: A definition or instance of a JavaBeans component. See also enterprise bean, JavaBeans.

bean class
: In Enterprise JavaBeans (EJB) programming, a Java class that implements a javax.ejb.EntityBean class or javax.ejb.SessionBean class.

bean-managed messaging
: A function of asynchronous messaging that gives an enterprise bean complete control over the messaging infrastructure.

bean-managed persistence (BMP)
: The mechanism whereby data transfer between an entity bean's variables and a resource manager is managed by the entity bean. (Sun) See also container-managed persistence.

bean-managed transaction (BMT)
: The capability of the session bean, servlet, or application client component to manage its own transactions directly, instead of through a container.

bearer token
: A Security Assertion Markup Language (SAML) token that uses the bearer subject confirmation method. In a bearer subject confirmation method, a sender of SOAP messages is not required to establish correspondence that binds a SAML token with contents of the containing SOAP message.

BEL
: See Business Events Language.

BIC
: See bank identifier code.

bidi
: See bidirectional.

bidirectional (bidi)
: Pertaining to scripts such as Arabic and Hebrew that generally run from right to left, except for numbers, which run from left to right.

big endian
: A format for storage or transmission of binary data in which the most significant value is placed first. See also little endian.

binary format
: Representation of a decimal value in which each field must be 2 or 4 bytes long. The sign (+ or -) is in the far left bit of the field, and the number value is in the remaining bits of the field. Positive numbers have a 0 in the sign bit and are in true form. Negative numbers have a 1 in the sign bit and are in twos complement form.

binary large object (BLOB)
: A block of bytes of data (for example, the body of a message) that has no discernible meaning, but is treated as one entity that cannot be interpreted.

bind
: To establish a connection between software components on a network using an agreed-to protocol. In web services, the bind operation occurs when the service requester invokes or initiates an interaction with the service at run time using the binding details in the service description to locate, contact, and invoke the service.

binding
: A temporary association between a client and both an object and a server that exports an interface to the object. A binding is meaningful only to the program that sets it and is represented by a bound handle.

black box
: A pool in which no content can be seen.

BLOB
: See binary large object.

block decryption
: Symmetric algorithms that decrypt a block of data at one time.

block encryption
: Symmetric algorithms that encrypt a block of data at one time.

BMP
: See bean-managed persistence.

BMT
: See bean-managed transaction.

BOM
: See business object model.

BOM property
: A property added to a type in a business object model (BOM). Business properties extend the original type without altering its source.

BOM-to-XOM mapping
: A mechanism that defines how business elements are mapped to the Execution Object Model.

Boolean
: Characteristic of an expression or variable that can only have a value of true or false.

boot BOM
: A set of files that define the system types, such as string or number, for the Business Action Language (BAL).

bootstrap

A small program that starts a computer by loading the operating system and other basic software.

bootstrap authorisation
: An authorization that has been recorded but not yet processed by an relationship management application (RMA).

bootstrap member
: An application server or cluster that is configured to accept application initialization requests into the service integration bus. The bootstrap member authenticates the request and directs the connection request to a bus member.

bootstrap period
: The period during which relationship management (RM) data is recorded and converted into authorization records.

bootstrapping
: The process by which an initial reference of the naming service is obtained. The bootstrap setting and the host name form the initial context for Java Naming and Directory Interface (JNDI) references.

bottleneck
: A place in the system where contention for a resource is affecting performance.

bottom-up development
: In web services, the process of developing a service from an existing artifact such as JavaBeans or an enterprise bean rather than a Web Services Description Language (WSDL) file. See also top-down development.

bottom-up mapping
: In Enterprise JavaBeans (EJB) programming, an approach for mapping enterprise beans to database tables, in which the schema is first imported from an existing database and then enterprise beans and mappings are generated.

boundary event
: An intermediate event that is attached to the boundary of an activity. A boundary event can be triggered only while the activity is running, either leaving the activity running or interrupting the activity.

boundary zone
: A zone that is used for implementing access control to areas that are not covered by event devices and therefore cannot be controlled completely or directly.

bound component
: In the Type Designer, a component for which each occurrence of the data can be identified without considering the context in which that occurrence is placed.

bound type
: In the Type Designer, a type whose data object can be identified without considering the context in which that data object is placed.

BPD
: See business process definition.

BPEL
: See Business Process Execution Language.

BPM
: See business process management.

BPML
: See Business Process Modeling Language.

BPML activity
: A step in a business process that provides directions for how data should be handled.

BPMN
: See Business Process Modeling Notation.

branch
: 1. A distinct path leading to or originating from an element in a process model or UML diagram.
  2. In the CVS team development environment, a separate line of development where changes can be isolated. When a programmer changes files on a branch, those changes do not appear on the main trunk or other branches.
  3. In a rule flow, a node that organizes conditional transitions. Several transitions can go to and from a branch node. All transitions created from a branch must have a condition, except the Else transition.

breadcrumb trail
: A navigation technique used in a user interface to give users a way to keep track of their location within the program or documents.

breakpoint
: A marked point in a process or programmatic flow that causes that flow to pause when the point is reached, typically to allow debugging or monitoring.

bridge
: In the connection of local loops, channels, or rings, the equipment and techniques used to match circuits and to facilitate accurate data transmission. See also web application bridge.

bridge interface
: A node and a server that run a core group bridge service.

BRLDF
: See Business Rule Language Definition Framework.

BRMS
: See business rule management system.

broker archive
: A file that is the unit of deployment to the broker that can contain any number of compiled message flow and message set files and a single deployment descriptor. A separate broker archive file is required for each configuration that is deployed.

brokerlist section
: A section in a customization definition document (CDD) that describes which BAR files are deployed, which execution group and broker the files are deployed to, and which tuning parameters the files use.

broker topology definition (BTD)
: A description of the brokers, execution groups, and broker archive (BAR) files that are used in a runtime environment, and the actions that are required to implement the current broker topology (for example, deploying the BAR files for a new service).

broker topology definition document (BTDD)
: An XML document that describes a broker topology definition.

browser
: A client program that initiates requests to a web server and displays the information that the server returns.

brute force collision
: A programming style that relies on computing power to try all the possibilities with a known hash until the solution is found.

BTD
: See broker topology definition.

BTDD
: See broker topology definition document.

bucket
: One or more fields that accumulate the result of an operation.

build
: To create or modify resources, typically based on the state of other resources. A Java builder converts Java source files into executable class files, for example, and a web link builder updates links to files whose name or location has changed.

build definition file
: An XML file that identifies components and characteristics for a customized installation package (CIP).

build path
: The path that is used during compilation of Java source code, in order to find referenced classes that reside in other projects.

build plan
: An XML file that defines the processing necessary to build generation outputs and that specifies the machine where processing takes place.

build time data
: Objects that are not used by the translator, such as EDI standards, record oriented data document types, and maps.

bulk decryption
: See block decryption.

bulk encryption
: See block encryption.

bulk resource
: A resource that is taken in quantity from a pool of generic resources. For example, a task might require 10 landscapers or 10 liters of water.

bundle
: 1. In the OSGi service platform, a Java archive file that contains Java code, resources, and a manifest that describes the bundle and its dependencies. The bundle is the unit of deployment for an application. See also bundle cache, bundle repository, enterprise bundle archive.
  2. A set of tokens that are transferred between nodes in a simulation as a complete group.

bundle cache
: A cell-wide store, or server-wide store for single-server systems, of bundles that OSGi applications refer to and that have been downloaded from both internal and external repositories. See also bundle, bundle repository.

bundle repository
: A common store of OSGi bundles that can be shared by multiple OSGi applications. See also bundle, bundle cache.

bus
: Interconnecting messaging engines that manage bus resources.

Business Action Language (BAL)
: A business rule language that uses an intuitive and natural language-like syntax for writing business rules.

business activity monitoring (BAM)
: The collection and presentation of real-time information that describes a business process or a series of activities spanning multiple systems and applications.

business analyst
: 1. A decision management user role that is responsible for modeling rule application projects.
  2. A specialist who analyzes business needs and problems, consults with users and stakeholders to identify opportunities for improving business return through information technology, and transforms requirements into a technical form.

Business Application Programming Interface (BAPI)
: A programming interface that is used to access SAP databases from with SAP or other development platforms. BAPI is used to achieve integration between the R/3 System and external applications and legacy systems.

business calendar
: A calendar that is used to model noncontiguous time intervals (intervals that do not proceed in a sequential manner). For example, a business calendar that defines regular working hours might refer to the non-overtime regular working hours of Monday to Friday, 9:00 a.m. to 5:00 p.m.

business component
: A component that defines the structure, behavior, and information displayed by a particular subject, such as a product, contact, or account, in Siebel Business Applications.

business ecosystem
: A business community supported by a foundation of interacting organizations and individuals. This community produces goods and services of value to customers, who are themselves members of the ecosystem. A business ecosystem contains business services networks, which contain business process, relevant to the transactions in that network.

business event
: 1. A significant occurrence in a business process, generally identified by a business analyst, that warrants monitoring over time to reveal a key performance indicator (KPI).
  2. An event that occurs during a business process.

Business Event Language
: A business rule language that expresses event rules. See also business rule language.

Business Events Language (BEL)
: A business rule language that uses an intuitive and natural language-like syntax for writing event rules.

business graph
: A wrapper that is added around a simple business object or a hierarchy of business objects to provide additional capabilities, such as carrying change summary and event summary information related to the business objects in the business graph. See also business object.

business group

A place to collect any elements to group together. Different business groups can be created for companies, processes, parts of processes, or any other grouping.

business integration system
: An integration broker and a set of integration adapters that allow heterogeneous business applications to exchange data through the coordinated transfer of information in the form of business objects.

business item
: A business document, work product, or commodity that is used in business operations. Examples of business items are a manufacturing order, system board, power supply, and memory chip (in a PC assembly process), itinerary and customer information record (in a trip reservation process), and passenger (in a transportation process). See also business object.

business item instance
: A particular occurrence or example of a business item. If there is a business item called Invoice, then an example of a business item instance would be "Invoice #1473.

business item template
: A category used to model a group of business items that share common properties. After these properties are defined in the template, they are inherited by all business items using the template. For example, an organization may define a number of forms to be used in human resource processes, all of which have fields for date, employee number, HR form number, and HR administrator.

business logic tier
: The set of components that reside between the presentation and database tiers. This logic tier hosts the enterprise bean containers, which run the business logic.

business measure
: A description of a performance management characteristic that you want to monitor. Business measures include instance metrics, aggregate metrics (also called measures), and key performance indicators (KPI).

business method

1. A method of an enterprise bean that implements the business logic or rules of an application. (Sun)
2. A method added to a type in a business object model. Business methods extend the original type without altering its source.

business object

1. A software entity that represents a business entity, such as an invoice. A business object includes persistent and nonpersistent attributes, actions that can be performed on the business object, and rules that the business object is governed by. See also binding, business graph, business item, data object, private business object, Service Data Objects.
2. An abstract representation of the fields that belong to the event and action definitions.

business objective
: A high-level business goal. Because business objectives are typically abstract, they are difficult to measure and are therefore translated into more measurable lower-level business goals.

business object map
: An artifact that assigns values to the target business objects based on the values in the source business objects.

business object model (BOM)

1. A representation of the core concepts of a business and their logical connections. The business object model is the basis for the vocabulary used in business rules. The elements of a business object model (BOM) map to those of a corresponding execution object model.
2. A model that defines how a system organizes its processes when interacting with business objects. An example of a business object model is the Enterprise JavaBeans (EJB) component model.

business operations
: The ways in which an organization operates, including its processes and organizational structure. For example, an organization might have a management structure and processes defined for everything from taking vacation days to submitting travel expenses.

business policy

1. A set of rules that define business processes, industry practices, or the scope and characteristics of business offerings.
2. A policy that is attached to an object in the ontology known as the business policy target. It optionally specifies a set of conditions that must be met for the business policy to apply. The policies declare a set of assertions that must be satisfied when the conditions are met.

business policy target
: An object in the ontology suitable for attaching business policies.

business process
: A defined set of business activities that represent the required steps to achieve a business objective. A business process includes the flow and use of information and resources.

business process container
: A process engine that contains process modules.

business process definition (BPD)
: A reusable model of a process that defines the common aspects of all runtime instances of that process model.

Business Process Execution Language (BPEL)
: An XML-based language for the formal specification of business processes and business interaction protocols. BPEL extends the web services interaction model and enables it to support business transactions.

business process management (BPM)
: The services and tools that support process management (for example, process analysis, definition, processing, monitoring and administration), including support for human and application-level interaction. BPM tools can eliminate manual processes and automate the routing of requests between departments and applications.

Business Process Modeling Language (BPML)
: An XML-based language that describes business processes designed by the Business Process Management Initiative (www.bpmi.org).

Business Process Modeling Notation (BPMN)
: A standardized graphical notation for creating diagrams of business processes.

business protocol

A set of rules and instructions (protocol) used to format and transmit information across a computer network. Examples include RosettaNet, cXML, and EDI-X12.

business rule

1. A policy, constraint, or required operation that applies to a specific set of business conditions or dependencies. An example of a business rule for a bank is that a credit check is not required when opening an account for an existing customer.
2. A representation of how business policies or practices apply to a business activity.

business rule application
: An application in which a business policy has been implemented by using business rules.

business rule group
: A set of scheduled business rules that are available as a service that can be invoked. The business rule group also provides the organizational structure for managing the set of business rules.

business rule language
: A language for expressing rules with natural language terms and syntax. See also Business Event Language.

Business Rule Language Definition Framework (BRLDF)
: A framework for defining custom business rule languages, using XML schemas and property files.

business rule management
: The practices that control and manage business rules through their life cycles.

business rule management system (BRMS)
: A system designed to modify and manage business logic independently from the applications within an organization.

business service
: An abstract representation of a business function, hiding the specifics of the function interfaces.

business service definition
: A representation of the WSDL PortTypes in a business service. A business service definition describes a specific set of business service operations that are used to perform related business functionality.

business service object
: A representation of an XML schema file (.xsd). There are inline XML schemas and schema types within WSDL files. A business service object is a collection of business service object definitions and business service object templates.

business service object definition
: A representation of the WSDL ComplexType in an inline schema, or the XML schema type (SimpleType, ComplexType, Anonymous ComplexType, or Anonymous SimpleType) in an XML schema file. There are inline XML schemas and schema types within WSDL files. A business service object definition is similar to a business item and is used to define the business data that is required when a business service operation is invoked.

business service operation
: A representation of the WSDL Operation in a business service definition. A business service operation describes a business function and includes the business service object definitions that are required when the operation is invoked. A business service operation also describes the business service object definitions that result from completing the business service operation. For example, a Product Search business service operation requires a Product name (a business service object definition) and returns a Product business service object definition. Business service operations can be added to process diagrams as non-editable services.

business services network
: A collection of business processes, services, subscribers, and policies that enable, control, or consume a portfolio of business services. The business services network can span enterprise boundaries and geographies or be confined to a single physical network or entity.

business situation
: A condition that might require business action. Examples of business situations are a declining sales volume or an unacceptable amount of time to respond to a customer.

business space
: A collection of related web content that conveys insight into the business and gives users the ability to react to changes in the business.

business subtype
: A subtype of a type in a business object model (BOM). Business subtypes are used to extend an object model using business methods and business properties.

business-to-business (B2B)
: Refers to Internet applications that exchange information or run transactions between businesses. See also business-to-consumer.

business-to-consumer (B2C)
: Refers to the subset of Internet applications that exchange information or run transactions between businesses and consumers. See also business-to-business.

business-to-employee (B2E)
: A business model that supports electronic communications between a business and its employees.

bus member
: An application server or server cluster that hosts one or more messaging engines in a service integration bus.

bus topology
: A physical arrangement of application servers, messaging engines and queue managers and the pattern of bus connections and links between them.

bytecode
: Machine-independent code generated by the Java compiler and executed by the Java interpreter. (Sun)

C

C2A
: See Click-to-Action.

CA
: See certificate authority.

cache
: A buffer that contains frequently accessed instructions and data; it is used to reduce access time.

cache instance resource
: A location where any Java Platform, Enterprise Edition (Java EE) application can store, distribute, and share data.

cache replication

The sharing of cache IDs, cache entries, and cache invalidations with other servers in the same replication domain.

calculation strategy
: The strategy used to calculate the final score of a scorecard table.

callback handler
: A mechanism that uses a Java Authentication and Authorization Service (JAAS) interface to pass a security token to the web service security run time for propagation in the web service security header.

callout
: The action of bringing a computer program, a routine, or a subroutine into effect.

callout node
: The connection point in a mediation request flow from which a service message is sent to a target. There must be one callout node for each target operation.

callout response node
: The starting point for a mediation response flow. There must be one callout response node for each target.

call stack
: A list of data elements that is constructed and maintained by the Java virtual machine (JVM) for a program to successfully call and return from a method.

candidate endpoint
: A known service endpoint that implements an interface for a particular request. The set of candidates is then filtered by the dynamic assembler to select the best endpoint out of all the candidates.

capability
: A group of functions and features that can be hidden or revealed to simplify the user interface. Capabilities can be enabled or disabled by changing preference settings, or they can be controlled through an administration interface.

capability list
: A list of associated resources and their corresponding privileges per user.

card
: 1. A Wireless Markup Language (WML) document that provides user-interface and navigational settings to display content on mobile devices. See also deck.
  2. In the Map Designer, a data object. There are two types of map cards: input and output.

cardinality
: The number of elements in a set.

card object
: An object used in the TX Programming Interface that represents an input or output card of a map in program memory.

Cascading Style Sheets (CSS)
: A language that defines a hierarchical set of style rules for controlling the rendering of HTML or XML files in browsers, viewers, or in print.

case
: A process instance and related set of documents, properties, roles, and tasks that are used to facilitate the collaboration of people to achieve a business outcome. See also task.

case property
: A property, such as a name or date, that is defined at the solution level and reused in a case type, document type, task, or step in that solution. See also case type, document type, step, task.

case type
: The definition of a case. The information that a case type provides is similar to that information that a process definition or template provides for a process instance. See also case property.

catalog
: A container that, depending on the container type, holds processes, data, resources, organizations, or reports in the project tree.

catalog service
: A service that controls placement of shards and discovers and monitors the health of containers.

catalog service domain
: A highly available collection of catalog service processes.

catching message intermediate event
: An intermediate event that is triggered when a specific message is received. See also intermediate event.

category
: 1. A classification of elements for documentation or analyses.
  2. A property that is set on an element of the business object model (BOM) and can be applied to business classes and filtered in business rules. This property allows the user to specify whether a business class and its members are visible in a rule.
  3. A container used in a structure diagram to group elements based on a shared attribute or quality.
  4. A type class that is used to organize types in a type tree in the Type Designer. Categories organize types that have common properties.

category filter
: A filter that is set on a business rule and removes the business element to which a category was attached from the completion menu.

CBPDO
: See Custom-built Product Delivery Option.

CBR
: See content based routing.

CBS
: See composite business service.

CCD table
: See consistent-change-data table.

CCI
: See common client interface.

CCSID
: See coded character set identifier.

CDD
: See customization definition document.

CD table
: See change-data table.

CEI
: See Common Event Infrastructure.

CEI event
: An event generated over the Common Event Infrastructure (CEI) and logged in a CEI data store.

CEI target
: An application server or server cluster where the Common Event Infrastructure (CEI) server is enabled.

cell
: 1. A group of managed processes that are federated to the same deployment manager and can include high-availability core groups.
  2. One or more processes that each host runtime components. Each has one or more named core groups.

cell-scoped binding
: A binding scope where the binding is not specific to, and not associated with any node or server. This type of name binding is created under the persistent root context of a cell.

center cell
: The only cell in a star topology with the ability to make autonomic decisions.

centralized installation manager
: A component that remotely installs and uninstalls product and maintenance packages in server environments.

certificate
: In computer security, a digital document that binds a public key to the identity of the certificate owner, thereby enabling the certificate owner to be authenticated. A certificate is issued by a certificate authority and is digitally signed by that authority.

certificate authority (CA)
: A trusted third-party organization or company that issues the digital certificates. The certificate authority typically verifies the identity of the individuals who are granted the unique certificate. See also certificate, Globus certificate service, Secure Sockets Layer.

certificate revocation list (CRL)
: A list of certificates that have been revoked before their scheduled expiration date. Certificate revocation lists are maintained by the certificate authority and used, during a Secure Sockets Layer (SSL) handshake to ensure that the certificates involved have not been revoked.

certificate set
: A set of primary and secondary certificates that can be associated to a participant connection.

certificate signing request (CSR)
: An electronic message that an organization sends to a certificate authority (CA) in order to obtain a certificate. The request includes a public key and is signed with a private key; the CA returns the certificate after signing with its own private key. See also certificate, keystore.

CGI
: See Common Gateway Interface.

chain
: The name of a channel framework connection that contains an endpoint definition.

chameleon schema
: A schema that inherits a target namespace from a schema that includes the chameleon schema.

change basis version
: The version of the server partition that changes were made against.

change-data table (CD table)
: In SQL replication, a replication table on the Capture control server that contains changed data for a replication source table.

change management
: 1. The process of planning for and executing changes to configuration items in the information technology environment. The primary objective of change management is to enable beneficial changes to be made with minimum disruption to services.
  2. The process of planning (for example, scheduling) and controlling (for example, distributing, installing, and tracking) software changes over a network.

change record
: A recorded instance that is created with each write action to the repository. The change record contains metadata about all repository changes (such as who was responsible for a commit action) and can be used as a version history view of the repository.

change set
: A cohesive unit consisting of a number of related changes that need to be made together.

channel
: 1. A communication path through a chain to an endpoint.
  2. A WebSphere MQ object that defines a communication link between two queue managers (message channel) or between a client and a queue manager (MQI channel). See also message channel.

channel action
: A business function that can be issued on a channel. Channel actions are role specific and an authorization policy makes it possible to control which role can perform which action in a channel.

channel framework
: A common model for connection management, thread usage, channel management, and message access within an application server.

character conversion
: The process of changing data from one character coding representation to another.

character encoding
: The mapping from a character (a letter of the alphabet) to a numeric value in a character code set. For example, the ASCII character code set encodes the letter "A" as 65, while the EBCIDIC character set encodes this letter as 43. The character code set contains encodings for all characters in one or more language alphabets.

chart series
: A selection of a category of data that will be represented by a chart in a report. A chart can have multiple chart series to represent multiple types of data.

chassis
: The metal frame in which various electronic components are mounted.

cheat sheet
: An interface that guides users through the wizards and steps required to perform a complex task, and that links to relevant sections of the online help.

check in
: In certain software configuration management (SCM) systems, to copy files back into the repository after changing them.

check out
: In certain software configuration management (SCM) systems, to copy the latest revision of a file from the repository so that it can be modified.

child node
: A node within the scope of another node.

choice type
: A group type with a subclass equal to choice that is used to define a selection from a set of components. A choice type defines a choice group, which is valid when the data matches one of the components in the choice group.

choreography
: An ordered sequence of message exchanges between two or more participants. In a choreography there is no central controller, responsible entity, or observer of the process.

CICS
: An IBM licensed program that provides online transaction-processing services and management for business applications.

CIP
: See customized installation package.

cipher
: A cryptographic algorithm used to encrypt data that is unreadable until converted into plain data with a predefined key.

cipher specifications
: Specifications that indicate the data encryption algorithm and key size to use for secure connections.

circular reference
: A series of objects where the last object refers to the first object, which can cause the series of references to be unusable.

class
: 1. In object-oriented design or programming, a model or template that can be used to create objects with a common definition and common properties, operations, and behavior. An object is an instance of a class.
  2. A basic unit of the classification hierarchy used in the Type Designer. There are three classes: item, group, and category.

class file
: A compiled Java source file.

class hierarchy
: The relationships between classes that share a single inheritance.

classification hierarchy
: The hierarchy of a type tree in the Type Designer. The deeper the subtype, the more specific the data characteristics are. See also compositional hierarchy.

classifier
: A specialized attribute used for grouping and color-coding process elements.

class loader
: Part of the Java virtual machine (JVM) that is responsible for finding and loading class files. A class loader affects the packaging of applications and the runtime behavior of packaged applications deployed on application servers.

class path
: A list of directories and JAR files that contain resource files or Java classes that a program can load dynamically at run time.

cleanup period
: The time period during which a database record that has reached its final state or condition is to remain in the database. After the cleanup period expires for such a record, database cleanup causes the record to be deleted from the database.

CLI
: See command-line interface.

Click-to-Action (C2A)
: A method for implementing cooperative portlets, whereby users can click an icon on a source portlet to transfer data to one or more target portlets. See also cooperative portlets, wire.

client
: A software program or computer that requests services from a server. See also host, server.

client application
: An application, running on a workstation and linked to a client, that gives the application access to queuing services on a server.

client message
: A message from a client application that is to be sent by means of a network to its destination, or a message that is routed to a client application to acknowledge the receipt of a client message by a network.

client project for RuleApps
: A predefined project for Eclipse that contains a class to execute a rule set within a RuleApp.

client proxy
: An object on the client side of a network connection that provides a remote procedure call interface to a service on the server side.

client reroute
: A method that allows a client application, upon the loss of communication with a database server and the predefinition of an alternative server, to continue working with the original database server or the alternative server with only minimal interruption of the work.

client/server
: Pertaining to the model of interaction in distributed data processing in which a program on one computer sends a request to a program on another computer and awaits a response. The requesting program is called a client; the answering program is called a server. See also distributed application.

client type detection
: A process in which a servlet determines the markup language type required by a client and calls the appropriate JavaServer Pages file.

clock event
: A special system event that is used to initiate a system-generated event.

cloud computing
: A computing platform where users can have access to applications or computing resources, as services, from anywhere through their connected devices. A simplified user interface and application programming interface (API) makes the infrastructure supporting such services transparent to users.

cloud group

A collection of hypervisors from a single vendor.

cluster
A group of application servers that collaborate for the purposes of workload balancing and failover.

CMP
See container-managed persistence.

CO
See configuration object.

coach
A user interface that can be created to collect input that is required for an underlying service.

COA report
See confirm-on-arrival report.

coarse-grained
Pertaining to viewing a group of objects from an abstract or high level. See also fine-grained.

cobrowsing
The interaction of multiple users sharing information about their individual web interactions. With this interaction users can share a view of the same web page simultaneously and share further interactions with the web page they are jointly viewing.

code assist
See content assist.

coded character set identifier (CCSID)
A 16-bit number that includes a specific set of encoding scheme identifiers, character set identifiers, code page identifiers, and other information that uniquely identifies the coded graphic-character representation.

code list

1. One or many dynamic pairs of code values that contains sender code and receiver code. Each code pair has one description and up to four additional codes relating to the pair.
2. A table, supplied by Data Interchange Services or defined by the user, that contains all acceptable values for a single data field.

code list table
A repository for lists of codes that can further define fields.

COD report
See confirm-on-delivery report.

coexistence
The ability of two or more entities to function in the same system or network.

coherent cache
Cache that maintains integrity so that all clients see the same data.

cold start
The process of starting an existing data replication configuration without regard for prior replication activity, causing reinitialization of all subscriptions.

collaboration

1. A diagram that shows the exchange of messages between two or more participants in a BPMN model.
2. The ability to connect customers, employees, or business partners to the people and processes in a business or organization, in order to facilitate improved decision-making. Collaboration involves two or more individuals with complementary skills interacting together to resolve a business problem.

collaborative components
UI-neutral API methods and tag libraries that allow developers to add collaborative functionality to their portlets.

collaborative filtering
Personalization technology that calculates the similarity between users based on the behaviors of a number of other people and uses that information to make recommendations for the current user.

collaborative unit
The configuration of the part of a deployment environment that delivers required behavior to an application module. For example, a messaging collaborative unit includes the host of the messaging engine and deployment targets of the application module, and provides messaging support to the application module.

collapsed subprocess
A subprocess that hides its flow details. The collapsed subprocess object has a marker that distinguishes it as a subprocess, rather than a task. The marker is a small square with a plus sign inside.

collection certificate store
A collection of intermediate certificates or certificate revocation lists (CRL) that are used by a certificate path to build up a certificate chain for validation.

collection page
A type of page in the administrative console that displays a collection list of administrative objects. From this type of page, you can typically select objects to act on or to display other pages for.

collective
A set of WebSphere DataPower XC10 appliances that are grouped together for scalability and management purposes.

collision arbiter
A plug-in that specifies how to handle change collisions in map entries.

comma delimited file
A file whose records contain fields that are separated by a comma.

command bean
A proxy that can invoke a single operation using an execute() method.

command line
The blank line on a display where commands, option numbers, or selections can be entered.

command-line interface (CLI)
A type of computer interface in which the input command is a string of text characters.

commit
To apply all the changes made during the current unit of recovery (UR) or unit of work (UOW). After the operation is complete, a new UR or UOW can begin.

common area

In a web page that is based on a page template, the fixed region of the page.

Common Base Event
: A specification based on XML that defines a mechanism for managing events, such as logging, tracing, management, and business events, in business enterprise applications. See also situation.

common client interface (CCI)
: A standard interface that allows developers to communicate with enterprise information systems (EISs) through specific resource adapters, using a generic programming style. The generic CCI classes define the environment in which a J2EE component can send and receive data from an EIS.

Common Criteria
: A framework for independent assessment, analysis, and testing of IT products to a set of security requirements.

Common Event Infrastructure (CEI)
: The implementation of a set of APIs and infrastructure for the creation, transmission, persistence, and distribution of business, system, and network Common Base Events. See also event emitter.

Common Gateway Interface (CGI)
: An Internet standard for defining scripts that pass information from a web server to an application program, through an HTTP request, and vice versa.

Common Object Request Broker Architecture (CORBA)
: An architecture and a specification for distributed object-oriented computing that separates client and server programs with a formal interface definition. See also Internet Inter-ORB Protocol.

Common Secure Interoperability Version 2
: An authentication protocol developed by the Object Management Group (OMG) that supports interoperability, authentication delegation and privileges.

communications enabled application
: A software application that uses an IP network and communications technology to accomplish business objectives. Enterprise applications can be communications enabled with web telephony components and collaborative web services that allow users to dynamically interact through shared browser sessions over a secure network.

community manager
: See internal partner.

community operator
: The service provider who has a restricted set of typical day-to-day administrative responsibilities for the hub.

compensation
: The means by which operations in a process that have successfully completed can be undone if an error occurs, to return the system to a consistent state.

compensation flow
: Flow that defines the set of activities that are performed while the transaction is being rolled back to compensate for activities that were performed during the normal flow of the process. A compensation flow can also be called from a compensate end or intermediate event.

compensation service
: The operation that is performed to compensate for a successful operation when a process generates a fault (which is not handled within the process).

compilation unit
: A portion of a computer program sufficiently complete to be compiled correctly.

compiled map component
: An Integration Flow Designer object that references an executable map in compiled file format.

compile time
: The time period during which a computer program is being compiled into an executable program.

complete lifecycle server
: A server that the user can create and manage within the administrative console.

complete type name
: The name of a type that represents its hierarchical structure within a type tree, which includes the names of all the types in the path from the root type down.

complex change
: A single operation that impacts one or more ontologies and spans multiple repository versions. Examples of a complex change are ontology content pack (OCP) imports and ontology deletions.

complex scorecard
: A collection of multiple scorecards within one rule flow. The rule flow is used to identify the dependency, the flow and the order in which the score from each of the scorecards will be included in the overall score.

complex type
: A type that contains elements and can include attributes. See also simple type.

component
: 1. A reusable object or program that performs a specific function and works with other components and applications.
2. In Eclipse, one or more plug-ins that work together to deliver a discrete set of functions.

component element
: An entity in a component where a breakpoint can be set, such as an activity or Java snippet in a business process, or a mediation primitive or node in a mediation flow.

component instance
: A running component that can be running in parallel with other instances of the same component.

component rule
: An expression about one or more components, which is defined in the Type Designer. A component rule is used for validating data and specifies what must be true for the data that is defined by that component to be valid.

component test
: An automated test of one or more components of an enterprise application, which may include Java classes, EJB beans, or web services. See also abstract test, test pattern.

composer
: In Java, a class used to map a single complex bean field to multiple database columns. Composition is needed for complex fields that are themselves objects with fields and behavior.

composite
: 1. A group of related data elements used in EDI transactions.
2. A Service Component Architecture (SCA) element that contains components, services, references, and wires that connect them.

composite business policy
: A runtime aggregation of business policies based on context, content and contract of a service request.

composite business service (CBS)
: A collection of business services that work together, along with the existing applications of a client, to provide a specific business solution.

composite service
: In service-oriented architecture, a unit of work accomplished by an interaction between computing devices.

composite state
: In a business state machine, an aggregate of one or more states that is used to decompose a complex state machine diagram into a simple hierarchy of state machines.

compositional hierarchy
: A hierarchy in which the composition of the data is reflected in the structure of the group type in the group window. See also classification hierarchy.

composition unit
: A unit that represents a configured asset and enables the asset contents to interact with other assets in the application.

compound activity
: An activity that has detail that is defined as a flow of other activities. A compound activity is a branch (or trunk) in the tree-structure hierarchy of process activities. Graphically, a compound activity is a process or subprocess.

compound element
: An item in the source or target document that contains child items, such as EDI Segments and EDI composite data elements, ROD records and ROD structures in record oriented data, and XML elements.

concept
: A class of entities that are represented by general metadata definitions rather than physical document standards.

concrete portlet
: A logical representation of a portlet object distinguished by a unique configuration parameter (PortletSettings).

concrete type
: A type that can be instantiated and is derived from an abstract type.

concurrency control
: The management of contention for data resources.

Concurrent Versions System (CVS)
: An open-source, network-transparent version control system.

condition
: 1. A test of a situation or state that must be in place for a specific action to occur.
  2. In a business state machine, an expression that guards the transition and allows transition to the next state only when and if the incoming operation evaluates to 'True'. Otherwise, the current state is maintained.

conditional mean
: An alternative method for choosing a reason code assignment. It is a reasoning strategy that the user specifies in the scorecard requirements, which evaluates every attribute’s possible value ranges. The reason codes are determined based on the expected value of the attributes and rank order. Typically, the four lowest expected and their corresponding reason codes are chosen. A conditional mean can be used in neural nets and fused scorecards.

condition column
: The condition part of a decision table.

condition node
: A node in a decision tree that defines a rule condition and groups a set of branches.

configuration
: In a broker domain, the brokers, execution groups, deployed message sets, and deployed message flows, and the defined topics and access control lists.

configuration administration
: The administration of the configuration object types (CTs), configuration objects (COs), and configuration object sets (COSs) that comprise the configuration data of organizational units (OUs). This is carried out after the product has been installed and customized.

configuration database
: The Data Interchange Services client database that stores parameters necessary for running Data Interchange Services client, including database definitions, messages, queries, and preferences.

configuration entity
: Entities used to model an organization and to specify how messages are processed. These entities include configuration object types (CTs), organizational units (OUs), configuration object sets (COSs), configuration objects (COs).

configuration object (CO)
: An instance of a configuration object type (CT) that represents an object in an organizational unit (OU). Which attributes can be added to a CO is determined by the definition of the CT on which the CO is based.

configuration object set (COS)
: A set of configuration objects, used to limit the scope of configuration data provided to message flows.

configuration object type (CT)
: A description of the class of configuration objects, including the attributes that each member of this class can have.

configuration repository
: A storage area of configuration data that is typically located in a subdirectory of the product installation root directory.

configured name binding
: Persistent storage of an object in the name space that is created using either the administrative console or the wsadmin program.

confirm-on-arrival report (COA report)
: A WebSphere MQ report message type created when a message is placed on that queue. It is created by the queue manager that owns the destination queue.

confirm-on-delivery report (COD report)
: A WebSphere MQ report message type created when an application retrieves a message from the queue in a way that causes the message to be deleted from the queue. It is created by the queue manager.

conflict
: A result that occurs when two simultaneous edit submissions are processed for the same object and where the intended outcome of the edit is unclear.

connection
: A link between two process elements. Connections can be used to specify the chronological sequence of activities in a process.

connection factory

A set of configuration values that produces connections that enable a Java EE component to access a resource. Connection factories provide on-demand connections from an application to an enterprise information system (EIS) and allow an application server to enroll the EIS in a distributed transaction.

connection handle
A representation of a connection to a server resource.

connection pool
A group of host connections that are maintained in an initialized state, ready to be used without having to create and initialize them.

connection pooling
A technique used for establishing a pool of resource connections that applications can share on an application server.

connectivity
The capability of a system or device to be attached to other systems or devices without modification.

connector

1. In Java EE, a standard extension mechanism for containers to provide connectivity to enterprise information systems (EISs). A connector consists of a resource adapter and application development tools (Sun). See also container.
2. A servlet that provides a portlet access to external sources of content, for example, a news feed from a website of a local television station.

connector packet
The set of data that is passed between the event processing server (runtime server) and external systems using the technology connectors.

consistent-change-data table (CCD table)
In data replication, a type of replication target table that is used for storing history, auditing data, or staging data. A CCD table can also be a replication source.

console
A user interface that allows you to list and manage objects or entities, such as catalogs, hierarchies, and items. See also module.

constant
In a business object model (BOM), a vocabulary element that verbalizes the public static final attribute of a class with the same type as the BOM class. See also verbalization.

constraint
A rule that limits the values that can be inserted, deleted, or updated in a table. See also foreign key, primary key.

consumer portal
A portal that uses the portlets that a producer portal provides. See also producer definition, producer portal.

container

1. An item that can contain other items. Tags that are added to a container inherit the position of the container.
2. An entity that provides life-cycle management, security, deployment, and runtime services to components. (Sun) See also connector, resource adapter.

container-managed persistence (CMP)
The mechanism whereby data transfer between an entity bean's variables and a resource manager is managed by the entity bean's container. (Sun) See also bean-managed persistence.

container-managed transaction
A transaction whose boundaries are defined by an EJB container. An entity bean must use container-managed transactions. (Sun)

container server
A server instance that can host multiple shards. One Java virtual machine (JVM) can host multiple container servers.

container transaction
See container-managed transaction.

containment hierarchy
A namespace hierarchy consisting of model elements, and the containment relationships that exist between them. A containment hierarchy forms an acyclic graph.

containment relationship
A relationship between two objects where one object is contained within the other. The destination is nested within the source.

content
The data semantics of a message that is received by the dynamic assembler.

content area
In a web page that is based on a page template, the editable region of the page.

content assist
A feature of some source editors that prompts the user with a list of valid alternatives for completing the current line of code or input field.

content based routing (CBR)
An optional feature of the caching proxy that provides intelligent routing to back-end application servers. This routing is based on HTTP session affinity and a weighted round-robin algorithm.

contention
A situation in which a transaction attempts to lock a row or table that is already locked.

content management
Software designed to help businesses manage and distribute content from diverse sources.

content model
The representation of any data that may be contained inside an XML element. There are four kinds of content models: element content, mixed content, EMPTY content and ANY content.

content provider
A source for content that can be incorporated into a portal page as a portlet.

content spot
A class file that is added to a JSP file to designate display of personalized data or content. Each content spot has a name and will accept a specific type of data from a rule.

context
An object created for a service request in the business service model. The object contains one or more of the following details of information captured from the metadata: a business process, organization, role, channel, and domain specific information. See also context propagation.

context propagation

In a multiple service transaction, the information about the details of a service request that passes from one invocation to another via the message header. See also context.

context root
: The web application root, which is the top-level directory of an application when it is deployed to a web server.

context-scoped business object
: A summary object or accumulating array object that is used to share data from events across events in a context.

contract
: The set of business policy assertions that have to be met by service provider at run time based on the context and content.

contracted component
: In the Integration Flow Designer, a component that does not display the sources and targets associated with it. See also expanded component.

contribution
: The primary asset that can contain Service Component Definition Language (SCDL) with composite definitions, as well as artifacts such as Java classes and Web Services Description Language (WSDL) and XML Schema Definitions (XSD).

control
: See widget.

control analysis
: A type of analysis that displays variations in values of the business measures over a specific period of time. This type of analysis reduces data variation, and is often used for quality control. Allowable variation is three times the standard deviation of the data.

controlled flow
: A flow that proceeds from one flow object to another through a sequence flow link but is subject to either conditions or dependencies from another flow as defined by a gateway. Typically, a controlled flow is a sequence flow between two activities, with a conditional indicator or a sequence flow that is connected to a gateway.

controller
: A component or a set of virtual storage processes that schedules or manages shared resources.

control link
: An object in a process that links nodes and determines the order in which they run.

control number
: A number that is used to identify an interchange, group, or EDI document.

control region adjunct
: A servant that interfaces with service integration buses to provide messaging services.

control string
: One of several compiled objects, which consist primarily of map control strings and document definition control strings.

control structure
: The beginning and ending segments (header and trailer) of EDI-enveloped documents.

conversational processing
: An optional IMS facility with which an application program can accumulate information acquired through multiple interchanges with a terminal, even if the program stops between interchanges. See also IMS conversation.

converter
: In Enterprise JavaBeans (EJB) programming, a class that translates a database representation to an object type and back.

cooperative portlets
: Two or more portlets on the same web page that interact by sharing information. See also Click-to-Action, wire.

Coordinated Universal Time (UTC)
: The international standard of time that is kept by atomic clocks around the world.

copy helper
: An access bean that contains a local copy of attributes from a remote entity bean. Unlike bean wrappers, copy helpers are optimized for use with a single instance of an entity bean.

CORBA
: See Common Object Request Broker Architecture.

core group
: A group of processes that is directly accessible to each other and is connected using a local area network (LAN).

core group access point
: A definition of a set of servers that provides access to the core group.

core group bridge
: The means by which core groups communicate.

core group member
: A server included in the cluster of a core group.

correlation
: 1. Data that enables a user to record document-specific correlation parameters generated during translation, by the correlation service, or by document tracking functions.
  2. A mechanism that bridges a point in a process flow between two or more process instances.
  3. The relationship, captured in a correlation expression, that describes how an incoming event is matched with one or more monitoring context instances to which it will be delivered.
  4. A record used with business processes and state machines to allow two partners to initialize a transaction, temporarily suspend an activity, and then recognize each other again when that activity resumes.

correlation property
: Data in an event that the runtime server uses to determine which instance of a task, process, or business state machine should receive the input at run time.

correspondent
: An institution to which your institution sends and from which it receives messages.

COS
: See configuration object set.

cost
: A number that is used as a weighting mechanism to differentiate one resource from another where a smaller value is always preferred.

counter

A specialized metric used to keep track of the number of occurrences of a specific situation or event. For example, you can use a counter to track the number of times that a task is started within a process, where that task is contained in a loop.

coupling
: The dependency that components have on one another.

create method
: In enterprise beans, a method defined in the home interface and invoked by a client to create an enterprise bean. (Sun)

credential
: 1. In the Java Authentication and Authorization Service (JAAS) framework, a subject class that owns security-related attributes. These attributes can contain information used to authenticate the subject to new services.
  2. Information acquired during authentication that describes a user, group associations, or other security-related identity attributes, and that is used to perform services such as authorization, auditing, or delegation. For example, a user ID and password are credentials that allow access to network and system resources.

critical path
: The processing path that takes the longest time to complete of all parallel paths in a process instance, where each path considered begins at a start node or an input to the process and ends at a terminate node.

CRL
: See certificate revocation list.

cross-cell communication
: The process of information sharing and request routing between cells.

cross-cell environment
: A production environment in which one or more servers in one cell can receive events from another server or set of servers in another cell.

cross-cutting concern
: A software concern (synchronization, logging, memory allocation, and so forth) that is external and orthogonal to the problem that a software component is designed to address.

cryptographic token
: A logical view of a hardware device that performs cryptographic functions and stores cryptographic keys, certificates, and user data.

CSR
: See certificate signing request.

CSS
: See Cascading Style Sheets.

CSV file
: A text file that contains comma-separated values. A CSV file is commonly used to exchange files between database systems and applications that use different formats.

CT
: See configuration object type.

cube
: A multidimensional representation of data needed for online analytical processing, multidimensional reporting, or multidimensional planning applications.

current customization definition
: A customization definition that describes an instance for which the corresponding resources have already been deployed and are running.

custom action
: 1. In JSP programming, an action described in a portable manner by a tag library descriptor and a collection of Java classes and imported into a JSP page by a taglib directive. (Sun)
  2. A Java or non-Java process definition that a user can define as a part of a health policy action plan or elasticity operation.

Custom-built Product Delivery Option (CBPDO)
: A software delivery package consisting of uninstalled products and unintegrated service. Installation requires the use of SMP/E. CBPDO is one of the two entitled methods for installing z/OS; the other method is ServerPac.

custom finder
: See finder method.

customization definition document (CDD)
: An XML document that describes the layout of an instance (that is, its organizational units (OUs) and servers, and which service bundles are assigned to each server-OU combination). The Customization Definition Program (CDP) uses a CDD to determine which deployment data to produce for an instance.

customization definition report
: A report that describes the servers, organizational units (OUs), and services of an instance, and how they are distributed within the instance.

customization time data
: See build time data.

customized installation package (CIP)
: A customized installation image that can include one or more maintenance packages, a configuration archive file from a stand-alone server profile, one or more enterprise archive files, scripts, and other files that help customize the resulting installation.

customizer
: A Java class (implementing the java.beans.Customizer interface) that is associated with a bean to provide a richer user interface for the properties of that bean.

custom profile
: A profile that describes an empty node, which becomes operational, as a managed node, when federated into a network deployment cell.

custom relationship
: An association between two or more data entities as provided by the user.

custom screen record
: A runtime view of the screen that allows access to available screen fields.

custom service
: A configurable service that defines a hook that runs when the server starts and shuts down when the server stops.

custom tag
: An extension to the JavaServer Pages (JSP) language that performs a specialized task. Custom tags are typically distributed in the form of a tag library, which also contains the Java classes that implement the tags.

custom user registry
: A customer-implemented user registry that implements the UserRegistry Java interface. This registry type can support virtually any kind of accounts repository from a relational database and can provide flexibility in adapting product security to various environments.

CVS
: See Concurrent Versions System.

cycle time
: The time required for a process instance in a process simulation run to finish processing its inputs. Cycle time includes idle time when an activity in the process is waiting for a resource to become available.

D

DAD
: See document access definition.

DAD script
: A file that is used by the DB2 XML Extender, either to compose XML documents from existing DB2 data or to decompose XML documents into DB2 data.

DADX
: See document access definition extension.

DADX group
: A folder that contains database connection (JDBC and JNDI) and other information that is shared between DADX files within the group.

DADX runtime environment
: The DADX runtime environment provides information to the DADX web service, including the HTTP GET and POST bindings, the test page, WSDL generation, and the translation of DTD data into XML schema data.

daemon
: A program that runs unattended to perform continuous or periodic functions, such as network control.

dashboard
: A web page that can contain one or more widgets that graphically represent business data.

data access bean
: A class library that provides a rich set of features and functions, while hiding the complexity associated with accessing relational databases.

database cleanup
: The act of deleting from a database those records for which the cleanup period has expired.

database definition
: A Data Interchange Services definition that contains information used by Data Interchange Services Client to connect to a database.

database management system (DBMS)
: See database manager.

database manager
: A program that manages data by providing centralized control, data independence, and complex physical structures for efficient access, integrity, recovery, concurrency control, privacy, and security.

database request module (DBRM)
: A data set member that is created by the DB2 for z/OS precompiler and that contains information about SQL statements. DBRMs are used in the bind process.

data binding
: A component that converts protocol-specific local data to and from a business object.

data catalog
: A collection of models representing objects, such as business items and notifications, to be used as inputs and outputs in process modeling.

data class
: An access bean that provides data storage and access methods for caching enterprise bean properties. Unlike copy helpers, data class access beans work with enterprise beans that have local client views as well as remote client views.

data connection
: A connection to a repository of data (for example, a DB2 database) with which the runtime server can retrieve data in order to enhance the event being processed.

data definition
: A data object that defines a database or table.

Data Definition Language (DDL)
: A language for describing data and its relationships in a database.

data dictionary
: A grouping of logically related components of a particular syntax type, such as ROD dictionaries, EDI dictionaries, and XML dictionaries.

data element delimiter
: A character, such as an asterisk (*), that follows the EDI segment identifier and separates each EDI data element in an EDI segment. See also segment ID separator.

Data Encryption Standard (DES)
: A cryptographic algorithm designed to encrypt and decrypt data using a private key.

Data Exchange SPI architecture (DESPI)
: The interface that resource adapters and runtime components use to exchange business object data. The Data Exchange SPI architecture, which is based on the concept of cursors and accessors, abstracts the data type so that an adapter can be written only once and then work on runtime environments that support different data types, such as data objects and JavaBeans.

datagram
: A form of asynchronous messaging in which an application sends a message, but does not require a response. See also request/reply.

data graph
: A set of Service Data Objects (SDO) interconnected with relationships.

data grid
: A system of data that dynamically caches, partitions, replicates, and manages application data and business logic across multiple servers.

data handler
: A Java class or library of classes that a process uses to transform data into and from specific formats. In the business integration environment, data handlers transform text data of specified formats into business objects, and transform business objects into text data of specified formats.

Data Interchange Services client (DIS client)

The Data Interchange Services tool used to document metadata and map documents to one another.

Data Interchange Services database
: The database that contains all Data Interchange Services objects.

Data Interchange Services translator
: The Data Interchange Services component responsible for transforming a document from one format to another.

data model
: A model defining the structure of business artifacts that are operated upon by business operations.

data object

1. A portion of data in a data stream that can be recognized as belonging to a specific type.
2. An object that provides information about required activities. Data objects can represent one object or a collection of objects.
3. Any object (such as tables, views, indexes, functions, triggers, and packages) that can be created or manipulated using SQL statements. See also business object.

data object filter
: A control that allows the exclusion of data objects (such as tables and schemas) from the tree view of the database.

data source

1. The means by which an application accesses data from a database.
2. In JDBC, an interface that provides a logical representation of a pool of connections to a physical data source. Data source objects provide application portability by making it unnecessary to supply information specific to a particular database driver.

data store

1. A data structure where documents are kept in their parsed form.
2. A place (such as a database system, file, or directory) where data is stored.

data store profile
: An object that defines properties used by the default data store plug-in, which is used to persistently store events received by the event server.

data structure
: The composition of the data, including repeating sub-structures, nested groupings, sequences, and choices.

Data Transformation Framework (DTF)
: An infrastructure that includes data bindings and function selectors, which enables an adapter to convert native data formats to business objects and to convert business objects back to native data formats, such as XML.

data transformation map
: A set of mapping instructions that describes how to translate data from a source document into a target document. Both the source and target documents can be one of several supported document types. A data transformation map is one of three supported map types.

Data Universal Numbering System (DUNS)
: A system in which internationally recognized nine-digit numbers are assigned and maintained by Dun & Bradstreet to uniquely identify worldwide businesses. See also partner profile.

DB2
: A family of IBM licensed programs for relational database management.

DB2 XML Extender
: A program that is used to store and manage XML documents in DB2 tables. Well-formed and validated XML documents can be generated from existing relational data, stored as column data, and the content of XML elements and attributes can be stored in DB2 tables.

DBMS
: See database management system.

DBRM
: See database request module.

DDL
: See Data Definition Language.

dead-letter queue (DLQ)
: A queue to which a queue manager or application sends messages that cannot be delivered to their correct destination.

deadlock
: A condition in which two independent threads of control are blocked, each waiting for the other to take some action. Deadlock often arises from adding synchronization mechanisms to avoid race conditions.

debug engine
: The server component of the debugger, whose client/server design enables both local and remote debugging. The debug engine runs on the same system as the program being debugged.

debugger
: A tool used to detect and trace errors in computer programs.

debugging session
: The debugging activities that occur between the time that a developer starts a debugger and the time that the developer exits from it.

decimal notation
: In an EDI Standard, the character that represents a decimal point.

decision

1. A gateway within a business process where the sequence flow can take one of several alternative paths.
2. A gateway that routes an input to one of several alternative outgoing paths, depending on its condition. A decision is like a question that determines the exact set of activities during the execution of a process. Questions might include: What type of order? Or How will the order be shipped?

Decision Center console
: A designated workspace where business users can work collaboratively to author, edit, organize, and search for business rules.

decision table
: A form of business rule that captures multi-conditional decision-making business logic in a table where the rows and columns intersect to determine the appropriate action. See also rule set.

decision tree

A way of representing business rules in a tree form. Decision trees provide a structure for laying out options and investigating the possible outcomes of choosing those options.

Decision Validation Services (DVS)
A set of testing and simulation capabilities with which business users and policy managers can verify the rules they have written, and determine if potential changes will have the intended outcome.

Decision Warehouse
A warehouse that saves execution traces to a database so that users can query the data store to get information on particular executions or transactions.

deck
An XML document that contains a collection of Wireless Markup Language (WML) cards. See also card.

declaration
In Java programming, a statement that establishes an identifier and associates attributes with it, without necessarily reserving its storage or providing the implementation. (Sun)

declarative security
The security configuration of an application during assembly stage that is defined in the deployment descriptors and enforced by the security run time.

decode
To convert data by reversing the effect of some previous encoding.

decoration
In graphical user interfaces (GUIs), a glyph that annotates a resource with status information, for example to indicate that a file has changed since it was last saved or checked out of a repository.

de-envelope
To extract a document from an EDI envelope.

de-enveloping
The process of removing one or more envelopes from a document or a set of documents.

default portal page
The page that displays to a user at initial portal deployment and before the user completes enrollment. Sometimes used as a synonym for home page.

default public place
A place whose membership automatically includes all users and which appears in the Places selector for every user. A user is always a member of this place.

definition file
A file that defines the content that is displayed within the navigation and work area frames.

delegation
The process of propagating a security identity from a caller to a called object. According to the Java Platform, Enterprise Edition (Java EE) specification, a servlet and an enterprise bean can propagate either the client identity when invoking enterprise beans, or can use another specified identity as indicated in the corresponding deployment descriptor.

delimited format
Data that has data objects that are separated by delimiters.

delimited text
A simple file format that consists of text separated into meaningful chunks by specific characters. The chunks of text are typically individual fields. The specific character is called a delimiter, and can be any character that is not found in the text. Comma and tab are common delimiters. If the delimiter is used as a character in the text, it must be enclosed by a pair of text qualifiers, usually double quotation marks.

delimiter

1. A flag that is formed by a character or a sequence of characters to group or separate items of data by marking the beginning and end of a unit of data. The delimiter is not a part of the flagged unit of data.
2. A character, such as comma or tab, used to group or separate units of text by marking the boundary between them.

delta business object
A business object used in an update operation. Such a business object contains only key values and the values to be changed. See also after-image.

delta deployment
Deployment of only that data that is required to transform a current runtime environment into a target runtime environment. See also full deployment.

demilitarized zone (DMZ)
A configuration that includes multiple firewalls to add layers of protection between a corporate intranet and a public network, such as the Internet.

denial-of-service attack (DoS)
In computer security, an assault on a network that brings down one or more hosts on a network such that the host is unable to perform its functions properly. Network service is interrupted for some period.

dependency

1. A requirement that one managed resource has on another managed resource in order to operate correctly.
2. A relationship that allows a module to use artifacts from a library or that allows a process application to use artifacts from a toolkit. A toolkit can also have a dependency on another toolkit.

dependency relationship
In UML modeling, a relationship in which changes to one model element (the supplier) impact another model element (the client).

deploy
To place files or install software into an operational environment. In Java Platform, Enterprise Edition (Java EE), this involves creating a deployment descriptor suitable to the type of application that is being deployed.

deployment
The process of transferring rules from a local development environment into an operational, or runtime, environment.

deployment code
Additional code that enables bean implementation code written by an application developer to work in a particular EJB runtime environment. Deployment code can be generated by tools that the application server vendor supplies.

deployment data
The resource files, generated during customization, that are used to create the resources for an instance.

deployment data set
A data set containing the resource files generated during customization.

deployment descriptor

An XML file that describes how to deploy a module or application by specifying configuration and container options. For example, an EJB deployment descriptor passes information to an EJB container about how to manage and control an enterprise bean.

deployment directory

1. The directory where the published server configuration and web application are located on the machine where the application server is installed.
2. The directory containing the subdirectories and resource files created during customization.

deployment environment
: A collection of configured clusters, servers, and middleware that collaborate to provide an environment to host software modules. For example, a deployment environment might include a host for message destinations, a processor or sorter of business events, and administrative programs.

deployment instruction
: A set of instructions that describe how to execute the resource files, and deploy, on the runtime systems, the resources required by the instance.

deployment manager
: A server that manages and configures operations for a logical group or cell of other servers. See also subprocess.

deployment phase
: A phase that includes a combination of creating the hosting environment for your applications and the deployment of those applications. This includes resolving the application's resource dependencies, operational conditions, capacity requirements, and integrity and access constraints.

deployment policy

1. An optional way to configure an eXtreme Scale environment based on various items, including: number of systems, servers, partitions, replicas (including type of replica), and heap sizes for each server.
2. A policy that modifies the domain configuration at deployment time to accommodate the environment in which the appliance operates.

deployment topology
: The configuration of servers and clusters in a deployment environment and the physical and logical relationships among them.

deployment vehicle
: A job or other executable file that is used to deploy resources. Each vehicle corresponds to a particular resource file.

deploy phase
: See deployment phase.

deprecated
: Pertaining to an entity, such as a programming element or feature, that is supported but no longer recommended and that might become obsolete.

dequeue
: To remove items from a queue. See also enqueue.

DER
: See Distinguished Encoding Rules.

Derby
: An embeddable, all Java, object-relational database management system (ORDBMS).

derivation
: In object-oriented programming, the refinement or extension of one class from another.

derived event
: See synthetic event.

derived page
: One or more child pages that have a shared layout that is inherited from the properties of the parent page.

DES
: See Data Encryption Standard.

deserialization
: A method for converting a serialized variable into object data. See also serializer.

DESPI
: See Data Exchange SPI architecture.

destination
: An exit point that is used to deliver documents to a back-end system or a trading partner.

developer
: A decision management user role that is responsible for implementing the rule applications.

device
: A component that is used for an event provider to provide location, notification, or telemetry data. Devices always belong to a hub and can be grouped in device groups.

device input format (DIF)
: The Message Format Service (MFS) control block that describes the format of the data that is entered on the device and presented to MFS.

device output format (DOF)
: The Message Format Service (MFS) control block that describes the format of the output data that is presented to the device.

dialog
: The recorded interaction between a user and the 3270 application that the user accesses. Users can record a dialog using the Record Dialog function in the 3270 terminal service recorder. A recorded dialog includes the keystrokes, inputs and outputs that move the user from one screen to another in the 3270 application.

dialog editor
: A 3270 terminal service development tool that enables a developer to modify the dialog that was recorded with the 3270 terminal service recorder.

dialog file
: The result of recording a dialog from the 3270 terminal service recorder. The dialog file is saved to a WSDL file in the workbench.

dictionary
: A grouping of logically related components of a particular syntax type, such as ROD dictionaries, EDI dictionaries, and XML dictionaries.

DIF
: See device input format.

digest code
: A number that is the result of a message digest function or a secure hash algorithm distilling a document.

digital certificate

An electronic document used to identify an individual, a system, a server, a company, or some other entity, and to associate a public key with the entity. A digital certificate is issued by a certification authority and is digitally signed by that authority.

digital signature
Information that is encrypted with a private key and is appended to a message or object to assure the recipient of the authenticity and integrity of the message or object. The digital signature proves that the message or object was signed by the entity that owns, or has access to, the private key or shared-secret symmetric key.

digital signature algorithm (DSA)
A security protocol that uses a pair of keys (one public and one private) and a one-way encryption algorithm to provide a robust way of authenticating users and systems. If a public key can successfully decrypt a digital signature, a user can be sure that the signature was encrypted using the private key.

dimension
A data category that is used to organize and select monitoring context instances for reporting and analysis. Examples of dimensions are time, accounts, products, and markets. See also member.

dimensional model
The part of the monitor model that defines the cubes and cube content that are used for storing, retrieving, and analyzing the data that is gathered over time.

dimension level
An element or subelement of a dimension that is arranged hierarchically. For example, the time dimension can have years, months, and days as its levels.

directive
A first-failure data capture (FFDC) construct that provides information and suggested actions to assist a diagnostic module in customizing the logged data.

dirty read
A read request that does not involve any locking mechanism. This means that data can be read that might later be rolled back resulting in an inconsistency between what was read and what is in the database.

DIS client
See Data Interchange Services client.

discover
In UDDI, to browse the business registry to locate existing web services for integration.

discovered server
A server that runs the middleware agent and is found outside of the administrative environment but has a server representation automatically created within the administrative environment. The representation that is created is an assisted life-cycle server.

dispatcher
A standalone application that acts as an intermediary between one or more devices and large event providers. The dispatcher retrieves all location messages from the event providers it is connected to and distributes them to one or more devices.

distinguishable types
Types that do not have common data objects.

Distinguished Encoding Rules (DER)
A standard, based on the Basic Encoding Rules, that is designed to ensure a unique encoding of each ASN.1 value, defined in ITU-T X.690.

distinguished name (DN)

1. A set of name-value pairs (such as CN=person name and C=country or region) that uniquely identifies an entity in a digital certificate.
2. The name that uniquely identifies an entry in a directory. A distinguished name is made up of attribute:value pairs, separated by commas.

distributed application
An application made up of distinct components that are located on different computer systems, connected by a network. See also client/server.

distributed eXtreme Scale
A usage pattern for interacting with eXtreme Scale when servers and clients exist on multiple processes.

DLL
See dynamic link library.

DLQ
See dead-letter queue.

DMZ
See demilitarized zone.

DN
See distinguished name.

DNS
See Domain Name System.

document
A business document, such as a purchase order or invoice, that can be represented in any supported format. For example, an XML purchase order and an EDI purchase order are both documents, but each uses a different format.

document access definition (DAD)
An XML document format used by DB2 XML Extender to define the mapping between XML and relational data.

document access definition extension (DADX)
An XML document format that specifies how to create a web service using a set of operations that are defined by DAD documents and SQL statements.

document definition
A description of a document layout that is used to identify the format of a document. Examples include record oriented data document definitions, EDI document definitions, XML schema document definitions, and XML DTD document definitions.

document envelope
A structure that is applied to a document to prepare it for exchange between trading partners.

document flow definition
A collection of information specified for each type of document that tells the hub how to process that particular type of document. Each document to be exchanged between the internal partner and a participant must have a document flow definition.

document ID
A unique identifier for a document.

document literal wrapped
A convention or style that is used to structure a web service definition to generate a SOAP message that is WS-I compliant and can be easily validated.

Document Object Model (DOM)

A system in which a structured document, for example an XML file, is viewed as a tree of objects that can be programmatically accessed and updated. See also Simple API for XML.

document type
A classification that helps to organize and classify documents that belong to a specific case. Properties can be assigned to a document type to provide additional information about the documents. An example of a document type is a job application form. See also case property.

document type definition (DTD)
The rules that specify the structure for a particular class of SGML or XML documents. The DTD defines the structure with elements, attributes, and notations, and it establishes constraints for how each element, attribute, and notation can be used within the particular class of documents.

DOF
See device output format.

DOM
See Document Object Model.

domain
1. A logical grouping of resources in a network for the purpose of common management and administration. See also federation domain.
2. An object, icon, or container that contains other objects representing the resources of a domain. The domain object can be used to manage those resources.

Domain Name System (DNS)
The distributed database system that maps domain names to IP addresses.

DOM element
One member of a tree of elements that is created when an XML file is parsed with a DOM parser. DOM elements make it easy to quickly identify all elements in the source XML file.

DoS
See denial-of-service attack.

do-while loop
A loop that repeats the same sequence of activities as long as some condition is satisfied. Unlike a while loop, a do-while loop tests its condition at the end of the loop. This means that its sequence of activities always runs at least once.

downstream
Pertaining to the direction of the flow, which is from the first node in the process (upstream) toward the last node in the process (downstream).

DSA
See digital signature algorithm.

DSO
See dynamic shared object.

DTD
See document type definition.

DTD document definition
A description or layout of an XML document based on an XML DTD.

DTF
See Data Transformation Framework.

dual authorization
A setting requiring that an action carried out by one person be confirmed by a second person. This prevents a single person from being able to carry out actions requiring a high level of security, for example the distribution of funds or the granting of access rights. See also single authorization.

DUNS
See Data Universal Numbering System.

durable subscription
A Java Message Service (JMS) subscription that persists and stores subscribed messages even when the client is not connected.

DVS
See Decision Validation Services.

dynaform
An instance of a DynaActionForm class or subclass that stores HTML form data from a submitted client request or that stores input data from a link that a user clicked.

dynamic analysis
The process of extracting targeted types of information based on the results of process simulations. This differs from static analysis, which extracts information from model elements in their static form.

dynamic assembly
A process that selects specific endpoints to meet the conditions of a service request at run time.

dynamic cache
A consolidation of several caching activities, including servlets, web services, and commands into one service where these activities share configuration parameters and work together to improve performance.

dynamic cluster
A server cluster that uses weights to balance the workloads of its cluster members dynamically, based on performance information collected from cluster members.

dynamic cluster isolation
The ability to specify whether the dynamic cluster runs on the same nodes as other instances of dynamic clusters, or if the dynamic cluster is the only dynamic cluster that runs on a single node.

dynamic domain
A domain in which the set of possible values for a type is defined. With a dynamic domain, the set of values is stored and managed outside the business object model (BOM), and changes to the set of values are automatically reflected in the business object model. When rule authors write business rules using the type, they choose from a list of values that is created dynamically and is always up-to-date.

dynamic link library (DLL)
A file containing executable code and data bound to a program at load time or run time, rather than during linking. The code and data in a DLL can be shared by several applications simultaneously. See also library.

dynamic operations
Operations that monitor the server environment and make recommendations that are based on the observed data.

dynamic policy

A template of permissions for a particular type of resource.

dynamic property
: A property that can be overridden at run time by inserting information into the service message object (SMO).

dynamic reloading
: The ability to change an existing component without restarting the server for the changes to become effective. See also hot deployment.

dynamic routing
: The automatic routing of a service request, a message, or an event that is based on conditions at the time of the routing.

dynamic shared object (DSO)
: A mechanism that provides a way to build a piece of program code in a special format for loading into the address space of an executable program at run time. The DSO gets knowledge of the executable program symbol set as if it had been statically linked with it in the first place.

dynamic web content
: Programming elements such as JavaServer Pages (JSP) files, servlets, and scripts that require client or server-side processing for accurate runtime rendering in a web browser.

dynamic web project
: A project that contains resources for a web application with dynamic content such as servlets or JavaServer Pages (JSP) files. The structure of a dynamic web project reflects the Java EE standard for web content, classes, class paths, the deployment descriptor, and so on.

dynamic workload manager
: A feature of the on demand router that routes workload based on a weight system, which establishes a prioritized routing system. The dynamic workload manager dynamically modifies the weights to stay current with the business goals.

E

EAR
: See enterprise archive.

EAR file
: See enterprise archive.

early bind
: To connect one process to another process so that a specific version of the called process is used. The calling process always uses the specified version of the invoked process even if updated versions are available.

early binding
: The connection between two processes that uses a specified version of the invoked process. As a result, the calling process uses the specified version of the process that it is invoking, even when updated versions are available.

EAR project
: See enterprise application project.

Eclipse
: An open-source initiative that provides independent software vendors (ISVs) and other tool developers with a standard platform for developing plug-compatible application development tools.

ECSA
: See extended common service area.

Edge Side Include (ESI)
: A technology supporting cacheable and noncacheable web page components that can be gathered and assembled at the edge of a network.

EDI
: See electronic data interchange.

EDI administrator
: The person responsible for setting up and maintaining Data Interchange Services.

EDI composite data element
: A group of related EDI data elements, such as the elements that make up a name and address.

EDI data element
: A single item of data in an EDI document, such as a purchase order number, that corresponds to a ROD field in a ROD document definition. An EDI data element is equivalent to a simple element. It is also used to maintain EDI composite data elements.

EDI document definition
: A description or layout of an EDI document, which comprises loops, EDI segments, EDI data elements, and EDI composite data elements. It is equivalent to the layout of an EDI transaction or an EDI message.

EDI envelope
: The EDI segments and EDI data elements that make up the headers and trailers that enclose EDI transaction sets, functional groups, and interchanges.

EDI loop
: A group of consecutive EDI segments that repeat together in an EDI document definition. There is no object type in Data Interchange Services that defines an EDI loop on its own. EDI loops are logically defined within an EDI document definition.

EDI message
: In UN/EDIFACT EDI Standards, a group of logically related data that makes up an electronic business document, such as an invoice. It is equivalent to an EDI transaction. Called an EDI document definition in Data Interchange Services.

EDI message set
: A group of logically related data that make up an electronic business document, such as an invoice or a purchase order. A single EDI document. The layout of an EDI transaction is described by an EDI document definition in Data Interchange Services.

EDI segment
: A group of related EDI data elements. An EDI segment is a single line in an EDI document definition, beginning with a segment identifier and ending with a segment terminator delimiter. The EDI data elements in the EDI segment are separated by data element delimiters.

EDI standard
: The industry-supplied, national or international formats to which information is converted, allowing different computer systems and applications to exchange information.

edit conflict
: The result of a user applying changes and the system detecting that another user has made intervening and potentially conflicting changes.

edition
: A successive deployment generation of a particular set of versioned artifacts.

edit mode

The state in which users can create or modify a document.

editor area
: In Eclipse and Eclipse-based products, the area in the workbench window where files are opened for editing.

EDI transaction
: In X12 EDI Standards, a group of logically related data that makes up an electronic business document, such as an invoice. It is equivalent to an EDI message. The layout of an EDI transaction is described by an EDI Document Definition in Data Interchange Services.

EDI transaction set
: A group of logically related data that make up an electronic business document, such as an invoice or a purchase order. A single EDI document.

EIS
: See enterprise information system.

EJB
: See Enterprise JavaBeans.

EJB container
: A container that implements the EJB component contract of the Java EE architecture. This contract specifies a runtime environment for enterprise beans that includes security, concurrency, life cycle management, transaction, deployment, and other services. (Sun) See also EJB server.

EJB context
: In enterprise beans, an object that allows an enterprise bean to invoke services provided by the container and to obtain information about the caller of a client-invoked method. (Sun)

EJB factory
: An access bean that simplifies the creating or finding of an enterprise bean instance.

EJB home object
: In Enterprise JavaBeans (EJB) programming, an object that provides the life cycle operations (create, remove, find) for an enterprise bean. (Sun)

EJB inheritance
: A form of inheritance in which an enterprise bean inherits properties, methods, and method-level control descriptor attributes from another enterprise bean that resides in the same group.

EJB JAR file
: A Java archive that contains an EJB module. (Sun)

EJB module
: A software unit that consists of one or more enterprise beans and an EJB deployment descriptor. (Sun)

EJB object
: In enterprise beans, an object whose class implements the enterprise bean remote interface (Sun).

EJB project
: A project that contains the resources needed for EJB applications, including enterprise beans; home, local, and remote interfaces; JSP files; servlets; and deployment descriptors.

EJB query
: In EJB query language, a string that contains an optional SELECT clause specifying the EJB objects to return, a FROM clause that names the bean collections, an optional WHERE clause that contains search predicates over the collections, an optional ORDER BY clause that specifies the ordering of the result collection, and input parameters that correspond to the arguments of the finder method.

EJB reference
: A logical name used by an application to locate the home interface of an enterprise bean in the target operational environment.

EJB server
: Software that provides services to an EJB container. An EJB server may host one or more EJB containers. (Sun) See also EJB container.

elasticity mode
: A mode that is used to dynamically grow or shrink a cell by adding or removing nodes. Nodes are added when a particular dynamic cluster is not meeting service policies and all possible servers are started. Nodes are removed if they are unused and service policies can be met without them.

elasticity operation
: An operation that adds or removes the resources of the application placement controller depending on the defined runtime behavior.

electronic data interchange (EDI)
: The exchange of structured electronic data between computer systems according to predefined message standards.

element
: 1. A component of a document, such as an EDI, XML, or ROD record. An element can be a simple element or a compound element.
  2. In markup languages, a basic unit consisting of a start tag, end tag, associated attributes and their values, and any text that is contained between the two.
  3. In Java development tools, a generic term that can refer to packages, classes, types, interfaces, methods, or fields.

element separator
: See data element delimiter.

embedded server
: A catalog service or container server that resides in an existing process and is started and stopped within the process.

emitter factory
: A type of factory that handles the details of event transmission such as the event server location, the filter settings, or the underlying transmission mechanism.

empty activity
: An activity with no defined implementation that can be used as a place holder in the design stage.

emulator
: A facility of the integration test client that enables the emulation of components and references during module testing. Emulators are either manual or programmatic. See also manual emulator, programmatic emulator.

encode
: To convert data by the use of a code in such a manner that reconversion to the original form is possible.

end event
: An event that ends a process flow and, therefore, does not have outgoing sequence flow paths. Types of end events are message, terminate, and error. See also error end event, message end event, terminate end event.

end node

1. A visual marker within a process that identifies where a particular flow ends. Other concurrent flows within the same process will still continue executing.
2. A node that identifies where a rule flow stops. A rule flow has at least one end node.

endpoint

1. The system that is the origin or destination of a session.
2. A JCA application or other client consumer of an event from the enterprise information system.

endpoint listener
: The point or address at which incoming messages for a web service are received by a service integration bus.

enqueue
: To put a message or item in a queue. See also dequeue.

enrollment

1. An entitlement for an organization to subscribe to a business service.
2. The process of entering and saving user or user group information in a portal.

enterprise application
: See Java EE application.

enterprise application project (EAR project)
: A structure and hierarchy of folders and files that contain a deployment descriptor and IBM extension document as well as files that are common to all Java EE modules that are defined in the deployment descriptor.

enterprise archive (EAR)
: A specialized type of JAR file, defined by the Java EE standard, used to deploy Java EE applications to Java EE application servers. An EAR file contains EJB components, a deployment descriptor, and web archive (WAR) files for individual web applications. See also Java archive, web archive.

enterprise bean
: A component that implements a business task or business entity and resides in an EJB container. Entity beans, session beans, and message-driven beans are all enterprise beans. (Sun) See also bean.

enterprise bundle archive
: A compressed file, with a .eba extension, that contains or refers to one or more OSGi bundles that are deployed as one OSGi application. See also bundle.

Enterprise Information Portal
: Software developed by IBM that provides tools for advanced searching, and content customization and summarization.

enterprise information system (EIS)
: The applications that comprise an enterprise's existing system for handling company-wide information. An enterprise information system offers a well-defined set of services that are exposed as local or remote interfaces or both. (Sun) See also resource adapter.

Enterprise JavaBeans (EJB)
: A component architecture defined by Sun Microsystems for the development and deployment of object-oriented, distributed, enterprise-level applications (Java EE).

enterprise service
: A service that typically accesses one or more enterprise information systems.

enterprise service bus (ESB)
: A flexible connectivity infrastructure for integrating applications and services; it offers a flexible and manageable approach to service-oriented architecture implementation.

entity

1. A simple Java class that represents a row in a database table or entry in a map.
2. In markup languages such as XML, a collection of characters that can be referenced as a unit, for example to incorporate often-repeated text or special characters within a document.

entity bean
: In EJB programming, an enterprise bean that represents persistent data maintained in a database. Each entity bean carries its own identity. (Sun) See also session bean.

entry breakpoint
: A breakpoint set on a component element that is hit before the component element is invoked.

envelope

1. A combination of header, trailer, and control segments that define the start and end of an individual EDI message. Each envelope in EDI data begins with a particular segment and ends with a particular segment.
2. A control structure containing documents.

environment
: A named collection of logical and physical resources used to support the performance of a function.

environment variable

1. A variable that provides values for each type of environment in which a process will run (for example, development, test, and production environments). A user can set environment variables for each process application.
2. A variable that defines an aspect of the operating environment for a process. For example, environment variables can define the home directory, the command search path, the terminal in use, or the current time zone.
3. A variable that specifies how an operating system or another program runs, or the devices that the operating system recognizes.

ephemeral port number
: In some TCP/IP implementations, a temporary port number that is assigned to a process for the duration of a call. Ephemeral port numbers are typically assigned to client processes that must provide servers with a client port number so that the server can respond to the correct process.

EPV
: See exposed process value.

error
: A discrepancy between a computed, observed, or measured value or condition and the true, specified, or theoretically correct value or condition.

error end event
: An end event that also throws an error. See also end event.

error event
: An event that indicates that an error has been caught or thrown.

error intermediate event
: An intermediate event that is triggered by a thrown error.

error log stream
: A continuous flow of error information that is transmitted using a predefined format.

error start event
: A start event that is triggered by a thrown error. An error start event is used only for event subprocesses as an error handling mechanism. See also start event.

ESB
: See enterprise service bus.

ESB server
: An application server that provides the execution environment for mediation modules in addition to application programs.

escalation
: A course of action that runs when a task is not completed satisfactorily within a specific period of time.

ESI
: See Edge Side Include.

ESI processor
: A processor that supports fragment caching and fragment assembly into full pages.

ESM
: See external security manager.

ETL
: See extract, transform, and load.

event
: 1. An occurrence of significance to a task or system. Events can include completion or failure of an operation, a user action, or the change in state of a process. See also alert, message, receiver, resource model, situation.
  2. A change to a state, such as the completion or failure of an operation, business process, or human task, that can trigger a subsequent action, such as persisting the event data to a data repository or invoking another business process.
  3. An element that is used to represent a change in state.

event catalog
: A repository of event metadata used by applications to retrieve information about classes of events and their permitted content.

event context
: An activity or group of activities in an expanded subprocess that can be interrupted by an exception (such as by an error intermediate event).

event correlation sphere
: The scope of an ECSEmitter method that allows an event consumer to correlate events. Each event includes the identifier of the correlation sphere to which it belongs and the identifier of its parent correlation sphere from the event hierarchy.

event data
: In an event message, the part of the message data that contains information about the event (such as the queue manager name, and the application that gave rise to the event).

event database
: A database in which events that can be monitored are stored, and which is required to support the persistence of those events.

Event Designer
: An event rule application development tool that is integrated into the Eclipse development environment and dedicated to the creation and management of event rule applications.

event-driven translation
: A translation automatically triggered by the receipt of a document.

event emitter
: A component of the Common Event Infrastructure that receives events from event sources, completes and validates the events, and then sends events to the event server based on filter criteria. See also Common Event Infrastructure, event source.

event flow
: A visual representation of the event processing that will take place when the application is run.

event gateway
: A gateway that represents a branching point in the process where the alternative paths that follow the gateway are based on events that occur rather than the evaluation of expressions using process data (as with an exclusive or inclusive gateway).

event group
: 1. A set of criteria that is applied to events to identify a subset of those events. The criteria include constraints expressions that define the filter conditions.
  2. A container for inbound events that enables the user to group events without having to create a new monitoring context. Event groups are purely a visual construct and are not represented in the monitor model.

event listener
: A type of asynchronous bean that serves as a notification mechanism and through which Java Platform, Enterprise Edition (Java EE) components within a single application can notify each other about various asynchronous events.

event model
: The part of the monitor model that contains references to all of the elements of the event definitions used in the monitor model.

event object
: A subset of the fields in the definition of an event.

event part
: An XML Schema Definition (XSD) type that provides information about the structure of part of an event. A single event definition can have different event parts that are defined by different XML schemas.

event project

A project in which the user can manage and event rules and business objects.

event queue
: An ordered list of events.

event rule
: A piece of business logic that is evaluated by the runtime server when an event is received.

event rule group
: A group of event rules that operate together and typically include an otherwise clause.

event run time
: A shared, secured component that runs event assets such as business objects, events, and actions.

event source
: An object that supports an asynchronous notification server within a single Java virtual machine. Using an event source, the event listener object can be registered and used to implement any interface.

event store
: A persistent cache where event records are saved until a polling adapter can process them.

evictor
: A component that controls the membership of entries in each BackingMap instance. Sparse caches can use evictors to automatically remove data from the cache without affecting the database.

exception

1. An event that occurs during the performance of the process that causes a diversion from the normal flow of the process. Exceptions can be generated by intermediate events, such as time, error, or message.
2. A condition or event that cannot be handled by a normal process.

exception flow
: A set of sequence flow paths that originates from an intermediate event that is attached to the boundary of an activity. The process does not traverse this path unless the activity is interrupted by the triggering of a boundary intermediate event. See also normal flow.

exception handler
: A set of routines that responds to an abnormal condition. An exception handler is able to interrupt and to resume the normal running of processes.

exception queue
: A queue to which messages associated with certain exceptional conditions, such as errors, are routed.

exception report
: A WebSphere MQ report message type that is created by a message channel agent when a message is sent to another queue manager, but that message cannot be delivered to the specified destination queue.

exclusive gateway
: A gateway that creates alternative paths in a process flow. The exclusive gateway indicates the diversion point in the flow of a process.

exclusive lock
: A lock that prevents concurrently executing application processes from accessing database data. See also shared lock.

executable map
: A compiled map.

execution component
: A component that authorizes the execution of a rule set by the execution unit (XU).

execution object model (XOM)
: A model that references implementation objects used in rules.

execution settings
: Settings that influence how a component behaves at execution time. These settings are compiled into the map file or system file. Many of these settings compiled into the map can be overridden (or partially overridden) using execution commands and options.

execution trace
: A chain of events that is recorded and displayed in a hierarchal format on the Events page of the integration test client.

execution unit (XU)
: A Java EE connector or resource adapter that handles the low-level details of rule set execution for a rule execution server.

exit breakpoint
: A breakpoint set on a component element that is hit after the component element is invoked.

exit condition
: A Boolean expression that controls when processing at a process node is completed.

exit zone
: A zone that defines where a tag exits the area. If a tag can no longer be detected within the zone, the item has left the area.

expanded component
: A component that displays the sources and targets that are associated with it in the Integration Flow Designer. See also contracted component.

expanded subprocess
: A subprocess that exposes its flow detail within the context of its parent process. An expanded subprocess is displayed as a rounded rectangle that is enlarged to display the flow objects within.

expected value
: The average value for a given attribute for a population dataset. This value is ultimately used to determine reason code assignment, it is typically used for linear and logistic models where the interaction of variables is controlled.

explicit format
: A format that relies upon syntax to separate data objects. Each data object can be identified by its position or by a delimiter in the data. Delimiters will also appear for missing data objects. See also implicit format.

export
: An exposed interface from a Service Component Architecture (SCA) module that offers a business service to the outside world. An export has a binding that defines how the service can be accessed by service requesters, for example, as a web service.

export file

1. A file created during the development process for inbound operations that contains the configuration settings for inbound processing.
2. The file containing data that has been exported.

exposed process value (EPV)

A variable that enables process participants to set or change a value while an instance of a process is running. Process participants use EPVs to adjust specific variable values as constants, thereby affecting the flow of a process or task assignment.

expression

1. An SQL or XQuery operand or a collection of SQL or XQuery operators and operands that yields a single value.
2. A statement about data objects. Expressions are a combination of literals, object names, operators, functions, and map names. Component rules are expressions that evaluate to either TRUE or FALSE. Map rules are expressions that evaluate to data to produce the desired output.

extended common service area (ECSA)

A major element of z/OS virtual storage above the 16 MB line. This area contains pageable system data areas that are addressable by all active virtual storage address spaces. It duplicates the common system area (CSA) which exists below the 16 MB line.

extended data element

An application-specific element that contains information relevant to an event.

extended messaging

A function of asynchronous messaging where the application server manages the messaging infrastructure and extra standard types of messaging beans are provided to add functionality to that provided by message-driven beans.

Extensible Access Control Markup Language (XACML)

A language used to express policies and rules for controlling access to information.

Extensible Hypertext Markup Language (XHTML)

A reformulation of HTML 4.0 as an application of XML. XHTML is a family of current and future DTDs and modules that reproduce, subset, and extend HTML.

Extensible Markup Language (XML)

A standard metalanguage for defining markup languages that is based on Standard Generalized Markup Language (SGML).

Extensible Stylesheet Language (XSL)

A language for specifying style sheets for XML documents. Extensible Stylesheet Language Transformation (XSLT) is used with XSL to describe how an XML document is transformed into another document.

Extensible Stylesheet Language Transformation (XSLT)

An XML processing language that is used to convert an XML document into another document in XML, PDF, HTML, or other format.

extension

1. In Eclipse, the mechanism that a plug-in uses to extend the platform. See also extension point.
2. A class of objects designated by a specific term or concept; denotation.
3. An element or function not included in the standard language.

extension point

In Eclipse, the specification that defines what attributes and values must be declared by an extension. See also extension.

external command

A command that causes the command-line interface (CLI) to generate a message and send it to a service to be processed.

external link

In the Integration Flow Designer, solid lines displayed in a system definition diagram that visually represent the data flow between two map components.

external partner

A trading community participant that sends business documents to and receives business documents from the internal partner. See also trading partner.

external security manager (ESM)

A security product that performs security checking on users and resources. RACF is an example of an ESM.

extract, transform, and load (ETL)

The process of collecting data from one or more sources, cleansing and transforming it, and then loading it into a database.

eXtreme Scale grid

A pattern that is used to interact with eXtreme Scale when all of the data and clients are in one process.

F

fabric

A complex network of hubs, switches, adapter endpoints, and connecting cables that support a communication protocol between devices. For example, Fibre Channel uses a fabric to connect devices.

Faces component

One of a collection of user interface components (such as input fields) and data components (representing data such as records in a database) that can be dragged to a Faces JSP file and then bound to each other to build a dynamic web project. See also JavaServer Faces.

Faces JSP file

A file that represents a page in a dynamic web project and contains JavaServer Faces UI and data components. See also JavaServer Faces.

factory

In object-oriented programming, a class that is used to create instances of another class. A factory is used to isolate the creation of objects of a particular class into one place so that new functions can be provided without widespread code changes.

failed event

An object that records the source, destination, description, and time of failure between two service connector components.

failover

An automatic operation that switches to a redundant or standby system in the event of a software, hardware, or network interruption.

FastCGI

See Fast Common Gateway Interface Protocol.

Fast Common Gateway Interface Protocol (FastCGI)

An extension of the Common Gateway Interface that improves performance and allows for greater scalability.

Fastpath mode

A rule execution mode that uses an optimized sequential algorithm.

fast response cache accelerator (FRCA)

A cache that resides in the kernel on AIX and Windows platforms that provides support for caching on multiple web servers and on servers with multiple IP addresses.

fast view

In Eclipse, a view that is opened and closed by clicking a button on the shortcut bar.

fault message
: An object that contains status information and details about a problem with a message.

favorite
: A library item that a user has marked for easy access.

feature
: In Eclipse, a JAR file that is packaged in a form that the update manager accepts and uses to update the platform. Features have a manifest that provides basic information about the content of the feature, which can include plug-ins, fragments and other files.

Federal Information Processing Standard (FIPS)
: A standard produced by the National Institute of Standards and Technology when national and international standards are nonexistent or inadequate to satisfy the U.S. government requirements.

federated search
: A search capability that enables searches across multiple search services and returns a consolidated list of search results.

federation
: The process of combining naming systems so that the aggregate system can process composite names that span the naming systems.

federation domain
: A domain that determines the scope over which the federated REST API provides federation support for business processes and human tasks. A federation domain spans one or many BPM environments. See also domain.

feed
: A data format that contains periodically updated content that is available to multiple users, applications, or both. See also Rich Site Summary.

FFDC
: See first-failure data capture.

field
: In object-oriented programming, an attribute or data member of a class.

field constructor
: An element that defines the mapping from an event object to a business object.

FileAct directory
: A directory that is used exclusively to store files that are involved in FileAct transfers.

FileNet P8 domain
: A domain that represents a logical grouping of physical resources and the Content Engine servers that provide access to those resources. Each resource and server belong to only one domain. A server can access any resource in the domain but cannot access any resource that lies outside of the domain.

file serving
: A function that supports the serving of static files by web applications.

file splitting
: The division of an event file, based on a delimiter or based on size, to separate individual business objects within the file and send them as if they are each an event file to reduce memory requirements.

file store
: A type of message store that directly uses files in a file system through the operating system.

File Transfer Protocol (FTP)
: In TCP/IP, an application layer protocol that uses TCP and Telnet services to transfer bulk-data files between machines or hosts.

filter
: 1. A reusable set of conditions that is used in an event rule to evaluate whether an event matches certain criteria.
  2. A device or program that separates data, signals, or material in accordance with specified criteria. See also servlet filtering.

filter expression
: An optional expression, used by a notification receiver to filter the notification instances that it will accept. The receiver is listening for a particular type of notification, and in addition it will only accept notification instances that meet the criteria specified by the filter expression.

FIN
: The SWIFT store-and-forward message-processing service defining message standards and protocols. See also SWIFTNet FIN.

final action
: An action attached to a rule flow task that is performed after the task has been executed.

final score
: An additive function of a continuous collection of weighted attributes.

find
: See discover.

finder method
: In enterprise beans, a method defined in the home interface and invoked by a client to locate an entity bean. (Sun)

fine-grained
: Pertaining to viewing an individual object in detail. See also coarse-grained.

fingerprint
: See digest code.

finite state machine (FSM)
: The theoretical base describing the rules of a service request state and the conditions to state transitions.

FIPS
: See Federal Information Processing Standard.

fire
: In object-oriented programming, to cause a state transition.

firewall
: A network configuration, typically both hardware and software, that prevents unauthorized traffic into and out of a secure network.

first-failure data capture (FFDC)
: A problem diagnosis aid that identifies errors, gathers and logs information about these errors, and returns control to the affected runtime software.

fixed syntax
: A group whose components have a fixed size. Each component is padded to a fixed size or its minimum and maximum content size values are equal.

fix pack

A cumulative collection of fixes that is made available between scheduled refresh packs, manufacturing refreshes, or releases. It is intended to allow customers to move to a specific maintenance level. See also interim fix, program temporary fix, refresh pack.

flat file
A file stored on a local file system, as opposed to a more complex set of files, such as those in a structured database.

floating segment
An EDI segment of an EDI document definition that can exist in many positions relative to other EDI segments.

flow
A directional connector between elements in a process, collaboration, or choreography that represents the overall progression of how a process or process segment is performed. There are two types of flows: sequence flow and message flow.

flow object

1. An object of the business process model that helps connect components in the workflow.
2. A graphical object that can be connected to or from a sequence flow. In a process, flow objects are events, activities, and gateways. In a choreography, flow objects are events, choreography activities, and gateways.

folder

1. A container used to organize objects.
2. A project element that can be used to group rules according to business logic.

foreign bus
A service integration bus with which a particular service integration bus can exchange messages.

foreign key
In a relational database, a key in one table that references the primary key in another table. See also constraint, primary key.

forest
A collection of one or more Windows 2000 Active Directory trees, organized as peers and connected by two-way transitive trust relationships between the root domains of each tree. All trees in a forest share a common schema, configuration, and Global Catalog. When a forest contains multiple trees, the trees do not form a contiguous namespace.

fork

1. A point in the process where one sequence flow path is split into two or more paths that run in parallel within the process, allowing multiple activities to run simultaneously rather than sequentially. BPMN uses multiple outgoing sequence flow paths from activities or events or a parallel gateway to perform a fork.
2. A process element that makes copies of its input and forwards them by several processing paths in parallel.
3. In a rule flow, a node that splits the execution flow into several parallel transitions. The transitions created from a fork do not have conditions.

for loop
A loop that repeats the same sequence of activities a specified number of times.

form
A display screen, printed document, or file with defined spaces for information to be inserted.

form-based login
An authentication process where a user ID and a password are retrieved using an HTML form, and sent to the server over the HTTP or HTTPS protocol.

form bean
In Struts, a class that stores HTML or JSP form data from a submitted client request or that stores input data from a link that a user clicked. The superclass for all form beans is the ActionForm class.

form logout
A mechanism to log out without having to close all web browser sessions.

forward
In Struts, an object that is returned by an action and that has two fields: a name and a path (typically the URL of a JSP). The path indicates where a request is to be sent. A forward can be local (pertaining to a specific action) or global (available to any action).

forwardable credential
A mechanism-specific security credential that is issued to access a resource, which is used to obtain another credential for access to a different resource.

FQDN
See fully qualified domain name.

frame
In hypertext markup language (HTML) coding, a subset of the web browser window.

frameset
An HTML file that defines the layout of a web page that is composed of other, separate HTML files.

FRCA
See fast response cache accelerator.

free float
A period of time in a process flow after a task runs and before the subsequent task can start. Free floats may result from parallel paths in a process that take varying lengths of time to complete.

free-form project
A monitored directory where Java EE artifacts or module files can be created or dropped. As artifacts are introduced or modified in the free-form project, the artifacts are placed in the appropriate Java EE project structures that are dynamically generated in the workspace. The rapid deployment tools generates deployment artifacts required to construct a Java EE-compliant application and deploy that application to a target server. See also monitored directory.

free-form surface
The open area in a visual editor where developers can add and manipulate objects. For example, the Struts application diagram editor provides a free-form surface for representing JSP pages, HTML pages, action mappings, other Struts application diagrams, links from JSP pages, and forwards from action mappings.

FSM
See finite state machine.

FSM instance directory
A directory used by a finite state machine (FSM) to store temporary files, such as shared memory handles and trace files.

FTP

See File Transfer Protocol.

full build
: In Eclipse, a build in which all resources within the scope of the build are considered. See also incremental build.

full deployment
: Deployment of all the data required to set up the resources for an entire instance. See also delta deployment.

fully qualified domain name (FQDN)
: In Internet communications, the name of a host system that includes all of the subnames of the domain name. An example of a fully qualified domain name is rchland.vnet.ibm.com. See also host name.

function
: A named group of statements that can be called and evaluated and can return a value to the calling statement.

functional acknowledgment
: An electronic acknowledgment returned to the sender to indicate acceptance or rejection of EDI documents.

functional acknowledgment map
: A set of mapping instructions that describe how to create an EDI Standard functional acknowledgment. One of three supported map types.

functional group
: One or more documents of a similar type transmitted from the same location and enclosed by functional group header and trailer segments.

function key
: A keyboard key that can be programmed to perform certain actions.

G

garbage collection
: A routine that searches memory to reclaim space from program segments or inactive data.

gate
: An entry to or an exit from an area or zone that is monitored by one device

gate condition
: A condition on a message being processed that must be fulfilled for a mediation policy to apply.

gateway

1. An element that is used to control the divergence and convergence of sequence flow paths in a process and in a choreography.
2. An element that controls the divergence and convergence of sequence lines and determines the branching, forking, merging, and joining of paths that a process can take during execution.
3. See destination.
4. An integration pattern that provides format-independent boundary functions that apply to all incoming messages.
5. A device or program used to connect networks or systems with different network architectures.
6. A middleware component that bridges Internet and intranet environments during web service invocations.

gateway destination
: A type of service destination that receives messages for gateway services. Gateway destinations are divided into those that are used for request processing and those that are used for reply processing.

gateway queue manager
: A cluster queue manager that is used to route messages from an application to other queue managers in the cluster.

gateway service
: A web service that is made available through the web services gateway.

General Inter-ORB Protocol (GIOP)
: A protocol that Common Object Request Broker Architecture (CORBA) uses to define the format of messages.

General System service
: A service that is used to coordinate other services or to manipulate variable data. See also service.

generic object
: An object that is used in API calls and XPATH expressions to refer to concepts, custom entities, or collections. For example, the XPATH expression /WSRR/GenericObject will retrieve all concepts from WebSphere Service Registry and Repository.

generic server
: A server or process, such as a Java server, a C or C++ server or process, a CORBA server, or a Remote Method Invocation (RMI) server, that is managed in the product administrative domain and supports the product environment.

generic server cluster
: A group of remote servers that need routing by the proxy server.

getter method
: A method whose purpose is to get the value of an instance or class variable. This allows another object to find out the value of one of its variables. See also setter method.

GIOP
: See General Inter-ORB Protocol.

global

1. Pertaining to information available to more than one program or subroutine. See also local.
2. Pertaining to an element that is available to any process in the workspace. A global element appears in the project tree and can be used in multiple processes. Tasks, processes, repositories, and services can be either global (referenced by any process in the project) or local (specific to a single process). See also local.

global asset
: A library item that is available to the entire process application in which it is located. For example, environment variables for a process application are global assets and can be called from any implementation.

global attribute
: In XML, an attribute that is declared as a child of the schema element rather than as part of a complex type definition. Global attributes can be referenced in one or more content models using the ref attribute.

global element

In XML, an element that is declared as a child of the schema element rather than as part of a complex type definition. Global elements can be referenced in one or more content models using the ref attribute.

global instance identifier
: A globally unique identifier that is generated either by the application or by the emitter and is used as a primary key for event identification.

global security
: Pertains to all applications running in the environment and determines whether security is used, the type of registry used for authentication, and other values, many of which act as defaults.

global transaction
: A recoverable unit of work performed by one or more resource managers in a distributed transaction environment and coordinated by an external transaction manager.

global transaction management (GTX)
: The monitoring of transactions that can include operations on two or more different data sources. This feature enables databases or servers to be returned to a pre-transaction state if an error occurs. Either all databases and servers are updated or none are. The advantage of this strategy is that databases and servers remain synchronized and data remains consistent.

global variable
: A variable that is used to hold and manipulate values assigned to it during translation and that is shared across maps and across document translations. One of the three types of variables supported by the Data Interchange Services mapping command language.

Globus certificate service
: An online service that issues low-quality GSI certificates for people who want to experiment with Grid (or distributed) computing components that require certificates but have no other means to acquire certificates. The Globus certificate service is not a true CA. Certificates from the Globus certificate service are intended solely for experimentation. Use caution when using these certificates, for they are not intended for use in production systems. See also certificate authority.

glue code
: A segment of code that is used to connect two pre-existing pieces of code and retain full functionality. See also API stub.

GMT
: See Greenwich mean time.

governance
: The decision making processes in the administration of an organization. The rights and responsibilities of these processes are typically shared among the organization's participants, especially the management and stakeholders.

governance lifecycle
: A life cycle that represents the states and transitions that can exist in SOA deployment.

governance policy validator
: A sample validator that enables the user to control the operations that can be performed on specific entities based on the metadata that is attached to those entities.

governance process
: A process that ensures that compliance and operational polices are enforced, and that change occurs in a controlled fashion and with appropriate authority as envisioned by the business design.

governance state
: A state defined within the governance life cycle, for example, "created", "planned", or "specified".

governance web service
: A service that retrieves information and runs actions, relating to the governance of objects, from a web service client.

governed collection
: Group of objects on which an operation may be performed automatically, as a result of an initial operation.

governed entity
: Controls visibility of artifacts as well as controlling who can perform which actions on specific governed entities.

GPM
: See Graphical Process Modeler.

grammar
: A document type definition (DTD) or schema providing a structured format used for successful processing by the trace service.

Graphical Process Modeler (GPM)
: A stand-alone graphical interface tool that is used in Sterling B2B Integrator to create and modify business processes. The GPM converts the graphical representation of business processes to well-formed BPML (source code) and saves the effort of writing code.

Greenwich mean time (GMT)
: The mean solar time at the meridian of Greenwich, England.

group
: 1. A set of elements that is associated with the same category.
2. A complex data object that consists of components.
3. A collection of users who can share access authorities for protected resources.

GTX
: See global transaction management.

H

HA
: See high availability.

HADR
: See high availability disaster recovery.

HA group
: A collection of one or more members used to provide high availability for a process.

handle
: In the Java EE specification, an object that identifies an enterprise bean. A client may serialize the handle, and then later deserialize it to obtain a reference to the enterprise bean. (Sun)

handler

In web services, a mechanism for processing service content and extending the function of a JAX-RPC runtime system.

handshake
: The exchange of messages at the start of a Secure Sockets Layer session that allows the client to authenticate the server using public key techniques (and, optionally, for the server to authenticate the client) and then allows the client and server to cooperate in creating symmetric keys for encryption, decryption, and detection of tampering.

HA policy
: A set of rules that is defined for an HA group that dictate whether zero (0), or more members are activated. The policy is associated with a specific HA group by matching the policy match criteria with the group name.

hash
: In computer security, a number generated from a string of text that is used to ensure that transmitted messages arrived intact.

hashed method authentication code (HMAC)
: A mechanism for message authentication that uses cryptographic hash functions.

header
: The portion of a message that contains control information.

headless
: Pertains to a program or application that can run without a graphical user interface or, in some cases, without any user interface at all. Headless operation is often used for network servers or embedded systems.

health
: The general condition or state of the database environment.

health controller
: An autonomic manager that constantly monitors defined health policies. When a specified health policy condition does not exist in the environment, the health controller verifies that configured actions correct the error.

Health Insurance Portability and Accountability Act
: A legislative act in the U.S. that requires health plans and providers to use a common format when electronically communicating health information.

health policy
: A set of rules that an administrator can define and use to monitor conditions and take actions when the conditions occur.

heap
: In Java programming, a block of memory that the Java virtual machine (JVM) uses at run time to store Java objects. Java heap memory is managed by a garbage collector, which automatically de-allocates Java objects that are no longer in use.

heartbeat
: A signal that one entity sends to another to convey that it is still active.

HFS
: See hierarchical file system.

hidden widget
: A fully functional widget that transforms business data so that another widget can use this data. A hidden widget is not displayed on a page, unless all widgets are displayed. When a hidden widget is made visible, the widget has a dashed frame.

hierarchical
: Pertaining to data that is organized on computer systems using a hierarchy of containers, often called folders (directories) and files. In this scheme, folders can contain other folders and files. The successive containment of folders within folders creates the levels of organization, which is the hierarchy.

hierarchical file system (HFS)
: A system for organizing files in a hierarchy, as in a UNIX system.

hierarchical loop (HL)
: A technique for describing the relationship of data entities which are related in a parent to child manner, like a corporate organization chart.

hierarchical property
: An extended rule property whose values are organized into a hierarchy.

high availability
: 1. The ability of IT services to withstand all outages and continue providing processing capability according to some predefined service level. Covered outages include both planned events, such as maintenance and backups, and unplanned events, such as software failures, hardware failures, power failures, and disasters.
  2. Pertaining to a clustered system that is reconfigured when node or daemon failures occur so that workloads can be redistributed to the remaining nodes in the cluster.

high availability disaster recovery (HADR)
: A disaster recovery solution that uses log shipping and provides data to a standby system if a partial or complete site failure occurs on a primary system.

high availability file system
: A cluster file system that can be used for component redundancy to provide continued operations during failures.

high availability manager
: A framework within which core group membership is determined and status is communicated between core group members.

high-level qualifier (HLQ)
: A qualifier that groups tables together with other tables that have different names, but the same qualifier.

HL
: See hierarchical loop.

HLQ
: See high-level qualifier.

HMAC
: See hashed method authentication code.

home interface
: In enterprise beans, an interface that defines zero or more create and remove methods for a session bean or zero or more create, finder, and remove methods for an entity bean. See also remote interface.

home method
: A method in the home interface that is used by a client to create, locate, and remove instances of enterprise beans.

home page
: The top-level web page of a portal.

homogeneous rule
: A rule for which the conditions are written on the same type and number of objects.

hook
: A location in a compiled program where the compiler has inserted an instruction that allows programmers to interrupt the program (by setting breakpoints) for debugging purposes.

horizontal scaling
: A topology in which more than one application server running on multiple computing nodes is used to run a single application.

host
: 1. A computer that is connected to a network and that provides an access point to that network. The host can be a client, a server, or both a client and server simultaneously. See also client, server.
2. In performance profiling, a machine that owns processes that are being profiled. See also server.

host name
: 1. In Internet communication, the name given to a computer. The host name might be a fully qualified domain name such as mycomputer.city.company.com, or it might be a specific subname such as mycomputer. See also fully qualified domain name, IP address.
2. The network name for a network adapter on a physical machine in which the node is installed.

host system
: An enterprise mainframe computer system that hosts 3270 applications. In the 3270 terminal service development tools, the developer uses the 3270 terminal service recorder to connect to the host system.

hot deployment
: The process of adding new components to a running server without stopping and restarting the application server or application. See also dynamic reloading.

hot directory
: See monitored directory.

hot servant region
: A servant region that had a request dispatched to it previously and now has available threads.

HTTP channel
: A type of channel within a transport chain that provides client applications with persistent HTTP connections to remote hosts that are either blocked by firewalls or require an HTTP proxy server. An HTTP channel is used to exchange application data in the body of an HTTP request and an HTTP response that is sent to and received from a remote server.

HTTP over SSL (HTTPS)
: A web protocol for secure transactions that encrypts and decrypts user page requests and pages returned by the web server.

HTTPS
: 1. See HTTP over SSL.
2. See Hypertext Transfer Protocol Secure.

hub administrator
: The superuser who configures the hub and who has the ability to perform all the tasks associated with setting up and administering the hub.

human task
: An interaction between people and business processes or services. See also inline task, stand-alone task.

human workflow
: A business process flow that includes human interactions.

Hypertext Transfer Protocol Secure (HTTPS)
: An Internet protocol that is used by web servers and web browsers to transfer and display hypermedia documents securely across the Internet.

hypervisor
: A program or a portion of Licensed Internal Code that allows multiple instances of operating systems to run simultaneously on the same hardware.

I

IAMS
: See inbound application message store.

ICAP
: See Internet Content Adaptation Protocol.

ICMP
: See Internet Control Message Protocol.

IDE
: See integrated development environment.

identifier
: 1. In the 3270 terminal services development tool, a field on a screen definition that uniquely identifies the state of the screen. Users can choose which fields will be identifiers when creating recognition profiles.
2. The name of an item in a program written in the Java language.

identifier attribute
: An attribute that can be assigned to one component to identify a collection of components, when creating type trees and defining components of a group. An identifier attribute is used during data validation to determine whether a data object exists.

identity
: The data that represents a person and that is stored in one or more repositories.

identity assertion
: The invocation credential that is asserted to the downstream server. This credential can be set as the originating client identity, the server identity, or another specified identity, depending on the RunAs mode for the enterprise bean.

identity token
: A token that contains the invocation credential identity, which with the client authentication token are required by the receiving server to accept the asserted identity.

IDL

See Interface Definition Language.

if-then rule
: A rule in which the action (then part) is performed only when the condition (if part) is true. See also action rule, rule set.

IIOP
: See Internet Inter-ORB Protocol.

ILOG Rule Language (IRL)
: An executable rule language. Rules in ILOG Rule Language (IRL) can reference any execution object and invoke methods on these objects.

i-mode
: An Internet service for wireless devices.

implicit format
: A format that defines a group type whose data objects are distinguishable by content, not syntax. Implicit format relies on the properties of the component types. Unlike explicit format, if delimiters separate data objects, they do not appear for missing data objects. See also explicit format.

import

1. The point at which an SCA module accesses an external service, (a service outside the SCA module) as if it was local. An import defines interactions between the SCA module and the service provider. An import has a binding and one or more interfaces.
2. A development artifact that imports a service that is external to a module. See also import file.

import file
: A file created during the development process for outbound operations that contains the configuration settings for outbound processing. See also import.

IMS
: See Information Management System.

IMS command
: A request from a terminal or AO (automated operator) to perform a specific IMS service, such as altering system resource status or displaying specific system information.

IMS Connect
: The product that runs on a z/OS platform and through which IMS Connector for Java communicates with IMS. IMS Connect uses OTMA to communicate with IMS. See also Open Transaction Manager Access.

IMS conversation

1. In IMS Connector for Java, the dialog between a Java client program and a message processing program.
2. A dialog between a terminal and a message processing program using IMS conversational processing facilities. See also conversational processing.

IMS transaction
: A specific set of input data that triggers the execution of a specific process or job. A transaction is a message destined for an IMS application program.

IMS transaction code
: A 1- to 8-character alphanumeric code that invokes an IMS message processing program.

inbound
: In communication, pertaining to data that is received from the network. See also outbound.

inbound application message store (IAMS)
: A message store, implemented by means of the database table DNF_IAMS, in which WebSphere BI for FN stores messages that are received from remote destinations (OSN messages).

inbound authentication
: The configuration that determines the type of accepted authentication for inbound requests.

inbound document
: See source document.

inbound event
: A declaration that a monitoring context or KPI context will accept a specific event at run time.

inbound port
: A type of port that takes a message that is received at an endpoint listener and passes it to the service integration bus for forwarding to the appropriate inbound service.

inbound processing
: The process by which changes to business information in an enterprise information system (EIS) are detected, processed, and delivered to a runtime environment by a JCA Adapter. An adapter can detect EIS changes by polling an event table or by using an event listener.

inbound service
: The external interface for a service that is provided by your own organization and hosted in a location that is directly available through the service destination.

inbound transport
: Network ports in which a server listens for incoming requests.

inclusive gateway
: A gateway that creates alternative or parallel paths in a process flow where all outgoing sequence flow condition expressions are evaluated independently.

incremental build
: In Eclipse, a build in which only resources that have changed since the last build are considered. See also full build.

index
: A set of pointers that is logically ordered by the values of a key. Indexes provide quick access to data and can enforce uniqueness of the key values for the rows in the table.

individual resource
: A single resource that can be uniquely identified, such as a person or computer. Individual resources are used when a specific resource must be allocated to a task. For example, the Mary Smith resource must perform the Approve Payment task.

industry capability map
: A logical view of the business competencies that an industry needs to process.

information center
: A collection of information that provides support for users of one or more products, can be launched separately from the product, and includes a list of topics for navigation and a search engine.

Information Management System (IMS)

Any of several system environments that have a database manager and transaction processing that can manage complex databases and terminal networks.

inheritance
: An object-oriented programming technique in which existing classes are used as a basis for creating other classes. Through inheritance, more specific elements incorporate the structure and behavior of more general elements.

initial action
: An action attached to a rule flow task that is performed before the task is executed.

initial CDD
: A customization definition document (CDD) to which placeholders have not yet been added.

initial context
: Starting point in a namespace.

initialization point
: A user-defined constant or variable used to initialize the attributes of an object.

initial option set
: For a scenario that uses an option set group, the first option set that the scenario used. The initial option set is used to determine when all of the option sets of an option set group have been used at least once.

initial reference
: A well-known reference associated with an identifier.

initiator
: A syntax object in a data stream that signals the beginning of a data object. For example, if a record begins with an asterisk (*), the asterisk would be the record's initiator.

inline
: In Content Manager, the property of an object that is online and in a drive, but has no active mounts.

inline schema
: An XML schema in a Web Service Description Language file (.wsdl).

inline task
: A unit of work that is defined within an implementation of a business process. See also human task, stand-alone task.

inout parameter
: A parameter value that is provided as input to a rule set when it is executed. It can be modified by the execution process and is provided as output when the execution is completed.

in parameter
: A parameter value that is provided as input to the rule set at execution time.

input
: An entry point through which an element is notified that it can start, typically because an upstream element, on which it depends, has completed. If the element has all of its required input, then it will start.

input activity
: The origin of the process that is the source of the invocation data of the entire process.

input branch
: The area of a decision, fork, join, or merge that contains the inputs.

input card
: In the Map Designer, a component that contains the complete definition of input for the map, including information such as source identification, retrieval specifics, and the behavior that should occur during processing.

input criteria
: Number and types of inputs required to start a task or process.

input node
: 1. A message flow node that represents a source of messages for a message flow or subflow.
2. The point where a service message from a source enters the request flow.

input response node
: The end point for a mediation response flow from which the service message object is sent to the source.

input terminal node
: A primitive through which a message is received by a subflow. Each input terminal node is represented as an input terminal of the corresponding subflow node.

INS
: See Interoperable Naming Service.

insertion
: The action of adding a new object into the object set provided to the rule engine for execution.

installation image
: A copy of the software, in backup format, that the user is installing, as well as copies of other files the system needs to install the software product.

installation package
: An installable unit of a software product. Software product packages are separately installable units that can operate independently from other packages of that software product.

installation target
: The system on which selected installation packages are installed.

instance
: 1. A specific occurrence of an object that belongs to a class. See also object.
2. A set of servers that share a common runtime database, plus their corresponding brokers and queue managers.
3. An active process element, for example, the performance of a process.

instance document
: An XML document that conforms to a particular schema.

instance metric
: A metric that returns the result, such as the amount of an order, from one run of the process. See also metric.

instantiate

To represent an abstraction with a concrete instance.

integrated development environment (IDE)
A set of software development tools, such as source editors, compilers, and debuggers, that are accessible from a single user interface.

integration broker
A component that integrates data among heterogeneous applications. An integration broker typically provides various services that can route data, as well as a repository of rules that govern the integration process, connectivity to various applications, and administrative capabilities that facilitate integration.

integration service
A service that is used to integrate with an external system, such as a web service. See also Advanced Integration service, service.

intelligent page
A page that is based on platform capabilities that deliver a unified presentation and architecture, rapid assembly of multiple component types including feeds, widgets, and portlets, and rich media that provide access to dynamic web pages, enabling real-time web-page analysis and channel-delivery analysis.

interaction
A definition that explains what the target document should be. An interaction consists of the source document, target document, action, and a transformation map.

interaction endpoint
A service requester or provider.

interaction pattern
A communication method for sending or receiving messages in a service interaction. Examples of interaction patterns include request/reply, one-way interaction, and publish/subscribe.

interactive process design
The development of deployable processes through modeling, testing, and revision by business users.

interactive session
A work session in which there is an exchange of communication between a 3270 application and the 3270 terminal service recorder.

Interactive System Productivity Facility (ISPF)
An IBM licensed program that serves as a full-screen editor and dialog manager. Used for writing application programs, it provides a means of generating standard screen panels and interactive dialogs between the application programmer and the terminal user. See also Time Sharing Option.

interactive view
In 3270 terminal services, real-time access to a host application in the 3270 terminal service recorder editor.

interchange
The exchange of information between trading partners. Also a set of documents grouped together, such as EDI documents enclosed within an EDI envelope.

interface
A collection of operations that are used to specify a service of a class or a component. See also class, port type.

Interface Definition Language (IDL)
In CORBA, a declarative language that is used to describe object interfaces, without regard to object implementation.

interface map
A map that resolves and reconciles the differences between the interfaces of interacting components. There are two levels of interface maps: operation mappings and parameter mappings.

interim fix
A certified fix that is generally available to all customers between regularly scheduled fix packs, refresh packs, or releases. See also fix pack, refresh pack.

intermediate CDD
A customization definition document (CDD) to which placeholders have been added, but for which placeholder values have not yet been specified.

intermediate event
An event that occurs after a process has been started, affecting the flow of the process by showing where messages and delays are expected and distributing the normal flow through exception handling. Intermediate event types are message, timer, tracking, and error. See also catching message intermediate event, message intermediate event, throwing message intermediate event, timer event, tracking intermediate event.

internal command
A command that is processed directly by and that controls the command-line interface (CLI).

internal link
In the Integration Flow Designer, a solid line displayed by an expanded map component that visually represents the source and target of the map.

internal partner
A company that acts as the hub community for its partners. The internal partner has one administrative user and the manager administrator who is responsible for the health and maintenance of the internal partner's portion of the community.

internal rate of return (IRR)
The interest rate received for an investment, based on anticipated expenses and income that will occur at regular periods

Internet Content Adaptation Protocol (ICAP)
A high-level protocol for requesting services from an Internet-based server.

Internet Control Message Protocol (ICMP)
An Internet protocol that is used by a gateway to communicate with a source host, for example, to report an error in a datagram.

Internet Inter-ORB Protocol (IIOP)
A protocol used for communication between Common Object Request Broker Architecture (CORBA) object request brokers. See also Common Object Request Broker Architecture.

Internet Protocol (IP)
A protocol that routes data through a network or interconnected networks. This protocol acts as an intermediary between the higher protocol layers and the physical network. See also Transmission Control Protocol.

interoperability
The ability of a computer or program to work with other computers or programs.

Interoperable Naming Service (INS)
A program that supports the configuration of the Object Request Broker (ORB) administratively to return object references.

interoperable object reference (IOR)
An object reference with which an application can make a remote method call on a CORBA object. This reference contains all the information needed to route a message directly to the appropriate server.

interrupt
A condition that applies to a simulation that causes the simulation execution to be halted if the condition is met.

interval
: The defining range or ranges of an attributes value. Intervals are a one-to-many relationship to the attributes utilized in the scorecard.

introspector
: In Java, a class (java.beans.Introspector) that provides a standard way for tools to learn about the properties, events, and methods supported by a target bean. Introspectors follow the JavaBeans specification.

invocation
: The activation of a program or procedure.

invocation credential
: An identity with which to invoke a downstream method. The receiving server requires this identity with the sending server identity to accept the asserted identity.

invoker attribute
: An assembly property for a web module that is used by the servlet that implements the invocation behavior.

IOR
: See interoperable object reference.

IP
: See Internet Protocol.

IP address
: A unique address for a device or logical unit on a network that uses the Internet Protocol standard. See also host name.

IP group
: A range of IP addresses that can be selected for use with specific hypervisors.

IP sprayer
: A device that is located between inbound requests from the users and the application server nodes that reroutes requests across nodes.

IRL
: See ILOG Rule Language.

IRR
: See internal rate of return.

ISPF
: See Interactive System Productivity Facility.

item
: 1. A simple data object that does not consist of other objects. An item type is represented by a blue dot next to the type name in the type tree.
  2. An entity within a location that can be equipped with tags and whose positions can therefore be tracked, such as an asset or person.

iteration
: See loop.

iterator
: A class or construct that is used to step through a collection of objects one at a time.

iWidget
: A browser-oriented component, potentially extending a server-side component, that provides either a logical service to the page or a visualization for the user (typically related to a server-side component or a configured data source).

iWidget specification
: An open-source specification upon which Business Space widgets are based.

J

J2C
: See J2EE Connector architecture.

J2EE
: 1. See Java 2 Platform, Enterprise Edition.
  2. See Java Platform, Enterprise Edition.

J2EE Connector architecture (J2C)
: See Java EE Connector Architecture.

J2SE
: See Java 2 Platform, Standard Edition.

JAAS
: See Java Authentication and Authorization Service.

JAF
: See JavaBeans Activation Framework.

JAR
: See Java archive.

JAR file
: A Java archive file. See also Java archive.

JASPI
: See Java Authentication for SPI for containers.

Java
: An object-oriented programming language for portable interpretive code that supports interaction among remote objects. Java was developed and specified by Sun Microsystems, Incorporated.

Java 2 Connector security
: See Java Connector security.

Java 2 Platform, Enterprise Edition (J2EE)
: See Java Platform, Enterprise Edition.

Java 2 Platform, Standard Edition (J2SE)
: See Java Platform, Standard Edition.

Java API for XML (JAX)

A set of Java-based APIs for handling various operations involving data defined through Extensible Markup Language (XML).

Java API for XML-based RPC (JAX-RPC, JSR 101)
A specification that describes application programming interfaces (APIs) and conventions for building web services and web service clients that use remote procedure calls (RPC) and XML.

Java API for XML Web Services (JAX-WS)
The next-generation web services programming model that is based on dynamic proxies and Java annotations.

Java Architecture for XML Binding (JAXB)
A Java binding technology that supports transformation between schema and Java objects, as well as between XML instance documents and Java object instances.

Java archive (JAR)
A compressed file format for storing all of the resources that are required to install and run a Java program in a single file. See also enterprise archive, JAR file, web archive.

Java Authentication and Authorization Service (JAAS)
In Java EE technology, a standard API for performing security-based operations. Through JAAS, services can authenticate and authorize users while enabling the applications to remain independent from underlying technologies.

Java Authentication for SPI for containers (JASPI)
A specification that supports third-party security providers handling the Java Platform, Enterprise Edition (Java EE) authentication of HTTP request and response messages that are sent to web applications.

JavaBeans
As defined for Java by Sun Microsystems, a portable, platform-independent, reusable component model. See also bean.

JavaBeans Activation Framework (JAF)
A standard extension to the Java platform that determines arbitrary data types and available operations and can instantiate a bean to run pertinent services.

Java class
A class that is written in the Java language.

Java Command Language
A scripting language for the Java environment that is used to create web content and to control Java applications.

Java Connector security
An architecture designed to extend the end-to-end security model for Java EE-based applications to include enterprise information systems (EIS).

Java Database Connectivity (JDBC)
An industry standard for database-independent connectivity between the Java platform and a wide range of databases. The JDBC interface provides a call level interface for SQL-based and XQuery-based database access. See also Open Database Connectivity.

Java Development Kit (JDK)
See Java SE Development Kit.

Javadoc

1. Pertaining to the tool that parses the declarations and documentation comments in a set of source files and produces a set of HTML pages describing the classes, inner classes, interfaces, constructors, methods, and fields.
2. A tool that parses the declarations and documentation comments in a set of source files and produces a set of HTML pages describing the classes, inner classes, interfaces, constructors, methods, and fields. (Sun)

Java EE
See Java Platform, Enterprise Edition.

Java EE application
Any deployable unit of Java EE functionality. This unit can be a single module or a group of modules packaged into an enterprise archive (EAR) file with a Java EE application deployment descriptor. (Sun)

Java EE Connector Architecture (JCA)
A standard architecture for connecting the Java EE platform to heterogeneous enterprise information systems (EIS).

Java EE server
A runtime environment that provides EJB or web containers.

Java file
An editable source file (with .java extension) that can be compiled into bytecode (a .class file).

JavaMail API
A platform and protocol-independent framework for building Java-based mail client applications.

Java Management Extensions (JMX)
A means of doing management of and through Java technology. JMX is a universal, open extension of the Java programming language for management that can be deployed across all industries, wherever management is needed.

Java Message Service (JMS)
An application programming interface that provides Java language functions for handling messages.

Java Naming and Directory Interface (JNDI)
An extension to the Java platform that provides a standard interface for heterogeneous naming and directory services.

Java Persistence API
An object/relational mapping facility to Java developers for managing relational data in Java applications.

Java platform
A collective term for the Java language for writing programs; a set of APIs, class libraries, and other programs used in developing, compiling, and error-checking programs; and a Java virtual machine which loads and runs the class files. (Sun)

Java Platform, Enterprise Edition (J2EE, Java EE)
An environment for developing and deploying enterprise applications, defined by Sun Microsystems Inc. The Java EE platform consists of a set of services, application programming interfaces (APIs), and protocols that provide the functionality for developing multitiered, web-based applications. (Sun)

Java Platform, Standard Edition (Java SE)
The core Java technology platform. (Sun)

Java project
In Eclipse, a project that contains compilable Java source code and is a container for source folders or packages.

Java project for Rules
A predefined Java project for Eclipse that contains a single, runnable main class to execute rules contained in a rule project.

Java runtime environment (JRE)

A subset of a Java developer kit that contains the core executable programs and files that constitute the standard Java platform. The JRE includes the Java virtual machine (JVM), core classes, and supporting files.

JavaScript
: A web scripting language that is used in both browsers and web servers. (Sun)

JavaScript Object Notation (JSON)
: A lightweight data-interchange format that is based on the object-literal notation of JavaScript. JSON is programming-language neutral but uses conventions from languages that include C, C++, C#, Java, JavaScript, Perl, Python.

Java SE
: See Java Platform, Standard Edition.

Java Secure Socket Extension (JSSE)
: A Java package that enables secure Internet communications. It implements a Java version of the Secure Sockets Layer (SSL) and Transport Layer Security (TSL) protocols and supports data encryption, server authentication, message integrity, and optionally client authentication.

Java SE Development Kit
: The name of the software development kit that Sun Microsystems provides for the Java platform.

JavaServer Faces (JSF)
: A framework for building web-based user interfaces in Java. Web developers can build applications by placing reusable UI components on a page, connecting the components to an application data source, and wiring client events to server event handlers. See also Faces component, Faces JSP file, JavaServer Pages.

JavaServer Pages (JSP)
: A server-side scripting technology that enables Java code to be dynamically embedded within web pages (HTML files) and run when the page is served, in order to return dynamic content to a client. See also JavaServer Faces, JSP file, JSP page.

Java Specification Request (JSR)
: A formally proposed specification for the Java platform.

Java virtual machine (JVM)
: A software implementation of a processor that runs compiled Java code (applets and applications).

Java virtual machine Profiler Interface (JVMPI)
: A profiling tool that supports the collection of information, such as data about garbage collection and the Java virtual machine (JVM) API that runs the application server.

JAX
: See Java API for XML.

JAXB
: See Java Architecture for XML Binding.

JAX-RPC
: See Java API for XML-based RPC.

JAX-WS
: See Java API for XML Web Services.

JCA
: See Java EE Connector Architecture.

JCA contract
: A collaborative agreement between an application server and an EIS system-level. A JCA contract indicates how to keep all mechanisms (for example, transactions, security, and connection management) transparent from the application components.

JCL
: See job control language.

JDBC
: See Java Database Connectivity.

JDBC connection filter
: A control that limits the amount of data that is transferred during the JDBC metadata load. The filter enhances performance.

JDK
: See Java Development Kit.

Jetspeed
: The open-source portal that is part of the Jakarta project by Apache.

JMS
: See Java Message Service.

JMS data binding
: A data binding that provides a mapping between the format used by an external JMS message and the Service Data Object (SDO) representation used by a Service Component Architecture (SCA) module.

JMS destination
: An object in which message queuing applications use the Java Message Service specification to put messages, and from which they can get messages.

JMS provider
: A messaging engine that implements the JMS messaging specification, for example WebSphere MQ or SIBus.

JMX
: See Java Management Extensions.

JNDI
: See Java Naming and Directory Interface.

job class
: Any one of a number of job categories that can be defined.

job control language (JCL)
: A command language that identifies a job to an operating system and describes the job requirements. See also xJCL.

job group security
: A security model in which groups of users can access and control a common set of jobs owned by that group.

job log
: A record of requests submitted to the system by a job, the messages related to the requests, and the actions performed by the system on the job. The job log is maintained by the system program.

job management console
: A stand-alone web interface that is used to submit, monitor, view, and manage jobs.

job manager
: An administrative process that manages multiple base application servers or network deployment cells.

job scheduler
: A component that provides all job-management functions. A job scheduler maintains a history of all jobs and usage data for jobs that have run.

job step
: The execution of a computer program explicitly identified by a job control statement. A job may specify that several job steps be executed. [A]

join
: 1. In a rule flow, a node that combines all the transitions created from a fork.
  2. A point in the process where two or more parallel sequence flow paths are combined into one sequence flow path. BPMN uses a parallel gateway to perform a join.
  3. An SQL relational operation in which data can be retrieved from two tables, typically based on a join condition specifying join columns.
  4. A process element that recombines and synchronizes parallel processing paths after a decision or fork. A join waits for input to arrive at each of its incoming branches before permitting the process to continue.

join condition
: A condition that determines whether to run the next activity.

join failure
: A fault that is thrown if a join condition cannot be evaluated.

JRas
: A toolkit that consists of a set of Java packages that enable developers to incorporate message logging and trace facilities into Java applications.

JRE
: See Java runtime environment.

JSF
: See JavaServer Faces.

JSON
: See JavaScript Object Notation.

JSP
: See JavaServer Pages.

JSP file
: A scripted HTML file that has a .jsp extension and allows for the inclusion of dynamic content in web pages. A JSP file can be directly requested as a URL, called by a servlet, or called from within an HTML page. See also JavaServer Pages, JSP page.

JSP page
: A text-based document using fixed template data and JSP elements that describes how to process a request to create a response. (Sun) See also JavaServer Pages, JSP file.

JSR
: See Java Specification Request.

JSR 101
: See Java API for XML-based RPC.

JSSE
: See Java Secure Socket Extension.

junction
: A logical connection created to establish a path from one server to another.

JUnit
: An open-source regression testing framework for unit-testing Java programs.

JVM
: See Java virtual machine.

JVMPI
: See Java virtual machine Profiler Interface.

Jython
: An implementation of the Python programming language that is integrated with the Java platform.

K

kernel
: The part of an operating system that contains programs for such tasks as input/output, management and control of hardware, and the scheduling of user tasks.

key
: 1. Information that characterizes and uniquely identifies the real-world entity that is being tracked by a monitoring context.
  2. A cryptographic mathematical value that is used to digitally sign, verify, encrypt, or decrypt a message. See also private key, public key.

key class
: In EJB query language, a class that is used to create or find an entity bean. It represents the identity of the entity bean, corresponding to the primary-key columns of a row in a relational database.

key database
: In security, a storage object, either a file or a hardware cryptographic card, where identities and private keys are stored for authentication and encryption purposes. Some key databases also contain public keys. See also stash file.

key database file
: See key ring.

Keyed-Hashing Message Authentication Code
: A mechanism for message authentication that uses cryptographic hash functions.

key field
: In EJB query language, a container-managed field in an entity bean that corresponds to one of the primary-key columns of a row in a relational database. Each key field is a member of the entity bean key class.

key file

See key ring.

key locator
: A mechanism that retrieves the key for XML signing, XML digital signature verification, XML encryption, and XML decryption.

key pair
: In computer security, a public key and a private key. When the key pair is used for encryption, the sender uses the public key to encrypt the message, and the recipient uses the private key to decrypt the message. When the key pair is used for signing, the signer uses the private key to encrypt a representation of the message, and the recipient uses the public key to decrypt the representation of the message for signature verification.

key performance indicator (KPI)
: A quantifiable measure that is designed to track one of the critical success factors of a business process.

key ring
: In computer security, a file that contains public keys, private keys, trusted roots, and certificates.

keystore
: In security, a file or a hardware cryptographic card where identities and private keys are stored, for authentication and encryption purposes. Some keystores also contain trusted, or public, keys. See also certificate signing request, truststore.

keystring
: Additional specification of the entry within a naming service.

key value pair
: Information that is expressed as a paired set of parameters. For example, if you want to express that the specific sport is football, this data can be expressed as key=sport and value=football.

keyword
: One of the predefined words of a programming language, artificial language, application, or command. See also parameter.

keyword parameter
: A parameter that consists of a keyword followed by one or more values.

knowledge asset
: A document external to the scope of the product that contains information associated to existing metadata.

KPI
: See key performance indicator.

KPI context
: A container for key performance indicators (KPIs) and their associated triggers and events.

KPI model
: The part of the monitor model that contains the KPI contexts, which in turn contain key performance indicators and their associated triggers and events.

L

label
: A node in a portal that cannot contain any content, but can contain other nodes. Labels are used primarily to group nodes in the navigation tree.

lane
: A container in a pool for the activities and events that take place during process execution. A lane is designated by a user and typically represents departments in a business organization. For example, a Call Center lane would include all activities to be handled by Call Center personnel during process execution. See also pool.

language code
: A two character (ISO 639-1) or three letter (ISO 639-2) abbreviation for a language. For example: en or eng for English. Country codes and language codes together form the basis for locale names.

large object (LOB)
: A data object whose data type supports the storage and manipulation of more data than most other data types.

late bind
: To connect one process to another process so that the connection is resolved dynamically in the runtime environment and the calling process uses the currently valid version of the process that it is invoking.

late binding
: The connection between two processes that is resolved dynamically in the runtime environment. As a result, the calling process uses up the currently valid version of the process that it is invoking.

LAU
: See local authentication.

launch configuration
: A mechanism for defining and saving different workbench configurations that can be launched separately. Configurable options include run and debug settings.

launchpad
: A graphical interface for launching the product installation wizard.

layout box
: In Page Designer, a control that web designers can use to move text and images within the page. Layout boxes can be stacked or aligned by using a grid.

layout manager
: In programming graphical user interfaces, an object that controls the size and position of Java components within a container. The Java platform supplies several commonly used layout managers for AWT and Swing containers.

lazy authentication
: The process whereby the security run time environment obtains the required authentication data when the Java client accesses a protected enterprise bean for the first time.

LDAP
: See Lightweight Directory Access Protocol.

LDAP directory
: A type of repository that stores information on people, organizations, and other resources and that is accessed using the LDAP protocol. The entries in the repository are organized into a hierarchical structure, and in some cases the hierarchical structure reflects the structure or geography of an organization.

leaf
: In a tree, an entry or node that has no children.

library

1. In Business Process Management, a project that is used for the development, version management, and organization of shared resources. Only a subset of the artifact types can be created and stored in a library, such as business objects and interfaces. See also project.
2. A collection of model elements, including business items, processes, tasks, resources, and organizations.

lifecycle
: One complete pass through the four phases of software development: inception, elaboration, construction and transition.

Lightweight Directory Access Protocol (LDAP)
: An open protocol that uses TCP/IP to provide access to directories that support an X.500 model and that does not incur the resource requirements of the more complex X.500 Directory Access Protocol (DAP). For example, LDAP can be used to locate people, organizations, and other resources in an Internet or intranet directory.

Lightweight Third Party Authentication (LTPA)

1. A protocol that uses cryptography to support security in a distributed environment.
2. An authentication framework that allows single sign-on across a set of web servers that fall within an Internet domain.

link
: A line or arrow that connects activities in a process. A link passes information between activities and determines the order in which they run.

link aggregation
: The grouping of physical network interface cards, such as cables or ports, into a single logical network interface. Link aggregation is used to increase bandwidth and network availability. See also aggregate interface.

link name
: A name defined in the deployment descriptor of the encompassing application.

link pack area (LPA)
: The portion of virtual storage below 16 MB that contains frequently used modules.

listener
: A program that detects incoming requests and starts the associated channel.

listener port
: An object that defines the association between a connection factory, a destination, and a deployed message-driven bean. Listener ports simplify the administration of the associations between these resources.

literal
: A symbol or a quantity in a source program that is itself data, rather than a reference to data.

Literal XML
: An encoding style for serializing data over SOAP protocol. Literal XML is based on an XML schema instance.

little endian
: A format for storage or transmission of binary data in which the least significant value is placed first. See also big endian.

load balancing
: The monitoring of application servers and management of the workload on servers. If one server exceeds its workload, requests are forwarded to another server with more capacity.

loader
: A component that reads data from and writes data to a persistent store.

LOB
: See large object.

local

1. Pertaining to an element that is available only in its own process. See also global.
2. Pertaining to a device, file, or system that is accessed directly from a user system, without the use of a communication line. See also remote.

local authentication (LAU)
: The process of validating a user identity to the system according to the local operating system account to which the user logged in. If the user is authenticated, the user is mapped to a principal.

local database
: A database that is located on the workstation in use. See also remote database.

locale
: A setting that identifies language or geography and determines formatting conventions such as collation, case conversion, character classification, the language of messages, date and time representation, and numeric representation.

local history
: Copies of files that are saved in the workbench in order to compare the current version with previous versions. Subject to configurable preferences, the workbench updates the local history each time an editable file is saved.

local home interface
: In EJB programming, an interface that specifies the methods used by local clients for locating, creating, and removing instances of enterprise bean classes. See also remote home interface.

local queue
: A queue that belongs to the local queue manager. A local queue can contain a list of messages waiting to be processed. See also remote queue.

local queue manager
: The queue manager to which the program is connected and that provides message queuing services to the program. See also remote queue manager.

local server
: A predefined server that designates the current computer to run the Integration Flow Designer.

local transaction
: A recoverable unit of work managed by a resource manager and not coordinated by an external transaction manager.

local transaction containment (LTC)
: A bounded scope that is managed by the container to define the application server behavior in an unspecified transaction context.

location

1. A particular occurrence or example of a location definition. If there is a location definition called USA Call Center, an example of a location would be Toledo Call Center.
2. A physical space that is being monitored. A location can contain many areas. See also area.

location service daemon
: A component of the Remote Method Invocation and Internet Inter-ORB Protocol (RMI/IIOP) communication function that works with workload management to distribute RMI requests among application servers in a cell.

lock
: A means of preventing uncommitted changes made by one application process from being perceived by another application process and for preventing one application process from updating data that is being accessed by another process. A lock ensures the integrity of data by preventing concurrent users from accessing inconsistent data.

logger
: A named and stateful object with which the user code interacts and that logs messages for a specific system or application component.

logging
: The recording of data about specific events on the system, such as errors.

logging level
: A value that controls which events are processed by Java logging.

log handler
: A class that uses loggers, levels, and filters to direct whether events are processed or suppressed.

logical derivation
: A derivation from a physical document that can have additional service description metadata allocated to the derivation. See also logical model.

logical model
: A set of logical derivations. See also logical derivation.

logical terminal (LT)
: In SWIFT, the logical entity through which users send and receive SWIFT messages. A logical terminal is identified by its LT name.

logical terminal table (LTT)
: A MERVA table used to define logical terminals, their synonyms, and other attributes.

logical unit of work (LUW)
: The work that occurs between the start of a transaction and commit or rollback and between subsequent commit and rollback actions. This work defines the set of operations that must be considered part of an integral set.

login binding
: A definition of the implementation to provide login information per authentication methods.

login mapping
: A Java Authentication and Authorization Service (JAAS) login configuration that is used to authenticate a security token in a web service security header.

long name
: The property that specifies the logical name for the server on the z/OS platform.

long-running process
: A process that can come to a complete stop while waiting for input or instructions. The most common form of this interruption is a human interaction or decision.

loop
: A sequence of instructions performed repeatedly.

loop ID
: A unique code that identifies an EDI loop.

loop repeat
: A number indicating the maximum number of times a loop can be used in succession.

loose coupling
: A coupling that supports an extensible software architecture.

LPA
: See link pack area.

LT
: See logical terminal.

LTC
: See local transaction containment.

LT code
: The ninth character of an LT name. For example, the LT code of the LT name XXXXUSNYA is A.

LT name
: A nine-character name of the form BBBBCCLLX, where BBBBCCLL represents the eight-character bank identifier code (BIC8), and X represents the logical terminal (LT) code.

LTPA
: See Lightweight Third Party Authentication.

LTT
: See logical terminal table.

LUW
: See logical unit of work.

M

MAC
: See Media Access Control.

macroflow
: See long-running process.

mail session
: A resource collection of protocol providers that authenticate users and control user access to messaging systems.

maintenance mode
: A state of a node or server that an administrator can use to diagnose, maintain, or tune the node or server without disrupting incoming traffic in a production environment.

manageability
: The ability to manage a resource, or the ability of a resource to be managed. (OASIS)

manageability capability

A capability associated with one or more management domains. (OASIS)

manageability capability interface
: A web service interface representing one manageability capability. (OASIS)

manageability consumer
: A user of manageability capabilities associated with one or more manageable resources. (OASIS)

manageability endpoint
: A web service endpoint associated with and providing access to a manageable resource. (OASIS)

manageability interface
: The composition of one or more manageability capability interfaces. (OASIS)

manageable resource
: A resource capable of supporting one or more standard manageability capabilities. (OASIS)

Managed Bean (MBean)
: In the Java Management Extensions (JMX) specification, the Java objects that implement resources and their instrumentation.

managed deployment environment
: A set of server components that are used to test and deploy applications in a controlled environment.

managed environment
: An environment where services, such as transaction demarcation, security, and connections to Enterprise Information Systems (EISs), are managed on behalf of the running application. Examples of managed environments are the web and Enterprise JavaBeans (EJB) containers.

managed file
: A library item that is created outside of IBM Process Designer and that is part of a process application, such as an image or Cascading Style Sheet (CSS). Creating managed files ensures that all required files are available and installed when a project is ready for testing or production.

managed mode
: An environment in which connections are obtained from connection factories that the Java EE server has set up. Such connections are owned by the Java EE server.

managed node
: A node that is federated to a deployment manager and contains a node agent and can contain managed servers. See also node.

managed resource
: An entity that exists in the runtime environment of an IT system and that can be managed. See also sensor.

managed server
: A server within a managed node, to which SCA modules and applications can be deployed.

management domain
: An area of knowledge relative to providing control over, and information about the behavior, health and life cycle of manageable resources.

Management Information Base (MIB)
: In the Simple Network Management Protocol (SNMP), a database of objects that can be queried or set by a network management system. See also Simple Network Management Protocol.

manifest
: A special file that can contain information about the files packaged in a JAR file. (Sun)

manual emulator
: An emulator that requires users to specify response values for an emulated component or reference at run time. See also emulator, programmatic emulator.

map
: 1. A file that defines the transformation between sources and targets.
  2. A data structure that maps keys to values.
  3. In the EJB development environment, the specification of how the container-managed persistent fields of an enterprise bean correspond to columns in a relational database table or other persistent storage.

map chaining
: The process of producing multiple documents from a single document by executing several maps to translate the single document.

map component
: An Integration Flow Designer object that encapsulates a reference to an executable map, along with its execution settings. There are three types of map components: source, compiled, and pseudo.

map control string
: An object compiled from a map, which contains the instructions used by the translator to translate a document from one format to another.

map object
: An object used in the TX Programming Interface that represents an instance of a map in the program memory.

mapped expression
: Part of an SQL statement that is used to retrieve data from a data connection for a field in a business object.

mapping
: 1. The process of transforming data from one format to another.
  2. The relationship between fields in different abstractions of event and action objects.
  3. The act of developing and maintaining a map.

mapping specialist
: The person responsible for creating data transformation maps, validation maps, and functional acknowledgment maps using the Data Interchange Services client.

map rule
: An expression that evaluates to data and produces the required output. A map rule is entered on an output card in the Map Designer and cannot be longer than 32KB.

marker bar
: The gray border at the left of the editor area of the workbench, where bookmarks and breakpoints are shown.

marshal
: To convert an object into a data stream for transmission over a network.

mashup

A graphical interface that features two or more reusable web applications (widgets) presenting seemingly disparate data in an understandable combination for a specific purpose.

master configuration
: The configuration data held in a set of files that form the master repository for either a deployment manager profile or a stand-alone profile. For a deployment manager profile, the master configuration stores the configuration data for all the nodes in the network deployment cell.

matching rule
: The portion of a policy rule in a processing policy that defines the criteria to determine whether the message is processed by its processing rule.

maximum possible score
: A score that describes the maximum of the maximum scores of all individual scorecards. The maximum possible score is a complex scorecard property, its value should be the same in all the scorecards used in a complex scorecard.

maximum score
: The upper limit in a given interval for an attribute that is used in determining reason code assignment. Typically used for linear and logistic models where variable interaction is controlled.

maximum transmission unit (MTU)
: The largest possible unit of data that can be sent on a given physical medium in a single frame. For example, the maximum transmission unit for Ethernet is 1500 bytes.

maximum use
: A number indicating the maximum number of times a compound or simple element can repeat.

MBean
: See Managed Bean.

MBean provider
: A library containing an implementation of a Java Management Extensions (JMX) MBean and its MBean Extensible Markup Language (XML) descriptor file.

MD5
: A type of message algorithm that converts a message of arbitrary length into a 128-bit message digest. This algorithm is used for digital signature applications where a large message must be compressed in a secure manner.

MDB
: See message-driven bean.

measure
: A metric combined with an aggregation type such as average, count, maximum, minimum, sum, or average. See also aggregate metric.

Media Access Control (MAC)
: In networking, the lower of two sublayers of the Open Systems Interconnection model data link layer. The MAC sublayer handles access to shared media, such as whether token passing or contention will be used.

mediation
: An application of service interaction logic to messages flowing between service requesters and providers.

mediation flow
: A sequence of processing steps, or mediation primitives, that run to produce the mediation when a message is received. See also message flow.

mediation flow component
: A component that contains one or more mediation primitives arranged into request and response flows. Rather than performing business functions, mediation flow components are concerned with the flow of messages.

mediation framework
: A mechanism that supports creation of mediation flows through the composition of mediation primitives.

mediation module
: An SCA module that includes a mediation flow component and primarily enables communication between applications by changing the format, content, or target of service requests.

mediation policy
: A policy that is held in a registry and is applied to a Service Component Architecture (SCA) module. The mediation policy enables mediation flows, which are in the module, to be configured at run time by using dynamic properties.

mediation policy attachment
: An attachment that is a prerequisite for using the mediation policy and gate conditions on the mediation policy.

mediation primitive
: The building blocks of mediation flow components.

mediation service
: A service that intercepts and modifies messages that are passed between client services (requesters) and provider services.

mediation subflow
: A preconfigured set of mediation primitives that are wired together to create a common pattern or use case. Mediation subflows run in the context of a parent flow, and can be reused in mediation flows or in subflows.

meet-in-the-middle mapping
: An approach for mapping enterprise beans to database tables in which enterprise beans and database schema are created simultaneously but independently.

member
: In the Type Designer, a single occurrence of a component in a group in a type tree. If a component has a range, each occurrence of that component might be referred to as a member of a series.

membership
: The state of being a portal user and a place member. Membership in the portal is controlled by the administrator during the installation and set up of portal servers. Membership in places is controlled by a place manager, who determines the level of access for each place member: participant, place designer, or place manager.

membership policy
: A subexpression that is evaluated against the nodes in a cell to determine which nodes host dynamic cluster instances.

memory leak
: The effect of a program that maintains references to objects that are no longer required and therefore need to be reclaimed.

merge
: 1. A point in the process where two or more alternative sequence flow paths are combined into one sequence flow path. No synchronization is required because no parallel activity runs at the join point. BPMN uses multiple incoming sequence flow paths for an activity or an exclusive gateway to perform a merge.
  2. A process element that recombines multiple processing paths, typically after a decision. A merge brings several alternative paths together.

message

1. An object that depicts the contents of a communication between two participants. A message is transmitted through a message flow and has an identity that can be used for alternative branching of a process through the event-based exclusive gateway.
2. A set of data that is passed from one application to another. Messages must have a structure and format that is agreed by the sending and receiving applications. See also category.
3. A communication sent from a person or program to another person or program.

message body
: The part of the message that contains the message payload. See also message header.

message category
: A group of messages that are logically related, such as message that are all used by one application.

message channel
: In distributed message queuing, a mechanism for moving messages from one queue manager to another. A message channel comprises two message channel agents (a sender at one end and a receiver at the other end) and a communication link. See also channel.

message definition
: Information that describes the structure of the messages of a particular type, the elements that each message of that type can or must contain, how a message of that type is represented in various network formats, and the validation rules that apply to a message of that type.

message digest
: A hash value or a string of bits resulting from the conversion of processing data to a number.

message domain
: A group of all the message definitions that are required to satisfy a particular business need (for example, transferring SWIFTNet FIN messages, transferring SWIFTNet Funds messages, or transferring SWIFTNet system messages).

message-driven bean (MDB)
: An enterprise bean that provides asynchronous message support and clearly separates message and business processing.

message-driven rule bean
: An enterprise bean that allows Java EE applications to process messages asynchronously. The bean invokes the execution unit (XU) when a JMS message arrives and posts the results of the rule engine processing to a JMS destination.

message end event
: An end event that also sends a message. See also end event.

message event
: An event that arrives from a participant and triggers another event. If the message event is attached to the boundary of the activity, it changes the normal flow into an exception flow upon being triggered.

message file
: A file containing messages sent in bulk through a message bulking service.

message flow

1. A sequence of processing steps that execute in the broker when an input message is received. Message flows are defined in the workbench by including a number of message flow nodes, each of which represents a set of actions that define a processing step. The connections in the flow determine which processing steps are carried out, in which order, and under which conditions. See also mediation flow, subflow.
2. A connecting object that shows the flow of messages between two collaborating participants. A message flow is represented by a dashed line.

Message Format Service (MFS)
: An IMS editing facility that allows application programs to deal with simple logical messages instead of device-dependent data, thus simplifying the application development process.

Message Format Service control block (MFS control block)
: In MFS, the representation of a message or format that is stored in the IMS.FORMAT library and called into the MFS buffer pool as needed for online execution.

message header
: The part of a message that contains control information such as a unique message ID, the sender and receiver of the message, the message priority, and the type of message. See also message body.

message input descriptor (MID)
: The Message Format Service (MFS) control block that describes the format of the data presented to the application program. See also message output descriptor.

message intermediate event
: An intermediate event that can be used to either receive or send a message. See also intermediate event.

message log
: A file in which an application logs messages about errors that occur or metadata about the message.

message output descriptor (MOD)
: The Message Format Service (MFS) control block that describes the format of the output data produced by the application program. See also message input descriptor.

message processing node
: A node in a message flow that represents a processing step. A message processing node can be either a primitive or a subflow node.

message processing unit (MPU)
: A message processing unit is used to correlate information within a message, for example reason or completion information, and a message text.

message queue
: A named destination to which messages can be sent until they are retrieved by programs that service the queue.

message reception registry (MRR)
: The registry where SWIFT stores the central routing rules. Each receiver defines its own rules and submits them to SWIFT. SWIFT uses these rules to determine the destination of message traffic, that is, to which store and forward queue or to which SWIFTNet Link it is to route each message.

message reference number (MRN)
: A unique 16-digit number assigned to each message for identification purposes. The message reference number consists of an 8-digit domain identifier that is followed by an 8-digit sequence number.

message sequence number (MSN)
: A sequence number for messages.

message standard

A standard that describes a family of message definitions.

message start event
: A start event that is triggered when a specific message is received. See also start event.

message type
: The logical structure of the data within a message. For example, the number and location of character strings.

message warehouse table
: A database table in which the message warehouse service stores index and status information about each message processed by services.

messaging API
: A programming interface that enables an application to send and receive messages and attached files over a messaging system.

messaging engine
: The messaging and connection point to which applications connect to the bus.

messaging middleware
: Software that provides an interface between applications, allowing them to send data back and forth to each other asynchronously. Data sent by one program can be stored and then forwarded to the receiving program when it becomes available to process it.

messaging system
: Software used to deliver electronic messages.

metadata
: Data that describes the characteristics of data; descriptive data. See also application-specific information.

metadata tree
: A list in a tree structure, which is prepared and displayed by the external service wizard, that presents all of the objects discovered from the enterprise information system (EIS).

method

1. A way to implement a function on a class.
2. In object-oriented programming, an operation that an object can perform. An object can have many methods. See also operation.

method extension
: An IBM extension to the standard deployment descriptors for enterprise beans that define transaction isolation methods and control the delegation of credentials.

method permission
: A mapping between one or more security roles and one or more methods that a member of a role can call.

metric
: A holder for information, typically a business performance measurement, in a monitoring context. See also aggregate metric, instance metric.

MFS
: See Message Format Service.

MFS control block
: See Message Format Service control block.

MIB
: See Management Information Base.

microflow
: A short-running process that runs in one transaction. A microflow, which is an IBM extension to the BPEL programming language, runs automatically from start to finish and cannot be interrupted.

micropattern
: A pattern that creates a reusable subprocess from a main process. See also pattern.

MID
: See message input descriptor.

middleware agent
: An agent that enables the administrative domain to manage servers that run middleware software.

middleware descriptor
: An XML file that contains information about different middleware platform types, including discovery sensor intervals and installation information.

middleware node
: A node that is federated to the deployment manager. These nodes must include nodes that run the node agent or middleware agent.

MIME
: See Multipurpose Internet Mail Extensions.

MOD
: See message output descriptor.

model
: A representation of a process, system, or subject area, typically developed for understanding, analyzing, improving, and replacing the item being represented. A model can include a representation of information, activities, relationships, and constraints.

modeled fault
: A fault message that is returned from a service that has been modeled on the Web Services Description Language (WSDL) port type.

model element
: An element that is an abstraction drawn from the system being modeled. In the MOF specification, model elements are considered to be meta-objects.

model view controller (MVC)
: A software architecture that separates the components of the application: the model represents the business logic or data; the view represents the user interface; and the controller manages user input or, in some cases, the application flow. See also view.

module

1. In Java EE programming, a software unit that consists of one or more components of the same container type and one deployment descriptor of that type. Examples include EJB, web, and application client modules. (Sun) See also project.
2. A software artifact that is used for developing, managing versions, organizing resources, and deploying to the runtime environment.
3. A program unit that is discrete and identifiable with respect to compiling, combining with other units, and loading.

monitor

1. In performance profiling, to collect data about an application from the running agents that are associated with that application.

2. A facility of the integration test client that listens for requests and responses that flow over the component wires or exports in the modules of a test configuration.

monitor configuration server
: The application server installation that owns the overall application server configuration for a cell.

monitor details model
: A container for monitoring contexts and their associated metrics, keys, counters, stopwatches, triggers, and inbound and outbound events. The monitor details model holds most of the monitor model information.

monitored directory
: The directory where the rapid deployment tools detect added or changed parts and produce an application that can run on the application server. See also automatic application installation project, free-form project.

monitoring context
: A definition that corresponds to an object to be monitored, such as a process execution, an ATM, a purchase order, or the stock level in a warehouse. At run time, monitoring contexts process the events for a particular object.

monitor model
: A model that describes the business performance management aspects of a business model, including events, business metrics, and key performance indicators (KPIs) that are required for real-time business monitoring.

monitor model CEI configuration owner
: The server installation that owns the overall server configuration that contains the monitor model Common Event Infrastructure (CEI) server target.

mount point
: A logical drive through which volumes are accessed in a sequential access device class. For removable media device types, such as cartridges, a mount point is a logical drive associated with a physical drive. For the file device type, a mount point is a logical drive associated with an I/O stream.

MPMT
: See multiprocess multithread.

MPU
: See message processing unit.

MRN
: See message reference number.

MRR
: See message reception registry.

MSN
: See message sequence number.

MTU
: See maximum transmission unit.

multidimensional analysis
: The process of assessing and evaluating an enterprise on more than one level.

multiple configuration instances
: More than one instance of a product running in the same machine at the same time.

multiple-occurrence mapping
: A form of mapping in which all occurrences of a repeating compound or simple element are mapped to the same repeating compound or simple element in another document.

multiprocess multithread (MPMT)
: A process architecture of the IBM HTTP Server that supports multiple processes as well as multiple threads per process.

Multipurpose Internet Mail Extensions (MIME)
: An Internet standard that allows different forms of data, including video, audio, or binary data, to be attached to email without requiring translation into ASCII text.

MVC
: See model view controller.

N

named constant
: A descriptive name that is given to a value and can be used in a filter in place of a value.

namespace
: A logical container in which all the names are unique. The unique identifier for an artifact is composed of the namespace and the local name of the artifact.

namespace object
: A Data Interchange Services object that contains information about an XML namespace and assists the translator in being namespace aware when translating a source document to an XML document.

naming
: An operation that is used to obtain references to objects that are related to applications.

naming context
: A logical namespace containing name and object bindings.

naming federation
: The process of binding naming systems so that the aggregate system can process composite names that span the naming systems.

naming service
: An implementation of the Java Naming and Directory Interface (JNDI) standard.

NAS
: See network access server.

NAT
: See network address translation.

native
: Pertaining to the relationship between a transport user and a transport provider that are both based on the same transport protocol.

navigation bar
: A set of links to other web pages in a website. For example, a navigation bar is typically located across the top or down the side of a page and contains direct links to the major sections within the website.

navigation phrase
: In the vocabulary, a phrase that associates two business elements. A navigation phrase corresponds to a method that has a return value or an attribute in the business object model (BOM).

net change
: The cumulative effect of multiple changes to an object. For example, an add action followed by a remove action cancels out other changes, consequently yielding no net change.

netmask
: See network mask.

net present value (NPV)
: The estimated monetary value of an investment based on expected returns and expected costs, where these expected returns and expenses are discounted by a rate that reflects inflation and opportunity costs.

network
: A system of resources, such as appliances, computers, and storage devices, that are connected virtually or physically.

network access server (NAS)
: A device that functions as an access control point for users in remote locations who connect to an internal network or to an ISP. A NAS might include its own authentication services or rely on a separate authentication server. A NAS can be a dedicated server or a software service within a regular server.

network acknowledgment
: A response from the network indicating the status of an interchange envelope, such as sent or received.

network address translation (NAT)
: The conversion of a network address that is assigned to a logical unit in one network into an address in an adjacent network.

network delivery notification
: A delivery notification that conforms to the network protocol. See also application delivery notification.

network deployment cell
: A logical group of servers, on one or more machines, managed by a single deployment manager.

Network File System (NFS)
: A protocol, developed by Sun Microsystems, Incorporated, that allows a computer to access files over a network as if they were on its local disks.

network identifier
: A single character that is placed before a message type to indicate which network is to be used to send the message; for example, S for SWIFT.

Network Installation Management (NIM)
: An environment that provides installation and configuration of software within a network interface.

network mask (netmask)
: A number that is the same as an Internet Protocol (IP) address. A network mask identifies which part of an address is to be used for an operation, such as making a TCP/IP connection.

network protocol stack
: A set of network protocol layers and software that work together to process the protocols.

Network Time Protocol (NTP)
: A protocol that synchronizes the clocks of computers in a network.

NFS
: See Network File System.

NIM
: See Network Installation Management.

node
: 1. An endpoint or junction used in a message flow.
  2. Any element in a tree.
  3. In XML, the smallest unit of a valid, complete structure in a document.
  4. A logical group of managed servers. See also managed node.

node agent
: An administrative agent that manages all application servers on a node and represents the node in the management cell.

node federation
: The process of combining the managed resources of one node into a distributed network such that the central manager application can access and administer the resources on the node.

node group
: A collection of application server nodes that defines a boundary for server cluster formation.

node name
: The machine name or host name that must be unique.

nonce
: A unique cryptographic number that is embedded in a message to help detect a replay attack.

none start event
: A start event that does not have a defined trigger. A none start event can be used in a descriptive process that does not require technical information or in a subprocess where the control of the process flow is passed from its parent process. See also start event.

nonrepudiation
: In business-to-business communication the ability of the recipient to prove who sent a message based on the contents of the message. This can derive from the use of a digital signature on the message, which links the sender to the message.

nonrepudiation data repository
: The repository in which copies of documents (and authentication information for signed documents) are stored in case disputes arise regarding the authenticity of document exchanges.

normal flow
: All sequence flow paths in a process except those paths that originate from an intermediate event that is attached to the boundary of an activity. See also exception flow.

notation
: An XML construct that contains a note, a comment or an explanation about information in an XML file. A notation can be used to associate a binary description with an entity or attribute.

notification

1. A message that contains the event descriptions that are sent to managed resources, web services and other resources.
2. An occurrence within a process that can trigger an action. Notifications can be used to model conditions of interest to be transmitted from a sender to a (typically unknown) set of interested parties (the receivers).

notification broadcaster
: An element that is responsible for publishing notifications. Notification receivers listen for these notifications.

notification channel
: A mode by which a subscriber uses a business service.

notification program
: A program or web service that can be triggered when an event occurs.

notification receiver
: An element that listens for and receives notifications. By default, this element starts listening when its owning process starts.

NPV
: See net present value.

NTP
: See Network Time Protocol.

numeric constant
: The actual numeric value to be used in processing, instead of the name of a field containing the data. A numeric constant can contain any of the numeric digits 0 through 9, a sign (plus or minus), and a decimal point.

O

OAEP
: See optimal asymmetric encryption padding.

OAMS
: See outbound application message store.

object
: In object-oriented design or programming, a concrete realization (instance) of a class that consists of data and the operations associated with that data. An object contains the instance data that is defined by the class, but the class owns the operations that are associated with the data.

object adapter
: In Common Object Request Broker Architecture (CORBA), the primary interface that a server implementation uses to access Object Request Broker (ORB) functions.

object-oriented programming
: A programming approach based on the concepts of data abstraction and inheritance. Unlike procedural programming techniques, object-oriented programming concentrates not on how something is accomplished but instead on what data objects comprise the problem and how they are manipulated.

object reference
: In Common Object Request Broker Architecture (CORBA), the information needed to reliably identify a particular object.

Object Request Broker (ORB)
: In object-oriented programming, software that serves as an intermediary by transparently enabling objects to exchange requests and responses.

observer
: A task that watches a process and its associated repositories, and produces output when a certain condition becomes true (for example, a threshold value has been reached).

ODBC
: See Open Database Connectivity.

OLAP
: See online analytical processing.

on-demand configuration
: A component that detects and dynamically configures routing rules, which tell the on demand router (ODR) how to route requests.

on demand router
: A proxy server that is the point of entry into the product environment and is a gateway through which prioritized HTTP requests and Session Initiation Protocol (SIP) messages flow to the middleware servers in the environment.

one-way hash
: An algorithm that converts processing data into a string of bits; known as a hash value or a message digest.

one-way interaction
: A type of messaging interaction in which a request message is used to request function without a reply.

online analytical processing (OLAP)
: The process of collecting data from one or many sources; transforming and analyzing the consolidated data quickly and interactively; and examining the results across different dimensions of the data by looking for patterns, trends, and exceptions within complex relationships of that data.

ontology
: An explicit formal specification of the representation of the objects, concepts, and other entities that can exist in some area of interest and the relationships among them. See also Web Ontology Language.

Open Database Connectivity (ODBC)
: A standard application programming interface (API) for accessing data in both relational and nonrelational database management systems. Using this API, database applications can access data stored in database management systems on a variety of computers even if each database management system uses a different data storage format and programming interface. See also Java Database Connectivity.

Open Mobile Alliance
: An industry forum for developing interoperable mobile service enablers.

open relationship
: A relationship on an object that no longer points to a second object because the second object has been deleted.

Open Servlet Engine (OSE)
: A lightweight communications protocol developed by IBM for interprocess communication.

open source
: Pertaining to software whose source code is publicly available for use or modification. Open source software is typically developed as a public collaboration and made freely available, although its use and redistribution might be subject to licensing restrictions. Linux is a well known example of open source software.

Open Transaction Manager Access (OTMA)
: A component of IMS that implements a transaction-based, connectionless client/server protocol in an MVS sysplex environment. The domain of the protocol is restricted to the domain of the z/OS Cross-System Coupling Facility (XCF). OTMA connects clients to servers so that the client can support a large network (or a large number of sessions) while maintaining high performance. See also IMS Connect.

operation
: An implementation of functions or queries that an object might be called to perform. See also method.

operation mapping
: An interface map in which operations of the source interface are mapped to operations of the target interface.

operator
: A building block that lets the user compare or establish relationships between the different parts of business rule statements.

optimal asymmetric encryption padding (OAEP)
: In cryptography, a padding scheme that is often used with RSA encryption.

optimistic locking
: A locking strategy whereby no lock is held between the time that a row is selected and the time that an update or a delete operation is attempted on that row. See also pessimistic locking.

option
: A parameter that determines how a message is to be processed.

optional component
: Within a group type, a component that can be defined to represent a data object that is not required to be present in the data. The component range maximum specifies how many occurrences of the data object might optionally exist.

option set
: A named group of options and their settings that can be specified in a request or in another option set, thereby eliminating the need to specify each option individually.

ORB
: See Object Request Broker.

organization
: An entity where people cooperate to accomplish specified objectives, such as an enterprise, a company, or a factory.

organizational unit (OU)
: A body whose data is to be kept separate from that of other, similar bodies. WebSphere BI for FN uses OUs to control access to resources, and to ensure data segregation. Typically, OUs are used to represent different financial institutions, or different departments within a financial institution.

organization unit
: A particular occurrence or example of an organization definition. For an organization definition called Department, an example of an organization unit would be Sales and Marketing.

orphaned token
: A token that is associated with an activity that was removed from a business process definition (BPD).

OSE
: See Open Servlet Engine.

OSGi framework
: A general-purpose, secure, and managed Java framework that supports the deployment of extensible and downloadable applications known as bundles.

OSGi service
: An interface registered in the OSGi Service Platform and made available for receiving remote or local invocations.

OTMA
: See Open Transaction Manager Access.

OU
: See organizational unit.

outbound
: In communication, pertaining to data that is sent to the network. See also inbound.

outbound application message store (OAMS)
: A message store in which messages sent by local applications (ISN messages) and their acknowledgement messages (ISN ACKs) are stored.

outbound authentication
: The configuration that determines the type of accepted authentication for outbound requests.

outbound document
: See target document.

outbound event
: An event emitted from a monitoring context or from a KPI context.

outbound port
: The mechanism through which an outbound service communicates with the externally hosted web service. Messages pass between the outbound service and the external service through the appropriate port.

outbound processing
: The process by which a calling client application uses the adapter to update or retrieve data in an enterprise information system (EIS). The adapter uses operations such as create, update, delete, and retrieve to process the request.

outbound service
: The service that provides access through one or more outbound ports to a web service that is hosted externally.

out parameter
: A parameter value that is set by the execution process and provided as output from the rule set after the execution is completed.

output
: An exit point through which an element can notify downstream elements that they can now start.

output activity
: The end point of the business process.

output branch
: The area of a decision, fork, join, or merge that contains the outputs.

output card
: In the Map Designer, a card that contains the complete definition of an output for the map including information such as target identification, destination specifics and the behavior that should occur during processing.

output criteria

Number and types of outputs required to be produced by a task or process.

output screen
: A screen that a user navigates to based on data entry and keystrokes in a 3270 application. In the 3270 terminal service recorder, the access route from one screen to another can be recorded and saved in a dialog file.

output terminal node
: A primitive through which a message is propagated by a subflow. Each output terminal node is represented as an output terminal of the corresponding subflow node.

override
: An execution setting that overrides default source and target settings of a map.

OWL
: See Web Ontology Language.

P

package

1. To assemble components into modules and modules into enterprise applications.
2. In Java programming, a group of types. Packages are declared with the package keyword. (Sun)
3. The wrapper around the document content that defines the format used to transmit a document over the Internet, for example, RNIF, AS1, and AS2.

pack type
: A container, such as a case or pallet. Each pack type is associated with various pieces of information that are required for converting customer-specific product codes to EPC format.

pad character
: A character used to fill empty space. For example, in a database application, a field that is ten characters in length that has the word "file" in it contains four text characters and six pad characters

page
: A node in a portal that can contain content in addition to labels and other pages. Pages can contain child nodes, column containers, row containers, and portlets.

page list
: An assembly property that specifies the location to forward a request, but automatically tailors that location, depending on the Multipurpose Internet Mail Extensions(MIME) type of the servlet.

page template
: In Page Designer, a page that is used as a starting point to define consistent styles and layout for any new HTML or JavaServer Pages (JSP) page within a website.

palette

1. The location for building customized components and parenting them with other components. Subsequently, components can be reused by copying and moving them to other interfaces.
2. A range of graphically displayed choices, such as colors or collections of tools, that can be selected in an application.

pallet
: An industry standard sized wooden, plastic, or metal platform to facilitate the movement of materials. Cartons are stacked on the pallet allowing movement via pallet jacks or forklift trucks.

PAP
: See policy administration point.

parallel garbage collection
: A type of garbage collection that uses several threads simultaneously.

parallel gateway
: A gateway that creates parallel paths without checking conditions.

parallel job
: A job that is run as multiple concurrent steps. A top-level job is submitted to the job scheduler and after submission is divided into subordinate jobs that run at the same time.

parameter (parm)
: A value or reference passed to a function, command, or program that serves as input or controls actions. The value is supplied by a user or by another program or process. See also keyword.

parameter mapping
: An interface map that is one level deeper than operation mappings because it maps the parameters in the source operation to the parameters in the target operation. There are five types of parameter mappings: move, map, extract, Java, and assign.

parent document
: A document whose values are inherited by another document (the child document).

parent process
: A process that contains a subprocess.

parm
: See parameter.

parse
: To break down a string of information, such as a command or file, into its constituent parts.

parser
: A module used to break down a document into its component parts and to construct a document from its component parts.

participant
: A business entity (such as a company, company division, or a customer) or a business role (such as a buyer or a seller) that controls or is responsible for a business process.

partition

1. A group of cells in a decision table that are in the same condition column and have a common cell immediately to the left.

2. To divide a type into subtypes that are mutually exclusive.

partitioned data set (PDS)
: A data set on direct access storage that is divided into partitions, called members, each of which can contain a program, part of a program, or data.

partitioned type
: A type whose subtypes are distinguishable or mutually exclusive.

partner connection
: An interaction that has been associated with specific sending and receiving partners, and also specifies the destinations and other routing information necessary for an exchange.

partner profile
: A profile that includes information about the partner such as its name, its business identifier, such as a DUNS number, and a list of user IDs authorized to access the Community Console. See also Data Universal Numbering System.

part reference
: An object that is used by a configuration to reference other related configuration objects.

passivation
: In enterprise beans, the process of transferring an enterprise bean from memory to auxiliary storage. (Sun) See also activation.

PassTicket
: In RACF secured sign-on, a dynamically generated, random, one-time-use, password substitute that a workstation or other client can use to sign on to the host rather than sending a RACF password across the network.

password
: In computer and network security, a specific string of characters used by a program, computer operator, or user to access the system and the information stored within it. See also authentication.

password stashing
: Saving a password that is encrypted in a file or on a hard disk drive. The keydb password must reside in a file to use secure sockets layer (SSL).

path

1. A route that the flow can take through the activities in a process. There may be several alternative paths.
2. The route through a file system to a specific file.

path qualified mapping
: A form of mapping in which all occurrences of a repeating compound or simple element are mapped to the same repeating compound or simple element in another document.

pattern
: A reusable solution that encapsulates a tested approach to solving a common architecture, design, or deployment task in a particular context. See also micropattern.

payload
: The body of a message that holds content.

PCRE
: See Perl-compatible regular expression.

PDP
: See policy decision point.

PDS
: See partitioned data set.

peer access point
: A means by which core groups can communicate with other cells.

PEM
: See privacy enhanced mail.

people assignment criterion
: A property that defines the members of each of the role groups.

people awareness
: The collaboration feature that provides access to people from various contexts. People awareness lets you see references to people and contact people by name through the Sametime online status indicator. Throughout the portal, wherever you see the name of a person, you can view the online status of the person, send email, initiate a chat, or share an application via an electronic meeting. See also person link.

PEP
: See policy enforcement point.

Performance Monitoring Infrastructure (PMI)
: A set of packages and libraries assigned to gather, deliver, process, and display performance data.

Perl-compatible regular expression (PCRE)
: A regular expression C library that is much richer than classic regular expression libraries. See also regular expression.

permission
: Authorization to perform activities, such as reading and writing local files, creating network connections, and loading native code.

persist
: To be maintained across session boundaries, typically in nonvolatile storage such as a database system or a directory.

persistence

1. In Java EE, the protocol for transferring the state of an entity bean between its instance variables and an underlying database. (Sun)
2. A characteristic of data that is maintained across session boundaries, or of an object that continues to exist after the execution of the program or process that created it, typically in nonvolatile storage such as a database system.

persistence level
: A level that determines the degree of detail written to the database as a business process runs. Decreasing the persistence level increases the business process performance at the cost of full tracking for each step of the business process.

persistence service
: A service that provides private application programming interface (API) support to store and accesses executable resources.

persistent data store
: A nonvolatile storage for event data, such as a database system, that is maintained across session boundaries and that continues to exist after the execution of the program or process that created it.

person
: An individual authenticated by the portal and having a person record in one or more corporate directories. Persons can be members of places, public groups within the organization corporate directory, or personal groups that a user defines.

personal group
: In Sametime Connect, a group of people designated by the user as a group. A user can choose individuals from the public Directory (public group) and create personal groups, which are then stored locally. Users can add and remove people from a personal group, whereas the membership of the public group is defined by the owner of the public Directory.

personalization
: The process of enabling information to be targeted to specific users based on business rules and user profile information.

person link
: A reference to a person name or a group name that appears with the Sametime online status indicator. The reference lets you view the online status the person, send an email, start a chat, or share an application using an electronic meeting, among other actions shown on the person link menu. See also people awareness.

perspective
: A group of views that show various aspects of the resources in the workbench.

pessimistic locking
: A locking strategy whereby a lock is held between the time that a row is selected and the time that a searched update or delete operation is attempted on that row. See also optimistic locking.

phantom read
: A read request in which two identical queries run, and the collection of rows returned by the second query is different from the first query.

PHP Hypertext Preprocessor
: A widely-used general-purpose scripting language that is especially suited for web development and can be embedded into HTML.

phrase template
: A pattern for the verbalization of a business element.

PIP
: See RosettaNet Partner Interface Process.

pivot table
: A table characterized by having one metric as a column dimension and all the rest of the metrics represented as row dimensions.

PKA
: See public key algorithm.

PKCS
: See Public Key Cryptography Standards.

PKI
: See public key infrastructure.

place
: A virtual location that is visible in the portal where individuals and groups meet to collaborate. In a portal, each user has a personal place for private work, and individuals and groups have access to a variety of shared places, which can be either public places or restricted places.

place designer
: A member of a place who can edit place layout and bookmarks. See also participant, place manager.

placeholder
: A variable that is replaced with a value.

place manager
: A member of a place who can edit place membership, layout, and bookmarks. See also participant, place designer.

place member
: A individual or group who has joined or been granted access to a place. Place members have three levels of access to a place: manager, designer, and participant.

plug-in
: A separately installable software module that adds function to an existing program, application, or interface.

PMI
: See Performance Monitoring Infrastructure.

point
: The numeric value that is assigned to an attribute based on the value of the attribute and the interval in which the value is included.

point difference
: The upper limit in a given interval for an attribute that is ultimately used to determine reason code assignment. Typically, this limit is used for linear and logistic models where the interaction of variables is controlled.

point-to-point
: Pertaining to a style of messaging application in which the sending application knows the destination of the message.

poison message
: In a queue, an incorrectly formatted message that the receiving application cannot process. The message can be repeatedly delivered to the input queue and repeatedly backed out by the application.

policy
: A set of considerations that influence the behavior of a managed resource or a user. See also policy expression.

policy administration point (PAP)
: A capability that provides enterprise service-oriented architecture (SOA) policy administration capabilities, such as policy creation, modification, storage, and distribution.

policy-controlled mediation
: A mediation that has dynamic properties that are controlled by mediation policies.

policy decision point (PDP)
: A capability that decides, based on environmental conditions, which predefined policies in the environment should be enforced. For example, a policy decision point might use a requester identity to determine whether to limit access to a resource.

policy enforcement point (PEP)
: A capability that enforces policy decisions maybe by a policy decision point. For example, a policy enforcement point would permit or deny a requester access to a resource depending on what the policy decision point determined is the correct action.

policy expression
: A representation of a policy. See also policy.

policy manager
: A decision management user role who is responsible for enforcing decisions through the creation and maintenance of rules.

policy rule
: A rule in a processing policy that consists of a matching rule and a processing rule.

policy set
: A collection of assertions about how services are defined, which can be used to simplify security configurations.

pool
: The graphical representation of a participant in a collaboration.

port
: 1. In the Internet suite of protocols, a specific logical connector between the Transmission Control Protocol (TCP) or the User Datagram Protocol (UDP) and a higher level protocol or application.
  2. As defined in a Web Services Description Language (WSDL) document, a single endpoint that is defined as a combination of a binding and a network address.

portal
: A single, secure point of access to diverse information, applications, and people that can be customized and personalized.

Portal Administration
: The place where portal administrators set and maintain basic collaboration permissions, place records, place membership records, and server settings for companion products for advanced collaboration.

portal farm
: A series of identically configured, stand-alone portal server instances that offer a way to maintain a highly scalable and highly available server environment.

port destination
: The specialization of a service integration bus destination. Each port destination represents a particular message format and transport protocol that you can use to pass messages to an externally-hosted service.

portlet
: A reusable component that is part of a web application that provides specific information or services to be presented in the context of a portal.

portlet API
: The set of interfaces and methods that are used by Java programs running within the portal server environment to obtain services.

portlet application
: A collection of related portlets that can share resources with one another.

portlet container
: A column or row that is used to arrange the layout of a portlet or other container on a page.

portlet framework
: The set of classes and interfaces that support Java programs running within the portal server environment.

portlet mode
: A form assumed by a portlet to provide a distinctive interface for users to perform different tasks. Portlet modes can include view, edit, and help.

port number
: In Internet communications, the identifier for a logical connector between an application entity and the transport service.

port type
: An element in a Web Services Description Language (WSDL) document that comprises a set of abstract operations, each of which refers to input and output messages that are supported by the web service. See also interface.

POST
: In HTTP, a parameter on the METHOD attribute of the FORM tag that specifies that a browser will send form data to a server in an HTTP transaction separate from that of the associated URL.

postcondition
: A constraint that must be true at the completion of an operation.

precondition
: 1. A group of rule statements in which the user defines global variables for a decision table or decision tree and conditions that must be met before any rows or branches in the decision table or tree can be executed.
  2. A definition of what must be true when a task or process starts.

predefined business process
: A business process that is ready to use upon installation of Sterling B2B Integrator.

predicate
: A Boolean logic term denoting a logical expression that determines the state of a variable.

presumed trust
: A type of identity assertion where trust is presumed and additional trust validation is not performed. Use this mode only in an environment where trust is established with some other mechanism.

primary document
: A document that the services in a business process act on or in relation to. A primary document is usually the document passed to a business process by the initiating adapter.

primary key
: 1. An object that uniquely identifies an entity bean of a particular type.
  2. In a relational database, a key that uniquely identifies one row of a database table. See also constraint, foreign key.

primary server
: The server on which all resources that are to be deployed exactly once per instance or once per organization unit (OU) are deployed.

primitive
: A message processing node that cannot be further subdivided. See also subflow node.

primitive type
: In Java, a category of data type that describes a variable that contains a single value of the appropriate size and format for its type: a number, a character, or a Boolean value. Examples of primitive types include byte, short, int, long, float, double, char, boolean.

principal

An entity that can communicate securely with another entity. A principal is identified by its associated security context, which defines its access rights.

priority
A property that determines the order in which business rules are executed in an application.

privacy enhanced mail (PEM)
A standard for secure email on the Internet.

private business object
1. In XSD, a business object attribute that defines an anonymous complex type instead of referencing a named complex type.
2. A business object that is contained within other business objects. Private business objects are visible only to the containing business object, thereby making them private. See also business object.

private key
In secure communication, an algorithmic pattern used to encrypt messages that only the corresponding public key can decrypt. The private key is also used to decrypt messages that were encrypted by the corresponding public key. The private key is kept on the user system and is protected by a password. See also key, public key.

private process
A process that is strictly internal to a specific organization.

private service bundle
A service bundle that is not explicitly mentioned in the customization definition document (CDD), but that is included in a service bundle set and provides resources required by another service bundle. In a customization definition report, private service bundles are listed, and their names are followed by the string [private].

probe
A reusable set of Java code fragments and supporting attributes for collecting detailed runtime information about objects, arguments, and exceptions. See also Probekit.

Probekit
A scriptable framework for doing byte-code insertion to probe the workings of a target program. See also probe.

process
1. A progressively continuing procedure consisting of a series of controlled activities that are systematically directed toward a particular result or end.
2. The sequence of documents or messages to be exchanged between the Community Managers and participants to run a business transaction.
3. A sequence or flow of activities in an organization with the objective of carrying out work. In BPMN, a process is depicted as a graph of flow elements, which are a set of activities, events, gateways, and sequence flow paths that adhere to BPMN execution semantics.

process application
A container in the Process Center repository for process models and supporting implementations. A process application typically includes business process definitions (BPDs), the services to handle implementation of activities and integration with other systems, and any other items that are required to run the processes. Each process application can include one or more tracks.

process case
A possible path through a process, identified by a unique set of process decision outcomes and possibly determined by attributes and values of incoming data.

Process Center Console
An interface to the Process Center repository where administrators can create and manage process applications, manage user access to library items, install snapshots on test or production servers, and perform other tasks.

process control information
Map component settings that can be changed at run time by specifying overrides at the command line, in a command file, or by configuring the Launcher.

process data
Data that is accumulated in an XML document about a business process during the life of the process. Activities in the process add elements to the process data and use components of the process data to complete configured processing tasks.

process definition
A specification of the runtime characteristics of an application server process.

process diagram
A diagram that represents the flow of work for a process. The objects within a process diagram include tasks, processes, connections, business items, resources, and decisions.

process flow
The representation of interdependencies between activities in a structured format.

processing action
A defined activity in a processing rule that is performed against messages. See also action.

processing policy
A collection of policy rules that define message processing through a service.

processing rule
The portion of a policy rule in a processing policy that identifies the processing actions to perform against messages.

process instance
A manifestation of a modeled process that is created in a simulated or real environment.

process model
A representation of a real-time business process. A business process model is composed of the individual steps or activities that make up the process, contains the conditions that dictate when the steps or activities occur, and identifies the resources that are required to run the business process.

process module
A program unit that contains a set of process templates that support administrative tasks.

producer definition
A set of interfaces that are defined for the producer portal. The producer definition can include the producer service description, the producer portal URL, and the security setup. See also consumer portal, producer portal.

producer portal
A portal that provides portlets as a service so that other portals, called consumer portals, can use the portlets and make the portlets available to their users. See also consumer portal, producer definition.

profile
Data that describes the characteristics of a user, group, resource, program, device, or remote location.

programmatic emulator
: An emulator that uses a Java or visual snippet to automatically specify response values for an emulated component or reference at run time. See also emulator, manual emulator.

programmatic login
: A type of form login that supports application presentation site-specific login forms for the purpose of authentication.

programmatic security
: A collection of methods used by applications when declarative security is not sufficient to express the security model of the application.

program temporary fix (PTF)
: For System i, System p, and System z products, a package containing individual or multiple fixes that is made available to all licensed customers. A PTF resolves defects and might provide enhancements. See also fix pack.

project
: 1. A specific organization of rules and other elements that facilitates the authoring and management of a logical grouping of rules.
  2. An organized collection used to group folders or packages. Projects are used for building, version management, sharing, and organizing resources related to a single work effort. See also library, module.

project versioning
: The component that interacts with a CVS or Rational ClearCase server to share and create version projects and project data.

promoted property
: A property of a mediation module made visible by the solution integrator to the runtime administrator, so that its value can be changed at run time.

prompt
: A component of an action that indicates that user input is required for a field before making a transition to an output screen.

propagation
: The point at which the properties of a type are inherited by its subtypes.

property
: A characteristic of an object that describes the object. A property can be changed or modified. Properties can describe an object name, type, value, or behavior, among other things.

protocol binding
: A binding that enables the enterprise service bus to process messages independently of the communication protocol.

protocol-level RAS granularity
: The level of RAS granularity at which RAS attribute values are assigned on a protocol-wide basis. RAS attribute values defined at the protocol-level are assigned to all requests for a particular protocol, such as the HTTP protocol or IIOP protocol. See also RAS granularity.

proxy
: An application gateway from one network to another for a specific network application such as Telnet or FTP, for example, where a firewall proxy Telnet server performs authentication of the user and then lets the traffic flow through the proxy as if it were not there. Function is performed in the firewall and not in the client workstation, causing more load in the firewall.

proxy cluster
: A group of proxy servers that distributes HTTP requests across the cluster.

proxy peer access point
: A means of identifying the communication settings for a peer access point that cannot be accessed directly.

proxy server
: 1. A server that receives requests intended for another server and that acts on behalf of the client (as the client's proxy) to obtain the requested service. A proxy server is often used when the client and the server are incompatible for direct connection. For example, the client is unable to meet the security authentication requirements of the server but should be permitted some services.
  2. A server that acts as an intermediary for HTTP Web requests that are hosted by an application or a web server. A proxy server acts as a surrogate for the content servers in the enterprise.

pseudoattribute
: An attribute that cannot have a value, and is used to indicate a binary state, such as yes/no or on/off. For example, the attribute local might be present for some resources and absent for others, indicating whether the resource is local. Pseudo attributes are especially useful for implementing access rights, such as read, update, or delete. See also real attribute.

pseudolink
: In the Integration Flow Designer, dotted lines manually drawn in a system definition diagram that visually represent a data flow relationship between two map components that has not yet been determined precisely.

pseudomap component
: An Integration Flow Designer object that is a placeholder for an executable map that has not yet been implemented.

PTF
: See program temporary fix.

public
: 1. In object-oriented programming, pertaining to a class member that is accessible to all classes.
  2. In the Java programming language, pertains to a method or variable that can be accessed by elements residing in other classes. (Sun)

public key
: In secure communication, an algorithmic pattern used to decrypt messages that were encrypted by the corresponding private key. A public key is also used to encrypt messages that can be decrypted only by the corresponding private key. Users broadcast their public keys to everyone with whom they must exchange encrypted messages. See also key, private key.

public key algorithm (PKA)
: An algorithm designed so that the key used for encryption is different from the key used for decryption. The decryption key cannot be derived, at least not in any reasonable amount of time, from the encryption key.

public key cryptography
: A cryptography system that uses two keys: a public key known to everyone and a private or secret key known only to the recipient of the message. The public and private keys are related in such a way that only the public key can be used to encrypt messages and only the corresponding private key can be used to decrypt them.

Public Key Cryptography Standards (PKCS)

A set of industry-standard protocols used for secure information exchange on the Internet. Domino Certificate Authority and Server Certificate Administration applications can accept certificates in PKCS format.

public key infrastructure (PKI)
A system of digital certificates, certification authorities, and other registration authorities that verify and authenticate the validity of each party involved in a network transaction. See also public key, SWIFTNet public key infrastructure.

public place
A shared place that is open to all portal users. The person who creates the place (and who automatically becomes the place manager) designates it as a public place during place creation.

public process
The interactions between a private business process and another process or participant.

publish

1. In UDDI, to advertise a web service so that other businesses can find it and bind with it. Service providers publish the availability of their services through a registry.
2. To make a web site public, for example by putting files in a path known to the HTTP server.
3. To send a rule to a server for storage and management.

publish/subscribe
A type of messaging interaction in which information, provided by publishing applications, is delivered by an infrastructure to all subscribing applications that registered to receive that type of information.

Q

QoS
See quality of service.

qualifier
A simple element that gives another generic compound or simple element a specific meaning. Qualifiers are used in mapping single or multiple occurrences. A qualifier can also be used to denote the namespace used to interpret the second part of the name, typically referred to as the ID.

quality of service (QoS)
A set of communication characteristics that an application requires. Quality of Service (QoS) defines a specific transmission priority, level of route reliability, and security level.

quartile analysis
A type of analysis that displays the value of the business measures boundaries at the 25th, 50th, or 75th percentiles of a frequency distribution divided into four parts, each containing a quarter of the population.

query

1. A reusable request for information about one or more model elements
2. A statement, or combination of statements, that is used to search a rule project (or other scope) and to select rule project elements that meet certain criteria.
3. A request for information from a database that is based on specific conditions: for example, a request for a list of all customers in a customer table whose balances are greater than USD1000.

queue
An object that holds messages for message-queueing applications. A queue is owned and maintained by a queue manager.

queue destination
A service integration bus destination that is used for point-to-point messaging.

queue manager
A component of a message queuing system that provides queuing services to applications.

queuing network
A group of interconnected components.

quiesce

1. To end a process or shut down a system after allowing normal completion of active operations.
2. To pause or alter the state of running processes on a computer, particularly those processes that might modify information stored on a disk during backing up, in order to guarantee a consistent and usable backup.

R

RACF
See Resource Access Control Facility.

RADIUS
See remote authentication dial-in user service.

range

1. The number of consecutive occurrences of the component in the data stream. The range is composed of two numbers separated by a colon.
2. The categorization of an attribute into different segments.

range operator
The logic used when comparing two attributes in a range.

rank
A property that determines the order of a reason.

rapid deployment tool
One of a set of tools to rapidly develop and deploy Java EE artifacts on the server and package the Java EE artifacts into the deployed EAR file.

RAR
See resource adapter archive.

RAS

See reliability, availability, and serviceability.

RAS attribute
: An attribute that the server applies to a request to control how the server processes that request. RAS attribute values can be defined with server-level, protocol-level, or request-level granularity. See also reliability, availability, and serviceability.

RAS granularity
: The extent to which a user can assign different RAS attribute values to different sets of requests within the same application server. The user can define RAS attribute values on a per-server, per-protocol, or per-request basis. See also protocol-level RAS granularity, reliability, availability, and serviceability, request-level RAS granularity, server-level RAS granularity.

Rational Unified Process (RUP)
: A configurable software development process platform that is used to assign and manage tasks and responsibilities within a development organization.

RC
: See return code.

RDMA
: See Remote Direct Memory Access.

read-through cache
: A sparse cache that loads data entries by key as they are requested. When data cannot be found in the cache, the missing data is retrieved with the loader, which loads the data from the back-end data repository and inserts the data into the cache.

real attribute
: An attribute that must have a value. See also pseudoattribute.

realize
: In the web diagram editor, to associate a node with an actual resource by creating that resource or by editing the node path so that it points to an existing resource. See also unrealized.

realm
: A collection of resource managers that honor a common set of user credentials and authorizations.

realm name
: The machine name of a user registry.

reason code
: A code assigned to identify a reason. Each scorecard can have multiple reasons.

reasoning strategy
: The strategy used to sort and compute the reasons returned from a scorecard table.

receiver
: A component that accepts documents from external partners and from back end applications and stores them in a file system for the Document Manager to process. Specifically, it receives a document over a supported transport protocol, writes the document and metadata relating to the document to the shared file system, records any transport-specific data to the metadata file, and completes any transport-specific technical acknowledgment.

receiver bean
: In extended messaging, a message-driven bean or a session bean. A message-driven bean is invoked when a message arrives at a JMS destination for which a listener is active. A session bean polls a JMS destination until a message arrives, gets the parsed message as an object, and can use methods to retrieve the message data.

recognition profile
: In the 3270 Terminal Services tool, a list of the identifiers that uniquely identify the state of a screen, that is, the set of conditions that apply to the screen at the time the screen was imported from the host. Each screen state needs to be uniquely defined in its own recognition profile.

recognition table
: In the 3270 terminal services development tool, the table that appears in the screen editor and provides a screen definition view and a recognition profile view of the screen that was imported.

record ID information object
: A Data Interchange Services object that contains control information for ROD document definitions. It identifies the type of ROD document definition being used and where the record ID, if any, is located in the records associated with the document definition.

record oriented data (ROD)
: The type of document definition used to describe proprietary document formats. One of the supported document syntax types.

record oriented data dictionary (ROD dictionary)
: A logical grouping of related ROD document definition components.

record oriented data document definition (ROD document definition)
: A description or layout of a proprietary document, comprising loops, records, structures, and fields.

record oriented data field (ROD field)
: A single item of data, such as a purchase order number, in a record oriented data (ROD) document definition. A ROD field corresponds to an EDI data element in an EDI document definition.

record oriented data loop (ROD loop)
: A group of consecutive records and loops that repeat together in a ROD document definition.

record oriented data record (ROD record)
: A group of logically related fields set up as a record in a ROD document definition.

record oriented data structure (ROD structure)
: A group of related fields in a ROD document definition, such as the fields making up the line item of an invoice. The record oriented data (ROD) structure corresponds to an EDI composite data element in an EDI document definition.

record processing pattern
: A job step pattern that reads and applies business logic to one record at a time from an input data source. The job step writes the results to an output data source and repeats the steps until all input records are processed.

recurring wait time trigger
: A trigger that is evaluated based on a period of time. For example, a recurring wait time trigger can be evaluated every 30 minutes and fire if it detects that a specific business situation has occurred.

recursion
: A programming technique in which a program or routine calls itself to perform successive steps in an operation, with each step using the output of the preceding step.

reentrance
: A situation where a thread of control attempts to enter a bean instance again.

refactor

To make changes across a set of artifacts without changing the behavior of the application or its relationships to other elements.

reference
: Logical names defined in the application deployment descriptor that are used to locate external resources for enterprise applications. At deployment, the references are bound to the physical location of the resource in the target operational environment.

reference binding
: A binding that maps a logical name (a reference) to a JNDI name.

reference delete conflict
: An edit conflict that occurs when one user has deleted an object that another user has referred to or vice versa.

referenced type
: An object that is referred to by a source object. See also associated type.

referential integrity

1. The condition that exists when all intended references from data in one column of a table to data in another column of the same or a different table are valid.
2. In Extensible Markup Language (XML) tools, the condition that exists when all references to items in the XML schema editor or DTD editor are automatically cleaned up when the schema is detected or renamed.

refresh pack
: A cumulative collection of fixes and new functions that moves the product up one modification level and a particular service level. For example, a refresh pack might move a product from Version 1 Release 1 Modification level 1 Fix Pack 5 to Version 1 Release 1 Modification level 2 Fix Pack 3. See also fix pack, interim fix.

region
: A contiguous area of virtual storage that has common characteristics and that can be shared between processes.

registered user (RU)
: A portal user who has a user ID and password for logging in to a portal. See also anonymous user, authenticated user.

registry
: A repository that contains access and configuration information for users, systems, and software.

regular expression
: A set of characters, meta characters, and operators that define a string or group of strings in a search pattern. See also Perl-compatible regular expression.

rejection code
: A code assigned when a score cannot be derived. Typically, one reject code per scorecard only is assigned.

relationship instance
: The runtime instantiation of the relationship. The relationship definition is a template for the relationship instance.

relationship management application (RMA)
: An application used to manage authorizations. Among other things, it converts bootstrap authorizations created by WebSphere BI for FN into the RMA authorizations required to satisfy FIN PV03.

relationship management data store (RMDS)
: A set of database tables in which WebSphere BI for FN stores data about bootstrap and relationship management application (RMA) authorisations.

relationship manager
: A tool for creating and manipulating relationship and role data at run time.

relationship role
: In EJB programming, a traversal of the relationship between two entity beans in one direction or the other. Each relationship that is coded in the deployment descriptor defines two roles.

relationship service
: A service used to model and maintain relationships across business objects and other data

relative type name
: The name of a type relative to another type. Relative type names are used when defining components, syntax items, and comment types.

release
: To send changed files from the workbench to the team server so that other developers on the team can catch up (synchronize) with the updated version.

release character
: The character that indicates that a separator or delimiter is to be used as text data instead of as a separator or delimiter. The release character must immediately precede the delimiter.

reliability, availability, and serviceability (RAS)
: A combination of design methodologies, system policies, and intrinsic capabilities that, taken together, balance improved hardware availability with the costs required to achieve it. Reliability is the degree to which the hardware remains free of faults. Availability is the ability of the system to continue operating despite predicted or experienced faults. Serviceability is how efficiently and nondisruptively broken hardware can be fixed. See also RAS attribute, RAS granularity.

remote
: Pertaining to a system, program, or device that is accessed through a communication line.

remote authentication dial-in user service (RADIUS)
: An authentication and accounting system that uses access servers to provide centralized management of access to large networks.

remote database
: A database to which a connection is made by using a database link, while connected to a local database. See also local database.

Remote Direct Memory Access (RDMA)
: A communication technique in which data is transmitted from the memory of one computer to that of another without passing through a processor. RDMA accommodates increased network speeds.

remote file system
: A file system residing on a separate server or operating system.

remote file transfer instance
: A file that contains information about the method used for remotely transferring a file.

remote home interface
: In enterprise beans, an interface that specifies the methods used by remote clients for locating, creating, and removing instances of enterprise bean classes. See also local home interface.

remote interface
: In EJB programming, an interface that defines the business methods that can be called by a client. See also home interface.

remote messaging, remote support, and web applications pattern
: A reusable deployment environment architecture for IBM Business Process Management products and solutions in which the functional components of the environment (messaging, support, web-based components, and application deployment) are split across four clusters.

remote messaging and remote support pattern
: A reusable deployment environment architecture for IBM Business Process Management products and solutions in which the functional components of the environment (messaging, support, web-based components, and application deployment) are split across three clusters. Web-based components reside on the support or the application-deployment cluster.

remote method
: A business method in the remote interface that is callable by a client. See also Remote Method Invocation.

Remote Method Invocation (RMI)
: A protocol that is used to communicate method invocations over a network. Java Remote Method Invocation is a distributed object model in which the methods of remote objects written in the Java programming language can be invoked from other Java virtual machines, possibly on different hosts. See also remote method.

Remote Method Invocation over Internet InterORB Protocol (RMI/IIOP)
: Part of the Java Platform, Standard Edition (Java SE) model that developers can use to program in the Java language to work with RMI interfaces, but use IIOP as the underlying transport.

Remote OSE
: A transport mechanism that is based on the Open Servlet Engine (OSE) protocol and is used to communicate between two separate machines in the application server environment.

Remote Procedure Call (RPC)
: A protocol that allows a program on a client computer to run a program on a server.

remote product installation
: A product installation onto a remote workstation that has a pre-installed operating system.

remote queue
: A queue that belongs to a remote queue manager. Programs can put messages on remote queues, but they cannot get messages from remote queues. See also local queue.

remote queue manager
: A queue manager to which a program is not connected, even if it is running on the same system as the program. See also local queue manager.

remove method
: In enterprise beans, a method defined in the home interface and invoked by a client to destroy an enterprise bean.

repeating data element
: An EDI data element or EDI composite data element that occurs more than once consecutively in an EDI segment.

repertoire
: Configuration information that contains the details necessary for building a Secure Sockets Layer (SSL) connection.

replica
: A server that contains a copy of the directory or directories of another server. Replicas back up servers in order to enhance performance or response times and to ensure data integrity.

replication
: 1. The process of copying objects from one node in a cluster to one or more other nodes in the cluster, which makes the objects on all the systems identical.
2. The process of maintaining a defined set of data in more than one location. Replication involves copying designated changes for one location (a source) to another (a target) and synchronizing the data in both locations.

replication domain
: A collection of application server components that share data. These components might include HTTP sessions, dynamic cache, stateful session beans, or the session initiation protocol (SIP) component.

replication entry
: A runtime component that handles the transfer of internal data.

reply message
: A type of message used for replies to request messages. See also report message, request message.

reply-to queue
: The name of a queue to which the program that issued an MQPUT call wants a reply message or report message sent.

report
: A formatted presentation of information relating to a model or to process simulation results. Reports can be viewed online, printed, or exported to a variety of file formats.

report container
: A group of settings that define the overall presentation of a report, including page dimensions and orientation, margin sizes, and options for displaying title, author, and summary information.

report message
: A type of message that gives information about another message. A report message can indicate that a message has been delivered, has arrived at its destination, has expired, or could not be processed for some reason. See also reply message, request message.

repository
: A persistent storage area for data and other application resources.

repository checkpoint
: A function that backs up copies of files from the master configuration repository. The backup files can be used to restore the configuration to a previous state if future configuration changes cause operational problems.

Representational State Transfer (REST)
: A software architectural style for distributed hypermedia systems like the World Wide Web. The term is also often used to describe any simple interface that uses XML (or YAML, JSON, plain text) over HTTP without an additional messaging layer such as SOAP. See also RESTful.

request
: In a request/response interaction, the role performed by a business object that instructs a connector to interact with an application or other programmatic entity.

request consumer binding
: A definition of the security requests for the request message that is received by a web service.

request flow

The flow of the message from the service requester.

Request for Comments (RFC)
In Internet communication, one of a series of numbered documents that describe Internet communication protocols.

request generator binding
A definition of the security requests for the request message that is sent to a web service.

request-level RAS granularity
The level of RAS granularity at which RAS attributes are assigned on a request-by-request basis to all requests for a particular request classification, such as HTTP requests that end in .jpg, a specific HTTP request for a URI such as /PlantsByWebSphere/index.html, or all IIOP requests for a particular EJB. See also RAS granularity.

request message
A type of message used to request a reply from another program. See also reply message, report message.

request metrics
A mechanism to monitor and troubleshoot performance bottlenecks in the system at an individual request level.

request receiver binding
A definition of the security requirements for the request message that is received from a request to a web service.

request/reply
A type of messaging application in which a request message is used to request a reply from another application. See also datagram.

request sender binding
A definition of the security requirements for the request message that is sent to a web service.

required component
A component that can be defined within a group type to represent a data object that must be present in the data. The component range minimum specifies how many occurrences of the data object are required.

resource
A person, piece of equipment, or material that is used to perform an activity.

Resource Access Control Facility (RACF)
An IBM licensed program that provides access control by identifying users to the system; verifying users of the system; authorizing access to protected resources; logging unauthorized attempts to enter the system; and logging accesses to protected resources.

resource adapter

1. Map input and output data sources that are used to retrieve and route data. Resource adapters provide access to databases, files, messaging systems, and other data sources and targets. Each adapter includes a set of adapter commands that can be used to customize its operation.
2. A system-level software driver that is used by an EJB container or an application client to connect to an enterprise information system (EIS). A resource adapter plugs in to a container; the application components deployed on the container then use the client API (exposed by adapter) or tool-generated, high-level abstractions to access the underlying EIS. (Sun) See also container, enterprise information system.

resource adapter archive (RAR)
A Java archive (JAR) file that is used to package a resource adapter for the Java 2 Connector (J2C) architecture.

resource class
An attribute of a resource that is used to group resources according to the subsystem to which they belong and the purpose for which they are used.

resource distribution report
A report, generated by the Customization Definition Program (CDP), that describes the resources required by an instance.

resource environment reference
A reference that maps a logical name used by the client application to the physical name of an object.

resource file
A file that is used to create, in a runtime environment, one or more resources of a particular class.

resource manager

1. An application, program, or transaction that manages and controls access to shared resources such as memory buffers and data sets. WebSphere MQ, CICS, and IMS are resource managers.
2. A participant, in the execution of a one-phase or two-phase commit, that has recoverable resources that could have been modified. The resource manager has access to a recovery log so that it can commit or roll back the effects of the logical unit of work to the recoverable resources.

resource manager local transaction (RMLT)
A resource manager view of a local transaction that represents a unit of recovery on a single connection that is managed by the resource manager.

resource model
A model that defines the resources used in business operations, including their roles, availability, and cost characteristics.

resource property
A property for a JDBC data source in a server configuration, for example the server name, user ID, or password.

Resource Recovery Services (RRS)
A component of z/OS that uses a sync point manager to coordinate changes among participating resource managers.

resource set
A collection of resources that are members of the same class and that share a common scope. A resource set also determines which other resource sets are its prerequisites and which place holders are used within the corresponding resource file templates.

response file
A file containing predefined values that is used instead of someone having to enter those values one at a time. See also silent installation.

response flow
The flow of the message from the service provider to the service requester.

response generator binding
A definition of the security requests for the response message that is sent to a web service.

response receiver binding
A definition of the security requirements for the response message that is received from a request to a web service.

response sender binding
A definition of the security requirements for the response message that is sent to a web service.

REST
See Representational State Transfer.

restart attribute

An attribute that specifies that processing of the input data should continue even though a data object of the component is invalid. The restart attribute provides instructions for handling errors encountered in a data stream and can be assigned to a component within a group type.

RESTful
: Pertaining to applications and services that conform to Representational State Transfer (REST) constraints. See also Representational State Transfer.

result
: The consequence of reaching an end event. Types of results include message, error, compensation, and signal. There can be multiple results, such as a result that produces a message and another result that sends a signal.

result event
: An action that is generated by the technology connectors and sent back to the runtime server to be processed as a new event.

result set
: A set of row values as returned by, for example, a cursor or procedure.

result tree
: The output document that is created when an XSL file is used to transform an XML file.

resume
: To continue execution of an application after an activity has been suspended.

RetePlus mode
: A rule execution mode for matching patterns with objects. The RetePlus mode is used by the rule engine to minimize the number of rules and conditions that need to be evaluated, compute which rules should be executed, and identify in which order these rules should be fired.

retraction
: The action of removing an object bound to a rule variable from the working memory.

return code (RC)
: A value returned by a program to indicate the result of its processing. Completion codes and reason codes are examples of return codes.

reverse proxy
: An IP-forwarding topology where the proxy is on behalf of the back-end HTTP server. It is an application proxy for servers using HTTP.

RFC
: See Request for Comments.

rich media
: In a web page, content that is aural, visual, or interactive, such as audio or video files.

Rich Site Summary (RSS)
: An XML-based format for syndicated web content that is based on the RSS 0.91 specification. The RSS XML file formats are used by Internet users to subscribe to websites that have provided RSS feeds. See also feed.

rich text
: A field that can contain objects, file attachments, or pictures as well as text with formatting options such as italics or boldface.

ripplestart
: An action where the system waits for a member in a cluster to start before starting the next member of the cluster.

RMA
: See relationship management application.

RMA authorisation
: An authorisation that has been processed by a relationship management application (RMA).

RM distribution file
: A file used to exchange relationship data with an relationship management application (RMA). It is the file that is created when you export bootstrap authorizations, and it is the file from which you import authorizations from an RMA.

RMDS
: See relationship management data store.

RMI
: See Remote Method Invocation.

RMI/IIOP
: See Remote Method Invocation over Internet InterORB Protocol.

RMLT
: See resource manager local transaction.

RM report
: A report used to determine whether all the relationships that are required when using PV03 exclusively have already been recorded, and whether corresponding authorisations already exist.

ROD
: See record oriented data.

ROD dictionary
: See record oriented data dictionary.

ROD document definition
: See record oriented data document definition.

ROD field
: See record oriented data field.

ROD loop
: See record oriented data loop.

ROD record
: See record oriented data record.

ROD structure
: See record oriented data structure.

role

1. A collection of access rights that can be assigned to a user, group of users, system, service, or application that enable it to carry out certain tasks.
2. A logical group of principals that provides a set of permissions. Access to operations is controlled by granting access to a role.
3. A job function that identifies the tasks that a user can perform and the resources to which a user has access. A user can be assigned one or more roles.
4. In a relationship, a role determines the function and participation of entities. Roles capture structure and constraint requirements on participating entities and their manner of participation. For example, in an employment relationship, the roles are employer and employee.

5. A description of a function to be carried out by an individual or bulk resource, and the qualifications required to fulfill the function. In simulation and analysis, the term role is also used to refer to the qualified resources.

role-based authorization
: The use of authorization information to determine whether a caller has the necessary privilege to request a service.

role-based security
: Security that provides access rights to certain files, business processes, web templates, and features, according to the permissions associated with the user account.

role mapping
: The process of associating groups and principals recognized by the container to security roles specified in the deployment descriptor.

rollback
: The process of restoring data that was changed by an application program or user.

root
: The user name for the system user with the most authority.

root element
: The implicit highest-level node of a parsed XML document. You may not always be able to predict which element will be the document element of a parsed instance, but it will always have a root node that you can count on being able to use for preliminary or setup processing.

root type
: The type from which all other types stem. The root type represents the data objects of all the types in the tree.

RosettaNet Partner Interface Process (PIP)
: A specialized system-to-system XML-based dialog that depicts the activities, decisions, and partner role interactions that fulfill a business transaction between two partners in a given supply chain.

routing policy
: A set of rules that determine how the server routes incoming requests.

row
: The horizontal component of a table, consisting of a sequence of values, one for each column of the table.

RPC
: See Remote Procedure Call.

RRS
: See Resource Recovery Services.

RSA encryption
: A system for public-key cryptography used for encryption and authentication. It was invented in 1977 by Ron Rivest, Adi Shamir, and Leonard Adleman. The security of the system depends on the difficulty of factoring the product of two large prime numbers.

RSS
: See Rich Site Summary.

RU
: See registered user.

rule

1. A condition that must be satisfied when a business activity is being performed.
2. A statement that defines or constrains some aspect of the business. See also business rule, event rule.
3. The criteria or circumstances that are defined to trigger an event. For example, rules can be triggered during entry to or exit from a zone and can be specified for a tag ID, class, or group.

rule analysis
: A mechanism for checking whether business rules are semantically consistent. Inconsistencies can be found either in the rule itself, or with respect to other rules.

RuleApp
: A deployment and management unit for Rule Execution Server that can contain one or more rule sets.

RuleApp archive
: An archive that allows RuleApps to be stored to a file system. RuleApp archives are saved in a strict directory structure.

RuleApp project
: An Eclipse project that performs the deployment of a RuleApp to a running Rule Execution Server.

rule artifact
: An item used to express a business policy in a business rule application. Action rules and decision tables are examples of rule artifacts.

Rule Designer
: A business rule application development tool integrated into the Eclipse development environment and dedicated to the creation and management of business rule applications.

RuleDoc
: A document containing business rules and rule metadata that can be edited.

rule editor
: A graphical tool used to create rules.

rule engine
: Accessible through a class, an engine that takes a rule set and executes it against a set of objects. The rule engine evaluates the conditions of rules in the rule set against the object in an object set to determine which rules are eligible to be executed.

Rule Execution Server
: A module that integrates into the Java EE environment, and as such offers the standard services of an application to execute, control, and monitor rule sets contained in RuleApps.

Rule Execution Server configuration project
: A project in which a server configuration persists. The configuration provides the information necessary to make a connection to the rule execution server when a RuleApp is applied.

Rule Execution Server console
: A web user interface that provides support for deploying RuleApps and the management of executable resources on Rule Execution Server.

rule execution set
: A collection of rules that are intended to be executed together.

rule flow

A method of controlling and ordering the execution of rule artifacts. A rule flow is defined in terms of tasks.

rule instance
: An occurrence of a rule that includes the combination of objects in the working memory that match the patterns specified in the rule. More than one instance of the same rule may exist in the agenda at any time because the rule patterns may be satisfied by more than one object or set of objects.

rule logic
: The business logic, which is expressed by a business rule, that consists of decisions that affect how a business responds to specific business conditions. For example, a decision that determines how much of a discount to give to a preferred customer is rule logic.

rule model
: A model that defines the set of items that are managed in a rule and event projects, and their associated properties.

rule package
: A container for organizing rule artifacts according to business logic. Rule packages become folders after they have been published to Decision Center.

rule perspective
: An Eclipse perspective that defines the initial set and layout of views in the workbench window that will be used in the development of a rule project.

rule project
: A type of project in which the user can manage and organize rule artifacts and business object models.

rule project template
: A partly completed rule project that can be used to create a series of rule projects with the same structure.

rules-based personalization
: Personalization technology that enables you to customize web content based on user needs and preferences, and business requirements.

rule schedule
: An interface for modifying the values of a business rule in the rule logic selection record.

rule session
: A runtime connection between a client and a rule engine. A rule session may consume initialized rule engine resources.

rule set
: 1. A set of rules that can be executed by the rule engine and includes rule artifacts and non-rule artifacts.
  2. An if-then statement that is composed of a set of textual statements, or rules, that are evaluated sequentially. if is the condition and then is the action. Each condition that evaluates to true is acted upon. See also action rule, decision table, if-then rule.

rule set extractor
: A mechanism for selecting the rules of the rule set to be deployed. Selection is typically based on the value of rule properties.

rule set interceptor
: A mechanism that allows services to be added to an execution component transparently and to be triggered automatically when certain events occur.

rule set parameter
: A parameter that can be defined to set and retrieve values on a rule set. Rule set parameters are accessible from outside of the rule set, and therefore are a bridge between the business logic and the application.

rule set signature
: The list of in, out, and inout parameters of a rule set.

rule set variable
: A variable that can be defined to be used in all the rule artifacts of a rule set.

rule task
: In a rule flow, a task that refers to rule artifacts and orders them.

rule template
: A partly completed business rule that can be used to create a series of rules with the same structure.

RunAs role
: A role used by a servlet or an enterprise bean component to invoke and delegate a role to another enterprise bean.

run map
: An executable map that is called using the RUN function.

runtime
: Pertaining to the time period during which a computer program is running.

run time
: The time period during which a computer program is running.

runtime environment
: A set of resources that are used to run a program or process.

runtime object
: An object used by the translator, such as a control string, code list, translation table, or user exit profile.

runtime rule selection
: In a rule task, a way to filter rule artifacts at run time. Runtime rule selection is expressed in rule statements.

runtime task
: A generated administrative action plan that contains recommendations to improve the health and performance of a runtime environment.

runtime topology
: A depiction of the momentary state of the environment.

RUP
: See Rational Unified Process.

S

SAAJ
: See SOAP with attachments API for Java.

SACL
: See State Adaptive Choreography Language.

SAF
: See System Authorization Facility.

SAG
: See SWIFTAlliance Gateway.

SAG MQ connection
: An entity within an SAG that encapsulates a WebSphere MQ connection.

SAML
: See Security Assertion Markup Language.

SAS
: See Secure Association Service.

SAX
: See Simple API for XML.

SCA
: See Service Component Architecture.

SCA component
: A building block of the Service Component Architecture, used to build SCA modules such as mediation modules.

SCA export binding
: A concrete definition that specifies the physical mechanism used by a service requester to access an SCA module; for example, using SOAP/HTTP.

SCA export interface
: An abstract definition that describes how service requesters access an SCA module.

SCA import binding
: A concrete definition that specifies the physical mechanism used by an SCA module to access an external service; for example, using SOAP/HTTP.

SCA import interface
: An abstract definition that describes how an SCA module accesses a service.

scalability
: The ability of a system to expand as resources, such as processors, memory, or storage, are added.

SCA module
: A module with interfaces that conforms to the Service Component Architecture (SCA).

SCA request
: A service request that conforms to the Service Component Architecture (SCA). An SCA module routes the request to a service provider, after having done any additional processing specified by the module.

SCA run time
: The server functions that provide support for the Service Component Architecture.

scenario
: 1. A set of actions representing a business process within the context of a collaboration. Scenarios can be used to partition collaboration logic. For example, if a collaboration handles one type of business object with various possible verbs, the user might develop Create, Update, and Delete scenarios. See also activity.
  2. A real or fictitious use case that can be used to validate the behavior of rules with test suites or simulations. Each scenario contains all the necessary information required for rules to execute properly.

scenario provider
: An object that defines how scenarios are loaded for test suites and simulations.

scheduler
: A service that provides time-dependent services.

schema
: A collection of database objects such as tables, views, indexes, or triggers that define a database. A schema provides a logical classification of database objects.

schema document definition
: A description or layout of an XML document based on an XML schema.

SCM
: See software configuration management.

scope
: 1. In web services, a property that identifies the lifetime of the object serving the invocation request.
  2. A specification of the boundary within which system resources can be used.

scorecard
: A set of measurements on a subject to help to make a business decision. See also scoring strategy.

scorecard property
: A property that defines the reasoning strategy and the scoring strategy. Scorecard properties are used together to determine the final score and the reason codes that are displayed.

scoring strategy
: A strategy to calculate the final score from each of the attribute scores for the overall scorecard. See also scorecard.

scratchpad area (SPA)
: A work area used in conversational processing to retain information from an application program across executions of the program.

screen
: The display that the user sees when connected to a 3270 application on the host system. A single 3270 application can include many screens, each of which has a purpose within the context of the application.

screen editor
: A 3270 terminal service development tool that enables a developer to create and modify recognition profiles for an imported screen and to assign names to the fields on the screen definition.

screen file
: The result of importing a screen definition from a 3270 application into the 3270 terminal service development workbench. A screen file represents a screen definition. The screen definition contains identifiers such as the number of fields on the screen and the row and column position of fields on the screen. There are multiple screen files per 3270 terminal service project. Each screen file can have multiple recognition profiles assigned to it.

screen import
: The process of importing a screen definition (in its current state) and saving it to a screen file within the 3270 terminal service tools workbench, for the purpose of generating recognition profiles and custom screen records. Use the 3270 terminal service recorder to import screens.

screen recognition

A runtime function that determines the state of a screen and processes the screen in accordance with the identifiers in the recognition profiles. Screen recognition compares the screen as presented by the 3270 application to the defined recognition profiles to determine which screen state applies.

screen state
: The set of conditions (at the time the screen was imported from the host) that determine the allowed and required processing on the screen. A screen state operates on input to change the status, cause an action, or result in a particular output screen. A single screen can have multiple states and the allowed user actions for the screen vary depending on which state the screen is in.

script
: A series of commands, combined in a file, that carry out a particular function when the file is run. Scripts are interpreted as they are run.

scripting
: A style of programming that reuses existing components as a base for building applications.

scriptlet
: A mechanism for adding scripting language fragments to a source file.

script package
: A compressed file consisting of an executable file and supporting files that are added to pattern topologies to customize the behavior of a cell.

SDK
: See software development kit.

SDO
: See Service Data Objects.

SDO repository
: A database that is used for storing and serving the Web Services Description Language (WSDL) definitions of web services. For example, the WSDL definitions for service integration bus-enabled web services are stored as service data objects in an SDO repository.

search center
: A portlet that enables site users to search for keywords. See also search collection, search service.

search collection
: A searchable collection of documents that can span multiple content sources. See also search center, search service.

search service
: A service that is used to define the configuration parameters for a search collection. A search service can be local, remote, inside the product, or outside the product. See also search center, search collection.

secret key
: A key that both encrypts and decrypts information. In symmetric cryptography, both communicating parties use a secret key. In asymmetric or public key cryptography, a public key and a private key are used to encrypt and decrypt information.

Secure Association Service (SAS)
: An authentication protocol used to communicate securely for the client principal by establishing a secure association between the client and server.

Secure FTP
: An FTP protocol that uses Secure Sockets Layer (SSL) protocol.

Secure Hash Algorithm (SHA)
: An encryption method in which data is encrypted in a way that is mathematically impossible to reverse. Different data can possibly produce the same hash value, but there is no way to use the hash value to determine the original data.

Secure Internet Protocol Network
: A SWIFT network based on the Internet Protocol (IP) and related technologies.

Secure Shell (SSH)
: A UNIX-based command interface and protocol for securely getting access to a remote computer.

Secure Sockets Layer (SSL)
: A security protocol that provides communication privacy. With SSL, client/server applications can communicate in a way that is designed to prevent eavesdropping, tampering, and message forgery. See also certificate authority.

security administrator
: The person who controls access to business data and program functions.

Security Assertion Markup Language (SAML)
: An XML framework for exchanging authentication and authorization information.

security attribute propagation
: The transportation of security attributes from one server to another server in an application server configuration.

security constraint
: A declaration of how to protect web content, and how to protect data that is communicated between the client and the server.

security domain
: The set of all the servers that are configured with the same user registry realm name.

security entity
: Entities used to specify what a user is authorized to do. Security entities include roles and users.

security permission
: Authorization granted to access a system resource.

security policy
: A written document that defines the security controls that you institute for your computer systems. A security policy describes the risks that you intend these controls to minimize and the actions that should be taken if someone breaches your security controls.

security role
: In Java EE, an abstract logical grouping of users that is defined by the application assembler. When an application is deployed, the roles are mapped to security identities, such as principals or groups, in the operational environment. (Sun)

security role reference
: A role that defines the access levels that users have and the specific resources that they can modify at those levels.

security token
: A representation of a set of claims that are made by a client that can include a name, password, identity, key, certificate, group, privilege, and so on.

segment
: An EDI logical unit of information. EDI segments are made up of data elements and composites. Segments are delimited; their components are separated by a delimiter.

segmentation
: A strategy that is used for building complex scorecards. This strategy defines segments or subgroups where a scorecard split might be necessary.

segmentation score

The maximum score of the scorecard when complex reasoning is not used. It is used to tune the contribution factor of a scorecard within the complex scorecard. The segmentation score is a property in a complex scorecard.

segment directory
: A file containing the format of all EDI segments in an EDI standard.

segment identifier
: A unique three-character identifier at the beginning of each EDI segment.

segment ID separator
: The character that separates the segment identifier from the EDI data elements in the EDI segment. See also data element delimiter.

segment terminator
: The character that marks the end of an EDI segment.

selector component
: A component that provides a means of interposing a dynamic selection mechanism between the client application and a set of target implementations.

sender bean
: In extended messaging, an enterprise bean (stateless session bean) that can be built to send asynchronous messages. A sender bean translates its method invocation into a JMS message, then passes that message to JMS. It can also retrieve a response message, translate that message into a result value, and return it to the caller.

sensor
: A program that reads information from a managed software system to create configuration information.

sequence flow
: A connecting object, represented by a solid graphical line, that shows the order of flow objects in a process or choreography. A sequence flow can cross the boundaries between swimlanes of a pool, but cannot cross the boundaries of a pool. There are two types of sequence flows: exception flow and normal flow.

sequence grouping
: The specification of the order in which entity beans update relational database tables.

sequence line
: An element that controls the sequence of activities and events during process execution.

sequence number
: A number assigned to each message exchanged between two nodes. The number is increased by one for each successive message. It starts from zero each time a new session is established.

sequential mode
: A rule execution mode for stateless pattern-matching. With this mode, rules can be processed sequentially, which can improve the speed of rule processing in specific cases. The sequential mode can be selected for individual tasks in a rule flow.

serialization
: In object-oriented programming, the writing of data in sequential fashion to a communications medium from program memory.

serializer
: A method for converting object data to another form such as binary or XML. See also deserialization.

series
: The consecutive occurrences of a component. In map rules, the [ ] characters denote an indexed member of a series.

servant region
: A contiguous area of virtual storage that is dynamically started as load increases and automatically stopped as load eases.

server
: A software program or a computer that provides services to other software programs or other computers. See also client, host.

server and bus environment
: The environment in which servers, service integration buses, and their resources are configured and managed.

server cluster
: A group of servers that are typically on different physical machines and have the same applications configured within them, but operate as a single logical server.

server configuration
: A resource that contains information required to set up and deploy to an application server.

server definition
: A definition for a computer that hosts a command server, to which systems under development in the Integration Flow Designer can be assigned as the intended execution server.

server group
: A group of Rule Execution Server for z/OS instances that are configured to be transferred to another if a server fails or if there is a planned outage. A server group can include one to 32 server instances.

server implementation object
: Enterprise beans that client applications require to access and implement the services that support those objects.

server-level RAS granularity
: The level of RAS granularity at which RAS attribute values are assigned on a server-wide basis. RAS attribute values defined at the server-level are assigned to all requests that the server processes. See also RAS granularity.

server message
: A message that is routed to a server application for processing, or a delivery notification that is routed to a client application to acknowledge the receipt of a client message by its destination.

server operation
: A collection of Java or non-Java process definitions that you can define to run on middleware servers. You can create server operations to enable or disable tracing, start or stop applications, query the running state of a server, and so on.

server project
: A project that contains information about test and deployment servers and their configurations.

server-side
: Pertaining to an application or component of an application that runs on a server rather than on the client. JSP and servlets are two examples of technologies that enable server-side programming.

server-side include (SSI)
: A facility for including dynamic information in documents sent to clients, such as current date, the last modification date of a file, and the size or last modification of other files.

service

1. In service-oriented architecture, a unit of work accomplished by an interaction between computing devices.
2. An offering that provides skilled assistance to customers. A service may include consulting, education and training, offering enabling services, managed operations, integration and application development. Services are distinguished from products by their intangibility, inseparability, perishability and variability. See also Advanced Integration service, General System service, integration service.
3. A component that accepts as input a message, and processes the message. For example, a service translates its payload into a different format, or routes it to one of several output queues. Most services are implemented as message flows or primitives.
4. A program that is used to implement activities or to perform one-time or recurring system tasks.

service application
: An application used to deploy mediation modules.

service bundle (SVB)
: A set of services that logically belong together, for example, because they share resources such as a status table or error processing queue. A service bundle contains the definition files for all resources required to provide the services, for example definition files for message flows, queues, and database tables. A service bundle has a unique name in the scope of an instance. A service bundle must be assigned to an organizational unit and loaded into a server before it is operational.

service bundle set
: A group of service bundles that are packaged together to simplify ordering. A definition file that defines the resource classes, resource file types, place holders, and server types that can be used by the service bundles in the set is associated with each service bundle set.

service class
: A group of work that has the same service goals or performance objectives, resource requirements, or availability requirements. For workload management, a service goal and, optionally, a resource group is assigned to a service class.

service client
: A requester that invokes functions in a service provider.

service component
: A collection of processes that represents a business service that publishes or operates on business data.

Service Component Architecture (SCA)
: An architecture in which all elements of a business transaction, such as access to web services, Enterprise Information System (EIS) service assets, business rules, workflows, databases and so on, are represented in a service-oriented way.

service context
: Part of a General InterORB Protocol (GIOP) message that is identified with an ID and contains data used in specific interactions, such as security actions, character code set conversion, and Object Request Broker (ORB) version information.

Service Data Objects (SDO)
: An open standard for enabling applications to handle data from heterogeneous data sources in a uniform way, based on the concept of a disconnected data graph. See also business object.

service definition
: One or more WSDL files that describe a service. Service definitions are produced by the Definition, Deployment, Adapter, Skeleton, and Proxy wizards.

service description
: The description of a web service, which can be defined in any format such as WSDL, UDDI, or HTML.

service destination
: A specialization of a service integration bus destination. Each service destination can directly represent the web service implementation or can indirectly represent the service through a Web Services Description Language (WSDL) document.

service document
: A document that describes a web service, for example a Web Services Description Language (WSDL) document.

service endpoint
: The physical address of a service which implements one or more interfaces.

service input queue
: The queue from which a service retrieves the messages it is to process. In WebSphere BI for FN, this queue is implemented as a WebSphere MQ local queue.

service integration bus (SIBus)
: A managed communication mechanism that supports service integration through synchronous and asynchronous messaging. A bus consists of interconnecting messaging engines that manage bus resources.

service integration bus link
: A link between messaging engines on different service integration buses. This enables requests and messages to pass between the buses.

service integration bus web services enablement
: A software component that enables web services to use IBM service integration technologies. This capability provides a quality of service choice and message distribution options for web services, with mediations that support message rerouting or modification.

service integration logic
: Integration logic on an enterprise service bus to mediate between requesters and providers. The logic performs a number of functions such as to transform and augment requests, convert transport protocols, and route requests and replies automatically

service integration technology
: Technology that provides a highly-flexible messaging system for a service-oriented architecture (SOA). This supports a wide spectrum of quality of service options, protocols, and messaging patterns. The technology supports both message-oriented and service-oriented applications.

service interface queue
: The queue into which applications place messages that are to be processed by a service. In WebSphere BI for FN, each OU that uses a particular service has its own service interface queue, and this queue is implemented as a WebSphere MQ alias queue.

service level
: A class of service that can be used in business policies to aggregate a set of implied service qualities.

service level agreement (SLA)

1. In IBM Business Process Management, a rule that a user creates to analyze the performance of business processes over time. An SLA establishes a condition that triggers a consequence and creates a report for one or more activities. Conditions in SLAs are based on a standard or custom key performance indictator (KPI).
2. A contract between a customer and a service provider that specifies the expectations for the level of service with respect to availability, performance, and other measurable objectives.

service message object (SMO)

A service data object that can exist only in a mediation flow component. The service message object is composed of a body and headers. The body contains the parameters of the invoked interface operation, and the headers may contain information such as service invocation, transport protocol, mediation exception, JMS properties, or correlation information.

service-oriented architecture (SOA)
A conceptual description of the structure of a software system in terms of its components and the services they provide, without regard for the underlying implementation of these components, services and connections between components.

service policy
A performance goal that is assigned to a specific application URI to help designate the business importance of different request types.

service portfolio
The collection of business services that a subscriber is entitled to use.

service project
A collection of related items used to build a service.

service provider
A company or program that provides a business function as a service.

service registry
A repository that contains all of the information that is required to access a web service.

service requester
The application that initiates an interaction with a web service. The service requester binds to the service by using the published information and calls the service.

services
Collections of network endpoints or ports that are used to aggregate a set of related ports.

service segment
The EDI segment used when an EDI document is enveloped (such as ISA, GS, ST, UNB, UNH, UNT, and so on).

service task
A task that uses a service implementation, such as a web service, that a BPM execution engine runs. This task does not require user interaction and does not appear on a task list.

service type definition
In Universal Discovery Description and Integration (UDDI), a description of specifications for services or taxonomies.

service virtualization
A virtualization that compensates for the differences in the syntactic details of the service interactions so that the service requester and provider do not have to use the same interaction protocol and pattern or the same interface, nor do they have to know the identities of the other participants.

servlet
A Java program that runs on a web server and extends the server functions by generating dynamic content in response to web client requests. Servlets are commonly used to connect databases to the web.

servlet archive
A file that contains the same components as a servlet application. Unlike web archives, servlet archives can have only a sip.xml deployment descriptor and not a web.xml deployment descriptor.

servlet container
A web application server component that invokes the action servlet and that interacts with the action servlet to process requests.

servlet filtering
The process of transforming a request or modifying a response without exposing the resource used by the servlet engine. See also filter.

servlet mapping
A correspondence between a client request and a servlet that defines their association.

session

1. A logical or virtual connection between two stations, software programs, or devices on a network that allows the two elements to communicate and exchange data for the duration of the session. See also transaction.
2. A series of requests to a servlet originating from the same user at the same browser.
3. In Java EE, an object used by a servlet to track user interaction with a web application across multiple HTTP requests.

session affinity
A method of configuring applications in which a client is always connected to the same server. These configurations disable workload management after an initial connection by forcing a client request to always go to the same server.

session bean
An enterprise bean that is created by a client and that typically exists only for the duration of a single client/server session. (Sun) See also entity bean, stateful session bean, stateless session bean.

session facade
A mechanism for separating the business and client tiers of an enterprise application by abstracting the data and business methods so that clients are not tightly coupled with the business logic and not responsible for data integrity. Implemented as session enterprise beans, session facades also decouple lower-level business components from one another.

Session Initiation Protocol (SIP)
A protocol for initiating interactive multi-media sessions. See also siplet.

session sequence number
A sequentially incremented 10 byte identifier that is assigned to each request unit in an LT session. It is formed by concatenating the 4 byte session number with a 6 byte sequence number.

setter method
A method whose purpose is to set the value of an instance or class variable. This capability allows another object to set the value of one of its variables. See also getter method.

severity code
A number that indicates the seriousness of an error condition.

SHA
See Secure Hash Algorithm.

shadow zone
A zone where the tags might not be visible temporarily because they are out of reach of the tag reader infrastructure or the signals are shielded. WebSphere Sensor Events assumes that a tag continues to be in the shadow zone at the last reported position after it has been seen. No alert is generated if the tag is no longer visible.

shard
An instance of a partition. A shard can be a primary or replica.
shared library file
A file that consists of a symbolic name, a Java class path and a native path for loading Java Native Interface (JNI) libraries. Applications that are deployed on the same node as this file can access this information.
shared lock
A lock that limits concurrently running application processes to read-only operations on database data. See also exclusive lock.
shared place
A place created for a community of people with a common purpose. Shared places can be public or restricted. The place creator (who automatically becomes the place manager) specifies whether a place is public or restricted during place creation.
shared service instance
An application capability that is made available in the cloud as an always-on, multitenant, elastic service for multiple users or applications.
shell script
A program, or script, that is interpreted by the shell of an operating system.
shortcut bar
In Eclipse, the vertical toolbar at the left side of the workbench window that contains buttons for open perspectives and for fast views.
shortest path
The processing path that takes the shortest time to complete of all parallel paths in a process instance, where each path considered begins at a start node or an input to the process and ends at a terminate node.
Short Message Service (SMS)
A message service that is used to send alphanumeric messages that are 160 characters or less between mobile phones.
short name
In personal communications, the one-letter name (A through Z) of the presentation space or emulation session.
short-running process
See microflow.
showcase
A business space that displays example widgets and data that describes a particular scenario to the user.
shredding
The process of breaking up an XML document for storage in database tables.
SIBus
See service integration bus.
side effect
An undesirable result caused by altering the values of nonlocal variables by a procedure or function.
signer certificate
The trusted certificate entry that is typically in a truststore file.
silent installation
An installation that does not send messages to the console but instead stores messages and errors in log files. A silent installation can use response files for data input. See also response file.
silent mode
A method for installing or uninstalling a product component from the command line with no GUI display. When using silent mode, you specify the data required by the installation or uninstallation program directly on the command line or in a file (called an option file or response file).
Simple API for XML (SAX)
An event-driven, serial-access protocol for accessing XML documents, used. A Java-only API, SAX is used by most servlets and network programs to transmit and receive XML documents. See also Document Object Model.
simple element
An item in the source or target document that does not contain child items, only data. For example: EDI data elements, ROD fields, XML attributes, and XML PCData values. See also element.
Simple Mail Transfer Protocol (SMTP)
An Internet application protocol for transferring mail among users of the Internet.
Simple Network Management Protocol (SNMP)
A set of protocols for monitoring systems and devices in complex networks. Information about managed devices is defined and stored in a Management Information Base (MIB). See also Management Information Base, SNMP trap.
simple type
A characteristic of a simple element that defines the type of data in a message (for example, string, integer, or float). In XML, a simple type cannot have element content and cannot carry attributes. See also complex type.
simple type name
The type name that appears next to the type icon in the type tree.
simulation
A faster-than-real-time performance of a process. Simulation enables organizations to observe how a process will perform in response to variations of inputs to the process, just as in a real-life work environment.
simulation profile
A copy of a process model and the elements on which it depends, augmented with simulation attributes, that you use to run a simulation. Each simulation profile in a snapshot is based on the process as it existed at the time that the snapshot was taken.
simulation snapshot
A record of the complete process model in a state that you want to preserve for simulation purposes. This record contains a copy of all the project elements the process uses, as well as any additional project elements.
single authorization
A setting allowing an action to be carried out by a single person. See also dual authorization.
single-cluster pattern
A reusable deployment environment architecture for IBM Business Process Management products and solutions in which the functional components of the environment (messaging, support, web-based components, and application deployment) are on one cluster.
single-occurrence mapping
A form of mapping in which a specific occurrence of a repeating compound or simple element is mapped to a compound or simple element.
single sign-on (SSO)
An authentication process in which a user can access more than one system or application by entering a single user ID and password.

singleton
: A class that can be instantiated only once. A singleton class cannot be an interface.

SIP
: See Session Initiation Protocol.

siplet
: A Session Initiation Protocol (SIP) servlet that performs SIP signaling to back-end applications of the SIP server, such as the presence server or instant messaging server. See also Session Initiation Protocol.

situation
: A significant occurrence that is detected when a set of conditions are met. For example, exceeding the limits of a Key Performance Indicator (KPI).

situation event
: A Common Base Event that is emitted when a defined situation occurs.

sized attribute
: An attribute that can be assigned to one or more components within a group type, whose value specifies the size, in bytes, of the component immediately following it.

skeleton
: Scaffolding for an implementation class.

skin
: An element of a graphical user interface that can be changed to alter the appearance of the interface without affecting its functionality.

SLA
: See service level agreement.

smart card
: An intelligent token that is embedded with an integrated circuit chip that provides memory capacity and computational capabilities.

smart folder
: A view on a rule project that allows the user to display project elements grouped by property.

SMO
: See service message object.

SMP/E
: See SMP/E for z/OS.

SMP/E for z/OS (SMP/E)
: An IBM licensed program that is used to install software and software changes on z/OS systems.

SMS
: See Short Message Service.

SMTP
: See Simple Mail Transfer Protocol.

snapshot
: 1. The state of a project or branch as captured at a specific time.
  2. A capture of data at a point time for performance analysis.
  3. In Business Process Manager, a capture of a process application or toolkit at a point in time. With a snapshot, a user can revert to a different version of a process or artifact.

snippet
: An excerpt of source code.

SNL
: See SWIFTNet Link.

SNMP
: See Simple Network Management Protocol.

SNMP trap
: An SNMP message sent from the SNMP agent to the SNMP manager. The message is initiated by the SNMP agent and is not a response to a message sent from the SNMP manager. See also Simple Network Management Protocol.

SOA
: See service-oriented architecture.

SOAP
: A lightweight, XML-based protocol for exchanging information in a decentralized, distributed environment. SOAP can be used to query and return information and invoke services across the Internet. See also web service.

SOAP encoding
: Rules for serializing data over the SOAP protocol. SOAP encoding is based on a simple type system that is a generalization of the common features found in type systems in programming languages, databases, and semi-structured data.

SOAP with attachments API for Java (SAAJ)
: An application programming interface (API) that is used to send XML documents over the Internet from a Java base.

Society for Worldwide Interbank Financial Telecommunication (SWIFT)
: An industry-owned cooperative that supplies standardized messaging services and software to financial institutions.

socket
: An identifier that an application uses to uniquely identify an end point of communication. The user associates a protocol address with the socket by associating a socket address with the socket.

Sockets Secure
: A client/server architecture that transports TCP/IP traffic through a secure gateway. A SOCKS server performs many of the same services that a proxy server does.

softcopy
: One or more files that can be electronically distributed, manipulated, and printed by a user.

software configuration management (SCM)
: The tracking and control of software development. SCM systems typically offer version control and team programming features.

software development kit (SDK)
: A set of tools, APIs, and documentation to assist with the development of software in a specific computer language or for a particular operating environment.

solution

A set of one or more related case types, tasks, steps, and other components that provide documents, data, business processing, and routing to case workers. For example, a solution for a human resources department might include a case type for new hires, a case type for retirement, and a case type for employee termination.

source based map
: A map based on the order elements that are defined in the source document definition.

source code
: A computer program in a format that is readable by people. Source code is converted into binary code that can be used by a computer.

source document
: A document that is going to be translated.

source document definition
: A description of a document layout that is used to identify the format of the source document for a translation.

source interface
: In a mediation flow component, the interface that allows the service requester to access the mediation flow through an export.

source map component
: An object that references an executable map within a source map file.

source tree
: The XML input document that is transformed by an XSL stylesheet.

SPA
: See scratchpad area.

spec
: See specification.

special-subject
: Generalization of a particular class of users; a product-defined entity independent of the user registry.

special variable
: A variable that is similar to a local or global variable, except that it is predefined in Data Interchange Services. Special variables are created during translation at the start of a document and cannot be created or maintained by the user.

specification (spec)
: A declarative description of what something is or does.

SPUFI
: See SQL Processor Using File Input.

SQL
: See Structured Query Language.

SQLJ
: See Structured Query Language for Java.

SQL Processor Using File Input (SPUFI)
: A facility of the TSO attachment subcomponent that enables the DB2I user to run SQL statements without embedding them in an application program.

SQL query
: A component of certain SQL statements that specifies a result table.

SSH
: See Secure Shell.

SSH File Transfer Protocol
: A network protocol that provides the ability to transfer files securely over any reliable data stream.

SSI
: See server-side include.

SSL
: See Secure Sockets Layer.

SSL channel
: A type of channel within a transport chain that associates a Secure Sockets Layer (SSL) configuration repertoire with the transport chain.

SSO
: See single sign-on.

stack
: An area in memory that typically stores information such as temporary register information, values of parameters, and return addresses of subroutines and is based on the principle of last in, first out (LIFO).

stack frame
: A section of the stack that contains the local variables, arguments, and register contents for an individual routine, as well as a pointer to the previous stack frame.

stacking number
: The number of application servers that are required for a dynamic cluster to use all the power of a node.

staff activity
: An activity in a process that queries human interaction for decisions on how to proceed. A staff activity is used in a long-running process where the process will halt to await the outcome of the human interaction.

staging
: The process of returning return data or an object from an offline or low-priority device to an online or higher priority device, typically on demand of the system or on request of the user.

stand-alone
: Independent of any other device, program, or system. In a network environment, a stand-alone machine accesses all required resources locally.

stand-alone server
: 1. A fully operational server that is managed independently of all other servers, using its own administrative console.
  2. A catalog service or container server that is managed from the operating system that starts and stops the server process.

stand-alone task
: A unit of work that exists independently of a business process, and implements human interaction as a service. See also human task, inline task.

standard envelope
: See EDI envelope.

standard portlet

A portlet that complies with one of the OASIS portlet standards: JSR168 or JSR286.

Standard Widget Toolkit (SWT)
: An Eclipse toolkit for Java developers that defines a common, portable, user interface API that uses the native widgets of the underlying operating system. See also Abstract Window Toolkit, Swing Set.

star schema
: A type of relational database schema that is composed of a set of tables comprising a single, central fact table surrounded by dimension tables.

start event
: An event that indicates where a process starts. The start event starts the flow of the process and does not have any incoming sequence flow but can have a trigger. Start event types are none, message, timer, ad hoc, and error. See also ad hoc start event, error start event, message start event, none start event, timer start event.

start node

1. A node that identifies where a rule flow begins. A rule flow has one and only one start node.
2. A node that identifies where a process begins.

star topology
: In network architecture, a network topology in which every node on the network is connected to a central node or "hub," through which they communicate with each other.

stash file
: A file that hides other data files within it.

state
: In a business state machine, one of several discrete individual stages that are organized in sequence to compose a business transaction.

State Adaptive Choreography Language (SACL)
: An XML notation that is used to define state machines.

stateful session bean
: A session bean that acts on behalf of a single client and maintains client-specific session information (called conversational state) across multiple method calls and transactions. See also session bean, stateless session bean.

stateless session bean

1. A session bean that is a collection of operations. The server can optimize resources by reusing bean instances on every method call.
2. A session bean with no conversational state. All instances of a stateless bean are identical. (Sun) See also session bean, stateful session bean.

state machine
: A behavior that specifies the sequences of states that an object or an interaction goes through during its life in response to events, together with its responses and actions.

static
: A Java programming language keyword that is used to define a variable as a class variable.

static analysis
: The process of extracting targeted types of information on the models in their static form. This differs from dynamic analysis, which extracts information based on the results of process simulations.

static cluster
: A group of application servers that participates in workload management. Membership for the static cluster is manually managed.

static web page
: A web page that can be displayed without the additional client- or server-side processing that would be required for JavaServer Pages, servlets, or scripts.

static web project
: A project that contains resources for a web application with no dynamic content such as servlets or JavaServer Pages (JSP) files, or Java code. A static web project can be deployed to a static HTTP server and does not require additional application server support.

step
: A stage in a workflow where a distinct, well-defined action is performed. Each step on a workflow map represents a specific activity or task in the business process described by the map. For example, in insurance claims processing, verify account number and calculate deductible could be individual steps. A workflow consists of two or more steps. See also case property.

stored procedure
: A block of procedural constructs and embedded SQL statements that is stored in a database and that can be called by name. Stored procedures allow an application program to be run in two parts, one on the client and the other on the server, so that one call can produce several accesses to the database.

STP
: See straight through processing.

straight through processing (STP)
: A series of uninterrupted electronic processes across and throughout an enterprise which (1) secures an initial transaction as an electronic message, (2) transforms and transports it to its initial execution/processing location and (3) passes it through the processing cycle with little, if any, human intervention.

stream
: In the CVS team programming environment, a shared copy of application resources that is updated by development team members as they make changes. The stream represents the current state of the project.

stream decryption
: A symmetric algorithm that decrypts data one bit or byte of data at a time.

stream encryption
: A symmetric algorithm that encrypts data one bit or byte of data at a time.

stream object
: An object used in the TX Programming Interface that permits overrides to the loaded map input and output specifications.

string
: In programming languages, the form of data used for storing and manipulating text.

structure
: A series of elements that have been graded or ranked in some useful manner. In WebSphere Business Modeler, a graphical representation of the relationships between different real entities in an organization.

Structured Query Language (SQL)
: A standardized language for defining and manipulating data in a relational database.

Structured Query Language for Java (SQLJ)

A standard for embedding SQL in Java programs, defining and calling Java procedures and user-defined functions, and using database structured types in Java.

structured viewing
: The tabular aspect of the Design view of the XML editor that separates the structural constituents of an XML document, such as elements and attribute types, from values, such as attribute values and textual content.

Struts
: An open source framework designed to help developers create web applications that keep database code, page design code, and control flow code separated from each other.

Struts action
: A class that implements a portion of a web application and returns a forward. The superclass for a Struts action is called the Action class.

Struts module
: A Struts configuration file and a set of corresponding actions, form beans, and web pages. A Struts application comprises at least one Struts module.

Struts project
: A dynamic web project with Struts support added.

stub
: A small program routine that substitutes for a longer, possibly remote, program. For example, a stub might be a program module that transfers procedure calls (RPCs) and responses between a client and a server. In web services, a stub is an implementation of a Java interface generated from a Web Services Description Language (WSDL) document.

style sheet
: A specification of formatting instructions that, when applied to structured information, provides a particular rendering of that information (for example, online or printed). Different style sheets can be applied to the same piece of structured information to produce different presentations of the information.

subarea
: An area that is nested within another area.

subclass
: In Java, a class that is derived from a particular class, through inheritance.

subelement
: In UN/EDIFACT EDI standards, an EDI data element that is part of an EDI composite data element. For example, an EDI data element and its qualifier are subelements of an EDI composite data element.

subelement separator
: A character that separates the subelements in an EDI composite data element.

subflow
: A sequence of processing steps, implemented using message flow nodes, that is designed to be embedded in a message flow or in another subflow. A subflow must include at least one Input or Output node. A subflow can be executed by a broker only as part of the message flow in which it is embedded, and therefore it cannot be deployed. See also message flow.

subflow node
: A message flow node that represents a subflow. See also primitive.

subflow task
: In a rule flow, a task that refers to another rule flow. A subflow task can reference a rule flow in the current project, or in a parent project.

subnet
: See subnetwork.

subnet mask
: For internet subnetworking, a 32-bit mask used to identify the subnetwork address bits in the host portion of an IP address.

subnetwork (subnet)
: A network that is divided into smaller independent subgroups, which still are interconnected.

subprocess
: A local process that is also a part of another process. See also deployment manager.

subquery
: In SQL, a subselect used within a predicate, for example, a select-statement within the WHERE or HAVING clause of another SQL statement.

subscriber
: The consumer of a business service.

subscription
: A record that contains the information that a subscriber passes to its local broker to describe the publications that it wants to receive.

substate
: A state that is part of a composite state.

subsystem component
: An Integration Flow Designer object that references another system which a user has defined.

subtree
: A branch of a type tree that includes a type and all of the subtypes that stem underneath it.

subtype
: A type that extends or implements another type; the supertype.

superclass
: In Java, a class from which a particular class is inherited, perhaps with one or more classes in between.

superset
: Given two sets A and B, A is a superset of B if and only if all elements of B are also elements of A. That is, A is a superset of B if B is a subset of A.

supertype
: In a type hierarchy, a type that subtypes inherit attributes from.

suspend
: To pause a process instance.

SVB
: See service bundle.

SWIFT
: See Society for Worldwide Interbank Financial Telecommunication.

SWIFT address
: See bank identifier code.

SWIFTAlliance Gateway (SAG)

A SWIFT interface product extending SWIFTNet Link by additional services such as profile-based processing, and offering a WebSphere MQ interface.

SWIFTNet FileAct
: A SWIFT interactive communication service supporting exchange of files between two applications.

SWIFTNet FIN
: A SWIFT service providing FIN access using the Secure IP Network (SIPN) instead of the SWIFT Transport Network (STN). See also FIN.

SWIFTNet FIN batching
: The transporting of more than one FIN message within a single InterAct message.

SWIFTNet InterAct
: A SWIFT interactive communication service supporting exchange of request and response messages between two applications.

SWIFTNet Link (SNL)
: A SWIFT mandatory software product to access all SWIFTNet services.

SWIFTNet PKI
: See SWIFTNet public key infrastructure.

SWIFTNet public key infrastructure (SWIFTNet PKI)
: SWIFT's mandatory security software and hardware installed with SWIFTNet Link. See also public key infrastructure.

SWIFTNet service
: A SWIFT IP-based communication service that runs on the SIPN.

SWIFTNet service application
: An application that uses SWIFTNet services. Financial organizations such as Continuous Linked Settlement (CLS) or the Global Straight Through Processing Association (GSTPA) offer such applications to financial institutions.

SWIFT transport network
: A SWIFT network providing FIN and IFT service based on X.25 technology.

swimlane
: 1. See pool.
  2. A visually separated row within a process flow diagram that groups all the activities in the process that are performed by a particular combination of roles, resources, organization units, or locations.

Swing Set
: A collection of GUI components that runs consistently on any operating system that supports the Java virtual machine (JVM). Because they are written entirely in the Java programming language, these components provide functionality above and beyond that provided by native-platform equivalents. See also Abstract Window Toolkit, Standard Widget Toolkit.

SWT
: See Standard Widget Toolkit.

symbolic link
: A type of file that contains a pointer to another file or directory.

symmetric algorithm
: An algorithm where the encryption key can be calculated from the decryption key and vice versa. In most symmetric algorithms, the encryption key and the decryption key are the same.

synchronization
: The process of publishing and updating changes in a rule to a server.

synchronize
: To add, subtract, or change one feature or artifact to match another.

synchronous process
: A process that starts by invoking a request-response operation. The result of the process is returned by the same operation.

synchronous replica
: A shard that receives updates as part of the transaction on the primary shard to guarantee data consistency, which can increase the response time compared with an asynchronous replica. See also asynchronous replica.

sync point
: A point during the processing of a transaction at which protected resources are consistent.

sync point manager
: A function that coordinates the two-phase commit process for protected resources, so that all changes to data are either committed or backed out.

syntax
: The rules for the construction of a command or statement.

syntax highlighting
: In source editors, the ability to differentiate text and structural elements, such as tags, attributes, and attribute values, using text highlighting differences, such as font face, emphasis, and color.

syntax object
: One or more characters used as separators between portions of data. A syntax object can be a number separator, a delimiter, a terminator, an initiator, or a release character.

syntax type
: A category used to classify different formats of documents. Data Interchange Services supports three syntax types: XML, EDI, and record oriented data. The user can map and translate between any of these syntax types.

synthesized event
: See synthetic event.

synthetic event
: An event that is triggered in response to a condition that was detected while processing the current event. Unlike an action, which is also triggered in response to a condition that was detected during the processing of the current event, a synthetic event is not sent to an external system.

sysplex
: A set of z/OS systems that communicate with each other through certain multisystem hardware components and software services.

system
: A collection of referenced executable maps that are organized into a unit.

System Authorization Facility (SAF)
: A z/OS interface with which programs can communicate with an external security manager, such as RACF.

system configuration administration
: The administration of configuration object types, organizational units, and roles. This is carried out after the product has been installed and is running.

system definition diagram
: The graphical representation of a system viewed within a system window in the Integration Flow Designer. A user can interact with system definition diagrams to design systems.

system logger
: An integrated logging facility that is provided by MVS and can be used by system and subsystem components. For example, it is used by the CICS log manager.

system menu
: A drop-down menu that is activated by clicking the icon at the left of a window title bar and that allows users to restore, move, size, minimize, or maximize the window.

systems analyst
: A specialist who is responsible for translating business requirements into system definitions and solutions.

system task
: See service task.

system window
: A window in the Integration Flow Designer in which system definition diagrams are created, maintained, and displayed.

T

tag

1. An item that contains identifying information about a person or device. Tags enable tracking and monitoring of assets within locations, areas, and zones.
2. A word or phrase that users create and assign to an asset. Users create tags to develop search criteria that is meaningful to themselves.
3. In UN/EDIFACT EDI Standards, the segment identifier. In export and import, a code that is assigned to each field in the database and used to identify the field in the export file. Such export files are known as tagged files.

taglib directive
: In a JSP page, a declaration stating that the page uses custom tags, defines the tag library, and specifies its tag prefixes. (Sun)

tag library
: In JSP technology, a collection of tags identifying custom actions described using a taglib descriptor and Java classes. A JSP tag library can be imported into any JSP file and used with various scripting languages. (Sun)

TAI
: See trust association interceptor.

target

1. See receiver.
2. The destination for an action or operation.
3. A value that a Key Performance Indicator (KPI) should achieve, such as "300" or "5 days."

target based map
: A map based on the order elements that are defined in the target document definition.

target CDD
: A customization definition document (CDD) to which placeholders have been added, and for which placeholder values have been specified. A target CDD describes a particular target customization definition.

target component
: A component that is the final target of a client service request.

target customization definition
: A customization definition that describes a changed version of a current customization definition. Each target customization definition has a target CDD that describes it.

target document
: A translated version of a document.

target document definition
: A description of the document layout used to create an output document from a translation.

target document definition window
: One of the pages on the Details tab of the Data Transformation Map Editor and the Functional Acknowledgement Map Editor. It displays the target document definition.

target namespace
: A unique logical location for information about the service that associates a namespace with a WSDL location.

target service
: A service that exists outside of the gateway.

task

1. The basic unit of organization in a rule flow.
2. An atomic activity that is included within a process. A task is used when the work in the process is not broken down to a finer level of process model detail. Generally, an end-user, an application, or both perform the task. A task object is the same shape as the subprocess, which is a rectangle that has rounded corners. See also case property.
3. A unit of work to be accomplished by a device or process.
4. One or more actions associated with a case. A task has one or more steps that must be completed to finalize the task. For example, a task might be to review new hire applications. A case is not complete until all required tasks are completed or manually disabled. Each task has roles that are associated with it. See also activity, case.

task-related user exit (TRUE)
: A user exit program that is associated with specified events in a particular task, rather than with every occurrence of a particular event in CICS processing (as is the case with global user exits).

taxonomy
: The hierarchical classification of information according to a known system that is used to easily discuss, analyze, or retrieve that information.

TC
: See test case.

TCP
: See Transmission Control Protocol.

TCP channel
: A type of channel within a transport chain that provides client applications with persistent connections within a local area network (LAN).

TCP/IP
: See Transmission Control Protocol/Internet Protocol.

TCP/IP monitoring server
: A runtime environment that monitors all requests and responses between a web browser and an application server, as well as TCP/IP activity.

TDCC
: See Transportation Data Coordinating Committee.

team development
: The practice of several members of a team contributing to a single project, with the potential for multiple team members to work in parallel on the same files.

team support
: The component that interacts with a repository to share and version projects and project data. See also version control.

technical rule
: A rule written in a technical rule language, such as ILOG Rule Language (IRL).

technology adapter
: An adapter that is designed for interactions that conform to a specific technology. For example, the WebSphere Adapter for FTP, is an intermediary through which an integration broker sends data to a file system that resides on a local or remote FTP server.

technology connector
: An API that passes data between the event processing server (runtime server) and external systems using a standard protocol such as SMTP, HTTP, FTP, or SOAP.

template
: 1. A grouping of elements that share common properties. These properties might be defined only once and are inherited by all elements using the template. In Java terms, this is an abstract class.

template library
: The database, known as the Portal Template Catalog, that stores place template specifications and portlets forms, subforms, and profiles.

temporary file system (TFS)
: A temporary, in-memory physical file system that supports in-storage mountable file systems. Normally, a TFS runs in the kernel address space, but it can be run in a logical file system (LFS) colony address space.

temporary page
: A page that closes and cannot be reopened after a user navigates away from it.

terminal file
: The resource in a 3270 service project that contains the information necessary for connecting to the host system during build time. Terminal files are automatically generated when the 3270 terminal service project is created. In the Navigator view, if a terminal file is selected, the 3270 terminal service recorder opens in the editor area.

terminate end event
: An end event that will stop all parallel activities within its process level and all lower process levels. See also end event.

terminate node
: A node that marks the end of a process. When a flow reaches a terminate node while the process is running, the process immediately terminates, even if there are other currently executing flows within the process.

terminator
: A syntax object that signifies the end of a data object. For example, a carriage return/linefeed at the end of a record might be the record's terminator.

test case (TC)
: A set of tasks, scripts, or routines that automate the task of testing software.

test configuration
: A property of the integration test client that is used to specify modules for testing and to control the tests.

test harness
: A series of script files used to enable a DB2 database for use by the DB2 XML Extender. A test harness is optionally created when a DAD file is generated from a relational database to XML mapping. Once enabled, it tests composing XML from data as well as decomposing XML files into relational data.

test pattern
: A template used for the automatic generation of component tests. There are several test patterns available for testing both Java and EJB components. See also component test.

test suite
: 1. A collection of test cases that define test behavior and control test execution and deployment.
2. A set of usage scenarios with which the user can verify that business rules are correctly designed and written. Running test suites produces a report comparing the expected results and the actual results obtained when applying rules to the scenarios.

text annotation
: An artifact that provides additional textual information about a BPMN diagram.

TFS
: See temporary file system.

theme
: The style element that gives a place a particular look. The portal provides several themes, similar to virtual wallpaper, which can be chosen when creating a place.

thin application client
: A lightweight, downloadable Java application run time capable of interacting with enterprise beans.

thin client
: A client that has little or no installed software but has access to software that is managed and delivered by network servers that are attached to it. A thin client is an alternative to a full-function client such as a workstation.

thread
: A stream of computer instructions that is in control of a process. In some operating systems, a thread is the smallest unit of operation in a process. Several threads can run concurrently, performing different jobs.

thread contention
: A condition in which a thread is waiting for a lock or object that another thread holds.

threshold
: A setting that applies to an interrupt in a simulation that defines when a process simulation should be halted based on a condition existing for a specified proportion of occurrences of some event.

throughput
: The measure of the amount of work performed by a device, such as a computer or printer, over a period of time, for example, number of jobs per day.

throwing message intermediate event
: An intermediate event that sends a message. See also intermediate event.

thumbnail
: An icon-sized rendering of a larger graphic image that permits a user to preview the image without opening a view or graphical editor.

TID
: See transaction identifier.

time-delayed rule
: The delay before an event rule or event rule group is evaluated.

timeout
: A time interval that is allotted for an event to occur or complete before operation is interrupted.

timer
: An event that is triggered by an occurrence at a specific time.

timer event
: An event that is triggered when a time condition is satisfied. See also intermediate event.

timer intermediate event
: An intermediate event that is triggered when a time condition is satisfied. A timer intermediate event can delay the flow of the process or can generate a timeout for activities that exceed the time condition.

timer start event
: A start event that is triggered when a time condition is satisfied. A timer start event is used only for event subprocesses. See also start event.

Time Sharing Option (TSO)
: A base element of the z/OS operating system with which users can interactively work with the system. See also Interactive System Productivity Facility.

timetable
: A schedule of times. In business process modeling, timetables are typically associated with resources or costs. For resources, timetables indicate availability (such as Monday to Friday). For costs, timetables are useful if the cost varies with time of day (such as electricity) or time of year (such as seasonal foods).

time to live (TTL)
: The time interval in seconds that an entry can exist in the cache before that entry is discarded.

timing constraint
: A specialized validation action used to measure the duration of a method call or a sequence of method calls. See also validation action.

tip
: The current working version of a process application or toolkit.

Tivoli Performance Viewer
: A Java client that retrieves the Performance Monitoring Infrastructure (PMI) data from an application server and displays it in various formats.

TLS
: See Transport Layer Security.

token
: 1. A particular message or bit pattern that signifies permission or temporary control to transmit over a network.
  2. A marker that progresses through a process instance and indicates which element is currently running. A process instance can generate several tokens. A token can take only one path.

token-bucket
: A mechanism that controls data flow. As an application requests permission into a network, the token bucket adds characters (or tokens) into a buffer (or bucket). If enough room is available for all the tokens in the bucket, the application is allowed to enter the network.

toolkit
: A container where artifacts can be stored for reuse by process applications or other toolkits.

top-down development
: In web services, the process of developing a service from a Web Services Description Language (WSDL) file. See also bottom-up development.

top-down mapping
: An approach for mapping enterprise beans to database tables, in which existing enterprise beans and their design determines the database design.

topology
: The physical or logical mapping of the location of networking components or nodes within a network. Common network topologies include bus, ring, star, and tree.

track
: An optional subdivision in a process application that is based on team tasks, process application versions, or both. When enabled, tracks allow parallel development to occur with isolation from changes in other tracks. For example, using tracks one team can fix the current version of a process, while another team builds a completely new version based on new external systems and a new corporate identity.

track event
: An event that tracks certain data as it passes through the event run time.

tracking group
: A group of tracked process variables and data, such as KPIs, from one or more BPDs or process applications. Tracking groups are used to monitor performance and report analyses of information.

tracking intermediate event
: An intermediate event that indicates a point in a process when runtime data is captured for reporting. See also intermediate event.

trading partner

A company, such as a manufacturer or a supplier, that agrees to exchange information using electronic data interchange, or an entity in an organization that sends and receives documents that are translated. See also external partner.

trailer
A control structure that indicates the end of an electronic transmission.

transaction

1. A subprocess that represents a set of coordinated activities that are carried out by independent, loosely coupled systems in accordance with a contractually defined business relationship. This coordination leads to an agreed, consistent, and verifiable outcome across all participants.
2. A process in which all of the data modifications that are made during a transaction are either committed together as a unit or rolled back as a unit.

transaction class
A subcontainer of a service policy that is used for finer-grained monitoring.

transaction ID
See transaction identifier.

transaction identifier (TID, transaction ID, XID)
A unique name that is assigned to a transaction and is used to identify the actions associated with that transaction.

transaction manager
A software unit that coordinates the activities of resource managers by managing global transactions and coordinating the decision to commit them or roll them back.

transaction set
The basic business document in ANSI X12 data. Transaction sets are enclosed in an envelope that separates one transaction set from another (ST-SE envelope). Groups of transaction sets that are functionally related are enclosed in a functional group envelope (GS-GE envelope). Transaction sets are made up of segments and loops.

transcoding technology
Content adaptation to meet the specific capabilities of a client device.

transform

1. To convert a document from one form to another, such as using a purchase order formatted as an XML document to create the same purchase order formatted as an EDI document. See also translate.
2. Programming logic that converts data from one format into another format.

transform algorithm
A procedure that is used to transform the message for web services security message processing, such as the C14N (canonicalization) transform that is used for XML digital signatures.

transformation
The process of changing data from one format or structure to another format or structure.

Transformation API for XML (TrAX)
A programming interface that can transform XML and related tree-shaped data structures.

transition
A connection between two tasks in a rule flow. Transitions are unidirectional, and they can have conditions attached to them.

transition condition

1. In a rule flow, a specification of a transition that dictates when the target task can be executed.
2. A Boolean expression that determines when processing control should be passed to the targeted node.

translate
In early versions of WebSphere Data Interchange, to convert a document from one form to another. See also transform.

translation object
A source map that has been compiled to provide instructions for translating from one format to another in a way that can be interpreted by the translator.

translation table
A user-defined table that is used to translate data values that differ between the source and target documents. For example, a manufacturer and supplier with different part numbers for the same item can use a translation table to convert their part numbers to the other company part numbers during translation.

translator
A component, typically the Data Interchange Services translator component, responsible for translating a document from one format to another.

Transmission Control Protocol (TCP)
A communication protocol used in the Internet and in any network that follows the Internet Engineering Task Force (IETF) standards for internetwork protocol. TCP provides a reliable host-to-host protocol in packet-switched communication networks and in interconnected systems of such networks. See also Internet Protocol.

Transmission Control Protocol/Internet Protocol (TCP/IP)
An industry-standard, nonproprietary set of communication protocols that provides reliable end-to-end connections between applications over interconnected networks of different types.

transmission type
The largest object in an EDI type tree. A transmission might include many interchanges from or to many trading partners.

transparent decision service
A reusable decision service that is easily accessible to all participants of its life cycle: developers, business analysts, and policy managers. It is easy to adapt and contributes to an enterprise compliance strategy.

transport
The request queue between a web servers plug-in and a web container in which the web modules of an application reside. When a user requests an application from a web browser, the request is passed to the web server, then along the transport to the web container.

transport adapter
An adapter (such as an HTTP Adapter) that is used with an encoding/decoding adapter to support various protocols (for example, SOAP) in a transport-independent way. The transport adapter is used to transport the data either from the source or to the destination.

Transportation Data Coordinating Committee (TDCC)
An organization that sets standards for the motor, rail, ocean, and air industries administered by EDIA. This is the original EDI organization for the United States, and through it, the original EDI Standards were developed, published, and maintained. It has now changed its name to EDIA, and has become the national EDI user group for the United States.

transport chain
A representation of a network protocol stack that is operating within an application server.
transport channel chain
A specification of the transport channels that are used by a server for receiving information. Transport channel chains contain end points
transporting
A method of conveying data using a specified adapter following either an encode or decode command.
Transport Layer Security (TLS)
An Internet Engineering Task Force (IETF)-defined security protocol that is based on Secure Sockets Layer (SSL) and is specified in RFC 2246.
TrAX
See Transformation API for XML.
tree
A data structure whose elements are linked in a hierarchical fashion.
trend analysis
A type of analysis that displays the analysis of the changes in a given item of information over a period of time.
trigger

1. In database technology, a program that is automatically called whenever a specified action is performed on a specific table or view.
2. A mechanism that detects an occurrence and can cause additional processing in response.

triple Data Encryption Standard (triple DES)
A block cipher algorithm that can be used to encrypt data transmitted between managed systems and the management server. Triple DES is a security enhancement of DES that employs three successive DES block operations.
triple DES
See triple Data Encryption Standard.
TRUE
See task-related user exit.
trunk
In the CVS team development environment, the main stream of development, also referred to as the HEAD stream.
trust anchor
A trusted keystore file that contains a trusted certificate or a trusted root certificate that is used to assert the trust of a certificate.
trust association
An integrated configuration between the security server of the product and third-party security servers. A reverse proxy server acts as a front-end authentication server, while the product applies its own authorization policy onto the resulting credentials passed by the proxy server.
trust association interceptor (TAI)
The mechanism by which trust is validated in the product environment for every request received by the proxy server. The method of validation is agreed upon by the proxy server and the interceptor.
trusted identity evaluator
A mechanism that is used by a server to determine whether to trust a user identity during identity assertion.
trusted root
A certificate signed by a trusted certificate authority (CA).
trust file
A file that contains signer certificates.
trust policy
A trusted list of certificates that are used to control the trust and validity period of certificates. It enables the trust of certificates issued by a certificate authority to be limited.
trust relationship
An established and trusted communication path through which a computer in one domain can communicate with a computer in the other domain. Users in a trusted domain can access resources in the trusting domain.
truststore
In security, a storage object, either a file or a hardware cryptographic card, where public keys are stored in the form of trusted certificates, for authentication purposes in web transactions. In some applications, these trusted certificates are moved into the application keystore to be stored with the private keys. See also keystore.
truststore file
A key database file that contains the public keys for a trusted entity.
TSO
See Time Sharing Option.
TTL
See time to live.
tuple
See row.
type

1. In a WSDL document, an element that contains data type definitions using some type system (such as XSD).
2. The definition of a data object or set of data objects that is graphically represented in a type tree in the Type Designer.
3. In Java programming, a class or interface.

type checking
The action of checking the validity of business items against a business item template during process simulation or deployment. Type checking is available only with decision gateways.
type hierarchy
The complete context for a Java class or interface including its superclasses and subclasses.
type tree
In the Type Designer, the graphical representation of the definition and organization of data objects.

U

UCA
: See undercover agent.

UCS
: 1. See Uniform Communication Standard.
2. See universal character set.

UDDI
: See Universal Description, Discovery, and Integration.

UDDI Business Registry
: A collection of peer directories that contain information about businesses and services.

UDDI node
: A set of web services that supports at least one of the Universal Description, Discovery, and Integration (UDDI) APIs. A UDDI node consists of one or more instances of a UDDI application running in an application server or a cluster of application servers with an instance of the UDDI database.

UDDI node initialization
: The process by which values are set in the Universal Description, Discovery, and Integration (UDDI) database and the behavior of the UDDI node is established.

UDDI node state
: A description of the current status of the Universal Description, Discovery, and Integration (UDDI) node.

UDDI policy
: A statement of the required and expected behavior of a Universal Description, Discovery, and Integration (UDDI) registry that is specified through policy values that are defined in the UDDI specification.

UDDI property
: A characteristic or attribute that controls the behavior of a Universal Description, Discovery, and Integration (UDDI) node.

UDDI registry
: A distributed registry of businesses and their service descriptions that adheres to the Universal Description, Discovery, and Integration (UDDI) standard for managing the discovery of web services. UDDI registries come in two forms, public and private, both of which are implemented in a common XML format.

UDF
: See user-defined function.

UML
: See Unified Modeling Language.

unary operator
: An operator that changes the sign of a numeric value.

unaugment
: To remove the last template that was augmented to a profile. A profile must be unaugmented before it is deleted. See also augment.

unbound set
: The set of all possible types of data that might be listed last in a group.

uncontrolled flow
: A flow that proceeds without dependencies or conditional expressions. Typically, an uncontrolled flow is a sequence flow between two activities that do not have a conditional indicator (mini-diamond) or an intervening gateway.

undelivered message queue
: See dead-letter queue.

undercover agent (UCA)
: An agent that is attached to a message event in a business process definition (BPD) and that calls a service to handle the event. For example, when a message event is received from an external system, a UCA is needed to invoke the appropriate service in response to the message.

UN/EDIFACT
: See United Nations Electronic Data Interchange for Administration, Commerce and Transport.

Unicode
: A character encoding standard that supports the interchange, processing, and display of text that is written in the common languages around the world, plus many classical and historical texts.

Unified Modeling Language (UML)
: A standard notation for the modeling of real-world objects as a first step in developing an object-oriented design methodology.

Uniform Communication Standard (UCS)
: The EDI standard used in the grocery industry.

Uniform Resource Identifier (URI)
: 1. A unique address that is used to identify content on the web, such as a page of text, a video or sound clip, a still or animated image, or a program. The most common form of URI is the web page address, which is a particular form or subset of URI called a Uniform Resource Locator (URL). A URI typically describes how to access the resource, the computer that contains the resource, and the name of the resource (a file name) on the computer. See also Uniform Resource Name.
2. A compact string of characters for identifying an abstract or physical resource.

Uniform Resource Indicator (URI)
: A unique address that is used to identify content on the web, such as a page of text, a video or sound clip, a still or animated image, or a program. The most common form of URI is the web page address, which is a particular form or subset of URI called a Uniform Resource Locator (URL). A URI typically describes how to access the resource, the computer that contains the resource, and the name of the resource (a file name) on the computer.

Uniform Resource Locator (URL)
: The unique address of an information resource that is accessible in a network such as the Internet. The URL includes the abbreviated name of the protocol used to access the information resource and the information used by the protocol to locate the information resource.

Uniform Resource Name (URN)
: A name that uniquely identifies a web service to a client. See also Uniform Resource Identifier.

United Nations Electronic Data Interchange for Administration, Commerce and Transport (UN/EDIFACT)
: An international set of electronic data interchange (EDI) standards published by the United Nations that is built upon X12 and TDI (Trade Data Interchange) standards.

United Nations Standard Products and Services Classification (UNSPSC)

An open global standard for classifying products and services based on common function, purpose, and task.

United Nations Trade Data Interchange (UNTDI)
A standard that preceded the UN/EDIFACT EDI standard.

universal character set (UCS)
The ISO standard that allows all data to be represented as 2 bytes (UCS-2) or 4 bytes (UCS-4). Encoding in the UCS-2 form can accommodate the necessary characters for most of the written languages in the world.

Universal Description, Discovery, and Integration (UDDI)
A set of standards-based specifications that enables companies and applications to quickly and easily find and use web services over the Internet. See also web service.

universal integration hub
A unified page presentation architecture that enables site designers to create web portal pages by using various components, including HTML and web content, feeds, portlets, iWidgets, and elements that are derived from frameworks such as Adobe Flex.

Universally Unique Identifier (UUID)
The 128-bit numeric identifier that is used to ensure that two components do not have the same identifier.

UNIX System Services
An element of z/OS that creates a UNIX environment that conforms to XPG4 UNIX 1995 specifications and that provides two open-system interfaces on the z/OS operating system: an application programming interface (API) and an interactive shell interface.

unmanaged node
A node that is defined in the cell topology that does not have a node agent that manages the process. An unmanaged node is typically used to manage web servers.

unmanaged web application
A web application with a life cycle that is managed outside of the administrative domain. By creating a representation of these applications that are deployed through external tools, the on demand router can prioritize and route HTTP requests to the application.

unmodeled fault
A fault message that is returned from a service that has not been modeled on the Web Services Description Language (WSDL) port type.

unrealized
Pertains to a web diagram node that is not yet associated with an actual resource. See also realize.

unrecognized screen
In the 3270 terminal service development tools, a screen that cannot be identified by any of the recognition profiles currently defined.

UNSPSC
See United Nations Standard Products and Services Classification.

UNTDI
See United Nations Trade Data Interchange.

upgradeable lock
A lock that identifies the intent to update a cache entry when using a pessimistic lock.

upstream
Pertaining to the direction of the flow, which is from the start of the process (upstream) toward the end of the process (downstream).

URI
1. See Uniform Resource Identifier.
2. See Uniform Resource Indicator.

URL
See Uniform Resource Locator.

URL scheme
A format that contains another object reference.

URN
See Uniform Resource Name.

use case
The specification of a sequence of actions that a system can perform, interacting with users of the system. Use cases are used in system analysis to identify system requirements. See also scenario.

user account
The login directory and other information that gives a user access to the system.

user-defined function (UDF)
A function that is defined to the DB2 database system by using the CREATE FUNCTION statement and that can be referenced thereafter in SQL statements. See also function.

user exit profile
A profile that defines a user-provided program or exit routine to Data Interchange Services.

user group
A group consisting of one or more defined individual users, identified by a single group name.

user name token
A type of token that is represented by a user name and optionally, by a password.

user registry
A database of known users and user-provided information that is used for authentication purposes.

UTC
See Coordinated Universal Time.

UTF-8
Unicode Transformation Format, 8-bit encoding form, which is designed for ease of use with existing ASCII-based systems. The CCSID value for data in UTF-8 format is 1208.

UUID
See Universally Unique Identifier.

V

validation

The checking of data or code for correctness or for compliance with applicable standards, rules, and conventions.

validation action
A mechanism for verifying whether the actual value of a variable at run time corresponds to the expected value of that variable. See also timing constraint.

validation map
A set of mapping instructions that describe additional validation for an EDI document. One of five supported map types.

validator
A program that checks data or code for correctness or for compliance with applicable standards, rules, and conventions.

variable

1. Data that passes from one step to another in a process. For example, a process that automates escalation of customer issues needs variables to hold information, such as the customer's name and the issue ID.
2. A representation of a changeable value. See also global variable.

variable component name
A component of a group type that includes the literal at the end of the name because it represents more than one type. The literal ANY acts like a wild card, which represents any type whose name could appear in that place.

variant action
An action that is derived from another action so that the content of the action can vary. A field in the variant action object can derive its value in a different way from the way that the same field derives its value in the base action object.

verb
See people assignment criterion.

verbalization
The process of associating terms and phrases to elements of the business object model (BOM). See also constant.

version
A separately licensed program that typically has significant new code or new function.

version control
The coordination and integration of the history of work submitted by a team. See also team support.

vertical scaling
Setting up multiple application servers on one machine, typically by creating cluster members.

vertical stacking
The process of starting more than one instance of the dynamic cluster on a node to manage bottlenecks.

view

1. A logical table that is based on data stored in an underlying set of tables. The data returned by a view is determined by a SELECT statement that is run on the underlying tables.
2. A reusable user interface that is used for a business object or human service. A view consists of one or more other views, data bindings, layout instructions, and behavior.
3. In Eclipse-based user interfaces, a pane that is outside the editor area, which can be used to look at or work with the resources in the workbench.

view synchronous high-availability manager group
A special class of high availability (HA) group that can be created and used by components that require a certain virtual synchrony (VS) quality of service (QoS) for group communication.

VIPA
See virtual IP address.

virtual application layer
A group of components in a virtual application pattern that facilitate complex virtual application design. A virtual application layer enables virtual application patterns to be reused in different contexts; one virtual application pattern is used as a reference layer in another virtual application pattern.

virtual application pattern plug-in
The resources and automation that provide the specific capabilities for a virtual application component. See also virtual application pattern type.

virtual application pattern type
A set of virtual application pattern plug-ins for a specific type of application or application capability. For example, the IBM Web Application Pattern pattern type provides the components, links, policies, and automation that are required to deploy web applications. See also virtual application pattern plug-in.

virtual host
A configuration that enables one host to resemble multiple logical hosts. Each virtual host has a logical name and a list of one or more DNS aliases by which it is known.

virtual image
The operating system and product binary files that are required to create a virtual system pattern.

virtual IP address (VIPA)
An IP address that is shared among multiple domain names or multiple servers. Virtual IP addressing enables one IP address to be used either when insufficient IP addresses are available or as a means to balance traffic to multiple servers.

virtualization
A technique that encapsulates the characteristics of resources from the way in which other systems interact with those resources.

virtual local area network (VLAN)
A logical association of switch ports based upon a set of rules or criteria, such as Medium Access Control (MAC) addresses, protocols, network address, or multicast address. This concept permits the LAN to be segmented again without requiring physical rearrangement.

virtual machine
An abstract specification for a computing device that can be implemented in different ways in software and hardware.

virtual private network (VPN)
An extension of a company intranet over the existing framework of either a public or private network. A VPN ensures that the data that is sent between the two endpoints of its connection remains secure.

virtual synchrony (VS)
A property of group communication that guarantees how messages are delivered when the view changes, for example, when existing members fail or new members join.

virtual system instance
The virtual environment that runs on a hypervisor in the cloud.

virtual system pattern
: One or more virtual images, which can include script packages, that implement a deployment topology. A virtual system pattern is a shared topology definition used for repeatable deployment.

visibility
: In a user interface, the property of a control that declares whether the control is to be displayed or not displayed during run time.

visibility service
: A type of business service that monitors and displays the performance, behavior, or metrics of a business process.

visible widget
: A fully functional widget that displays business data. A visible widget has a solid frame.

visualization
: An association between a Scalable Vector Graphics (SVG) diagram and the set of actions that describe how the diagram should be updated based on the values of metrics or key performance indicators (KPIs).

visual snippet
: A diagrammatic representation of a fragment of Java programming language that can be manipulated with the visual snippet editor.

VLAN
: See virtual local area network.

vocabulary
: 1. The set of terms and phrases that are used for rule editing.
  2. A repository for storing reusable business elements, such as terms, business item definitions, roles, messages, and errors, that are used in a business process.

VPN
: See virtual private network.

VS
: See virtual synchrony.

W

W3C
: See World Wide Web Consortium.

waiter
: A thread waiting for a connection.

WAP
: See Wireless Application Protocol.

WAR
: See web archive.

WAR file
: See web archive.

watch
: A map, including the set of events that initiate it, as defined from the Integration Flow Designer.

watchpoint
: A breakpoint that suspends execution when a specified field or expression is modified.

WBMP
: See wireless bitmap.

WCCM
: See WebSphere Common Configuration Model.

web analytics page overlay
: Web page and channel delivery analysis that is rendered in place on the website.

web application
: An application that is accessible by a web browser and that provides some function beyond static display of information, for instance by allowing the user to query a database. Common components of a web application include HTML pages, JSP pages, and servlets.

web application bridge
: A virtual web application that passes request data, including selected HTTP headers, cookies, and POST data, to the content provider. The web application bridge sends the response data back to the requester, including selected HTTP headers, cookies, and POST data. See also bridge.

web archive (WAR)
: A compressed file format, defined by the Java EE standard, for storing all the resources required to install and run a web application in a single file. See also enterprise archive, Java archive.

web component
: A servlet, JavaServer Pages (JSP) file, or a HyperText Markup Language (HTML) file. One or more web components make up a web module.

web container
: A container that implements the web component contract of the Java EE architecture. (Sun)

web container channel
: A type of channel within a transport chain that creates a bridge in the transport chain between an HTTP inbound channel and a servlet or JavaServer Pages (JSP) engine.

web crawler
: A crawler that explores the web by retrieving a web document and following the links within that document.

web diagram
: A Struts file that uses icons and other images on a free-form surface to help application developers visualize the flow structure of a Struts-based web application.

web module
: A unit that consists of one or more web components and a web deployment descriptor. (Sun)

Web Ontology Language (OWL)
: A language that is used to explicitly represent the meaning of terms in vocabularies and the relationships between those terms. OWL is intended to be used when the information contained in documents needs to be processed by applications, as opposed to situations where the content only needs to be

presented to humans. See also ontology.

web portal
: See portal.

web project
: A container for other resources such as source files and metadata that corresponds to the Java EE-defined container structure and hierarchy of files necessary for web applications to be deployed.

web property extension (WPX)
: IBM extension to the standard deployment descriptors for web applications. These extensions include Multipurpose Internet Mail Extensions (MIME) filtering and servlet caching.

web resource
: Any one of the resources that are created during the development of a web application for example web projects, HTML pages, JavaServer Pages (JSP) files, servlets, custom tag libraries, and archive files.

web resource collection
: A list of URL patterns and HTTP methods that describe a set of resources to be protected. (Sun)

web server
: A software program that is capable of servicing Hypertext Transfer Protocol (HTTP) requests.

web server plug-in
: A software module that supports the web server in communicating requests for dynamic content, such as servlets, to the application server.

web server separation
: A topology where the web server is physically separated from the application server.

web service
: 1. An application that performs specific tasks and is accessible through open protocols such as HTTP and SOAP.
  2. A self-contained, self-describing modular application that can be published, discovered, and invoked over a network using standard network protocols. Typically, XML is used to tag the data, SOAP is used to transfer the data, WSDL is used for describing the services available, and UDDI is used for listing what services are available. See also SOAP, Universal Description, Discovery, and Integration, Web Services Description Language.

web service endpoint
: An entity that is the destination for web service messages. A web service endpoint has a Uniform Resource Identifier (URI) address and is described by a Web Service Definition Language (WSDL) port element.

web service interface
: A group of operations described by the content of a Web Service Definition Language (WSDL) 1.1 port element. These operations can provide access to resource properties and metadata. (OASIS)

Web Services Business Process Execution Language (WS-BPEL)
: See Business Process Execution Language.

Web Services Description Language (WSDL)
: An XML-based specification for describing networked services as a set of endpoints operating on messages containing either document-oriented or procedure-oriented information. See also web service.

Web Services Interoperability (WS-I)
: An open industry organization that is chartered to promote web services interoperability across platforms, operating systems, and programming languages.

Web Services Interoperability Organization (WSI)
: An open industry organization that promotes web services interoperability across platforms, operating systems, and programming languages.

Web Services Invocation Framework (WSIF)
: A Java API that supports dynamic invoking of web services, regardless of the format in which the service is implemented or the access mechanism.

Web Services Invocation Language (WSIL)
: An XML document format that facilitates the discovery of existing web services and provides a set of rules for how inspection-related information should be made available for consumption.

Web Services Policy Framework (WS-Policy)
: A model and framework for describing the capabilities, requirements, and general characteristics of a web service as a policy assertion or a collection of policy assertions.

Web Services Security (WS-Security)
: A flexible standard that is used to secure web services at the message level within multiple security models. SOAP messages can be secured through XML digital signature, confidentiality can be secured through XML encryption, and credential propagation can be secured through security tokens.

website
: A related collection of files available on the web that is managed by a single entity (an organization or an individual) and contains information in hypertext for its users. A website often includes hypertext links to other websites.

WebSphere BI for FN message
: A WebSphere MQ message that has a folder labeled ComIbmDni in the MQRFH2 header. This folder provides the data that is required by WebSphere BI for FN to process the message.

WebSphere Common Configuration Model (WCCM)
: A model that provides for programmatic access to configuration data.

weight
: See point.

weighted sum
: The result of multiplying the weight by the score assigned to an attribute. The weight is a percentage. An attribute with a higher weight is more significant than other attributes as it contributes a bigger share to the final score.

what you see is what you get (WYSIWYG)
: A capability of an editor to continually display pages exactly as they will be printed or otherwise rendered.

while loop
: A loop that repeats the same sequence of activities as long as some condition is satisfied. The while loop tests its condition at the beginning of every loop. If the condition is false from the start, the sequence of activities contained in the loop never runs.

widget
: A portable, reusable application or piece of dynamic content that can be placed into a web page, receive input, and communicate with an application or with another widget.

wiki

A collaborative website that anyone can edit by using a web browser.

wire

1. A connector used to pass control and data from a component or an export to a target.
2. To connect two or more components or cooperative portlets so that they work together. In an application, wiring identifies target services; for portlets, changes in the source portlet automatically update the target portlets.

Wireless Application Protocol (WAP)
: An open industry standard for mobile Internet access that allows mobile users with wireless devices to easily and instantly access and interact with information and services.

wireless bitmap (WBMP)
: A graphic format that is optimized for mobile computing devices. WBMP is part of the Wireless Application Protocol, Wireless Application Environment Specification.

Wireless Markup Language (WML)
: A markup language based on XML that is used to present content and user interfaces for wireless devices such as cellular phones, pagers, and personal digital assistants.

wizard
: An active form of help that guides users through each step of a particular task.

WLM
: See Workload Manager.

WML
: See Wireless Markup Language.

work basket
: A location where work waits for action by a user. This action can be taken either directly on the work in the work basket, or the work can be transferred to another work basket so that actions can be taken there.

workbench
: The user interface and integrated development environment (IDE) in Eclipse and Eclipse-based tools such as IBM Rational Application Developer.

work class
: A mechanism for grouping specific work together that must be associated with a common service policy or routing policy. Work classes group Uniform Resource Identifiers (URIs) or web services from an application.

workflow
: The sequence of activities performed in accordance with the business processes of an enterprise.

working data set
: A data set containing customized JCL that is used to configure and run an execution environment in Decision Server for z/OS.

working directory
: The active directory. When a file name is specified without a directory, the current directory is searched.

working memory
: A part of the rule engine that contains the current state of objects. It is this current state that determines which rules are added to the agenda, and in which order these rules are executed.

work item

1. In the human task editor, the representation of a task. Staff members can browse all work items that they have the authority to claim.
2. See also inline task, stand-alone task.

workload management
: The optimization of the distribution of incoming work requests to the application servers, enterprise beans, servlets and other objects that can effectively process the request.

Workload Manager (WLM)
: A component of z/OS that provides the ability to run multiple workloads at the same time within one z/OS image or across multiple images.

work manager
: A thread pool for Java Platform, Enterprise Edition (Java EE) applications.

work object
: A type of asynchronous bean that applications implement to run code blocks asynchronously.

workspace

1. A directory on disk that contains all project files, as well as information such as preferences.
2. In Eclipse, the collection of projects and other resources that the user is currently developing in the workbench. Metadata about these resources resides in a directory on the file system; the resources might reside in the same directory.
3. A temporary repository of configuration information that administrative clients use.

World Wide Web Consortium (W3C)
: An international industry consortium set up to develop common protocols to promote evolution and interoperability of the World Wide Web.

WPX
: See web property extension.

wrapper

1. An alternate and supported interface that hides unsupported data types required by a server object behind a thin intermediate server object.
2. An object that encapsulates and delegates to another object to alter its interface or behavior in some way. (Sun)

wrapper business object
: A top-level business object that groups child business objects for a component to use in a single operation or contains processing information about its child business object.

write-behind cache
: A cache that asynchronously writes each write operation to the database using a loader.

write-through cache
: A cache that synchronously writes each write operation to the database using a loader.

WS-BPEL

See Web Services Business Process Execution Language.

WSDL
See Web Services Description Language.

WSDL document
A file that provides a set of definitions that describe a web service in Web Services Description Language (WSDL) format.

WSDL file
See WSDL document.

WS-I
See Web Services Interoperability.

WSI
See Web Services Interoperability Organization.

WSIF
See Web Services Invocation Framework.

WSIL
See Web Services Invocation Language.

WS-Policy
See Web Services Policy Framework.

WS-Security
See Web Services Security.

WYSIWYG
See what you see is what you get.

X

X.25
A CCITT standard that defines an interface to packet-switched communication services.

X.500
The directory services standard of ITU, ISO, and IEC.

X.509 certificate
A certificate that contains information that is defined by the X.509 standard.

X12
A protocol from the American National Standards Institute (ANSI) for electronic data interchange (EDI).

XA
A bidirectional interface between one or more resource managers that provide access to shared resources and a transaction manager that monitors and resolves transactions.

XACML
See Extensible Access Control Markup Language.

Xalan processor
An XSLT processor that is part of the Apache project. See also XSL Transformation.

XDoclet
An open, source code generation engine that uses special JavaDoc tags to parse Java source files and generate output such as XML descriptors or source code, based on templates.

X field
The primary data field in a chart. In a line chart, typically the X field appears along the horizontal axis. For example, an X field can represent cost data for the elements that appear along the horizontal axis of the chart.

XHTML
See Extensible Hypertext Markup Language.

XID
See transaction identifier.

xJCL
An XML-based job control language that is used to define a batch job. See also job control language.

XML
See Extensible Markup Language.

XML catalog
A catalog that contains rules specifying how an XML processor should resolve references to entities. Use of a catalog eliminates the need to change URIs within XML documents as resources are moved during development.

XML digital signature
A specification that defines the XML syntax and the processing rules to sign and verify the digital signatures for the digital content.

XML document definition
A reference to either an XML DTD document definition or an XML schema document definition.

XML encryption
A specification that defines how to encrypt the content of an XML element.

XML parser
A program that reads XML documents and provides an application with access to their content and structure.

XML Path Language (XPath)
A language that is designed to uniquely identify or address parts of source XML data, for use with XML-related technologies, such as XSLT, XQuery, and XML parsers. XPath is a World Wide Web Consortium standard.

XML schema
A mechanism for describing and constraining the content of XML files by indicating which elements are allowed and in which combinations. XML schemas are an alternative to document type definitions (DTDs) and can be used to extend functionality in the areas of data typing, inheritance, and presentation.

XML Schema Definition Language (XSD, XSD, XSDL, XSDL)
A language for describing XML files that contain XML schema.

XML Schema Infoset Model (XSD)
A library that provides an API for manipulating the components of an XML Schema, as described by the W3C XML Schema specifications.

XML token

A security token that is in an XML format, such as a Security Assertion Markup Language (SAML) token.

XOM
: See execution object model.

X/Open XA
: The X/Open Distributed Transaction Processing XA interface. A proposed standard for distributed transaction communication. The standard specifies a bidirectional interface between resource managers that provide access to shared resources within transactions, and between a transaction service that monitors and resolves transactions.

XPath
: See XML Path Language.

XPath expression
: An expression that searches through an XML document and extracts information from the nodes (any part of the document, such as an element or attribute) in that document.

XSD

1. See XML Schema Infoset Model.
2. See XML Schema Definition Language.

XSD, XSDL
: See XML Schema Definition Language.

XSDL
: See XML Schema Definition Language.

XSL
: See Extensible Stylesheet Language.

XSL style sheet
: Code that describes how an XML document should be rendered (displayed or printed).

XSLT

1. See XSL Transformation.
2. See Extensible Stylesheet Language Transformation.

XSLT function
: Function that is defined by the XSL Transform (XSLT) specification for the manipulation of numbers, strings, Boolean values, and node-sets.

XSL Transformation (XSLT)
: A standard that uses XSL style sheets to transform XML documents into other XML documents, fragments, or HTML documents. See also Xalan processor.

XU
: See execution unit.

Y

Y field
: A secondary data field in a chart. In a line chart, typically the Y fields appear along the vertical axis. For example, an Y field can represent resources whose costs are represented along the vertical axis of the chart.

Z

zone

1. A function that enables rules-based shard placement to improve grid availability by placing shards across different data centers, whether on different floors or even in different buildings or geographies.
2. A logical section within an area. A zone can overlap areas but belongs only to the area where it was created. Zones are the units on which rules can be defined and run.

z/OS
: An IBM mainframe operating system that uses 64-bit real storage.

    - Tutorial: Run eXtreme Scale clients and servers in the Liberty profile
        - Liberty profile
        - Module 1: Install the Liberty profile
        - Module 2: Create a web application server in the Liberty profile
            - Lesson 2.1: Define a server to run in the Liberty profile
        - Module 3: Add the Liberty web feature to the Liberty profile
            - Lesson 3.1: Define a web application to run in the Liberty profile
        - Module 4: Configure clients to use client APIs in the Liberty profile
            - Lesson 4.1: Configure the Liberty profile to run with eXtreme Scale clients
        - Module 5: Run the data grid inside the Liberty profile
            - Lesson 5.1: Configure eXtreme Scale servers to use the Liberty profile
            - Lesson 5.2: Configuring a Liberty profile web application server to use eXtreme Scale for session replication
    - Tutorial: Integrate WebSphere eXtreme Scale security with WebSphere Application Server
        - Introduction
        - Module 1: Prepare WebSphere Application Server
            - Lesson 1.1: Understand the topology and get the tutorial files
            - Lesson 1.2: Configure the WebSphere Application Server environment
        - Module 2: Configure WebSphere eXtreme Scale to use WebSphere Application Server Authentication plug-ins
            - Lesson 2.1: Configure client server security
            - Lesson 2.2: Configure catalog server security
            - Lesson 2.3: Configure container server security
            - Lesson 2.4: Install and run the sample
        - Module 3: Configure transport security
            - Lesson 3.1: Configure CSIv2 inbound and outbound transport
            - Lesson 3.2: Add SSL properties to the catalog server properties file
            - Lesson 3.3: Run the sample
        - Module 4: Use Java Authentication and Authorization Service (JAAS) authorization in WebSphere Application Server
            - Lesson 4.1: Enable WebSphere eXtreme Scale authorization
            - Lesson 4.2: Enable user-based authorization
